Management includes patient education and total body photography for comparison at future skin examinations. Patients should avoid the sun and use sunscreens and protective clothing. These patients should have regular biannual or quarterly examinations of the entire integument, including the oral, genital, and perianal mucosa, the scalp, and an ophthalmologic examination. Comparison with the previous total body photographs and use of the dermatoscope can be helpful. Any lesions that are suspicious for melanoma should be excised. Examination of first-degree family members (parents, siblings, and children) of patients with melanoma or dysplastic melanocytic nevi is recommended to identify other persons at high risk.

PAPULOSQUAMOUS ERUPTIONS

Method of

Tam T. Nguyen, MD

CURRENT DIAGNOSIS

- Psoriasis can be clinically described as erythematous plaques with silvery white scales.
- Severity is rated as mild (< 5% body surface area [BSA]), moderate (5%–10% BSA), or severe (>10% BSA).

- Most cases are mild chronic plaques involving the extensor surfaces.
- Involvement of scalp and palmar and plantar surfaces is classified as severe.
- Psoriasis is commonly comorbid with several conditions, including cardiovascular disease, depression, and metabolic disorders.

CURRENT THERAPY

- Class I/II (super-potent) topical steroid is the mainstream treatment of mild to moderate psoriasis.
- For moderate to severe cases, systemic treatment with methotrexate is the gold standard.
- Narrowband ultraviolet B (UVB) remains a safe treatment option for all patients including children and pregnant women.
- Several immunomodulators or biologicals including etanercept (Enbrel) have been proved very effective therapy. Biologicals can be given as monotherapy or in combination with other modalities for very recalcitrant cases.
- Treatment of comorbid conditions is paramount.

Epidemiology

Psoriasis, a common chronic idiopathic inflammatory disorder, affects 2% to 3% of Americans. The number of persons affected by this condition has more than doubled from 1970 to 2000. It is a chronic disorder that can involve many organ systems including skin, mucosa, the gastrointestinal tract, and joints. Although the onset of psoriasis can occur at any age, there is a bimodal distribution peaking in young adults in their early 20s and again in persons in their 50s. There is an equal prevalence among male and female patients, but the incidence is higher in men among younger adult populations.

Risk Factors

There is a strong family history and association with HLA-Cw6, HLA-B13, and HLA-B27. Psoriatic genes appear to be located on four key genes called pSOR1-4, which show an autosomal dominant pattern. There are about 36 gene loci associated with psoriasis. The genome-wide association study (GWAS) showed that the genes STAT3 and STAT5 regulate the cytokines associated with psoriasis. In addition to the genetic etiology, environmental triggers, such as drugs, infection, and stress, also have a role in the pathogenesis of the psoriasis. Psychogenic stress from home and school is especially common in pediatric cases. Lithium and β -blockers are two well-known triggers of psoriasis. Certain conditions, such as Crohn's disease and multiple sclerosis, predispose patients to developing psoriasis.

Pathophysiology

Even though the exact mechanism is unknown, psoriasis is a disease of T cells that leads to abnormal epidermal differentiation and hyperproliferation. Normal skin has epidermal turnover of about 21 to 28 days, but psoriatic skin turns over every 3 to 4 days. Several cytokines, including IL-12 and IL-23, are part of the immune-mediated disease.

Diagnosis

Although most psoriatic lesions have characteristic scaly and silvery plaques, the lesions can be misleading. Refer to [Box 1](#) for the differential diagnosis. Psoriasis has several subtypes including erythrodermic, pustular, and vulgaris. Psoriasis vulgaris has several subtypes including chronic plaque, guttate ([Figure 1](#)), and inverse psoriasis. More than 80% to 90% of psoriasis cases are the chronic plaque psoriasis. Therefore this chapter focuses on this subtype.

BOX 1 Differential Diagnosis of Psoriasis

Plaque-like

Eczema
Fungal infection
Squamous cell carcinoma
Subacute cutaneous lupus erythematosus

Guttate

Secondary syphilis
Pityriasis rosea

Erythrodermic

Pityriasis rubra pilaris
Drug eruptions

Pustular

Candidiasis
Acute generalized exanthematic pustulosis

Inverse

Intertrigo
Cutaneous T-cell lymphoma

Figure 1 Guttate psoriasis with droplike, discrete papules and small plaques with scales.

Severity of psoriasis is classified based on the body surface area (BSA) involved. There are several severity instruments, such as Koo-Menter Psoriasis, for assessing the severity. One of the best validated tools is the Psoriasis Area Severity Index (PASI). These instruments are used to classify the condition according to coverage of body surface area (BSA) as either mild (< 5% of BSA), moderate (5%–10% of BSA), or severe (>10% of BSA). BSA can be estimated using the rule of 9s. Each upper extremity and the head is 9%, and the chest, back, and each lower extremity are 18%. For children, similar rules apply, except that each lower extremity is 13.5%. When the lesions involve difficult regions such as hands, feet, face, scalp, and genitalia, they are treated as severe regardless of the amount of BSA they cover.

Fortunately, more than 70% to 75% of cases are classified as mild to moderate, and there is no need for blood work. However, when psoriasis is associated with comorbidities, such as depression and heart disease, or when systemic medications cause serious side effects, it may be reasonable to get basic laboratory tests such as a complete blood count with platelet (CBC), chemistry, liver function tests (LFTs), cholesterol panel, hepatitis B and C, uric acid, and erythrocyte sedimentation rate (ESR). For patients at high risk, consider HIV testing. Also, consider evaluating for tuberculosis with a PPD test. These laboratory tests are even more crucial when considering treating with immunosuppressants like methotrexate (Trexall) and biological agents. Liver biopsy should be done if

Figure 2 Chronic plaque psoriasis on the extensor surfaces.

Figure 4 Chronic plaque psoriasis with limited scales.

Figure 3 Chronic plaque psoriasis with classic silvery scales.

Figure 5 Chronic plaque psoriasis without

methotrexate is used at a cumulative dose of 3.5 to 4 g. Equally important, patients' quality of life needs to be assessed, which can be done with an instrument called the Dermatology Life Quality Index (DLQI).

Differential Diagnosis

The differential diagnosis of psoriasis is lengthy and can be tricky. [Box 1](#) lists the differential diagnosis of psoriasis.

Clinical Manifestations

Most presentations of psoriasis are asymptomatic. When symptomatic, the most common clinical manifestation is pruritus. Other possible symptoms include fever and malaise, especially for more extensive disease. When psoriasis involves the joints, patients can have pain and stiffness in the involved joints; many of these cases involve the distal interphalangeal joints. On physical examination, the lesions are well-circumscribed dark pink to red plaques with

silvery to white scales ([Figures 2 and 3](#)). Scales can be absent in certain locations, such as the intertriginous area (gluteal folds) ([Figures 4 and 5](#)). The margins are sharp and distinct, especially over extensor surfaces such as the elbows and knees (see [Figure 2](#)). Lesions also can involve the sacral area, nails, scalp, and the genitalia. If psoriasis forms under a nail, onycholysis (lifting of the nail plate) can occur with pitting and subungual keratosis.

When the scales are removed, several distinctive minute blood droplets appear, called the Auspitz sign. Use caution when removing the scales because it can be painful. When new lesions form at a site of trauma, it is called the Koebner phenomenon. Diagnosis can be made clinically. However, when in doubt, biopsy the lesion, which will show a thickened epidermis with an absent granular cell layer. The stratum corneum is hyperkeratotic, with classic infiltration of neutrophils.

If this inflammatory process affects the joints, psoriatic arthritis ensues. Although this article does not discuss psoriatic arthritis, it

BOX 2**Classification of Topical Steroids, With a Few Samples From Each Class****Class 1: Super Potent**

Clobex lotion 0.05%, clobetasol propionate
 Cormax cream or solution, 0.05%, clobetasol propionate
 Diprolene gel or ointment, 0.05%, bethamethasone dipropionate
 Olux foam, 0.05%, clobetasol propionate

Class 2: Potent

Elocon ointment, 0.1%, mometasone furoate
 Florone ointment, 0.05%, diflorasone diacetate
 Halog ointment/cream, 0.1%, halcinonide
 Lidex cream, gel, ointment, 0.05%, fluocinonide

Class 3: Upper Mid-Strength

Cutivate ointment, 0.005%, fluticasone propionate
 Cyclocort cream/lotion, 0.1%, amcinonide
 Lidex-E cream, 0.05%, fluocinonide
 Maxivate cream/lotion, 0.05%, betamethasone dipropionate
 Valisone ointment, 0.1%, betamethasone valerate

Class 4: Mid-Strength

Aristocort cream, 0.1%, triamcinolone acetonide
 Cordran ointment, 0.05%, flurandrenolide
 Elocon cream, 0.1%, mometasone furoate
 Kenalog cream, ointment, spray, 0.1%, triamcinolone acetonide

Class 5: Lower Mid-Strength

DesOwen ointment, 0.05%, desonide
 Diprosone lotion, 0.1%, betamethasone dipropionate
 Kenalog lotion, 0.1%, triamcinolone acetonide
 Synalar cream, 0.025%, fluocinolone acetonide

Class 6: Mild

Derma-Smoother/FS Oil, 0.01%, fluocinolone acetonide
 DesOwen cream, 0.05%, desonide
 Synalar cream/solution, 0.01%, fluocinolone acetonide
 Tridesilon cream, 0.05%, desonide

Class 7: Least Potent

Topicals with hydrocortisone, dexamethasone⁶, methylprednisolone⁶, and prednisolone⁶

⁶May be compounded by pharmacists.

is important to recognize when it occurs. Unlike rheumatoid arthritis, the distal interphalangeal (DIP) joints are regularly involved, but it can affect any joints. Psoriatic arthritis only occurs in 4% to 42% of patients with psoriasis. Diagnosis can be made with the CASPAR criteria, which evaluates five possible presentations, including having psoriasis, nail dystrophy, negative rheumatoid factor, dactylitis, and radiographic evidence.

Treatment

Corticosteroids remain the mainstay for psoriasis therapy; they reduce inflammation, decrease mitosis, and reduce erythema. Because most cases are mild to moderate, the first-line therapy to consider is topical corticosteroids. Even for severe cases that require systemic treatment, topical steroids should still be considered as a first-line adjuvant therapy. Because psoriatic lesions are thickened, it is critical to go directly to super-potent steroids (class I), such as clobetasol (Clobex) (refer to [Box 2](#) for steroid potency). When the localized lesions are lichenified and do not respond to potent topical corticosteroids, using steroid-impregnated tapes (flurandrenolide tape [Cordran]), which function as an occlusive wrap, can help. However, for areas of thinner skin, such as mucosa and lesions on the face, use less-potent topical steroids. Use caution when using class 1 steroids owing to all the potential side effects, including skin atrophy, hypopigmentation, telangiectasis, striae, and potential systemic absorption. In addition to the possible side

effects, tachyphylaxis (reduced efficacy with prolonged use) can occur. Therefore it is crucial to limit the use of potent topical steroids to less than 12 weeks.

One way to reduce the use of topical steroids is by using the vitamin D₃ analogue class, such as calcipotriene (Dovonex). This class of drugs inhibits epidermal proliferation and stimulates cellular differentiation. It is considered as effective as medium-potency corticosteroids, without the side effects. However, one drawback is that it takes about 8 weeks to be effective. Therefore it should not be used for acute psoriatic eruptions. More often it is used in combination with topical steroids, since topical calcipotriene in combination with high dose topical steroids like betamethasone (Enstilar) works better than either alone. It is generally well tolerated topically, but about 10% of patients experience burning and itching or hypercalcemia.

Other topical applications include tazarotene (Tazorac) and anthralin (Dritho-Crème HP 1%, Dritho-Scalp 0.5%). Tazarotene is an acetylenic retinoid and can be as effective as high-potency topical corticosteroids. However, its use is limited owing to the side effects of erythema, burning, pruritus, and peeling. Therefore it is best to combine it with corticosteroids to reduce the irritation. In addition, tazarotene can stain clothing, and it is less popular owing to the side effects (redness and irritation on skin as well as staining) and the feel and smell of the solutions. However, it is a good alternative to topical corticosteroids.

For a limited number of thickened lesions, consider intralesional steroid injections, such as a single intralesional injection of a mid-potency steroid (e.g., triamcinolone acetonide or Kenalog-10, 5–10 mg/mL). Most injected plaques clear completely and remain in remission for months. However, as with other steroid injections, side effects of skin atrophy and telangiectasis can occur. Therefore the face and intertriginous areas should not be injected because of the increased risk of side effects.

For severe and recalcitrant cases, systematic medications are needed. One of the gold standards in the United States and many other countries is methotrexate (Trexall) because it is available as a generic. Its exact mechanism is unknown; initially it was believed to inhibit proliferation, but more-recent studies describe an antiinflammatory property. The most common serious side effect of this drug is hepatotoxicity (as many as 33% of patients show some liver disease). Therefore it is crucial to screen for alcohol dependency, liver disease, and obesity. Standard practice is to check baseline CBC and liver function enzymes, and then repeat these laboratory tests after 1 month of therapy. Methotrexate is highly teratogenic; hence it is absolutely contraindicated in pregnancy. After stopping the medication, men should wait at least 3 months and women should wait one ovulatory cycle before attempting to conceive.

There are two methods for initiating methotrexate. Most patients start at an initial dose of 7.5 mg (3 tabs of 2.5 mg) weekly; in pediatric cases dosage¹ is 0.2 to 0.7 mg/kg weekly. Others start at a higher dosage of 0.4 to 0.5 mg/kg weekly. Unfortunately, there is no current study to compare the two methods. With either dosing regimen, do not exceed 30 mg per week. Methotrexate depletes the body's storage of folic acid, so it is important to supplement folic acid 1 mg daily except the day when methotrexate is taken. The methotrexate can be titrated upward every 2 to 4 weeks.

Unlike methotrexate, which can take several weeks before it becomes effective, cyclosporine (Neoral), a calcineurin inhibitor, is rapidly effective for severe cases. It is dosed at a low dose of 2 to 5 mg/kg/day divided into two doses and increased slowly every 2 to 4 weeks. Maintenance dosage is about 3 to 5 mg/kg/day. A main concern for this drug is nephrotoxicity. As long as the use of cyclosporine is limited to 1 year, it is generally safe. However, kidney function still needs to be monitored regularly. Cyclosporine has been associated with an increased risk of squamous cell

¹Not FDA approved for this indication

BOX 3 Other Treatment Modalities for Moderate to Severe Psoriasis

Fumaric acid esters²: First-line therapy in a couple of European countries
 Hydroxyurea (Hydrea)¹: A good option because there is no liver or kidney toxicity; however, be cautious of bone marrow suppression
 Leflunomide (Arava)¹
 Mycophenolate mofetil (Cellcept)¹: good choice for HIV patients and patients with immunobullous disorders
 Retinoic acid metabolism–blocking agents: liarozole² and talarozole (Rombozale)⁵
 Alitretinoin topical (Panretin)¹
 Sulfasalazine (Azulfidine)¹
 Tacrolimus (Prograf)¹
 6 thioguanine (Tabloid)¹

¹Not FDA approved for this indication.

²Not available in the United States.

⁵Investigational drug in the United States.

carcinoma, especially when the patient has a history of psoralen plus ultraviolet A (PUVA) therapy.

Although not FDA-approved, azathioprine (Imuran) has been a successful systemic medication for psoriasis. Generally, it is initially dosed at 0.5 mg/kg. If there is cytopenia, then the dosage can be increased by 0.5 mg/kg/day every 4 to 6 weeks as needed. Another dosing method is based on thiopurine methyltransferase (TPMT) levels. If the TPMT is less than 5.0 U, do not use azathioprine. If the level is between 5 and 13.7 U, the maximum daily dose should be 0.5 mg/kg/daily. If the TPMT level is between 13.7 and 19.0 U, then the maximum daily dose may be increased to 1.5 mg/kg. There is only one FDA-approved phosphodiesterase type-4 inhibitor (PDE4), apremilast (Otezla). Taken orally twice a day, this drug inhibits PDE4 leading to increased intracellular cAMP levels.

Acitretin (Soriatane) and isotretinoin (Claravis)¹ are retinoids, which are vitamin A derivatives. Although acitretin is more commonly used, either may be used and requires a period of 3 to 6 months to achieve results. However, these retinoids are generally less effective than methotrexate and cyclosporine. Though they are less effective and a longer time is required for this class of agents to work, their main benefits include no malignancy potential and no immunosuppression. Therefore these drugs are safe in patients with HIV and other immunosuppressive conditions. Unfortunately, acitretin and isotretinoin are highly teratogenic. Both male and female patients need to be drug free for 1 year for isotretinoin and 3 years for acitretin before they conceive. For other possible treatment agents, refer to Box 3.

In recent years, immunomodulators or biologicals have revolutionized the treatment course of psoriasis. Generally, criteria for this class of therapy are PASI greater than 10 and failure of other therapies or a contraindication to other therapies such as methotrexate. Most agents are limited to 1 to 2 years of use because most studies have not been evaluated beyond 2 years. Tuberculosis should be evaluated (PPD and possibly chest x-ray) before starting these biologics. All the medications in this class should be avoided in pregnancy. Alefacept (Amevive)² and efalizumab (Raptiva) are T-cell inhibitors. Efalizumab (Raptiva) was withdrawn from the market in 2009 owing to reported cases of progressive multifocal leukoencephalopathy. Another class is tumor necrosis factor (TNF). Etanercept (Enbrel), one of the first TNF inhibitors, should not be used in patients with multiple sclerosis. Three monoclonal antibodies include infliximab (Remicade), adalimumab (Humira),

and golimumab (Simponi), and all are TNF inhibitors. In recent years, a new class of biologics that inhibit interleukin (IL)-12 and IL-23 has shown promising results. Ustekinumab (Stelara) was first approved within this class, followed by guselkumab (Tremfya). Secukinumab (Cosentyx), a new biological for plaque psoriasis is a recombinant, high-affinity, fully humanized IgG monoclonal antibody that selectively binds and neutralizes interleukin-17A (IL-17A). Additional two IL-17A inhibitors, ixekizumab (Taltz) and brodalumab (Siliq), have been approved for use.

Etanercept (Enbrel) blocks TNF- α . It is generally dosed at 50 mg SC twice weekly for 12 weeks and then 50 mg weekly. Patients can self-administer the drug; laboratory monitoring is not required. There are limited data beyond 2 years. Etanercept is the preferred drug for children. Infliximab (Remicade) blocks both soluble and bound TNF- α . Its dosage is 3 to 5 mg/kg IV on weeks 0, 2, and 6, and then every 6 to 8 weeks. Medication generally is infused over 2 hours. It is approved for 1 year. In a comparative study, infliximab was found to be superior to methotrexate. TNF does not appear to increase the risk of herpes zoster but could be associated with an increase in melanoma.

Adalimumab (Humira) blocks both soluble and bound TNF- α . Initiate the dose at 40 mg SC every 2 weeks, although some patients require dosing every 7 to 10 days. Alternatively, the initial dose may be 80 mg followed by 40 mg. Patients may self-administer the injections. As with infliximab, before initiating treatment, obtain a PPD (and consider chest x-ray as well). Antibodies can develop within the first 28 weeks, which will decrease the efficacy of the drug. Both infliximab, which has been in use for many years, and adalimumab have limited long-term safety data beyond 1 year. Some data suggest an increase in cancer risk beyond 1 year. Adalimumab is FDA approved for psoriatic arthritis.

Alefacept (Amevive), a T-cell inhibitor, is dosed at 15 mg IM or IV once a week for 12 weeks. Its efficacy follows the rule of thirds: It works well in about one-third of cases, does not work at all in one-third of cases, and the rest fall in between. After a cycle of 12 weeks, the courses may be repeated as needed. However, it is crucial initially to monitor T-cell counts biweekly. A newer agent, ustekinumab (Stelara), has been shown to improve lesions in 66% to 76% of cases. It is initially dosed at 45 to 90 mg SC at weeks 0 and 4, depending on body weight. Maintenance is every 12 weeks. Besides ustekinumab, another IL-12/IL-23 inhibitor, guselkumab (Tremfya), was approved in 2017 and is dosed at 100 mg/mL SC in weeks 0 and 4, then every 8 weeks.

When these therapies are contraindicated, one alternative is phototherapy. This is the reason many patients report decreased symptom severity during the summer months due to the natural UV light. Phototherapy started with photochemotherapy with oral or topical psoralens combined with UVA light (PUVA). Although phototherapy is very effective for psoriasis, even in very thick lesions, recent studies have shown an increased risk of skin cancer. Therefore PUVA has become less popular since the advent of UVB radiation treatment, especially with narrow-band UVB (NB-UVB). NB-UVB is equally effective as PUVA and does not have the risk of skin cancer. The exact mechanism is unknown, but it is believed to affect DNA and to suppress IL-17 and IL-23, creating photoproducts that interfere with cell cycle progression. NB-UVB is first-line course of therapy for pregnant and pediatric patients. There are two methods for initiating NB-UVB phototherapy: the skin type protocol, which is easier to execute; and the minimum erythema dose (MED), which is more detailed but more accurate. Refer to Table 1 for treatment protocols. Both protocols generally require 30 to 35 treatments with the optimal frequency of three times a week.

Given all the treatment options (refer to Box 4), the choice of the treatment regimen depends on several factors. First, the severity of the psoriasis must be determined as well as the social and emotional impact of the condition. Another consideration is financial, including the insurance coverage, copayment, and deductibles. The lowest-cost treatment is methotrexate, and alefacept is the highest. The patient's conveniences and preferences should be discussed. If

¹Not FDA approved for this indication.

²Not available in the United States.

TABLE 1 Methods for Initiating Narrow-Band Ultraviolet B (NB-UVB) Therapy and Subsequent Dosing of Phototherapy

THERAPY	MED NB-UVB PROTOCOL						MED NB-UVB PROTOCOL
	TYPE 1	TYPE 2	TYPE 3	TYPE 4	TYPE 5	TYPE 6	
Initial dose	130 mJ/cm ²	220 mJ/cm ²	260 mJ/cm ²	330 mJ/cm ²	350 mJ/cm ²	400 mJ/cm ²	Start with 50%–70% MED The starting dose should be based on the provider’s comfort and the patient’s history of response to light; e.g., start closer to 70% if the patient has a history of tanning and start closer to 50% if the patient has a history of burning; most centers start at 70%
Subsequent Doses							
Severe erythema	No treatment. When burn resolves, decrease by 50% of last dose and then increase dose by 10%						
Mild erythema	Same dose	Same dose	Same dose	Same dose	Same dose	Same dose	Decrease dose by 20%
Barely perceptible erythema	—	—	—	—	—	—	Same (erythmogenic) or slight decrease (suberythmogenic)
No erythema: increase dose by	15 mJ/cm ²	25 mJ/cm ²	40 mJ/cm ²	45 mJ/cm ²	60 mJ/cm ²	65 mJ/cm ²	20%
Dosing Schedule							
Optimal schedule	3 ×/wk (M, W, F) is the optimal schedule because less is not as effective and more does not improve the resolution. Subsequent treatments should not be less than 24 hours from the last treatment. For the treatment of eczema, no clear guideline to the frequency. Some use 5 ×/wk.						
Dose Adjustments for Missed Days							
MISSED DAYS				DOSE ADJUSTMENT			
1–7				Increase doses per skin type			
8–11				Same dose			
12–14				Decrease by 2 treatments’ worth			
15–20				Decrease by 25%			
21–27				Decrease by 50%			
28 +				Start over			

the severity is only mild to moderate without much emotional impact, topical steroid and vitamin D analogue should be considered the first options. Other topicals include tar (Balnetar, Psoriasis, Scytera), anthralin (Dritho-Crème HP, Dritho-Scalp), and tretinoin (Retin-A)¹. If the degree is severe and/or the patient has emotional impact, systemic medications should be used. Most insurance plans will probably require that the patient try at least one oral medication before employing the biologicals. If systemic therapy is used, consider combining it with phototherapy (if possible). If there is no improvement within 2 to 4 months, the regimen should be changed to biologicals. Other combinations may be employed for better resolution.

For healthy patients, any of these therapies may be tried. Unfortunately, there are limitations with children, pregnant women, and patients trying to conceive. For pediatric patients, topical agents should be tried first, followed by UVB monotherapy. If the plaques are still recalcitrant, add either methotrexate (Trexall) or phototherapy. If phototherapy is not available and topical agents have failed, consider using methotrexate or cyclosporine (Neoral). Other options for pediatric patients include adalimumab (Humira) and etanercept (Enbrel). For pregnant women and patients trying to conceive, first try topical agents followed by UVB (ideally

narrowband). This combination remains the safest option. If stronger options are needed, the only class B drugs are systemic steroids, adalimumab, alefacept (Amevive), infliximab (Remicade), and ustekinumab (Stelara). An absolute contraindication in this population is the retinoid class, such as isotretinoin (Claravis)¹ and acitretin (Soriatane).

Complications

Patients suffering from psoriasis cope with the physical appearance of their lesions as well as the associated mental anguish associated with many other chronic ailments. Furthermore, psoriasis is associated with other chronic diseases, such as abdominal obesity, metabolic syndrome, and atherogenic dyslipidemia. Weight loss can improve the appearance of psoriatic plaques. Patients with psoriasis are more likely to have coronary artery disease, elevated blood pressure, obesity, and insulin resistance. Treating psoriasis decreases the cardiovascular risks. There is an increased risk of malignancy, such as lymphoma. Substance abuse and smoking are common among these patients as well.

PARASITIC DISEASES OF THE SKIN

Method of

Andreas Katsambas, MD, PhD; and Clio Dessinioti, MD, MSc, PhD

CURRENT DIAGNOSIS
Cutaneous Amebiasis

- Purulent, foul-smelling nodules, ulcers, cysts, sinuses
- Microscopic identification of *Entamoeba histolytica* in stool or biopsy samples
- Molecular methods

Cutaneous Leishmaniasis

- Ulcerated nodule (i.e., volcano sign)
- Identification of *Leishmania* parasites by direct examination or culture from the lesion aspirate or biopsy
- Montenegro skin test
- In vitro lymphocyte proliferation assay
- Polymerase chain reaction

Trypanosomiasis
Chagas' Disease

- Chagoma: painful erythematous nodule
- Regional adenopathy
- Cardiomyopathy, megaesophagus, megacolon
- Microscopic examination of *Trypanosoma cruzi* in blood, lymph node biopsy, or skin biopsy or culture

African Sleeping Sickness

- Trypanosome chancre: painful, inflammatory nodule
- Regional adenopathy
- Fever, generalized pruritic eruption with erythematous annular plaques
- Central nervous system involvement
- Microscopic identification of *Trypanosoma brucei* in chancre fluid, lymph node aspirates, blood, bone marrow, cerebrospinal fluid

Cutaneous Toxoplasmosis

- Roseola, urticaria, prurigo-like nodules
- Isolation of *Toxoplasma gondii* in the skin

Ascariasis

- Urticaria
- Identification of adult worm or eggs in stool

Cutaneous Larva Migrans

- Creeping eruption
- Intense pruritus

Cysticercosis

- Subcutaneous nodules
- Isolation of *Taenia solium* in skin lesion
- Serologic tests

Dracunculiasis

- Ruptured blister with prolapsing worm

Filariasis
Lymphatic Filariasis

- Fever with lymphangitis and lymphadenitis
- Chronic pulmonary infection
- Progressive lymphedema leading to massive tissue thickening, especially of the legs and scrotum (i.e., elephantiasis)
- Microscopic identification of microfilariae in blood

Onchocerciasis (River Blindness)

- Subcutaneous nodules, dermatitis, "leopard skin," "lizard skin," lymphedema

Topical
Steroid

Tar (e.g., Balnetar, Psoriasin, Scytera)
 Anthralin (Dritho-Crème HP, Dritho-Scalp)
 Calcipotriene (Dovonex)
 Calcitriol (Vectical)
 Adapalene (Differin)¹
 Tazarotene (Tazorac)
 Tretinoin (Retin-A)¹
 Calcineurin inhibitors (pimecrolimus [Elidel]¹, tacrolimus [Protopic]¹)

Oral or Systemic

Methotrexate (Trexall)
 Acitretin (Soriatane)/Isotretinoin (Claravis)¹
 Cyclosporine (Neoral)
 Mycophenolate mofetil (Cellcept)¹

Immunomodulators

Alefacept (Amevive)²
 Etanercept (Enbrel)
 Infliximab (Remicade)
 Adalimumab (Humira)
 Ustekinumab (Stelara)
 Secukinumab (Cosentyx)
 Ixekizumab (Taltz)
 Brodalumab (Siliq)

Phototherapy

UVA
 UVB

¹Not FDA approved for this indication.

²Not available in the United States.

Dracunculiasis

- Ruptured blister with prolapsing worm

Filariasis
Lymphatic Filariasis

- Fever with lymphangitis and lymphadenitis
- Chronic pulmonary infection
- Progressive lymphedema leading to massive tissue thickening, especially of the legs and scrotum (i.e., elephantiasis)
- Microscopic identification of microfilariae in blood

Onchocerciasis (River Blindness)

- Subcutaneous nodules, dermatitis, "leopard skin," "lizard skin," lymphedema

- Identification of microfilariae in skin snips
- Blindness

Loiasis (Calabar Swellings)

- Pruritus, localized subcutaneous swellings
- Serpiginous lesion on the conjunctivae
- Microscopic identification of microfilariae in blood

Schistosomiasis (Snail Fever)

- Pruritic papules, edema
- Fever, lymphadenopathy, diarrhea
- Bilharzias cutanea tarda: pruritic, grouped papules
- Identification of the eggs in stool, urine, biopsy of affected tissues
- Enzyme-linked immunosorbent assay (ELISA) tests

Cercarial Dermatitis (Swimmer's Itch)

- Extremely pruritic erythematous macules, papules, vesicles on body areas exposed to infested water

Human Scabies

- Pruritus worsening at night
- Papules, excoriations, nodules, burrows on genitals, interdigital spaces, axillae, wrists
- Microscopic identification of mites or eggs or feces from burrows or papules

Pediculosis

Pediculosis Capitis

- Intense pruritus of the scalp
- Nape dermatitis
- Identification of lice and nits on the hair

Pediculosis Corporis (Vagabond's Itch)

- Intense pruritus, erythema, urticarial lesions, papules, nodules, and excoriations
- Identification of lice and nits on clothing

Pediculosis Pubis

- Pruritus
- Blue macules
- Identification of lice and nits on pubic hair

East African Sleeping Sickness

- Suramin (Germanin)¹⁰ 100 to 200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14, 21
- For late disease with involvement of the central nervous system, melarsoprol (Mel-B)¹⁰ 2 to 3.6 mg/kg/day IV for 3 days; after 7 days, 3.6 mg/kg/day for 3 days; repeat after 7 days

West African Sleeping Sickness

- Pentamidine (Pentam 300)¹ 4 mg/kg/day IM for 10 days, or
- Suramin (Germanin)¹⁰ 100 to 200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14, 21
- For late disease with involvement of the central nervous system, melarsoprol (Mel-B)¹⁰ 2.2 mg/kg/day IV for 10 days, or
- For late disease with involvement of the central nervous system, eflornithine (Ornidyl)¹⁰ 400 mg/kg/day IV in four doses for 14 days

Cutaneous Toxoplasmosis

- Self-limited disease; treatment not needed in healthy, non-pregnant persons
- For pregnant women or immunocompromised patients: pyrimethamine (Daraprim) 25 to 100 mg/day PO for 3 to 4 weeks (plus leucovorin 10–25 mg with each dose of pyrimethamine) and sulfadiazine¹ 1 to 1.5 g PO four times daily for 3 to 4 weeks

Ascariasis

- Albendazole (Albenza)¹ 400 mg PO once, or
- Mebendazole (Vermox) 100 mg PO twice daily for 3 days or 500 mg once, or
- Ivermectin (Stromectol)¹ 150 to 200 µg/kg PO once

Cutaneous Larva Migrans

- Ivermectin (Stromectol)¹ 200 µg/kg PO once; a second dose may be needed, or
- Albendazole (Albenza)¹ 400 mg daily PO for 3 days
- Topical thiabendazole² 10% to 15% applied three times daily for 5 to 7 days for a limited number of lesions

Dracunculiasis

- Slow extraction of the worm, which is facilitated by metronidazole (Flagyl)¹ 250 mg PO three times daily for 10 days

Filariasis

Lymphatic Filariasis

- Diethylcarbamazine (DEC, Hetrazan)¹⁰ 6 mg/kg/day PO in three doses for 12 days, or
- Ivermectin (Stromectol)¹ 200 µg/kg PO once together with albendazole (Albenza)¹ 400 mg PO once; kills only the microfilaria, not the adult worms
- For patients with microfilaria in the blood, DEC as follows: day 1: 50 mg; day 2: 50 mg three times daily; day 3: 100 mg three times daily; days 4 through 14: 6 mg/kg in three doses

Onchocerciasis

- Ivermectin (Stromectol) 150 µg/kg PO once for 6 to 12 months, until asymptomatic
- DEC: contraindicated because it may lead to blindness

Loiasis

- DEC¹⁰ 6 mg/kg/day PO in three doses for 12 days
- For patients with microfilaria in the blood, DEC as follows: day 1: 50 mg; day 2: 50 mg three times daily; day 3: 100 mg three times daily; days 4 through 14: 9 mg/kg in three doses

Schistosomiasis

- Praziquantel (Biltricide) 40 mg/kg/day³ in two doses for 1 day (*S. haematobium* and *S. mansoni*) and 60 mg/kg/day³ in three doses for 1 day (*S. japonicum*, *S. mekongi*)

Human Scabies

- Permethrin (Acticin, Elimite) 5% cream rinse, applied for 10 hours; a second application 7 to 10 days later, or
- Benzyl benzoate 25% solution⁶ applied topically; second application 7 to 10 days later, or

CURRENT THERAPY

Cutaneous Amebiasis

- Metronidazole (Flagyl) 750 mg PO three times daily for 7 to 10 days, or
- Tinidazole (Tindamax) 2 g once PO daily for 5 days, followed by iodoquinol (Aloquin) 650 mg PO three times daily for 20 days or paromomycin (Humatin) 25 to 35 mg/kg/day PO in three doses for 7 days

Cutaneous Leishmaniasis

- Sodium stibogluconate (Pentostam)¹⁰ 20 mg/kg/day IV or IM for 20 days, or
- Meglumine antimoniate (Glucantime)¹ 20 mg/kg/day IV or IM for 20 days, or
- Miltefosine (Impavido) 2.5 mg/kg/day PO (up to 150 mg/day) for 28 days, or
- Topical paromomycin, a formulation of 15% paromomycin and 12% methylbenzethonium chloride in soft white paraffin (Lesheutan)^{1,6} applied twice daily for 10 days or
- Pentamidine (Pentam 300)¹ 2 to 3 mg/kg IV or IM daily or every second day for four to seven doses

Trypanosomiasis

Chagas' Disease (American Trypanosomiasis)

- Nifurtimox (Lampit)¹⁰ 8 to 10 mg/kg/day PO in three or four doses for 90 to 120 days, or
- Benznidazole (Radanil, Rochagan)¹⁰ 5 to 7 mg/kg/day PO in two doses for 60 to 120 days

- Crothamiton 10% (Eurax) applied twice daily for 2 days; second application 7 to 10 days later
- Sulfur 6% to 10% ointment in petrolatum⁶
- Ivermectin (Stromectol)¹ 200 µg/kg PO once: treatment of choice for crusted scabies

Pediculosis

Pediculosis Capitis

- Malathion (Ovide) 0.5% lotion, applied for 8 to 12 hours before being washed off; approved for children older than 6 years, or
- Permethrin (Nix) 1% lotion, applied to shampooed hair and washed off after 10 minutes; second application 7 to 10 days later; approved for children older than 2 years
- Pyrethrins with piperidyl butoxide (RID) applied for 10 minutes
- Benzyl benzoate 25% solution⁶
- Lindane shampoo: for recalcitrant disease, associated with serious reactions not to be used in children
- Ivermectin 0.5% lotion (Sklice), apply to dry hair and scalp then rinse off after 10 minutes

Pediculosis Corporis

- Disinfection of clothes

Pediculosis Pubis

- Same treatment as pediculosis capitis: three times daily

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Parasitic diseases are a common cause of morbidity and mortality, particularly in tropical and developing countries. They may be caused by protozoa, helminths, or arthropods. Because of the immigration of persons from tropical and subtropical countries worldwide and the travel of people from industrialized to tropical regions, parasitic diseases may be found in temperate climates. Skin lesions may provide important diagnostic clues for parasitic infections, and they are reviewed in the following sections, along with updated treatment guidelines.

Diseases Caused by Protozoa

Cutaneous Amebiasis

Intestinal amebiasis is caused by *Entamoeba histolytica*, which may rarely invade the skin and cause cutaneous amebiasis. The disease is transmitted by ingestion of food or water contaminated with cyst forms of the parasite and through fecal exposure during sexual contact.

Cutaneous amebiasis develops at the site of the invasion of the parasites into the skin from an underlying amebic abscess, usually at the perianal area or the abdominal wall. Cutaneous findings include purulent, foul-smelling nodules, cysts, and sinuses, which are associated with regional adenopathy and dysentery. Skin lesions grow rapidly and may lead to death if left untreated.

Diagnosis of cutaneous amebiasis is confirmed by microscopic identification of *E. histolytica* in the stool and in aspirates or biopsy samples obtained during colonoscopy, during surgery, or from the border of an ulcer. Treatment of choice for extraintestinal amebiasis is oral metronidazole (Flagyl) 750 mg PO three times daily for 7 to 10 days or tinidazole (Tindamax). Tinidazole was FDA approved in 2004 for the treatment of intestinal amebiasis in adults (2 g/day for 3 days) and children older than 3 years, and it appears to be as effective as, and better tolerated than, metronidazole. Either treatment should be followed by iodoquinol (Aloquin) 650 mg PO three times daily for 20 days or paromomycin 25 to 35 mg/kg/day PO divided in three doses for 7 days.

Leishmaniasis

Leishmaniasis results from the infection with intracellular protozoan parasites belonging to the genus *Leishmania*. Leishmania

Figure 1 Cutaneous leishmaniasis is characterized by an ulcerated nodule with a raised and indurated border (i.e., volcano sign).

parasites are transmitted to humans and other mammalian hosts (e.g., dogs, rodents) during feeding by infected female phlebotomine sandflies that serve as vectors. The parasites exist as promastigotes in the midgut of sandflies and as amastigotes (i.e., Leishman-Donovan bodies) within macrophages of humans and other mammals. Based on the extent and the severity of involvement in the human host, leishmaniasis may be clinically classified as cutaneous leishmaniasis, diffuse cutaneous leishmaniasis, mucocutaneous leishmaniasis, and visceral leishmaniasis.

Cutaneous leishmaniasis (New World or Old World form) begins as a small erythematous papule at the site of the bite of the sandfly, which evolves into an ulcerated nodule with a raised and indurated border (i.e., volcano sign) (Figure 1). The lesions gradually heal with a depressed scar. Diffuse cutaneous leishmaniasis is characterized by widespread cutaneous involvement without visceralization. Mucocutaneous leishmaniasis (known as espundia in South America) affects the skin, the mucosa, and the cartilages of the upper respiratory tract (especially the nose and the larynx) and may result in severe disfigurement. Visceral leishmaniasis results from the involvement of the bone marrow, spleen, and the liver, and it may lead to death if left untreated. It manifests with fever, splenomegaly, pancytopenia, and wasting. Post-kala azar dermal leishmaniasis may appear within a year after visceral disease independent of treatment, and it is characterized by macules, papules, and nodules, which are usually hypopigmented.

Diagnosis of leishmaniasis is based on finding the parasites in the skin from the lesion aspirate or biopsy by direct examination or culture. The leishmanin (Montenegro) skin test shows past and current infections, and it detects the inflammatory response in the skin after injection of phenol-killed parasites into the dermis. A past or current infection is also documented by an in vitro lymphocyte proliferation assay that requires a drop of blood from a finger prick. Polymerase chain reaction (PCR) techniques may be used to identify different *Leishmania* species. Circulating antibody levels are not considered a useful diagnostic sign.

Cutaneous leishmaniasis is usually self-limited and may not require treatment. Treatment of cutaneous leishmaniasis is indicated in case of numerous lesions or when lesions affect the face to avoid scarring. Therapies include sodium stibogluconate (Pentostam)¹⁰ 20 mg/kg/day IV or IM for 20 days. Meglumine antimoniate (Glucantime)² 20 mg/kg/day IV or IM for 20 days or miltefosine (Impavido) for 28 days may be used. In 2014, FDA approved oral miltefosine for the treatment of cutaneous leishmaniasis caused by *L. braziliensis*, *L. paramensis*, and *L. guyanensis* in adults and adolescents who are not pregnant or breastfeeding. The FDA-approved treatment regimen for persons who weigh from 30 to 44 kg is one 50-mg oral capsule of miltefosine twice a day (total

²Not available in the United States.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

of 100 mg per day) for 28 consecutive days. The approved regimen for persons who weigh at least 45 kg (99 pounds) is one 50-mg capsule three times a day (total of 150 mg per day) for 28 consecutive days. Miltefosine is contraindicated in pregnant women during treatment and for 5 months thereafter. Alternatively, intraleisional injections of antimonials 1 mg/kg once weekly, cryotherapy, local heat, oral ketoconazole (Nizoral)¹, topical amphotericin B², pentamidine (Pentam)¹ 2 to 3 mg/kg IV or IM daily or every second day for four to seven doses, or topical paromomycin^{1,6} (applied twice daily for 10–20 days) may be used.

The production of antileishmanial antibodies does not correlate with resolution of the disease. Infection and recovery are associated with lifelong immunity to reinfection by the same species of *Leishmania*, although interspecies immunity may also exist.

Trypanosomiasis

There are three types of trypanosomiasis:

- American trypanosomiasis or Chagas' diseases, caused by *Trypanosoma cruzi*
- East African sleeping sickness, caused by *Trypanosoma brucei rhodesiense*
- West African sleeping sickness, caused by *Trypanosoma brucei gambiense*

American trypanosomiasis (i.e., Chagas' disease) is caused by the parasite *T. cruzi*, and it is endemic in Central and South America. The disease is transmitted by the bite of infected "cone-nosed" insects, by transfusion of infected blood, by organ transplantation, and across the placenta. During the acute stage, Chagas' disease manifests with a painful erythematous nodule, known as chagoma, which is associated with regional adenopathy. The chronic stage manifests with cardiomyopathy, megaesophagus, and megacolon. Diagnosis is confirmed by microscopic identification of the parasite in fresh anticoagulated blood, in blood smears, by lymph node biopsy or skin biopsy, or by culture. Treatment includes benznidazole (Radanil, Rochagan)¹⁰ 5 to 7 mg/kg/day PO in two doses for 60 to 90 days or nifurtimox (Lampit)¹⁰ 8 to 10 mg/kg/day PO in three or four doses for 90 to 120 days.

African trypanosomiasis (i.e., East and West African sleeping sickness) occurs in Africa and is transmitted by the bite of infected male and female tsetse flies. It manifests with a highly inflammatory, painful, red or violaceous, indurated nodule surrounded by an erythematous halo, called trypanosome chancre, at the site of the inoculation of the parasites. There is regional adenopathy. Later, the chancre resolves spontaneously, and the patient has fever, malaise, a generalized pruritic eruption with erythematous annular plaques or urticarial lesions, and central nervous system (CNS) involvement with personality changes, apathy, somnolence, coma, and death. Diagnosis is based on the identification of trypanosomes by microscopic examination in chancre fluid, affected lymph node aspirates, blood, bone marrow, or in the late stages of infection, cerebrospinal fluid.

Treatment of East African sleeping sickness consists of suramin (naphthylamine sulfonic acid, Germanin)¹⁰ 100 to 200 mg (test dose) IV and then 1 g IV on days 1, 3, 7, 14, and 21. For late disease with CNS involvement, melarsoprol B (a trivalent organic arsenical, Mel-B)¹⁰ is used in the following dosage regimen: 2 to 3.6 mg/kg/day IV for 3 days; after 7 days, 3.6 mg/kg/day for 3 days; and the latter repeated after 7 days. For West African sleeping sickness, treatment of choice is pentamidine isethionate (Pentam 300)¹ 4 mg/kg/day IM for 10 days or suramin (Germanin)¹⁰ as used for East African sleeping sickness. For late disease with involvement of the CNS, eflornithine (Ornidyl)¹⁰ 400 mg/kg/day IV in four doses for 14 days is used.

¹Not FDA approved for this indication.

²Not available in the United States.

⁶May be compounded by pharmacists.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Cutaneous Toxoplasmosis

Systemic toxoplasmosis (congenital or acquired) is caused by the parasite *Toxoplasma gondii*, and it usually is transmitted from contact with infected cats. The disease may also be acquired by eating raw or undercooked meats from infected animals. Cutaneous involvement is rare. It manifests with punctate macules or ecchymoses in the congenital form, and the acquired form manifests with roseola and erythema multiforme lesions, urticaria, prurigo-like nodules, and maculopapular lesions. Diagnosis of cutaneous toxoplasmosis is confirmed by isolation of the parasite in the skin. Treatment is not needed for healthy nonpregnant patients because symptoms resolve in a few weeks. Treatment for pregnant women or immunocompromised patients includes pyrimethamine (Dara-prim) 25–100 mg/d PO for 3–6 wks together with sulfadiazine¹ 1–15 g PO qid for 3–6 wks. Leucovorin¹ should be taken with each dose of pyrimethamine.

Diseases Caused by Helminths

Ascariasis

Ascariasis is caused by *Ascaris* species, mainly *Ascaris lumbricoides*. It is transmitted by the ingestion of eggs in soil contaminated with human feces. Skin involvement of ascariasis manifests with urticaria. Diagnosis is based on finding the adult worm or eggs in the feces. Treatment includes albendazole (Albenza)¹ 400 mg PO once or mebendazole (Vermox) 100 mg PO twice daily for 3 days (or 500 mg once) or ivermectin (Stromectol)¹ 150 to 200 µg/kg PO once.

Cutaneous Larva Migrans

Cutaneous larva migrans is also known as creeping eruption, with the first term describing a syndrome and the second a clinical sign found in various conditions. The syndrome cutaneous larva migrans is caused when various nematode larvae (i.e., hookworms, such as *Ancylostoma braziliense*, *Ancylostoma caninum*, *Bunostomum phlebotomum*) of dogs, cats, and other mammals penetrate and migrate through the skin. Cutaneous larva migrans is transmitted by skin contact to soil contaminated with animal feces. In humans, larvae are unable to reach internal organs and eventually die. Cutaneous larva migrans manifests with intensely pruritic, papular lesions, which evolve as the larvae migrate to a characteristic linear, minimally elevated, serpiginous tract that moves forward in an irregular pattern. Diagnosis is easily made clinically and is supported by a travel history or by possible exposure in an endemic area.

Treatment of choice consists of ivermectin (Stromectol)¹ at a single dose of 200 µg/kg. In case of treatment failure, a second dose usually suffices. Ivermectin has an excellent safety profile, without any notable adverse events, and it has been used in millions of individuals in developing countries during onchocerciasis and filariasis control operations. It is contraindicated in children who weigh less than 15 kg (or are younger than 5 years) and in pregnant or breastfeeding women. Alternatively, repeated courses of oral albendazole (Albenza)¹ 400 mg daily for 3 days may be used. Treatment with oral thiabendazole (Mintezol)² 50 mg/kg daily for 2 to 4 days has been associated with adverse events such as dizziness, nausea, vomiting, and intestinal cramps, and it is therefore not recommended. In the absence of multiple or widespread lesions, topical treatments may be considered, such as topical thiabendazole² 10% to 15%, applied three times daily for 5 to 7 days, which has similar efficacy with oral ivermectin and no adverse events.

Cysticercosis

Cysticercosis is caused by the larval stage (i.e., cysticerci) of the pork tapeworm *Taenia solium*, and it is the most common helminthic infection of the CNS. It is transmitted by ingesting eggs in food, in water, or on hands contaminated with human feces. Cutaneous manifestations are subcutaneous nodules that occur mainly on the

¹Not FDA approved for this indication.

²Not available in the United States.

extremities and trunk. There may be involvement of the CNS (i.e., seizures), eye, intestines, skeletal muscle, heart, kidneys, lung, and liver. Diagnosis is confirmed by isolation of the parasite in a nodule and by serologic tests.

Treatment options include surgery, albendazole (Albenza) 400 mg PO twice daily for 8 to 30 days, or praziquantel (Biltricide)¹ 100 mg/kg/day PO in three doses for 1 day and then 50 mg/kg/day in three doses for 29 days. Any cysticercocidal drug may cause irreparable damage when used in the presence of ocular or spinal cysts.

Dracunculiasis

Dracunculiasis is caused by the nematode *Dracunculus medinensis*. It is transmitted by drinking water with copepods (i.e., tiny aquatic arthropods) infected with the larvae of *D. medinensis*. In the human stomach, copepods release the larvae that mature and migrate to the skin, causing an erythematous papule or blister. The blister ruptures, and the female worm can often be seen prolapsing through the skin. Treatment includes extraction of the worm combined with wound care. Metronidazole (Flagyl)¹ 250 mg PO three times daily for 10 days may be efficacious and facilitates removal of the worm.

Filariasis

Filariasis is caused by nematodes (i.e., roundworms) that inhabit the lymphatics and subcutaneous tissues. The most common filarial infections include lymphatic filariasis, onchocerciasis, and loiasis.

Lymphatic Filariasis

Lymphatic filariasis is caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and it is transmitted by mosquitoes. Adult worms result in a chronic inflammatory cell infiltrate around lymphatic vessels, causing their dilatation, hypertrophy, and obstruction. Many patients are asymptomatic, but some may develop fever with lymphangitis and lymphadenitis, chronic pulmonary infection, and progressive lymphedema leading to massive tissue thickening, especially of the legs and scrotum (i.e., elephantiasis). The overlying skin is thickened. Diagnosis is based on microscopic identification of the microfilariae in the blood and affected tissues.

Treatment consists of diethylcarbamazine (DEC, Hetrazan)¹⁰ in the following regimen: 50 mg on day 1, 50 mg three times daily on day 2, 100 mg three times daily on day 3, and 6 mg/kg in three doses on days 4 through 14. Prophylaxis with DEC 500 mg/day for 2 days each month is effective against *W. bancrofti* infection for travelers in endemic areas.

Onchocerciasis

Onchocerciasis (i.e., blinding filariasis) is caused by the filarial nematode *Onchocerca volvulus*, which is transmitted by the black-flies *Simulium*. It may manifest with subcutaneous onchocercid nodules, acute or chronic dermatitis, depigmentation (i.e., leopard skin), and skin atrophy (i.e., lizard skin), and in later stages, it may manifest with lymphadenopathy and lymphedema. The microfilariae have a predilection for the eyes, and the infection can lead to blindness (i.e., river blindness). Diagnosis is based on identification of microfilariae in skin snips.

Treatment consists of ivermectin (Stromectol) 150 µg/kg PO every 6 to 12 months until asymptomatic. DEC is contraindicated as it may lead to blindness.

Loiasis

Loiasis (i.e., Calabar swellings) is caused by the parasite *Loa loa*, which is transmitted by deerflies (*Chrysops*). Cutaneous

manifestations include pruritus, urticaria, and Calabar swellings, which are erythematous, warm, subcutaneous swellings associated with the migration of the worm through the subcutaneous tissues. Occasionally, there is subconjunctival migration of the adult worm, producing a migrating serpiginous lesion on the conjunctivae. Diagnosis is confirmed by identification of microfilariae in the blood by microscopic examination.

DEC¹⁰ is the treatment of choice in the following regimen: 50 mg on day 1, 50 mg three times daily on day 2, 100 mg three times daily on day 3, and 9 mg/kg/day in three doses on days 4 through 14. Ivermectin (Stromectol)¹ may cause encephalopathy in patients with a heavy *L. loa* infection. Prophylaxis with DEC is effective for *L. loa* in adults who travel in endemic areas.

Schistosomiasis

Schistosomiasis (i.e., snail fever) in humans is caused mainly by the trematodes *Schistosoma haematobium*, *Schistosoma japonicum*, and *Schistosoma mansoni*. All trematodes have a life cycle that involves the snail as an intermediate host. The infective cercariae leave the snail, swim, and penetrate the human skin, causing a pruritic papular dermatosis. The disease is transmitted by exposure to contaminated water with live cercariae or by drinking infested water. Skin findings of acute schistosomiasis include pruritic schistosomal dermatitis due to a hypersensitivity response to the cercariae and edema of the face, extremities, genitals, and trunk. Schistosomal fever (i.e., Katayama fever), lymphadenopathy, and diarrhea may also develop. Late skin findings (i.e., bilharziasis cutanea tarda) appear in patients with visceral disease and include firm, pruritic, grouped papules. Secondary infection, ulceration, and development of squamous cell carcinoma may follow. Diagnosis is confirmed by identification of the eggs in the urine or stool, by biopsy of affected tissues, or by enzyme-linked immunosorbent assay (ELISA).

Treatment includes praziquantel (Biltricide) 40 mg/kg/day³ in two doses for 1 day (for *S. haematobium* and *S. mansoni*) or 60 mg/kg/day³ in three doses for 1 day (for *S. japonicum*).

Cercarial Dermatitis

Cercarial dermatitis (i.e., swimmer's itch) is caused by cercariae (i.e., larvae) of nonhuman schistosomes that penetrate the skin and die without invading other tissues. It is transmitted by contact with fresh or salt water contaminated with cercariae. It manifests with extremely pruritic, erythematous macules of sudden onset, which evolve into papules, vesicles, and urticarial lesions located on parts of the body directly exposed to the water, while sparing clothed areas. Cercarial dermatitis is a self-limited disease, and treatment is symptomatic with topical steroids and oral antihistamines.

Diseases Caused by Arthropoda

Human Scabies

Scabies is a common skin infestation caused by the mite *Sarcoptes scabiei*, which is an obligate human parasite. Scabies is transmitted by direct contact with an infested individual or by contact with bedding and clothing. The incubation period for scabies is about 3 weeks, and reinfection results in symptoms within 1 to 3 days. Scabies is characterized by pruritus that usually worsens at night. Papules, nodules, excoriations, and burrows may be found. Lesions are usually located on interdigital spaces, wrists, ankles, axillae, waist, and genitals. Scabies manifests as red-brown nodules that represent a hypersensitivity response. In adults, the head is usually spared, whereas the involvement of the scalp, palms, and soles is common in infants.

¹Not FDA approved for this indication.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Crusted or Norwegian scabies manifests with hyperkeratotic papules or plaques of the hands and feet (often with nail involvement) and an erythematous scaly eruption on the face, neck, scalp, and trunk. Because pruritus is often absent, this disease can be misdiagnosed as psoriasis, eczema, or an adverse drug reaction. Lesions contain thousands of mites and are highly contagious. Crusted scabies mainly affects immunocompromised patients (e.g., patients with human immunodeficiency virus infection), mentally retarded persons, or debilitated patients.

Diagnosis is based on the microscopic identification of mites or their eggs or feces from burrows or papules. Treatment should be applied from the neck down in adults, and in infants, application should include the scalp and face (avoiding the eyes and mouth).

Treatment includes 5% permethrin (Elimite) applied for 10 hours and repeated after 1 week. A 25% benzyl benzoate solution⁶ is also efficacious in adults, and because of low toxicity, it is recommended in a lower concentration (10%) for children older than 4 months and for women during pregnancy. Sulfur ointments in petrolatum⁶ at concentrations of 6% to 10% may be used for scabies in children and pregnant women. Alternative treatments for scabies include crotamiton 10% (Eurax) applied once daily for 2 days, or ivermectin (Stromectol)¹ as a single- or two-dose regimen of 200 µg/kg/dose can be used. Aggressive treatment with ivermectin at a single dose of 200 µg/kg, repeated after 2 weeks with or without topical 5% permethrin cream (two applications, 1 week apart) and keratolytics (5% salicylic acid ointment¹ applied twice daily) is the treatment of choice for crusted scabies. All sexual and close personal and household contacts within the preceding 6 weeks should be treated simultaneously. Bedding and clothing should be decontaminated (i.e., machine washed and dried using the hot cycle or dry cleaned) or removed from body contact for at least 3 days, because the mite dies when separated from the human host.

Pediculosis

Pediculosis (i.e., lice) is a contagious dermatosis, caused by lice, which are blood-sucking, wingless insects and are obligate human parasites. Two species of lice infest humans causing three clinical forms of infestation: *Pediculus humanus capitis* (i.e., head louse), *Pediculus humanus corporis* (i.e., body louse), and *Phthirus pubis* (i.e., pubic louse). The body louse is the only louse that can carry human disease, including rickettsioses and epidemic typhus.

Pediculosis Capitis

Pediculosis capitis is caused by *P. humanus capitis*, and it is transmitted by close contact or by fomites with combs, brushes, towels, and hats. It manifests with pruritus (due to the saliva of the louse), excoriations, nape dermatitis, secondary bacterial infection, and cervical and suboccipital lymphadenopathy. Diagnosis is based on identification of lice and eggs or nits on the hair and on fluorescence of nits with Wood's light. Visible nits are deposited on the hair shaft, close to the scalp. After adequate treatment, nits found at 1.0 to 1.5 cm from the scalp are not alive.

Topical pediculicides should be applied according to the package instructions. Treatment includes malathion (Ovide) 0.5% lotion applied for 8 to 12 hours or permethrin (Nix) 1% cream rinse applied to shampooed hair for 10 minutes. A second application with permethrin is recommended 1 week later to kill hatching progeny. Alternatively, pyrethrins with piperidyl butoxide (RID) can be applied and washed off after 10 minutes. Benzyl benzoate 25% solution⁶ is mainly a scabicide, but it may also be used as a pediculicide. Ivermectin lotion 0.5% (Sklice) was approved by the FDA in 2012 for treatment of head lice in persons 6 months of

age and older, using a fine-toothed comb. Bedding, clothing, and headgear should be decontaminated (as for scabies) or removed from body contact for 2 weeks. Information for managing head lice can be found at the National Pediculosis Association web site (<http://www.headlice.org>).

Pediculosis Corporis

Pediculosis corporis (i.e., vagabond's itch) is caused by *P. humanus corporis*, which lives and reproduces in the lining of clothes and leaves the clothing only for feeding from the skin. This disease is usually found among vagabonds. Transmission occurs mainly through contact with contaminated clothing or bedding. Clinical manifestations include pruritus, excoriations, and small, red macules that usually occur on the back. Clothes should be examined carefully for lice.

Treatment is the same as for pediculosis capitis. Dry heat or washing in hot water followed by ironing is effective in killing the lice and their ova in clothing. Items that cannot be washed should be removed from body contact for 2 weeks.

Pediculosis Pubis

Pediculosis pubis is caused by *P. pubis* and affects the pubic hair. However, if left untreated, it may also affect very hairy regions of the chest, abdomen, axillary region, and especially in children, the eyelashes, edge of the scalp, and eyebrows. Patients present with pruritus. Useful diagnostic signs include small, blue-gray macules on the trunk, thighs, and axillae (i.e., taches bleuâtres or maculae ceruleae) due to conversion of bilirubin to biliverdin by the saliva of the louse and a brown "dust" found on underclothing due to the excreta of the insects. *P. pubis* is transmitted mainly by sexual contact, but it also may be transmitted by clothing or from parents to children.

Patients with pubic lice should be evaluated for other sexually transmitted diseases. Treatment of pediculosis pubis is the same as for pediculosis capitis. Bedding and clothing should be decontaminated (as for scabies) or removed from body contact for 2 weeks. Attention should be paid to treating sexual partners within the previous month because they are a common cause of reinfestation. For infested eyelashes and eyebrows, ophthalmic-grade petrolatum ointment may be used two to four times daily for 10 days, and lice and nits should be carefully removed from the eyelashes with forceps.

PIGMENTARY DISORDERS

Method of

Rebat M. Halder, MD; and Ahmad Reza Hossani-Madani, MD, MS

CURRENT DIAGNOSIS

Hyperpigmentation

- Ephelides: Multiple, small (1–4 mm), light to dark brown macules with poorly defined margins that occur on sun-exposed areas of the body
- Solar lentigines: Light brown to dark brown macular hyperpigmented lesions that are induced by natural or artificial sources of radiation and that can coalesce; they are located on face, neck, forearms, and hands
- Melasma: Arcuate or polycyclic brown to blue macules that coalesce into patches on face, neck, or forearms
- Postinflammatory hyperpigmentation: Dark patches or macules with indistinct margins at the location of an inciting inflammatory event

Hypopigmentation

- Pityriasis alba: two to three round, well-defined, paler macules with overlying powdery white scales, ranging in size from 0.5 to 5 cm in diameter, that transition to smooth, hypopigmented macules
- Vitiligo: Sharply demarcated, depigmented, milky white macules in a localized or generalized distribution
- Idiopathic guttate hypomelanosis: Multiple circular, smooth, small macules that are porcelain white, with occasional black dots, found on sun-exposed areas of upper and lower extremities
- Postinflammatory hypopigmentation: Off-white or tan macules, with ill-defined borders at the site of an inciting inflammatory event

CURRENT THERAPY

Hyperpigmentation

- Ephelides: Hydroquinone 4% (Epiquin Micro, Lustra) or glycolic plus kojic acid combination (Brown Spot Night Gel) plus maximum UVA-blocking sunscreen in the morning and tretinoin 0.05% cream (Retin-A)¹ in the evening
- Solar lentigines: Hydroquinone 4% (Epiquin Micro, Lustra) plus tretinoin 0.05% cream (Retin-A)¹ in the evening; cryotherapy; laser therapy
- Melasma: Monotherapy with hydroquinone 4% twice daily or tretinoin 0.05% in the evening; double therapy with hydroquinone 4% twice daily plus tretinoin 0.05% in the evening; triple therapy with fluocinolone acetonide 0.01% plus hydroquinone 4% plus tretinoin 0.05% (Tri-Luma Cream) in the evening
- Postinflammatory hyperpigmentation: Treat inciting event; hydroquinone 4% alone or in combination with topical steroid; fluocinolone acetonide 0.01% plus hydroquinone 4% plus tretinoin 0.05% combination (Tri-Luma Cream)¹ once daily

Hypopigmentation

- Pityriasis alba: Emollients, lubricants, sunscreen; tacrolimus 0.1% ointment (Protopic)¹ twice daily or mild nonhalogenated steroid for face and medium potency steroid for body; phototherapy (PUVA or UVB) for extensive disease
- Vitiligo: In patients with less than 20% body surface area (BSA) involvement, treat with cosmetics, topical (potent or very potent steroid or calcineurin inhibitor trial for less than 2 months), topical PUVA, or excimer laser. If local treatment fails, the

surgical approach may be used if the patient has less than 20% BSA involvement. For patients with more than 20% BSA involvement, UVB is preferred over oral PUVA. For patients with more than 50% BSA or disfiguring facial involvement, treat with monobenzyl ether of hydroquinone (monobenzone 20% [Benoquin]), 4-methoxyphenol or Q-switched ruby laser (694 nm).

- Idiopathic guttate hypomelanosis: Cryotherapy; dermabrasion; surgical minigrafting; intralesional steroids
- Postinflammatory hypopigmentation: Cosmetics; topical corticosteroids; topical PUVA

¹Not FDA approved for this indication.

Definition

The word *chromophore* is defined as elements that impart color to the skin. Hyperchromias describe abnormally darker skin, and hypochromias describe abnormally lighter skin. Pigmentation refers to melanotic causes of skin color change, differentiating it from skin color changes due to blood, carotene, bilirubin, or other causes. Hyperpigmentation refers to an increase in melanin production, melanocyte number, or both in the skin. Hypopigmentation refers to decrease of melanin, melanocytes, or both in the skin. Depigmentation refers to the absence of both melanin and melanocytes. Deposition of melanin in the epidermal layers visibly appears as a yellow to brownish hue. Dermal deposition appears as blue or blue-gray, with mixed epidermal and dermal melanin deposition appearing gray or blue-brown.

Evaluation

A thorough history and visual inspection of the pigmentary disorder can provide useful clues to the diagnosis, particularly recognition of pigmentary patterns (diffuse, circumscribed, linear, or reticulated). Further examination may be achieved by using the Wood's lamp to differentiate epidermal from dermal melanin.

General Recommendations for All Pigmentary Disorders

Broad-spectrum sunscreen with an SPF of 30 is recommended, in addition to wearing protective clothing. Avoiding prolonged sun exposure is also desired, if possible.

Hyperpigmentation

Ephelides

Description

Ephelides (freckles) are multiple, small (1–4 mm), light to dark brown macules with poorly defined margins that occur on sun-exposed areas of the body (face, upper back, arms). They are more commonly found in children (fading with age), fair-skinned persons, and those with red or blonde hair (especially those of Celtic ancestry). A relationship has been shown between painful sunburns in youth and development of ephelides, and the macules become darker with greater UV exposure. They are thought to be genetic in origin, following an autosomal dominant pattern, and are strongly associated with variants in the melanocortin-1-receptor (MC1R). Ephelides are significant because they are associated with an increased risk of melanoma and nonmelanoma skin cancer, perhaps serving as a marker for sun susceptibility.

Treatment

Although treatment is not necessary, modalities include either hydroquinone 4% (Epiquin Micro, Lustra) or glycolic plus kojic acid combination (Brown Spot Night Gel) plus maximum ultraviolet A (UVA)-blocking sunscreen in the morning and tretinoin 0.1% cream (Retin-A)¹ in the evening. Other therapies have included cryotherapy, lasers, and chemical peels.

¹Not FDA approved for this indication.

Solar Lentigo (Lentigo Senilis Et Actinicus)

Description

Solar lentigines are pigmented spots that share morphologic similarities with ephelides, making differentiation difficult. They are defined as light brown to dark brown macular hyperpigmented lesions induced by natural or artificial sources of radiation, which can coalesce. The incidence increases with age, and more than 90% of white persons older than 50 years demonstrate lesions. They appear most often on the face, neck, forearms, and hands. They can occur in nonclassic locations in those receiving phototherapy (such as the penis). Histologically, they differ from ephelides by the presence of epidermal hyperplasia, increased melanocyte number, and elongation of the rete ridges.

Treatment

Although treatment is not necessary, two different modalities have been used: physical therapies and topical therapies. Physical therapies include cryotherapy and lasers, and topical treatments include retinoids or combinations of agents. Liquid nitrogen may be used with a cotton swab for 5 to 10 seconds to induce lightening. Recurrence rates may be as high as 55% at 6 months. Side effects include atrophy with longer cryoprobe application, postinflammatory hyper- or hypopigmentation, and pain. The Q-switched Nd:YAG (532 nm) laser, among others, has been used with success.

Melasma

Description

Melasma is a hypermelanosis of the face, neck, and forearms that occurs with a higher incidence in women of African American, Latin American, and Asian descent. It appears on sun-exposed areas as arcuate or polycyclic macules that coalesce into patches. Epidermal melanin deposition causes a brownish appearance, and dermal melanin appears bluish. Combined epidermal and dermal melanin deposition appears gray. It is distributed in a central facial (65%), malar (20%), or mandibular (15%) pattern. It is more commonly seen in women and those with darker skin, but it can also be found in men. Contributing factors include a genetic predisposition, pregnancy, oral contraceptive use, endocrine dysfunction, hormonal treatment, UV light exposure, cosmetics, and phototoxic drugs.

Treatment

First-line treatment for melasma consists of broad-spectrum sunscreen with greater than SPF 30 coverage in addition to monotherapy with hydroquinone 4% twice daily or tretinoin 0.1% once daily. Double therapy with hydroquinone 4% twice daily plus tretinoin 0.05% may prove efficacious after an unsuccessful trial of monotherapy. If that fails, triple therapy may be attempted, with fluocinolone acetonide 0.01%, hydroquinone 4%, and tretinoin 0.05% (Tri-Luma) once daily being effective. Side effects of triple therapy include erythema, desquamation, burning, dryness, and pruritus at the site of application; telangiectasia; perioral dermatitis; acne breakouts; and hyperpigmentation. Chemical peels, superficial and medium depth, and Q-switched 1064 nm Nd:YAG laser may also be used for patients whose topical treatments have failed.

Postinflammatory Hyperpigmentation

Description

Postinflammatory hyperpigmentation is a very common condition that occurs as a result of a previous or ongoing inflammatory process, most commonly acne vulgaris, atopic dermatitis, infections, and phototoxic reactions and as a result of treatment with topical medications, chemical peels, and lasers. Postinflammatory hyperpigmentation occurs more commonly in persons with darker skin pigmentation and appears as dark patches or macules with indistinct margins at the location of the inciting inflammatory event.

Treatment

Primary treatment is aimed at treating the inciting cause of the hyperpigmentation. Additional effective therapies include 4%

hydroquinone alone or in combination with a topical steroid. Combination treatment includes fluocinolone acetonide 0.01%, hydroquinone 4%, tretinoin 0.05% (Tri-Luma)¹ once daily. Treatment must be temporarily stopped if irritation occurs. Broad-spectrum sunscreen should also be employed.

Hypopigmentation or Depigmentation

Pityriasis Alba

Description

Pityriasis alba is a childhood or adolescent condition that affects all races. It begins as an erythematous macule with ill-defined borders. The erythema fades after a few weeks, leaving two or three round, well-defined, paler macules with overlying powdery white scale, ranging in size from 0.5 cm to 5 cm in diameter. These eventually transition to smooth, hypopigmented lesions, which are generally located on the face. The pathogenesis of this disorder is unknown.

Treatment

Pityriasis alba is thought to be a self-limited skin disease. However, general treatment guidelines include use of emollients and lubricant, use of sunscreen, and decreasing sun exposure. Lesions limited to the face may be treated with hydrocortisone 1%¹ or other mild, nonfluorinated steroid. More potent steroids may be used for lesions on the body, including hydrocortisone valerate 0.2% (Westcort)¹ or alclometasone dipropionate 0.05% (Aclovate)¹. However, these can lead to atrophy if used over an extended period. Newer, safer, effective alternatives include tacrolimus 0.1% ointment (Protopic)¹ twice daily. Side effects include a burning sensation that fades over time. Extensive disease that is not amenable to topical therapy might benefit from photochemotherapy (psoralen plus UVA [PUVA] or UVB alone).

Vitiligo

Description

Persons with vitiligo acquire sharply demarcated, depigmented macules in a localized or generalized distribution. These macules appear milky white as compared with the surrounding normally pigmented skin. Lesions can increase in size. There is no predilection for race or sex, and three-quarters of patients generally present before the age of 30 years.

Treatment

General recommendations include the use of sunscreen, avoidance of the sun, and use of protective clothing. Treatments for localized vitiligo (<20% of body surface area) include cosmetics, a 2-month trial of topical treatment (potent or very potent corticosteroid or calcineurin inhibitor), excimer laser, or topical PUVA. Adults who have failed treatments for localized vitiligo may be considered for narrow-band UVB, oral PUVA, or surgical treatment, which includes split-skin grafting, transfer of suction blisters, or autologous epidermal suspensions added to dermabraded skin (followed by UVB). Surgical candidates should have localized, limited involvement and should not demonstrate lesion enlargement or Koebner phenomenon for 12 months prior to treatment. Patients with more than 20% body involvement may be considered for narrow-band UVB (311 nm) or oral PUVA. Those with greater than 50% body involvement or disfiguring facial involvement may be considered for complete depigmentation with monobenzyl ether of hydroquinone 20% (monobenzene 20% [Benoquin]). Children are generally not offered surgical treatment, and oral PUVA is relatively contraindicated in children younger than 10 years.

¹Not FDA approved for this indication.

Idiopathic Guttate Hypomelanosis

Description

This is an acquired, asymptomatic leukoderma with multiple, circular, smooth, small macules that have a porcelain white color. Black dots are occasionally observed within the macules. The macules increase in number with age, but they generally do not increase in size. They are most commonly located on sun-exposed areas of the upper and lower extremities.

Treatment

Treatments have included cryotherapy, dermabrasion, surgical minigrafting, and intralesional steroids; however, none of these have shown consistent acceptable results. Phototherapy has not been shown to be effective.

Postinflammatory Hypopigmentation

Description

Postinflammatory hypopigmentation is the result of an inciting inflammatory event leading to lesions that are off-white or tan, with ill-defined borders. This entity is noticed more commonly in those with darker skin.

Treatment

Hypopigmentation resolves with treatment of the underlying condition. Topical cosmetics may be useful. Topical corticosteroids tacrolimus 0.1% ointment (Protopic)¹ and topical PUVA therapy may also be used in patients who have lesions in cosmetically distressing areas.

¹Not FDA approved for this indication.

PREMALIGNANT SKIN LESIONS

Method of

Daniel Stulberg, MD; and Katarzyna Wilamowska, MD, PhD

CURRENT DIAGNOSIS

Actinic Keratoses

- Scaly white or flesh-colored lesions often with palpably rough surface
- Individuals with light skin and hair color are at high risk
- Most common on face, hands, and sun-exposed skin

Actinic Cheilitis

- Scale, thickening or fissures on the lips
- Lower lip more commonly involved than upper lip

Porokeratoses

- Macular lesions with slight scale or rice-paper appearance and hyperkeratotic border
- Disseminated superficial actinic porokeratoses (DSAP) predominant type—autosomal dominant transmission

Human Papillomavirus Disease

- Verrucous or papular flesh-colored lesions
- Genital, perineal, perirectal, or oral locations are at risk of malignancy

Atypical Nevi

- Multiple irregularly pigmented nevi in the familial atypical mole and melanoma syndrome
- Numerous, often raised nevi, especially with shades of red, brown, and black

CURRENT THERAPY

Actinic Keratoses or Cheilitis

- Cryosurgery first line if limited number of lesions
- Topical medications for extensive actinic change with multiple lesions
- 5-fluorouracil (Carac, Efudex) typically 2–3 weeks, although multiple protocols/variations
- Diclofenac sodium (Solaraze) longer protocol, less effective
- Imiquimod (Aldara, Zyclara) longer protocol, less effective
- Ingenol mebutate (Picato) 3-day course limited by maximum of 25-cm² treatment area and expense of medication
- Less commonly, laser, curettage, retinoids, photosensitizing medications followed by light therapy

Porokeratoses

- See treatment options for actinic keratoses

Actinic keratoses are the most common precancerous skin lesions seen in usual practice. If untreated, it is estimated that from 0.1% to 10% of these lesions will progress to squamous cell carcinoma that requires significantly more aggressive treatment. Fortunately, effective treatment is available, although it can cause significant discomfort. Risk factors for developing actinic keratoses are similar to those of developing basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and, to a certain extent, melanoma skin cancer. These risk factors include lighter skin colors, family history of actinic keratoses or nonmelanoma skin cancer, exposure to sunlight, ultraviolet radiation, use of tanning beds, and immunosuppression from disease, or immunosuppressant medications to prevent organ transplant rejection.

There are several other conditions or situations that can increase risk of precancerous and cancerous skin lesions. The first is arsenic. This is rare in developed countries and, other than avoiding arsenic exposures, is treated as outlined below for actinic keratoses. The human papilloma virus (HPV) can lead to papillomatous lesions and genital and oropharyngeal. Individuals with the familial atypical mole and melanoma syndrome (FAMMS), previously called atypical nevus syndrome, have multiple abnormal-appearing nevi and a family history of melanoma. Patients with atypical nevi and more than one first-degree relative with melanoma have a risk of melanoma approaching 100%.

Actinic keratoses should be treated to reduce the risk of progression to squamous cell carcinoma unless the patient has a limited life expectancy and the clinician determines that, based on the condition of the patient and their comorbidities, the discomfort of treatment would outweigh the benefits for the patient. Avoiding sun exposure and using broad-brimmed hats, sunscreen, and protective

Idiopathic Guttate Hypomelanosis

Description

This is an acquired, asymptomatic leukoderma with multiple, circular, smooth, small macules that have a porcelain white color. Black dots are occasionally observed within the macules. The macules increase in number with age, but they generally do not increase in size. They are most commonly located on sun-exposed areas of the upper and lower extremities.

Treatment

Treatments have included cryotherapy, dermabrasion, surgical minigrafting, and intralesional steroids; however, none of these have shown consistent acceptable results. Phototherapy has not been shown to be effective.

Postinflammatory Hypopigmentation

Description

Postinflammatory hypopigmentation is the result of an inciting inflammatory event leading to lesions that are off-white or tan, with ill-defined borders. This entity is noticed more commonly in those with darker skin.

Treatment

Hypopigmentation resolves with treatment of the underlying condition. Topical cosmetics may be useful. Topical corticosteroids tacrolimus 0.1% ointment (Protopic)¹ and topical PUVA therapy may also be used in patients who have lesions in cosmetically distressing areas.

¹Not FDA approved for this indication.

Porokeratoses

- See treatment options for actinic keratoses

Actinic keratoses are the most common precancerous skin lesions seen in usual practice. If untreated, it is estimated that from 0.1% to 10% of these lesions will progress to squamous cell carcinoma that requires significantly more aggressive treatment. Fortunately, effective treatment is available, although it can cause significant discomfort. Risk factors for developing actinic keratoses are similar to those of developing basal cell carcinoma (BCC), squamous cell carcinoma (SCC), and, to a certain extent, melanoma skin cancer. These risk factors include lighter skin colors, family history of actinic keratoses or nonmelanoma skin cancer, exposure to sunlight, ultraviolet radiation, use of tanning beds, and immunosuppression from disease, or immunosuppressant medications to prevent organ transplant rejection.

There are several other conditions or situations that can increase risk of precancerous and cancerous skin lesions. The first is arsenic. This is rare in developed countries and, other than avoiding arsenic exposures, is treated as outlined below for actinic keratoses. The human papilloma virus (HPV) can lead to papillomatous lesions and genital and oropharyngeal. Individuals with the familial atypical mole and melanoma syndrome (FAMMS), previously called atypical nevus syndrome, have multiple abnormal-appearing nevi and a family history of melanoma. Patients with atypical nevi and more than one first-degree relative with melanoma have a risk of melanoma approaching 100%.

Actinic keratoses should be treated to reduce the risk of progression to squamous cell carcinoma unless the patient has a limited life expectancy and the clinician determines that, based on the condition of the patient and their comorbidities, the discomfort of treatment would outweigh the benefits for the patient. Avoiding sun exposure and using broad-brimmed hats, sunscreen, and protective

clothing while outdoors can reduce the risk of additional lesions. Unfortunately, because of the long lead time between sun exposure and onset of disease, most patients will continue to develop more actinic keratoses due to the underlying skin damage. Patients should be counseled regarding the occurrence of additional precancerous and cancerous skin lesions and should be examined every 6 to 12 months, or even more frequently depending on the amount of disease burden, their individual risk factors, and clinical judgment.

There are several rare inherited genetic disorders that predispose patients to precancerous and cancerous cutaneous lesions, grouped under genodermatoses. Xeroderma pigmentosum (XP) is an autosomal recessive disorder where homozygotes have severe sun sensitivity due to inability to repair sun-damaged DNA, leading to development of BCCs, SCCs, and melanomas in early childhood. Basal cell nevus syndrome, another autosomal dominant disorder, is characterized by developmental anomalies and tumors, especially BCCs, starting in the fourth decade of life. Oculocutaneous albinism results from a group of autosomal recessive disorders of melanin biosynthesis. This deficiency leads to reduced or absent pigmentation of skin, hair, and eyes, leading to early photodamage.

Nevus sebaceous presents as a waxy yellow or brown congenital plaque or plaques. Around the time of puberty the plaque can thicken and develop into benign or, less commonly, malignant tumors. In addition to these specific disorders, patients with chronic ulceration, burn scars, radiation therapy fields, and inflammatory conditions including discoid lupus, lichen planus, lichen sclerosis, and lymphedema are at risk of developing skin cancers in affected areas.

Actinic Keratoses and Actinic Cheilitis

Clinical Manifestations

Actinic keratoses (AKs) are an abnormal proliferation of keratinocytes and a precursor of squamous cell carcinoma. Over time, 0.1% to 10% of the lesions will progress to squamous cell carcinoma. AKs present as rough or scaly white or flesh-colored lesions, often with a slightly erythematous base (Figure 1). A combination of visual inspection of the skin and tactile examination is useful to diagnose these lesions. Often they are easier to identify by gently

palpating the patient's skin for their characteristic rough surface on sun-exposed areas. If there is significant underlying erythematous thickened tissue, the clinician should consider whether the lesion has already progressed to squamous cell carcinoma, and potentially proceed with biopsy (Figure 2). Patients frequently note that they have scratched off a lesion but it returns over time, and many patients who have had multiple AKs become very adept at pointing them out to their clinician.

Actinic cheilitis is the same precancerous process when it occurs on the lips. It is more common on the lower lip, which catches the sun's rays more directly. The lip becomes rough, or the patient notes that it is always chapped. Dyshidrotic chapped lips can be in the differential diagnosis. A trial of topical lip balm may be initiated, and if the rough surface does not resolve, actinic cheilitis is the likely diagnosis. If there is ulceration or significant thickening of the lip, biopsy should be performed because of the possibility of squamous cell carcinoma of the lip.

Treatment

For patients with a limited number of lesions, destruction with cryosurgery is a quick and effective treatment with success rates generally above 95%. Cryosurgery can be performed using a variety of tools. Liquid nitrogen spray devices provide the coldest temperatures and fastest treatment in clinical practice. Other useful options include nitrous oxide spray devices, evaporative refrigerant liquids, mechanically cooled metal probes via refrigerant technology or compressed nitrous oxide or carbon dioxide devices or using a swab dipped in liquid nitrogen. Treatment protocols vary based on the instrument. For liquid nitrogen spray, there are multiple sized apertures available and freezing protocols based on clinician preference and lesion size. One protocol is to hold the spray tip 1 to 2 cm from the AK, spray until the lesion is frozen and keep frozen for 6 seconds, allow the lesion to thaw, and repeat the cycle. For clinical efficiency it is useful to treat several lesions in succession to allow the earlier lesions to thaw before repeating the freeze (Figure 3). Counsel the patient that the cold spray does cause discomfort and even feels like a burning or stinging sensation. After treatment, the lesions typically become erythematous, have slight

Figure 1 Early onset of actinic keratoses in young man with high-risk skin type.

Figure 2 Sun-damaged skin with multiple actinic keratoses and squamous cell carcinoma in situ, a.k.a. Bowen's disease.

Figure 3 Treating multiple actinic keratoses with cryosurgery.

Figure 4 BID 5- fluorouracil at 3 weeks.

swelling, and sometimes will blister. If they blister, topical petrolatum and an adhesive bandage may be used to protect the healing wound. If lesions do not resolve after adequate cryosurgery, consider biopsy for possible squamous cell carcinoma, which will require more aggressive treatment. Patient discomfort of cryosurgery varies. Most individuals will tolerate up to 15 lesions, although some patients will only tolerate cryosurgery of a few lesions, and some will tolerate treatment of dozens of lesions. Patients can return for additional cryosurgery on subsequent visits, or, if they have a very high density of lesions, topical agents may be more efficient to treat large areas with multiple lesions. The lips can be treated with cryosurgery or topical agents for actinic cheilitis. Because of the risk of swelling and discomfort, a lighter freeze protocol may be useful for the lips.

Topical chemotherapy with 5-fluorouracil (Carac, Efudex) has been used to treat AKs successfully for decades. It is particularly useful for field or blanket therapy in patients with multiple lesions and is very effective in clearing more than 90% of the lesions in treated areas. There are multiple variations in treatment protocols, and it is manufactured in 0.5% and 5% topical creams and 2% and 5% topical solutions. One option is to apply 5% 5-fluorouracil to the affected areas twice daily for 2 weeks until there is significant inflammation, often erosions and exudate (Figures 4 and 5). If there has been no reaction, the treatment can be extended out to 3 weeks. There is significant discomfort with this treatment protocol, which can be lessened by not treating the patient's entire affected areas all at once. Starting with treatment of one forearm and allowing that to heal before proceeding to the next forearm can be a useful way of starting and allowing the patient to get some familiarity with its use before starting it on a portion of their face or scalp. Treating the entire face or scalp can be very uncomfortable, so treating only one portion at a time and waiting until that heals before treating another area may be helpful. Because of photo sensitivity and increased risk of sunburn, it is preferable to perform treatment during the winter months or use strict sun avoidance. The 0.5% 5-fluorouracil formulation may be better tolerated on the lips for actinic cheilitis. Patients should be counseled to expect significant inflammation. It may also be useful to advise them that as a topical chemotherapy, this medication targets the lesions and typically does not cause inflammation of unaffected skin.

Because of the amount of inflammation with 5-fluorouracil, other topical treatments have been developed. They cause less inflammation but unfortunately also have lower efficacy rates. These other treatments include topical imiquimod (Aldara, Zylara), diclofenac (Solaraze), and ingenol mebutate (Picato). Imiquimod is used at bedtime twice a week for 16 weeks. Diclofenac is

Figure 5 Daily 5-fluorouracil at 5 weeks.

used twice daily for 8 to 12 weeks and is typically better tolerated. Both of these are less effective than topical 5-fluorouracil. Ingenol mebutate is used once daily for only 3 days. Its use is limited currently by its high cost and only being approved to use for 25 cm², approximately a 2" × 2" area, which is extremely small compared with the large amount of skin usually affected by AKs and an efficacy of less than 50%.

Outside of typical primary care practices, several other options exist. Photodynamic therapy can be used after a sensitizing application of aminolevulinic acid (Levulan) or methyl aminolevulinate (Metvixia). Nonselective chemical peels, dermabrasion, and ablative lasers can be used for field therapy to an entire area, treating

Figure 6 Porokeratosis with rice-paper appearance and peripheral ridge a.k.a. cornoid lamella.

both lesions and unaffected skin in the treatment field. Individual lesions may be treated with laser, trichloroacetic acid (Tri-Chlor),¹ or curettage.

Nicotinamide^{1,7} 500 mg orally BID has been shown to reduce the rate of developing additional lesions in patients already affected by actinic keratoses. The medication needs to be continued to maintain its effect.

Porokeratoses

Clinical Manifestations

Although much less common than actinic keratoses, porokeratoses also have malignant potential. Disseminated superficial actinic porokeratoses, like AKs, present on sun-exposed areas. They usually present as atrophic or rice-paper-appearing lesions surrounded by a slightly raised border (Figure 6). The plaque form (i.e., Mibelli's porokeratosis) is large and progressive, and the linear type may be generalized or segmental. Both of these types often manifest very early in life. Malignant transformation occurs mostly commonly in the linear type, followed by the Mibelli type. It is rare in the disseminated type and has not been reported in the punctate type.

Treatment

Disseminated superficial porokeratosis can be treated with locally destructive methods as outlined above for actinic keratoses and surgical excision.

Management of Complications

Treatment with cryosurgery is expected to cause local inflammation including possible vesicles and erosions. Topical petrolatum under an adhesive dressing or applied multiple times per day if used without a dressing can facilitate moist wound healing. Cryosurgery can cause hypopigmentation, which can be cosmetically distressing for patients with darker skin types and can predispose to sunburn in any skin type. Inflammation from topical medications for actinic keratoses can be soothed by application of petrolatum. Secondary infections, impetigo, and cellulitis are uncommon but possible after cryosurgery or inflammation associated with topical products. Antibiotics to cover methicillin-resistant *Staphylococcus aureus*

and *Streptococcus spp.*, should be prescribed if needed. Reactivation of herpes labialis can occur when treating the lips. Prophylactic antiviral therapy may reduce the risk of an outbreak in patients with history of herpes labialis.

PRESSURE INJURY

Method of

Rebecca M. Wester, MD

CURRENT DIAGNOSIS

- In April 2016, the National Pressure Ulcer Advisory Panel redefined the definition: pressure injury replaces the terms “pressure ulcer,” “decubitus ulcer,” and “bed sores.”
- Pressure injury develops from pathologic changes in combination with localized skin and underlying soft tissue damage, typically over a bony prominence or associated with a medical device. Skin can be intact or have an open ulcer.

CURRENT THERAPY

- Treatment is based on the stage and characteristics of the pressure injury.
- Nutrition and pressure relief are important interventions.
- Host-specific factors have profound effects on the healing process and have a greater influence than what is put on the wound.

Epidemiology

Most pressure injuries develop during acute hospitalizations, in spite of the adoption of national pressure ulcer prevention guidelines. Prevalence rates for pressure injuries have changed little over the past two decades. Hospitalized patients in intensive care or undergoing cardiovascular or hip surgery have higher rates.

End-stage skin failure occurs when hypoperfusion occurs at the end of life. The prevalence of pressure injuries is 11% to 18% for palliative care patients, nearly double in comparison with hospital rates. Pressure injuries impose a significant burden, not only on the patient but also on the entire health care system. To put it into perspective, the cost of treating 10 pressure injuries is equivalent to 5 knee replacements, 6 hip replacements, 9 pacemakers, or 5 bypass operations.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

Risk Factors

External factors that lead to the development of pressure injuries include pressure, shearing forces, friction, and moisture. Interaction of these external factors with host-specific factors such as immobility, sensory loss, incontinence, reduced perfusion, and compromised nutritional status culminates in tissue damage. Decreased skin perfusion resulting from hypotension, anemia, shock, or peripheral artery disease is increasingly recognized as an important cause of pressure ulcers. Other risk factors are cerebrovascular disease, cardiovascular disease, recent lower extremity fractures, medications, and diabetes.

Pressure ulcer risk assessment. The Braden and Norton scales are commonly used for pressure risk assessment. These scales assess risk factors such as physical and mental condition, mobility, moisture, continence, and nutrition. However, they are weak predictors of risk of ulcers and may be no better at reducing risk than clinical judgment.

Pathophysiology

Pressure alone is not sufficient to cause an ulcer; it's the addition of the confounding host-specific factors that ultimately leads to tissue damage. Superficial lesions are primarily the result of moisture and friction. Exposure to moisture in the form of perspiration, urine, or feces can lead to skin maceration. Friction occurs when patients are dragged across an external surface. This results in an abrasion with damage to the most superficial layer of skin. Friction contributes mostly to stage 2 pressure injuries, with limited contributions to stage 3 to 4 pressure injuries because it does not cause the necrotic changes associated with deep tissue injury. Pressure injuries are greatest over bony prominences where weight-bearing points come in contact with external surfaces and immobilization devices. Pressure over a bony prominence tends to result in a cone-shaped distribution, with the most affected tissues located deep, adjacent to the bone-muscle interface. Thus the extent of injury to deep tissues is often much greater than perceived from the visible ulcer on the skin surface. Typically, stage 3 to 4 pressure injuries start as a deep tissue injury that may then progress to the surface. There is little evidence to suggest that a stage 4 pressure injury develops as a gradual progression from stage 1 to stage 4.

Differential Diagnosis

Besides pressure injuries, other chronic skin ulcers are arterial ulcers, venous stasis ulcers, and diabetic ulcers: arterial ulcers occur in distal digits or over bony prominences, venous stasis ulcers occur on the lateral aspect of the lower leg in the setting of chronic edema, and diabetic ulcers occur in regions of callous formations. Traumatic injuries such as abrasions, skin tears, or burns are not pressure injuries; nor are surgical incision sites. Only pressure injuries are staged; never stage a wound that arises from a different etiology.

Diagnosis

Staging is done according to the National Pressure Ulcer Advisory Panel Pressure Injury Staging System:

Stage 1: Nonblanchable erythema of intact skin. May appear differently in darkly pigmented skin. Color changes do not include purple or maroon discoloration; this indicates deep tissue injury.

Stage 2: Partial-thickness skin loss with exposed dermis. The wound bed is viable, pink or red, and moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. This stage should not be used to describe moisture-associated skin damage (MASD) including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARS), or traumatic wounds (skin tears, burns, abrasions).

Stage 3: Full-thickness skin loss. Adipose (fat) is visible in the ulcer and granulation tissue and rolled skin edges are often present. Slough or eschar may be visible. The depth of tissue damage

varies by anatomic location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and bone are not exposed. If slough or eschar obscures the extent of tissue loss, then it is an unstageable pressure injury.

Stage 4: Full-thickness skin and tissue loss. Exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone is in the ulcer. Slough or eschar may be visible. Rolled edges, undermining, and tunneling often occur. Depth varies by anatomic location. If slough or eschar obscures the extent of tissue loss, then it is an unstageable pressure injury.

Unstageable: Obscured full-thickness skin and tissue loss. The extent of tissue damage within the ulcer cannot be determined because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or 4 pressure injury will be revealed. Stable eschar (dry, adherent, intact, without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

Deep tissue injury: Persistent, nonblanchable, deep red, maroon, or purple discoloration. May appear as a dark wound bed or blood-filled blister. Pain and temperature skin changes often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. The wound may evolve rapidly from intense or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structure is visible, then it is a full-thickness pressure injury (unstageable or stage 3 or 4). Do not use deep tissue injury to describe vascular, traumatic, neuropathic, diabetic, or dermatologic conditions.

Medical device-related pressure injury: Results from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury should be staged using the staging system.

Mucosal membrane pressure injury: Found on mucous membranes in patients with a history of a medical device in use at the location of the injury. Owing to the anatomy of the tissue, these ulcers cannot be staged.

Therapy

Pressure relief. Position the patient frequently at fixed intervals to relieve pressure over compromised areas. There is no evidence to suggest an optimal interval at which to reposition patients, although every 2 hours is recommended based on expert opinion. Advanced static support surfaces (mattress overlays and foam, gel, or air mattresses) rather than standardized hospital mattresses should be used to prevent pressure injuries in high-risk patients. Check the pressure-relieving devices for "bottoming out" by inserting your hand (palm up) between the device and the bed under the patient's sacral area. The device is considered ineffective if you are unable to slide your hand freely. For immobile individuals, off-load the heels by "floating the heels" with pillows under the patient's legs.

Pain. Dressing changes hurt. Use individualized pain management.

Assessment of nutrition/hydration. Pressure injuries occur in sicker individuals in whom overall intake may be reduced by coexisting illness. If adequate dietary intake is compromised, supplemental vitamins/minerals at the recommended daily allowance (RDA) should be considered. Protein supplementation may improve outcomes in the treatment of pressure ulcers, as per current guidelines. However, a 2014 Cochrane review concluded that there is no clear evidence that nutritional interventions (i.e., dietary supplementation) reduce the number of people who develop pressure injuries or help the healing of existing pressure injuries. There is no evidence to support the use of vitamin C or zinc to treat pressure injuries in patients who are not deficient in these nutrients. There is no difference in healing rates associated with supratherapeutic doses of vitamin C or zinc. The decision to use tube feeding must consider the patient's wishes, overall goal of care, and

TABLE 1 Débridement Methods

Mechanical: Wet-to-dry dressings; removes both devitalized and viable tissues; causes pain
Surgical (sharp): Scalpel, scissors, or forceps to remove devitalized tissue; quick and effective by skilled clinician; should be used when infection is suspected; causes pain
Enzymatic: Topical debriding agent to dissolve the necrotic tissue; appropriate when there are no signs or symptoms of local infection
Autolytic: Synthetic dressing to allow the devitalized tissue to self-digest from the enzymes found in the ulcer fluids; recommended for those who cannot tolerate débridement; may take a long time to be effective; commonly used with palliative wounds
Biosurgery: Larvae to digest devitalized tissue; quick and effective; good option for those who cannot tolerate surgical débridement; limited by access to larvae

TABLE 2 Pressure Injury Dressing Types

Dressing	Recommendations
Hydrocolloid	Light to moderate exudate ulcers Clean stage 2 or shallow (noninfected) stage 3 ulcers Consider using filler dressing beneath in deep ulcers to fill dead space
Transparent film	Partial thickness with minimal exudate ulcers or closed wounds Consider for autolytic débridement Consider as secondary dressing with alginate or other wound filler that will likely remain in the ulcer for an extended time (3–5 days) Do not use on moderately to heavily exudative ulcers Do not use as cover dressing over enzymatic debriding agents
Hydrogel	Full thickness with minimal or no exudate (stage 3 or 4) ulcers Consider use on shallow, minimally exudate ulcer Consider amorphous hydrogel for granulating noninfected ulcers Consider for dry ulcer beds
Alginate	Full thickness with moderate to heavy exudate ulcers with cavities (stage 3 or 4) Consider in clinically infected ulcer with concurrent treatment for the infection
Foams	Exudate stage 2 and shallow stage 3 ulcers Avoid using single small piece of foam in exudate ulcer with cavities Consider gelling foam in heavily exuding ulcers
Silver impregnated	Clinically infected or heavily colonized Avoid prolonged use; discontinue when wound infection is controlled

complications of tube feeding. Recent studies surprisingly observed that the use of tube feedings increased the incidence of pressure injuries and was associated with poorer healing. Tube feeding is associated with agitation, increased use of physical and chemical restraints and worsening of ulcers in individuals with severe dementia.

Removal (débridement) of necrotic tissue. Débridement by any of several methods (Table 1) may improve the time to a clean wound bed, but the effect of débridement on the time to healing remains to be determined.

Promotion of healing (reepithelialization). Pressure injuries should be cleansed with saline or tap water, and slough and

necrotic tissue debrided (see Table 1). The choice of a particular dressing depends on the wound characteristics, such as amount of exudate, dead space, or wound infection. A hydrocolloid, foam, or other nonadherent dressing that promotes a moist wound environment should be used (Table 2). Follow manufacturer recommendations regarding frequency of dressing changes.

Monitoring

Measurement. After staging the pressure injury, measure the length, width, and depth of ulcers. Document the presence of exudate, necrotic tissue, eschar, slough, undermining, and tunneling. Presence of healing tissue (pink granulation or epithelialization) should be recorded as well. Measurement frequency depends on the patient's care location, whether it's the hospital, a long-term care facility, or home care.

Infection. All pressure ulcers are colonized with bacteria. Never swab a chronic ulcer. The presence of bacteria alone does not indicate active infection, only colonization. Edema, odor, and purulent discharge are nonspecific. Worsening pain, erythema at wound edges, and warmth are signs of advancing cellulitis. Fever or delirium may be the only signs of infection. Systemic rather than topical antibiotics should be used to treat an infected pressure ulcer. Consider osteomyelitis when bone is exposed.

PRURITUS ANI AND VULVAE

Method of

Muhammad Ahmad Ghazi, MD

CURRENT DIAGNOSIS

- Anogenital pruritis is primarily idiopathic; most secondary etiologies can be divided into dermatologic, anogenital conditions, and systemic causes.
- Good history and physical examination are important for accurate diagnosis.
- Laboratory tests and procedures to diagnose the cause of pruritis ani and vulvae should be tailored to individual patients based on their presentation.

CURRENT THERAPY

- Initial treatment is usually conservative, and clinicians should focus on reassurance, education about hygienic practices, regular bowel movements, avoidance of moisture and irritants, and a trial of topical corticosteroids.
- Anogenital conditions such as hemorrhoids, fissures, skin tags, and fistulas—if present—must be treated first.

PRURITUS ANI AND VULVAE

Method of

Muhammad Ahmad Ghazi, MD

CURRENT DIAGNOSIS

- Anogenital pruritis is primarily idiopathic; most secondary etiologies can be divided into dermatologic, anogenital conditions, and systemic causes.
- Good history and physical examination are important for accurate diagnosis.
- Laboratory tests and procedures to diagnose the cause of pruritis ani and vulvae should be tailored to individual patients based on their presentation.

CURRENT THERAPY

- Initial treatment is usually conservative, and clinicians should focus on reassurance, education about hygienic practices, regular bowel movements, avoidance of moisture and irritants, and a trial of topical corticosteroids.
- Anogenital conditions such as hemorrhoids, fissures, skin tags, and fistulas—if present—must be treated first.

- Pruritus vulvae secondary to lichen planus, lichen sclerosus, and lichen simplex chronicus usually require superpotent topical steroid treatment.
- Refractory cases of pruritus ani may benefit from injectable treatments of methylene blue.¹
- Suspicious lesions of vulva and perineum that are resistant to initial treatment must be biopsied to rule out malignancy.

¹Not FDA approved for this indication.

Pruritus ani and vulvae is not a disease per se; rather, it is a symptom or manifestation of an underlying disease or the result of poor personal hygienic practices. Pruritus is derived from the Latin *prurire*, which means “to itch.” Pruritis ani is literally an unpleasant sensation leading to scratching the skin around the anal opening. Anogenital pruritus is a commonly ignored skin condition. Symptoms range from mild to severe and can be complicated by sleep disturbances, anxiety, depression, and social embarrassment. Pruritus ani and vulvae can be primary, in which case there is no identifiable cause, or be secondary to an underlying condition. Most of the secondary causes are anorectal, including hemorrhoids, fistulas, and fissures. Psoriasis, lichen sclerosus, and lichen simplex chronicus are common secondary dermatological causes of pruritus in the vulvar region.

Epidemiology

Pruritus ani is a common condition with an estimated prevalence of 1% to 5% of the population. It affects all ages and both genders. Male to female prevalence of pruritus ani is about 4:1. Symptoms are worse at night and in warm, moist climates. Pruritus vulvae is seen in women of all ages. Young females usually present with an infectious etiology while the primary disease is more common in postmenopausal women. Genital pruritus in men is rare and usually presents with balanitis.

Risk Factors

Poor personal hygiene, chronic diarrhea, obesity, high-risk sexual behaviors, and immunodeficiency states predispose a person to pruritus in the anogenital area. Heat, sweating, and tight undergarments may exacerbate the condition. A proposed list of causative factors is included in [Boxes 1 and 2](#).

Pathophysiology

The itching sensations of pruritus ani and vulvae are mediated by unmyelinated C fibers, which are distributed densely in the perineal region at the dermal-epidermal junction of the skin. Irritants in stool (exotoxins, intestinal lysosymes, endopeptidase, trypsin) and increased alkalinity of certain foods such as tomatoes, chocolate, and caffeine contribute to the perianal itching that precedes scratching. The itch-scratch cycle is mediated by several mechanical and inflammatory mediators, including histamine, kallikrein, bradykinin, trypsin, serotonin, and neuropeptides. The resulting nerve impulse is carried via spinothalamic tract to the thalamus, where the itching sensation is perceived. Intestinal transit time and altered anal sphincter pressure are influenced by certain foods that predispose people to perianal seepage and pruritus.

Pruritus vulvae is the result of increased permeability of the dermis resulting from a structurally thin stratum corneum as compared to the rest of the vulvar skin. Factors aggravating the pruritus include constant friction, rubbing, anatomic location, occlusion, moistness, fear of uncleanness in women, and excessive washing. The most common cause of pruritus vulvae is vulvar dermatitis or eczema, which affects one-third to half of all women presenting with this complaint. Dermatitis or eczema can be endogenous and the result of familial disposition, and it manifests as atopic dermatitis. Exogenous dermatitis such as contact dermatitis can be allergic, given that a trigger (allergen) might induce an immune response or contact irritant dermatitis. Common irritants include soaps, shampoos, vaginal creams, alcohol, tea tree

BOX 1 Common Causes of Pruritus Ani

Acute

Idiopathic up to 25% of cases
 Fecal contamination:
 Poor hygiene
 Fecal incontinence
 Anal sphincter dysfunction
 Anorectal pathology: 10% to 50% of cases
 Hemorrhoids, perianal fissures, pilonidal sinus, perianal abscess, rectal prolapse, polyps, and papilloma
 Mechanical factors:
 Excessive washing, rubbing, synthetic undergarments
 Infectious:
 Erythrasma (corynebacterium infection), Candida, dermatophytosis, herpes simplex, human papilloma virus, HIV, syphilis
 Parasitic:
 Scabies, pinworm
 Dermatoses:
 Allergic or contact dermatitis, psoriasis, drug eruptions
 Dietary factors:
 Tomatoes, chilis, coffee, beer, soda, dairy, chocolate, tea, citrus fruits

Chronic

Dermatoses:
 Allergic or contact dermatitis, psoriasis, lichen planus, lichen simplex chronicus, lichen sclerosus, Hailey-Hailey disease
 Inflammatory:
 Inflammatory bowel disease (ulcerative colitis and Crohn's disease)
 Malignant:
 Anal squamous cell cancer
 Extramammary Paget's disease
 Lymphoma/leukemia
 Metabolic:
 Diabetes mellitus, chronic liver disease and chronic kidney disease, celiac disease, iron deficiency anemia, hypovitaminosis A, B, D, E
 Miscellaneous:
 Hyperhidrosis
 Neuropathic pruritus
 Psychogenic (anxiety related)

oil,² douches, vaginal hygiene products, vaginal contraceptives, sanitary pads, nylon underwear, and toilet paper. Chemical allergens contributing to contact dermatitis in the genital area include benzocaine, neomycin, ethylenediamide, propylene glycol, latex dyes, nickels, semen, lanolin, perfumes, and tampons.

Clinical Manifestations

Perianal and vulvar itching, erythema, excoriations, fissures, hemorrhoids, pinworms, and fecal incontinence may be noticed on inspection of the perineal area. In the acute phase, skin redness of varying degrees is visible. Excoriations from the skin from itching may be present. Fissures in the labial folds may be present. Superinfection with yeast or bacteria may complicate the presentation.

Chronic anogenital dermatitis usually presents as erythema of varying degrees, and papillae appear in the labial folds. Hypo- or hyperpigmentation of the skin or thickening of the labial skin might develop over time, causing “lichenification,” which leads to lichen simplex chronicus.

Diagnosis of Pruritus Ani and Vulvae

A detailed history of bowel habits and personal hygiene (including products used, such as perfumes); dietary habits (e.g., caffeine consumption); and previous medical, psychiatric, and surgical history help elucidate the cause of pruritus ani. The patient should be asked about personal or family history of hives, asthma, conjunctivitis, or atopy when allergic dermatitis is suspected. Other relevant questions of history include recent use of antibiotics, clothing preferences, family history of cancers, other family members with similar symptoms (pinworms and scabies), rectal bleeding, change in bowel habits, or sexual preference (anal receptive intercourse). For pruritus vulvae, the patient should be asked about any history of itching, burning sensation, vaginal discharge, postcoital bleeding, or dyspareunia.

²Not available in the United States.

PREPUBERTAL AGE

Poor hygiene
Sensitization of vulvar skin: soaps, deodorants
Contact dermatitis
Parasitic infestations: Pinworms (*Enterobius vermicularis*), pediculosis, scabies
Bacterial infections (Group A beta hemolytic infections and *Escherichia coli*)
Vaginal candidiasis (rare in this age group)
Lichen sclerosis
Suspected child sexual abuse (based on evidence of genital trauma)

REPRODUCTIVE AGE

Vaginitis
Trichomonas
Bacterial vaginosis
Candidiasis
Rarely tinea cruris
Herpes simplex type II
HIV, syphilis
Dermatitis
Atopic dermatitis
Contact dermatitis
Psoriasis
Lichen planus
Lichen simplex chronicus
Lichen sclerosis
Seborrheic dermatitis
Pregnancy
Vulvar itching is worsened because of vulvar engorgement; pregnancy also predisposes women to vaginal discharge and candidiasis
Systemic diseases:
Diabetes, renal and liver diseases
Miscellaneous
Vulvar intraepithelial neoplasia (HPV)
Mechanical trauma
Idiopathic

POSTMENOPAUSAL AGE

Urinary or fecal incontinence
Menopause: Lack of estrogen leads to loss of skin elasticity and makes it prone to itching
Atrophic vaginitis
Lichen sclerosis
Paget's disease of vulvae
Vaginal malignancy (squamous cell cancer)

Physical Examination

Inspection with a bright light and a chaperone is recommended. Palpation includes a digital rectal exam and a female pelvic examination in case of pruritus vulvae. Wet preparation of vaginal secretions for *Candida*, bacterial vaginosis, potassium hydroxide testing, and cultures for *Neisseria gonorrhoeae* and chlamydia are recommended. Microscopic examination of scrapings will help to differentiate the parasitic and fungal infections.

Laboratory Tests

Laboratory tests should not be done routinely in all cases and should be tailored to the patient's history and physical examination. Below is a list of laboratory tests that should be considered when diagnosing possible causes of anogenital pruritus:

1. CBC (complete blood count) helps to differentiate between parasitic and infectious cases and diagnoses anemia (a possible cause of chronic pruritus ani)
2. Chemistry profile (to identify systemic causes such as hepatic and kidney diseases)
3. Urinalysis to screen for infection and systemic diseases such as diabetes
4. DNA polymerase chain reaction probe for gonorrhea and chlamydia
5. Cellophane tape test to look for pinworms
6. Stool for ova and parasites
7. Test for diabetes mellitus and HIV if suspected
8. Anal Pap smear for HPV is indicated if there is a history of anal receptive intercourse

Procedures

Anoscopy and proctoscopy are indicated to diagnose hemorrhoids and perianal fistulae. Colposcopic examination of the perineum may provide a detailed view of local pathology.

Colonoscopy is indicated for patients over 40 with a family history of colon cancers. Patch testing should be performed to diagnose allergic contact dermatitis. A skin biopsy is indicated in case of ulcerated skin lesions, refractory cases, and suspicious lesions to rule out malignancy. A 3 to 6 mm punch biopsy is recommended.

Differential Diagnosis

A broad range of clinical problems can be enumerated in the differential diagnosis, including (but not limited to) allergic skin reactions, infections, parasitic infestations, chronic liver disease, diabetes, and neoplasms; chronic conditions such as psoriasis or dermatitis; infections such as condylomata accuminata; and skin cancers such as Bowen's disease, squamous cell cancer, Paget's disease, or melanoma.

Prevention and Treatment
General Principles of Treatment

The goal of treatment should be the resolution of symptoms, restoration of skin anatomy, and prevention of recurrence. The most important step in the management of pruritus ani and vulvae is reassurance and patient education (Figure 1). An informed and educated patient tends to deal with symptom-related anxiety better. To identify and treat the cause, it should be understood that pruritus ani and vulvae are commonly idiopathic, and conservative measures are usually sufficient to treat the condition. However, secondary causes need to be identified and treated.

Anorectal conditions such as hemorrhoids, fistulas, and fissures may require surgical treatment and consultation. Antidiarrheals should be used in cases of loose stool. A high-fiber diet should be started.

Women presenting with vulvar pruritus should be screened and treated for vaginal infection (e.g., one dose of oral fluconazole [Diflucan] 150 mg for vulvovaginal candidiasis; metronidazole [Flagyl] 500 mg oral twice daily for 7 days for bacterial vaginosis). Dermatological conditions such as psoriasis and dermatitis are treated with topical steroids. Hormone replacement therapy can be used in cases of menopause. Topical estrogen creams are better alternatives for symptomatic relief.

Patients should be instructed to gently cleanse the perianal area twice daily and after each bowel movement. Sitz baths with plain warm water are recommended for perianal pruritus. The perianal area should be patted dry after washing. Patients with vulvar pruritus should avoid tight undergarments, jeans, and panty hose. The use of laundry detergents, bubble baths, feminine douches, or sprays containing protease should be discouraged. Women with a predisposition to vulvar dermatitis should wear loose pants. Panty liners should be avoided and replaced with tampons or cotton cloth.

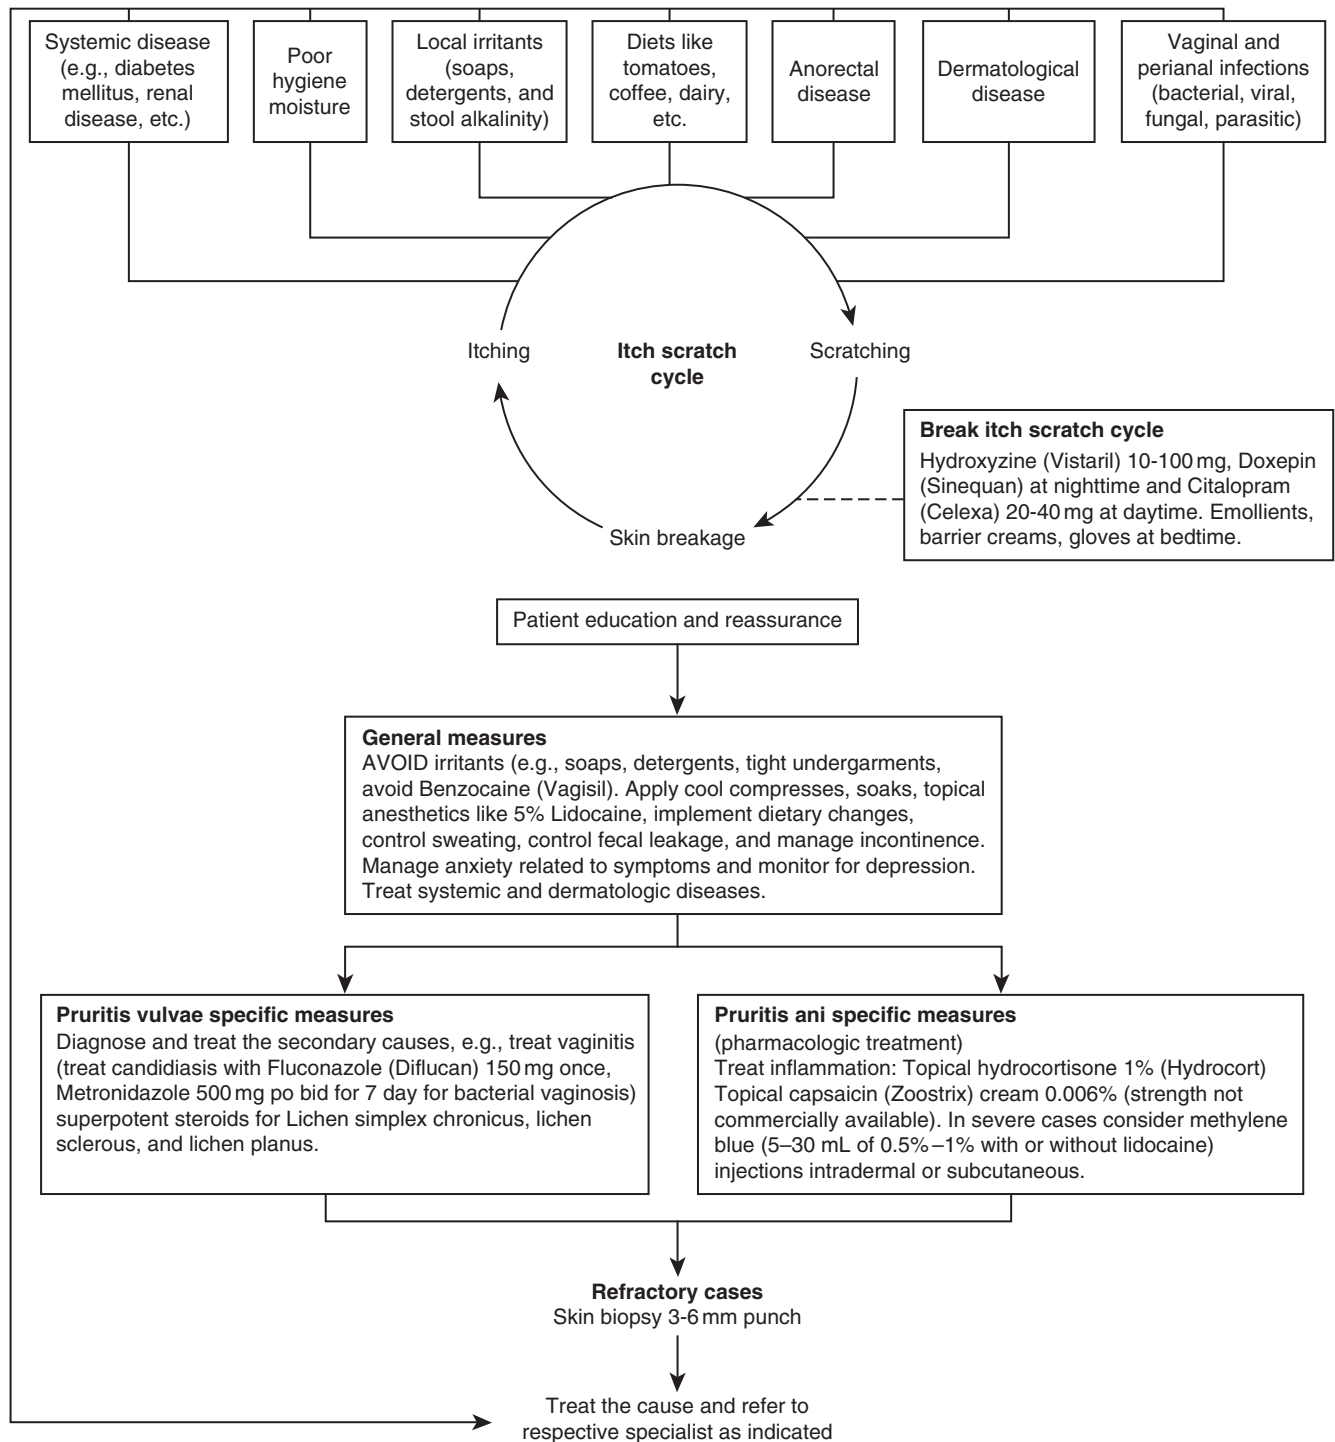

Figure 1 Pathogenesis and management of pruritus ani and vulvae.

Vulvae should be washed gently; women should avoid vigorous rubbing or cleaning. Patients with vulvar pruritus should use a bland moisturizer as a soap substitute to avoid irritation resulting from chemicals. The vulva should be dried before wearing underwear, and excessive perspiration should be controlled with talcum powder. Patients should be encouraged to manage incontinence and maintain an ideal body weight. Cornstarch should be avoided, as it can lead to bacterial colonization and exacerbation of symptoms.

Dietary modifications (for anal pruritus) are imperative, including limitations on the consumption of chocolate, tea, coffee, citrus fruits, and alcoholic beverages. Eating yogurt is recommended, especially while on antibiotics, to prevent diarrhea and worsening of perianal seepage.

Emollients such as aqueous creams or petrolatum or emulsifying ointments treat itching and dry skin, which can prevent erosion and

ulcer formation. These agents can be used irrespective of the etiology of pruritus. Zinc oxide (Desitin) cream is used topically to prevent excoriations in cases of perianal and vulvar pruritus. Combination products such as zinc oxide/bacitracin (rash relief antibacterial), zinc oxide/menthol (Calmoseptine), and zinc oxide/miconazole (Vusion) are available and can be used for symptomatic relief. Topical anesthetics (lidocaine 5% [L-M-X5 Anorectal, Topicaine 5]) may be used twice a day to help with acute symptoms. Topical benzocaine (Vagisil Anti-Itch Creme) should be avoided, as it is a strong irritant and allergen. Cool compresses and gel packs can help. Ice should not be used, as it can cause frostbite.

Antihistamines should be used to improve sleep, and patients should wear cotton gloves at night to prevent itching while asleep. Nails should be cut short, and nail varnish should be avoided.

Sedating antihistamines might help (e.g., hydroxyzine [Vistaril] 50 mg PO at bedtime; doxepin [Sinequan]¹ 10 to 100 mg at bedtime; citalopram [Celexa]¹ 20 to 40 mg during the daytime). Citalopram can also help with underlying anxiety symptoms, but caution is advised in the elderly and patients at risk of arrhythmias, because citalopram can cause QT interval prolongation. Any suspicious lesions of the vulvae and perineum should be biopsied to rule out underlying malignancy.

Pharmacologic Treatments

For mild pruritus ani, 1% to 2.5% hydrocortisone (Hydrocort) topical ointment is effective. Pramoxine (Prax, Senna Sensitive) can also be used alone or in combination with topical hydrocortisone cream (Analpram-HC, Pramoxone). 1% Hydrocortisone/1% iodoquinol (Vytone) can be used as an antiinflammatory treatment for external use in the anal and vulvar area. Topical capsaicin cream 0.006%³ has been used in cases of refractory itching and can be combined with topical hydrocortisone cream³ to avoid hypersensitivity. This strength of capsaicin cream is not commercially available. Mild topical corticosteroid ointments are sufficient to treat the perianal pruritus, and superpotent steroids should be avoided, as the skin is thin and there is a risk of ulcer formation. Methylene blue¹ injections are reserved for long-standing, intractable pruritus ani. Methylene blue 0.5% to 1% 5 to 30 mL mixed with normal saline and local anesthetics is injected intradermally, subcutaneously, and intracutaneously in the perianal skin to produce hypoesthesia. This treatment may be repeated, and studies report a success rate of 80% to 90%. Possible complications associated with methylene blue injections include cellulitis, transient urinary incontinence, urinary retention, skin abscess and skin necrosis. Long term effectiveness of these injections need further prospective studies.

For moderate vulvar disease, 0.1% triamcinolone (Kenalog) ointment is recommended. For severe cases and thickened skin, the superpotent steroid topical clobetasol (Temovate) or halobetasol (Ultravate) 0.05% ointments can be used. The use of these superpotent steroid creams should be limited and reserved for the resistant cases of pruritus vulvae, lichen simplex chronicus, lichen sclerosus, or resistant lichen planus. Vulvar lichen and lichen planus should be treated over the long term with superpotent steroids for adequate response and treatment. A very thin layer of steroid cream should be used, and patients should be educated about the side effects of the medication before starting the treatment. For vulvar lichen planus and lichen sclerosus, superpotent steroids are used topically once or twice daily for 2 to 3 months; three times a week for 1 month; then once or twice per week for the long term. For lichen simplex chronicus, treatment is twice daily for 2 weeks and then once daily for 2 weeks. It then moves to three times per week.

Topical calcineurin inhibitors 1% pimecrolimus cream (Elidel)¹ or 0.03% to 1% tacrolimus ointment (Protopic)¹ may be used for refractory cases as steroid-sparing agents. A common side effect of these agents is a burning sensation, so their use is controversial in cases of lichen sclerosis and lichen planus. Lichen sclerosis has 2-5% increased risk of developing squamous cell cancer, therefore clinical monitoring is recommended every 6-12 months and suspicious lesions must be biopsied.

In cases of neuropathic pruritus ani and vulvae, amitriptyline (Elavil)¹ 10 to 150 mg at bedtime is suggested. Other options are gabapentin (Neurontin)¹ 300 to 3600 mg three times a day⁴; pregabalin (Lyrica)¹ 75 to 400 mg/day; and mirtazapine (Remeron)¹ 7.5 to 15 mg at bedtime. In resistant and rare cases in which none of the above mentioned treatments is effective, radiation treatment may be indicated to destroy nerve endings. Naltrexone, an opioid antagonist has shown effectiveness in reducing itching episodes after one week of treatment in a case study. Several experimental treatments,

such as laser phototherapy, alcohol injection therapy, radiation, and surgery, have not been studied and are not recommended routinely.

Complications

Pruritus ani and vulvae can lead to myriad complications, including lichenification, skin excoriations, ulcers, secondary bacterial infections, and abscess formation.

Referral

For undiagnosed and resistant skin conditions, patients should be referred to a dermatologist. Persistent anal itching, a change in bowel habits, and rectal bleeding should prompt a referral to a gastroenterologist and colorectal specialist. Pruritus vulvae with vaginal bleeding and weight loss are indications for referral to a gynecologist.

Monitoring and Prognosis

Most cases of pruritus ani and vulvae are treated with general measures that lead to a full recovery. Long-term use of corticosteroids should be discouraged, and periodic monitoring for side effects, including skin erosions and bleeding, is advisable based on reported symptoms. The idiopathic disease usually persists and depicts a relapsing remitting course.

PSYCHOCUTANEOUS MEDICINE

Method of

Ladan Mostaghimi, MD

Psychocutaneous medicine explores the interactions between mind and skin. The spectrum of patients ranges from those who are delusional and refuse to see a psychiatrist to those who are depressed because of chronic disfiguring skin problems. The relationship between chronic skin diseases and psychological factors has been known for many years. In the first reference to psychocutaneous medicine from 1200 BC, the physician to the Prince of Persia speculated that his patient's skin disease (possibly psoriasis based on the description) was related to his anxiety about succeeding his father. Research in psychoneuroimmunology has better defined the relationship between skin and mind. This chapter discusses common psychodermatologic disorders and their treatment.

Classification

The five general categories encountered in psychocutaneous medicine are as follows:

- Psychophysiologic disorders: Emotional factors can exacerbate a skin disorder, such as psoriasis.
- Primary psychiatric disorders: Patients have no primary skin disorder, and the cutaneous signs are self-induced, such as delusions of parasitosis. This category includes primary psychiatric

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

⁴Not yet approved for use in the United States.

Sedating antihistamines might help (e.g., hydroxyzine [Vistaril] 50 mg PO at bedtime; doxepin [Sinequan]¹ 10 to 100 mg at bedtime; citalopram [Celexa]¹ 20 to 40 mg during the daytime). Citalopram can also help with underlying anxiety symptoms, but caution is advised in the elderly and patients at risk of arrhythmias, because citalopram can cause QT interval prolongation. Any suspicious lesions of the vulvae and perineum should be biopsied to rule out underlying malignancy.

Pharmacologic Treatments

For mild pruritus ani, 1% to 2.5% hydrocortisone (Hydrocort) topical ointment is effective. Pramoxine (Prax, Senna Sensitive) can also be used alone or in combination with topical hydrocortisone cream (Analpram-HC, Pramoxone). 1% Hydrocortisone/1% iodoquinol (Vytone) can be used as an antiinflammatory treatment for external use in the anal and vulvar area. Topical capsaicin cream 0.006%³ has been used in cases of refractory itching and can be combined with topical hydrocortisone cream³ to avoid hypersensitivity. This strength of capsaicin cream is not commercially available. Mild topical corticosteroid ointments are sufficient to treat the perianal pruritus, and superpotent steroids should be avoided, as the skin is thin and there is a risk of ulcer formation. Methylene blue¹ injections are reserved for long-standing, intractable pruritus ani. Methylene blue 0.5% to 1% 5 to 30 mL mixed with normal saline and local anesthetics is injected intradermally, subcutaneously, and intracutaneously in the perianal skin to produce hypoesthesia. This treatment may be repeated, and studies report a success rate of 80% to 90%. Possible complications associated with methylene blue injections include cellulitis, transient urinary incontinence, urinary retention, skin abscess and skin necrosis. Long term effectiveness of these injections need further prospective studies.

For moderate vulvar disease, 0.1% triamcinolone (Kenalog) ointment is recommended. For severe cases and thickened skin, the superpotent steroid topical clobetasol (Temovate) or halobetasol (Ultravate) 0.05% ointments can be used. The use of these superpotent steroid creams should be limited and reserved for the resistant cases of pruritus vulvae, lichen simplex chronicus, lichen sclerosus, or resistant lichen planus. Vulvar lichen and lichen planus should be treated over the long term with superpotent steroids for adequate response and treatment. A very thin layer of steroid cream should be used, and patients should be educated about the side effects of the medication before starting the treatment. For vulvar lichen planus and lichen sclerosus, superpotent steroids are used topically once or twice daily for 2 to 3 months; three times a week for 1 month; then once or twice per week for the long term. For lichen simplex chronicus, treatment is twice daily for 2 weeks and then once daily for 2 weeks. It then moves to three times per week.

Topical calcineurin inhibitors 1% pimecrolimus cream (Elidel)¹ or 0.03% to 1% tacrolimus ointment (Protopic)¹ may be used for refractory cases as steroid-sparing agents. A common side effect of these agents is a burning sensation, so their use is controversial in cases of lichen sclerosis and lichen planus. Lichen sclerosis has 2-5% increased risk of developing squamous cell cancer, therefore clinical monitoring is recommended every 6-12 months and suspicious lesions must be biopsied.

In cases of neuropathic pruritus ani and vulvae, amitriptyline (Elavil)¹ 10 to 150 mg at bedtime is suggested. Other options are gabapentin (Neurontin)¹ 300 to 3600 mg three times a day⁴; pregabalin (Lyrica)¹ 75 to 400 mg/day; and mirtazapine (Remeron)¹ 7.5 to 15 mg at bedtime. In resistant and rare cases in which none of the above mentioned treatments is effective, radiation treatment may be indicated to destroy nerve endings. Naltrexone, an opioid antagonist has shown effectiveness in reducing itching episodes after one week of treatment in a case study. Several experimental treatments,

such as laser phototherapy, alcohol injection therapy, radiation, and surgery, have not been studied and are not recommended routinely.

Complications

Pruritus ani and vulvae can lead to myriad complications, including lichenification, skin excoriations, ulcers, secondary bacterial infections, and abscess formation.

Referral

For undiagnosed and resistant skin conditions, patients should be referred to a dermatologist. Persistent anal itching, a change in bowel habits, and rectal bleeding should prompt a referral to a gastroenterologist and colorectal specialist. Pruritus vulvae with vaginal bleeding and weight loss are indications for referral to a gynecologist.

Monitoring and Prognosis

Most cases of pruritus ani and vulvae are treated with general measures that lead to a full recovery. Long-term use of corticosteroids should be discouraged, and periodic monitoring for side effects, including skin erosions and bleeding, is advisable based on reported symptoms. The idiopathic disease usually persists and depicts a relapsing remitting course.

PSYCHOCUTANEOUS MEDICINE

Method of

Ladan Mostaghimi, MD

Psychocutaneous medicine explores the interactions between mind and skin. The spectrum of patients ranges from those who are delusional and refuse to see a psychiatrist to those who are depressed because of chronic disfiguring skin problems. The relationship between chronic skin diseases and psychological factors has been known for many years. In the first reference to psychocutaneous medicine from 1200 BC, the physician to the Prince of Persia speculated that his patient's skin disease (possibly psoriasis based on the description) was related to his anxiety about succeeding his father. Research in psychoneuroimmunology has better defined the relationship between skin and mind. This chapter discusses common psychodermatologic disorders and their treatment.

Classification

The five general categories encountered in psychocutaneous medicine are as follows:

- Psychophysiologic disorders: Emotional factors can exacerbate a skin disorder, such as psoriasis.
- Primary psychiatric disorders: Patients have no primary skin disorder, and the cutaneous signs are self-induced, such as delusions of parasitosis. This category includes primary psychiatric

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

⁴Not yet approved for use in the United States.

disorders such as delusions of dysmorphosis, a variant of body dysmorphic disorder, and pathologic skin grooming behaviors (i.e., trichotillomania, onychotillomania [Figures 1 and 2], pathologic skin picking [Figure 3]), and nail biting).

- Secondary psychiatric disorders: A chronic, disfiguring skin disorder causes psychological problems.
- Cutaneous sensory disorders: Patients have purely sensory complaints, such as pruritus, burning, stinging, and biting, without visible primary skin disease or an underlying medical condition.
- Use of psychotropic medications for dermatologic conditions such as urticaria or postherpetic neuralgia.

Another, more practical classification of psychocutaneous conditions is based on the underlying psychopathology such as depression, anxiety, obsessive-compulsive disorder (OCD), delusional disorders, trichotillomania, excoriation disorder (skin picking), and body dysmorphic disorder. Standardized self-rating questionnaires are available for different conditions. These questionnaires can be administered and rated by office staff before the visit with the physician. This classification system can also help with treatment choices and follow-up plans.

An important area of psychocutaneous medicine's contribution to dermatology is assessing quality of life of patients with and without treatments. Research in this area guides clinicians on their treatment choices and risks/cost benefits of medications. With new accountable care measures, psychocutaneous medicine experts potentially could play an important role in designing quality-of-care measures in dermatology clinics.

Finally, for psychocutaneous research to be successful, the use of needs assessment surveys is important. The first sample of these surveys was published in the *International Journal of Dermatology* in 2009.

Figure 3 Skin picking at rough spots of skin.

Delusions of Parasitosis

CURRENT DIAGNOSIS

- The patient has false fixed beliefs about being infested.
- Look for the matchbox sign: samples of excoriated pieces of skin, scabs, clothing lint, or other debris are kept in bags, in plastic wrap, on adhesive tape, or in matchboxes by the patient and brought to the physician for examination to detect suspected parasites.
- Determine the type of delusional disorder: primary or secondary such as mood disorder with delusional features.
- For secondary delusions, determine the possible causes and contributing factors, such as substance abuse, organic brain pathology, pernicious anemia, hypothyroidism or hyperthyroidism, and systemic lupus erythematosus (SLE).
- Determine the extent of damage to the skin and history of skin infections.

CURRENT THERAPY

- In secondary delusional disorders, treatment of the main disorder will help to clear the delusions.
- Psychosocial intervention. Work with families. Provide a good support system.
- Evaluate and monitor safety for the patient, family members, and health care providers.
- Some patients may try to get rid of parasites by burning their belongings or their body, or by using toxic substances, damaging their skin and causing serious toxicity.
- Treatment may include psychoeducation and cognitive-behavioral therapy (CBT).
- Neuroleptics/antipsychotic medications:
 - Pimozide (Orap)¹ is a first-generation antipsychotic frequently used by dermatologists.
 - There are case reports of second-generation antipsychotics working well in these situations.
- The treatment needs to be customized based on each patient's profile and medication side effects.

¹Not US Food and Drug Administration (FDA) approved for this indication.

TABLE 1

Recommended Monitoring for Patients on Atypical Antipsychotics According to the American Diabetic Association Consensus Statement on Diabetes Care 2004

	BASELINE	4 WEEKS	8 WEEKS	12 WEEKS	QUARTERLY	ANNUALLY	EVERY 5 YEARS
Personal/family history	+					+	
Weight (body mass index [BMI])	+	+	+	+	+		
Waist circumference	+					+	
Blood pressure	+			+		+	
Fasting plasma glucose	+			+		+	
Fasting lipid profile	+			+			+

Delusions of parasitosis falls under the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) category of delusional disorder somatic type.

These patients have false fixed beliefs that they are infested by parasites. To meet the diagnostic criteria, the problem should last at least a month and should not be part of schizophrenia manifestations. Apart from the impact of the delusions, the patient's functioning is not markedly impaired and behavior is not always odd or bizarre.

Besides delusions about infestation, patients may have delusions of having foreign material in their skin (e.g., strings coming out of skin, materials getting crystalized under skin). Tactile and olfactory hallucinations, if present, are related to the main delusional theme.

Other delusional disorders for which a patient would seek dermatology advice are delusion of bromhidrosis (i.e., patients are convinced they have a foul odor that no one else can perceive) and the delusion of dysmorphism (i.e., patients are convinced that they have a defect in their appearance that no one else can appreciate). The delusion of dysmorphism is part of body dysmorphic disorder—delusional variant and it is differentiated in DSM-5 from other somatic delusions because it responds to the same treatments as the nondelusional variant of body dysmorphic disorder.

Another group of patients with delusions of parasitosis consists of patients with psychotic mood disorders such as depression or bipolar disorder and false fixed somatic beliefs. If the patient has mood symptoms in addition to delusional symptoms, treatment of the mood problem may correct the delusional beliefs. For about 12% of patients, the delusion of parasitosis is shared by a family member or significant other. This condition is called folie à deux (i.e., two-person shared madness) or folie partagée (i.e., shared delusions).

The DSM-5, published in May 2013, recommends eliminating the requirement that the delusion must be nonbizarre. The American Psychological Association (APA) also decided to change the “shared delusions.” Instead, if the criteria are met for delusional disorder, that diagnosis is used. If shared beliefs are present but the criteria are not met, then the term “other specified schizophrenia spectrum and other psychotic disorder” is used.

The patient with delusions of parasitosis usually has multiple superficial excoriations or deep wounds owing to manipulating the skin to try to remove the parasites. Physicians should be alert to the matchbox sign. In the matchbox sign, many samples of excoriated pieces of skin, scabs, clothing lint, or other debris are kept in bags, in plastic wrap, on adhesive tape, or in matchboxes by the patient and brought to physician's office for examination to detect suspected parasites. The patient can become very agitated when the physician denies the presence of any infestation after physical examination or assessment of the samples collected and brought in.

The physician should rule out substance abuse disorders. Some substances, especially amphetamines, cocaine, and phencyclidine (PCP), can cause formication and organic delusional syndrome in some patients. Organic reasons such as temporal lobe epilepsy or other brain pathology, neurosyphilis, pernicious anemia, hypothyroidism or hyperthyroidism, and SLE should be investigated, especially in older patients and if any neurologic symptoms are identified during the physical examination.

Treatment consists of antipsychotic or neuroleptic medications. For patients with psychotic mood disorder, treatment of the mood disorder usually improves the delusional symptoms. Depending on the amount of distress that the delusions are causing, treatment may start with a combination of a neuroleptic medication and an antidepressant, with subsequent tapering off of the neuroleptic and continuation of the antidepressant alone. Second-generation neuroleptics cause problems with weight gain and metabolic syndrome and require regular monitoring during treatment (Table 1). To facilitate acceptance of the treatment, it is important for the physician to have a good rapport with patients and address their concerns; at the same time, the physician must not accept or feed into patients' delusions by giving the impression that the delusion is believed to be real. Statements such as the following may encourage patients to accept treatment: “I'll be very honest with you; what you are telling me is very unusual. In most cases of infectious diseases, the doctors are able to easily identify the culprit. In your case, we have not found anything. Although we will keep looking to find the culprit, if any, I know it is difficult to live with this condition and we have medications that can help alleviate the symptoms you are experiencing.”

If the patient refuses psychotropic medications, he or she should be monitored for safety. If at any point the safety of the patient, family, or physician is threatened owing to dangerous behaviors related to delusional beliefs, local mental health providers should be consulted regarding institution of a court order for involuntary commitment for treatment.

Pimozide (Orap)¹ is a first-generation antipsychotic that dermatologists have traditionally used for delusions of parasitosis. However, most antipsychotic medications can help this condition. Physicians should be familiar with the first- and second-generation antipsychotics (Tables 2 and 3) and their side effect profiles and select the treatment that is best tailored to each patient. Notice the US Food and Drug Administration (FDA) warning on increased risk of stroke with the use of neuroleptics in elderly patients with Alzheimer disease.

A detailed, step-by-step approach to treating patients with delusions of parasitosis is discussed in *Cutis* (see references).

In recent years the Internet has been helpful in contributing to medical education and multiple other aspects of the physician's life. At the same time, the Internet has served as a medium to attract patients who feel their concerns are not validated by the medical community. Doctors are confronted with patients visiting their office with a self-diagnosis of diseases that do not exist in the medical literature.

One example of these “Internet-borne diseases” is “Morgellons disease” or, as the Centers for Disease Control and Prevention (CDC) named it, “unexplained dermatopathy.” In 2001, a former medical research laboratory technician believed that a nonhealing wound on her 2-year-old son's lip was due to an unknown parasite, called the disease “Morgellons,” and started a foundation and

¹Not FDA approved for this indication.

TABLE 2 Medications Used in Psychocutaneous Disorders

CLASS	NAME	DOSAGE RANGE	SIDE EFFECTS TO MONITOR
First-generation neuroleptics	Pimozide (Orap)*	1 mg daily in divided doses, gradually increase up to 0.2 mg/kg per day or maximum dose of 10 mg/d Perform CYP2D6 genotyping when the daily dose in adults is > 4 mg	Multiple drug–drug interactions due to metabolism through CYP4501A2 and CYP3A4; prolonged QT interval; torsades de pointes; GI, hematologic, hepatic, neurologic (tardive dyskinesia, neuroleptic malignant syndrome, extrapyramidal symptoms, acathisia); drug-induced SLE and priapism
	Haloperidol*	0.5–3 mg two to three times daily	Neurologic side effects, QT prolongation, drug–drug interactions
Second-generation neuroleptics	Olanzapine (Zyprexa)*	2.5–max 20 mg/d	Common side effects of second-generation neuroleptics include QT prolongation; neurologic side effects (extrapyramidal symptoms, tardive dyskinesia, neuroleptic malignant syndrome); risk of neurologic side effects is less with second-generation neuroleptics (least for quetiapine) but still exists; metabolic syndrome (needs regular monitoring; see Table 1); drug–drug interactions; blood dyscrasias (periodically assess and consider D/C if ANC <1000 or if unexplained decrease of WBC count)
	Risperidone (Risperdal)*	1–4 mg/d max 8 mg/d Age >65 keep max daily dose at 4 mg/d Doses above max recommended are rarely more effective and have more side effects	
	Aripiprazole (Abilify)*	2–max 30 mg/d	
	Quetiapine (Seroquel)*	25–max 800 mg/d in divided doses	
	Ziprasidone (Geodon)*	20–80 mg bid	
Antidepressants/ antianxiety SSRIs	Sertraline (Zoloft)*	50–200 mg/d	Each SSRI has its own side effect profile (e.g., fluoxetine may prolong QT interval; citalopram has dose-dependent QT interval prolongation with FDA warning on recommended dosage; fluvoxamine may cause Stevens-Johnson syndrome) Overall watch for sweating, GI symptoms, sexual side effects, myalgia, sleep problems, tremor, dizziness, bleeding tendencies, hyponatremia (rare), seizure (rare), manic episode, suicidal ideation, and suicide (rare); watch for drug–drug interactions
	Citalopram (Celexa)*	20–40 mg/d Do not exceed 20 mg for adults over age 60 or poor CYP2C19 metabolizers	
	Escitalopram (Lexapro)*	10–20 mg/d 10 mg/d in geriatric patients	
	Fluoxetine (Prozac)*	20–60 mg/d	
	Paroxetine (Paxil)*	20–50 mg/d, max 40 mg/d if age >60	
	Fluvoxamine,* works best in OCD	50–300 mg/d in divided doses (bid)	
Antidepressants/ antianxiety SNRIs	Venlafaxine,* extended-release form available (Effexor XR) Helpful in peripheral neuropathies	37.5–225 mg/d	Hypertension, sweating, GI symptoms, blurred vision, sexual side effects, hyponatremia, bleeding tendencies, neuroleptic malignant syndrome, serotonin syndrome, hepatitis (rare), drug–drug interactions
	Duloxetine (Cymbalta)* Also for treatment of fibromyalgia	30–60 mg/d, may increase to 120 mg/d but rarely more effective	Sweating, GI symptoms, sleep problems, bleeding tendencies, hepatotoxicity, fatigue, drug–drug interactions
Antidepressants/ antianxiety other	Trazodone,* helps insomnia and sometimes itching	50–400 mg/d	Sweating, weight change, GI symptoms, neurologic symptoms, blurred vision, hypertension, hypotension (rare), cardiac dysrhythmia (rare), priapism, seizure, drug–drug interactions

Continued

TABLE 2 Medications Used in Psychocutaneous Disorders—cont'd

CLASS	NAME	DOSAGE RANGE	SIDE EFFECTS TO MONITOR
	Mirtazapine (Remeron)* helps insomnia and itching with higher affinity for histamine receptors than doxepin	15–45 mg/d	Increased appetite, hyperlipidemia, somnolence, neurologic disorders, agranulocytosis and neutropenia (rare), seizure, drug–drug interactions
	Bupropion (Wellbutrin)* sustained-release and extended-release forms available	100–450 mg/d in divided doses	Hypertension, tachycardia, arrhythmia, pruritus, urticaria, GI symptoms, arthralgia, myalgia, neurologic symptoms, agitation, anger outbursts, menstrual problems, Stevens-Johnson syndrome, anaphylaxis, drug–drug interactions
	Buspirone (BuSpar)* works for anxiety problems	5–60 mg/d in divided doses	Nausea, blurred vision, nervousness, angry behavior, neurologic symptoms, congestive heart failure (rare), MI (rare), CVA (rare), drug–drug interactions
Tricyclic antidepressants for pruritus and hives	Doxepin* Topical 5% doxepin cream (Zonalon) has FDA approval for pruritus (for atopic dermatitis and lichen simplex chronicus)	25–300 mg/d in single and divided doses for depression, 10–25 mg/d for pruritus Topical: every 3–4 h max for 8 days; do not use under occlusion	Weight gain, GI symptoms, neurologic symptoms, blurred vision, urinary retention, arrhythmia (rare), blood pressure changes, bleeding tendencies, hematologic changes, drug–drug interactions
Tricyclic antidepressant for trichotillomania	Clomipramine (Anafranil)*	25–250 mg/d	Weight gain or loss, GI symptoms, blurred vision, neurologic symptoms, urinary retention, MI, orthostatic hypotension, hematologic side effects, hepatotoxicity
Neuropathic pain treatments Tricyclic antidepressant	Amitriptyline*	10–150 mg/d	Weight gain, GI symptoms, neurologic symptoms, blurred vision, cardiac dysrhythmia, hematologic symptoms, hepatic symptoms, CVA, drug–drug interactions
Antiepileptic medications	Gabapentin (Neurontin) FDA approved for postherpetic neuralgia	100 mg at night, gradually increase to up to 1800 mg daily in divided doses if needed	Myalgia, peripheral edema, neurologic symptoms, angry behavior, mood swings, problems with thinking, Stevens-Johnson syndrome, seizure, drug–drug interactions
	Pregabalin (Lyrica) FDA approved for neuropathic pain and postherpetic neuralgia. Also treatment of fibromyalgia	50 mg tid with gradual increase up to 600 mg/d in divided doses	Peripheral edema, weight gain, GI symptoms, ataxia, somnolence, blurred vision, euphoria, problems with thinking, angioedema
	Carbamazepine (Tegretol)*	50–1200 mg/d in divided doses for blood levels of 4–12 mcg/mL	Hyponatremia, severe blood dyscrasias (rare but needs regular CBC monitoring), toxicity over therapeutic ranges, atrioventricular block, cardiac dysrhythmia, congestive heart failure, syncope, hypertension or hypotension, GI symptoms, hepatitis, SLE, skin rash, Stevens-Johnson syndrome, TEN, psoriasis, acne, angioedema, nephrotoxicity, drug–drug interactions
	Lamotrigine (Lamictal)* helps impulsive behavior and neuropathic pain	25–200 mg/d in divided doses; do not increase to >50 mg/every 2 weeks	Headaches, sleep problems, diplopia, ataxia, GI symptoms, rhinitis, photosensitivity, rash, Stevens-Johnson syndrome, TEN, angioedema, hypersensitivity reactions, neutropenia, DIC, hematologic problems, hepatic failure, pancreatitis, rhabdomyolysis, teratogenicity, drug–drug interactions
Miscellaneous treatments for intractable pruritus	Thalidomide (Thalomid)* (also used in Behçet syndrome)	50–200 mg/d	Severe birth defects in pregnancy, edema, skin rash, GI symptoms, leukopenia, thrombotic disorder, peripheral neuropathy, Stevens-Johnson syndrome, TEN, seizure, pulmonary embolism, hypocalcemia, tremor, somnolence, drug–drug interactions
	Naltrexone (ReVia)* Vivitrol (IM Naltrexone)* Usually used for alcohol dependence and not in dermatology	50 mg/d 380 mg/mo IM	GI symptoms, headaches, anxiety, hepatic damage, opioid withdrawal (rare), drug–drug interactions

Continued

TABLE 2 Medications Used in Psychocutaneous Disorders—cont'd

CLASS	NAME	DOSAGE RANGE	SIDE EFFECTS TO MONITOR
	Cyclosporine (Sandimmune)* Monitor drug level	4–5 mg/kg per day	Hirsutism, pruritus in some patients, GI symptoms, neurologic symptoms (headaches, tremor, seizures, progressive multifocal encephalopathy [rare], coma [rare]), hepatotoxicity, nephrotoxicity, infections, hyperkalemia, hypomagnesemia, hypertension, anaphylaxis, lymphoproliferative disorder, drug–drug interactions
Benzodiazepines (sometimes used for burning mouth syndrome)	Clonazepam (Klonopin)*	0.25 mg at night with gradual increase. Usual dosage for neuralgia is 2–4 mg/d	Sialorrhea, ataxia, dizziness, somnolence, impaired cognition, aggravation of seizure, depression, behavioral problems, respiratory depression

*Not FDA approved for psychocutaneous disorders.

Abbreviations: ANC = absolute neutrophil count; bid = twice a day; CBC = complete blood count; CVA = cerebrovascular accident; D/C = discontinuation; DIC = disseminated intravascular coagulopathy; FDA = US Food and Drug Administration; GI = gastrointestinal; IM = intramuscular; MI = myocardial infarction; SLE = systemic lupus erythematosus; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor; TEN = toxic epidermal necrolysis; WBC = white blood cell.

TABLE 3 New Medications With Potential Use in Psychocutaneous Medicine but No FDA Approval for Any of the Psychocutaneous Ailments

CLASS	NAME	DOSAGE RANGE	SIDE EFFECTS TO MONITOR
Antidepressants/ anxiety Other	Vilazodone hydrochloride (Viibryd)* SRI plus 5-HT _{1A} partial agonist, like buspirone Desvenlafaxine (Pristiq)*; SNRI	10 mg/d × 7 d Then 20 mg/d × 7 d Then 40 mg/d Not tested in children 50 mg/d Not to exceed 100 mg/d Needs to be tapered gradually at discontinuation by increasing the dosage interval Dose adjustment needed for renal impairment	GI side effects: most frequent, diarrhea and nausea, occasionally vomiting; dry mouth; dizziness; insomnia; rare but serious: palpitation, ventricular premature beats, suicidal thoughts, and serotonin syndrome. Increased sweating in 10%–20% of patients May cause increase in triglycerides and cholesterol. Also watch for GI side effects, fatigue, blurred vision, proteinuria, anxiety. Rare but serious side effects including hypertension in 1%–2% and other cardiac effects to monitor, hyponatremia, GI hemorrhage, hypersensitivity reactions, seizure, mania, suicidal thoughts, withdrawal symptoms.
	Milnacipran (Savella)*; SNRI, pain reliever FDA application is only for fibromyalgia.	Start 12.5 mg daily Maximum dose 100 mg bid daily Dose adjustment needed for renal impairment, avoid using in hepatic disease	Increased blood pressure (2%–19.5%), tachycardia, palpitations, increased sweating (9%), sweats (12%), GI side effects, headache. Rare but serious: abnormal bleeding, serotonin syndrome, worsening of depression and suicidality, withdrawal symptoms.
	Selegiline transdermal (Emsam)*; MAOI FDA label for major depressive disorder and Parkinson disease.	6, 9, 12 mg patch/24 h May increase 3 mg/24 h every 2 weeks not to exceed 12 mg/24 h	Need to have low-tyramine diet. Decreased systolic pressure, orthostatic hypotension, application site reaction (24%), weight loss, diarrhea, indigestion, headache, insomnia, dry mouth. Rare but serious: atrial fibrillation, hypertensive crisis (with tyramine-containing food), suicidal thoughts.
New second-generation neuroleptics	Paliperidone (Invega)* A major active metabolite of risperidone IM form: Invega Sustenna FDA approved for schizophrenia and schizoaffective disorder Asenapine (Saphris)* FDA indications: bipolar I, acute mixed or manic	Start with extended-release tablets 6 mg/d and gradually increase to maximum of 12 mg/d Adjust dose for renal impairment For injectable Sustenna form dosage range is 39–234 mg IM once a month after initial titration Sublingual medication No titration is needed 5–10 mg bid	Tachycardia (up to 16%), hyperprolactinemia (45%–49%), weight gain (2%–19%), GI side effects, akathisia, dyskinesia, dystonia, EPS and parkinsonism, somnolence, tremor, anxiety, nasopharyngitis (up to 5%). Rare but serious: prolonged QT interval (7%), agranulocytosis, leukopenia, priapism, dysphagia, and TD. Weight gain (3%–5%), oral hypoesthesia (5%), akathisia, dizziness, EPS, somnolence. Rare but serious: QT prolongation, hypersensitivity reactions, angioedema,

TABLE 3 New Medications With Potential Use in Psychocutaneous Medicine but No FDA Approval for Any of the Psychocutaneous Ailments—cont'd

CLASS	NAME	DOSAGE RANGE	SIDE EFFECTS TO MONITOR
	episodes, and schizophrenia Lurasidone (Latuda)*	Initial dose titration not required 40 to maximum of 160 mg/d taken with food (350 calories), needs dose adjustment in renal and hepatic impairment	neuroleptic malignant syndrome. TD is not listed but is always a possibility. Nausea, akathisia, EPS, parkinsonism, somnolence. Rare but serious: orthostatic hypotension, syncope, agranulocytosis, CVA, seizure, TD, transient ischemic attack, suicidal thoughts, neuroleptic malignant syndrome.
	Iloperidone (Fanapt)* FDA approval: schizophrenia	1 mg bid on day 1 and titrate to maximum of 12 mg bid Do not use in patients with hepatic impairment	Weight gain (1%–18%), orthostatic hypotension (3%–5%), tachycardia, dizziness, somnolence, GI problems, nasal congestion, fatigue, hyperprolactinemia (26%). Rare but serious: prolonged QT interval, syncope (0.4%), hyperglycemia, CVA, transient ischemic attack, suicidal intent. TD is a risk in all neuroleptics. Risk differs per medication.
Miscellaneous For pathologic grooming behaviors (trichotillomania, skin picking, nail biting)	N-acetylcysteine (NAC) (Acetadote)*	1200–2400 mg/d	GI (nausea, indigestion), abdominal pain, headache, worsening of asthma. In long-term treatment needs to be taken with a multivitamin plus vitamin C.

*Not FDA approved for this indication.

Each year there are new medications added to this list, for example, cariprazine (Vraylar), brexpiprazole (Rexulti), pimavanserin (Nuplazid), aripiprazole lauroxil (Aristada, long-acting injection form of aripiprazole). These new medications are not FDA approved for psychocutaneous disorders and they should be used with extreme caution, recognizing that their mechanism of action and side effect profile for treatment of psychocutaneous disorders are unclear.

Abbreviations: CVA = cerebrovascular accident; EPS = extrapyramidal symptoms; FDA = US Food and Drug Administration; GI = gastrointestinal; IM = intramuscular; MAOI = monoamine oxidase inhibitor; SNRI = serotonin-norepinephrine reuptake inhibitor; SRI = serotonin reuptake inhibitor; TD = tardive dyskinesia. Please note that the information on tables is summarized and not comprehensive; refer to drug databases such as the *Physician's Desk Reference* for a complete list of side effects and black-box warnings.

website under that name. Very soon multiple patients self-identified with the symptoms, which included different-color fibers coming out of one's skin. The campaign spread rapidly. Both the Internet and mainstream media were involved in publicity for the new disease. The advocacy led Congress to request that the CDC investigate the cause of the disease. The CDC started the investigation but avoided calling the disease by its Internet name and named it "unexplained dermopathy." In January 2012, the CDC published the results of its investigation in the Public Library of Science online journal *PLoS ONE*, stating that "no common underlying medical condition or infectious source was identified, similar to more commonly recognized conditions such as delusional infestation." The prevalence reported in the CDC report was 3.65 per 100,000 enrollees.

Even after the CDC report, many patients continued to advocate for an infectious cause and argue against a noninfectious cause. Even though the Morgellons Research Foundation site has closed, other online sites are still active. These sites advise patients about how to talk to their physicians so they are not labeled as delusional and how to request more testing. Online advice includes instructions on avoiding the matchbox sign at the first visit. One such site is that of the Charles Holman Foundation. This foundation is invested in finding an organic cause for Morgellons disease. Physicians funded by this foundation have recently published articles referenced in PubMed. Their most recent theory is that Morgellons disease is a form of Lyme disease. The problem with this is that some patients become even more fixated in their delusions. Patients with negative Lyme tests may claim that Lyme testing is not diagnostic. This further delays appropriate treatment.

Our clinical approach is to do a complete physical examination and necessary laboratory testing. If we do not find a culprit and we believe the patient has somatic delusions, we give the patient the correct diagnosis and work closely with the patient and his or her family to treat the delusions. In the long run this will decrease individual and family suffering. It will also reduce unnecessary health care costs and doctor shopping.

Dermatitis Artefacta (Factitious Dermatitis), Neurotic Excoriation, and Acne Excoriée

CURRENT DIAGNOSIS

- Determine the type of problem: patient's need to assume sick role, secondary gain, or impulsive skin picking (neurotic excoriation and acne excoriée).
- Assess the severity and degree of scarring, which may require intensive treatment.

CURRENT THERAPY

- For dermatitis artefacta, the patient should be confronted in a nonjudgmental, empathetic way. Provide supportive dermatologic care for the skin and refer the patient for appropriate psychological interventions.
- For acne excoriée and neurotic excoriation, rule out underlying psychopathology and use a combination of therapy (CBT or behavioral therapy) and medications that help impulsive behavior such as selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), buspirone (BuSpar), anticonvulsants, naltrexone (ReVia), N-acetylcysteine (NAC), and neuroleptics, depending on the extent of the problem and scarring.
- There are no FDA-approved medications for this type of impulse control/compulsive behavior, and use of suggested medications should be based on the risk/benefit assessment for each patient.

Dermatitis Artefacta or Factitious Dermatitis

Dermatitis artefacta (i.e., factitious dermatitis) refers to intentional production of skin lesions to satisfy a psychological need. This could be achieved by different methods, such as excoriation, burning, or injection of toxic substances. Patients usually deny the self-induced nature of the problem. Clinically the lesions are located in reachable areas of the skin and can mimic any skin disease.

The DSM-5 has two subtypes of factitious disorder: factitious disorder imposed on self and factitious disorder imposed on another (previously, factitious disorder by proxy). The DSM-5 proposes the grouping of the factitious disorders with the somatic symptom disorders to facilitate research on the broad spectrum of symptom reporting by patients, from feigning symptoms to experiencing symptoms with no clinical findings.

Factitious dermatitis usually occurs in patients with underlying psychopathology. After a diagnosis is made, the physician needs to discuss it with the patient in a nonjudgmental, empathetic way. Supportive dermatologic care should be provided for wounds, and the patient should be referred for psychological evaluation. Antidepressant and anti-anxiety medications can help to treat underlying depression and anxiety. Supplementary therapies include biofeedback, relaxation, acupuncture, hypnosis, CBT, behavioral therapy, and family therapy if the family members are involved in care.

Neurotic Excoriation and Acne Excoriée

Patients with acne excoriée create excoriations by repetitive scratching or skin picking. Women are affected more than men. Patients scratch and pick at their acne, an insect bite, dermatitis, or other bumps or rough spots of the skin (Figure 4). Any part of the skin that is not smooth or is pruritic (Figures 4 and 5) can

Figure 4 Bruising of skin due to severe scratching in atopic dermatitis.

Figure 5 Scarring alopecia from chronic picking and new onset of lichen planopilaris around the scar on the scalp.

be a target. However, patients may inflict excoriations without the trigger of any skin pathology because the condition is a psychological process with dermatologic manifestations. Patients usually have ritualistic picking habits and report building of tension before picking and release of tension after picking.

Often patients with neurotic excoriations complain of pruritus. In this case a pruritus workup to rule out causes such as iron deficiency and gluten sensitivity is important.

The DSM-5 has recognized that pathologic skin picking is a prevalent and disabling condition (see Figures 3 and 4). The DSM-5 (as opposed to the DSM-IV, where skin picking was classified under impulse control disorders not otherwise specified) has skin picking classified under obsessive-compulsive and related disorders.

For any self-injurious behavior, patients must be screened for underlying psychopathologies such as personality disorders. However, in many patients, the behavior results from an impulse control problem or is a compulsive act in response to stressors or simply part of excessive grooming.

In addition to treatment of the underlying psychopathology, a combination of behavioral therapy and medications that help with impulsive behavior is used. The success of treatment depends on the patient's motivation to avoid scarring and to replace the self-injurious behavior with better behavior, including gentle skin care. Motivational interviewing could help patients explore and resolve their ambivalence and participate fully in treatment. Patients need to replace picking with other relaxing behaviors that are not harmful to skin, such as breathing relaxation or use of stress balls, Chinese exercise balls, Greek worry beads, stuffed animals, or Silly Putty. In finding appropriate replacement behavior, the physician should remember that tactile stimulation is important in these patients' anxiety relief.

Another therapy model for skin pickers is to consider chronic picking as an addiction and apply addiction therapy models to picking. Self-help groups and websites such as Pickers Anonymous (<http://www.stoppickingonme.com>) could help with treatment.

There is no FDA-approved medication for this condition. The use of different classes of medications is mostly based on case reports. The first step is to use an SSRI, such as fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), or citalopram (Celexa), or an SNRI, such as venlafaxine (Effexor XR) or duloxetine (Cymbalta). Dosage and side effect profiles are provided in Table 2. If this is insufficient, the physician can add anti-anxiety medications, such as buspirone (BuSpar), and some of the newer anticonvulsant medications, such as lamotrigine (Lamictal). In the case of severe picking, such as in patients with Prader-Willi syndrome, multiple infections and scarring can occur. Naltrexone (ReVia), as well as the occasional use of neuroleptics such as aripiprazole (Abilify) and quetiapine (Seroquel), can help to break the cycle of scratching and give time for behavioral treatments to take effect. Once the patient has improved, medications can be tapered and discontinued, but he or she may need to stay on a maintenance dose of medications.

Prurigo Nodularis and Lichen Simplex Chronicus

CURRENT DIAGNOSIS

- Prurigo nodularis (Figure 6): hard nodules that are 1 to 5 cm in diameter with hyperpigmentation and warty or excoriated surface
- Lichen simplex chronicus: lichenification (thickening) of the skin
- Different histopathology for prurigo nodularis and lichen simplex chronicus
- Drug history to rule out pruritus induced by medications or drugs of abuse
- Complete blood cell count to rule out lymphoma and polycythemia rubra vera
- Iron studies
- Renal function tests (blood urea nitrogen [BUN], creatinine, and electrolytes) to rule out renal failure
- Liver function tests to rule out chronic obstructive biliary disease

- Serology for hepatitis
- Test for diabetes mellitus
- Thyroid and parathyroid hormone levels
- Total serum immunoglobulin E (IgE) levels for atopy
- Patch test if allergies are suspected
- HIV test and purified protein derivative (PPD) (if indicated)
- Rapid plasma reagin (RPR) test
- Skin biopsy and direct and indirect immunofluorescence assays to rule out immunobullous and autoimmune diseases
- Stool check for parasites
- Gastrointestinal and serum testing to rule out malabsorption and gluten sensitivity
- Psychological evaluation
- Chest x-ray and computed tomography (CT) scan if lymphoma is suspected

CURRENT THERAPY

- Topical antipruritic creams such as topical doxepin (Zonalon), Sarna Anti-Itch, Eucerin Calming Cream; topical steroids or intralesional steroid injection.
- Topical capsaicin (Zostrix)¹
- Topical vitamin D₃ derivative (calcipotriene [Calcitrene])¹
- Cryosurgical treatment for a small number of prurigo nodularis lesions
- For lichen simplex chronicus, some reports of efficacy of tacrolimus (Protopic)¹
- Narrowband or broadband ultraviolet B (UVB) light more effective than UVA
- Psychosocial and therapy interventions to break the itch/scratch cycle
- Psychotropic medications to help with itching and sleep: mirtazapine (Remeron),¹ doxepin,¹ or trazodone¹
- In resistant cases, other treatments such as naltrexone (ReVia),¹ cyclosporine (Sandimmune),¹ thalidomide (Thalomid),¹ and lenalidomide (Revlimid)¹

¹Not FDA approved for this indication.

Clinically, prurigo nodularis (i.e., chronic circumscribed nodular lichenification, picker's nodules) is a chronic, severe itch accompanied by 1- to 5-cm hard nodules with smooth or warty surfaces and a hyperpigmented periphery (Figure 6). The new lesions are usually red and inflamed, whereas the old lesions are pigmented. The

Figure 6 Prurigo nodularis.

lesions may also be excoriated. Lesions are mostly located on the extensor surface of limbs, but they can also be located on the face, scalp, and trunk. Histopathology evaluation shows lichenification, a dense infiltrate in dermis and neural hyperplasia, and proliferation of Schwann cells.

A good history and physical examination should include a medication history because pruritus is a side effect of many classes of medications (e.g., diuretics, angiotensin-converting enzyme [ACE] inhibitors, beta-blockers, antidepressants).

Laboratory testing (see **Current Diagnosis** box) is required before treatment. CT scans and chest radiographs are obtained if lymphoma is suspected. In chronic cases laboratory testing needs to be repeated at regular intervals since in some diseases itch may be the first sign and other symptoms may take some time to appear.

Topical treatments with antipruritic creams are not very helpful. Potent topical steroids such as betamethasone dipropionate (Diprosone) ointment under occlusion or intralesional injection of steroids such as triamcinolone acetonide (Kenalog-10) may be successful, but they have the risk of skin atrophy. Topical capsaicin (0.025%–0.1% Zostrix),¹ a component of red pepper, can help in early stages. In some cases topical vitamin D₃ derivative (calcipotriene [Calcitrene])¹ may help.

For diffuse and resistant forms of prurigo nodularis, broadband and narrowband UVB and UVA can be effective. Narrowband UVB is more effective and has fewer side effects than UVA.

Also, for resistant forms, cyclosporine (Sandimmune)¹ 4 mg/kg per day can help. It should be continued for at least 6 months (see **Table 2**).

Thalidomide (Thalomid)¹ 200 to 400 mg in different studies has been an effective treatment for prurigo nodularis. Thalidomide is difficult to obtain because of its teratogenicity, and it does have serious side effects such as irreversible peripheral neuropathies. A similar compound, lenalidomide (Revlimid)¹ 5 mg/day, with less potential for peripheral neuropathy, was effective in one case of a patient resistant to all the other treatments.

Naltrexone (ReVia),¹ an opioid antagonist, 50 mg/day is effective in some cases. It has an FDA black-box warning on hepatotoxicity.

More recently low-dose Naltrexone (ReVia)¹ (1.5 mg qhs × 7 days then 3 mg qhs × 7 days then 4.5 mg qhs) has been reported to be effective in some autoimmune/inflammatory disorders and some pruritic conditions.

Another treatment that has had some success is the synthetic retinoid etretinate (Tigason),² but it was removed from the US market because of the high risk of birth defects. Other synthetic retinoids such as acitretin (Soriatane)¹ may be considered in severe resistant cases. They all have serious teratogenicity risk.

Psychological intervention is important in breaking the itch/scratch cycle. Help can be obtained with techniques such as biofeedback, in which subjects learn how to consciously control their automatic responses; hypnosis; CBT; and supportive counseling.

Some psychotropic medications can help with excessive itching and compulsive scratching, including doxepin¹ (10 mg at bedtime, can be increased up to 25 mg; the recommended dose for pruritus is lower than the dose for the treatment of depression, anxiety, or alcoholism, where it can be increased up to a maximum of 300 mg daily in divided doses), mirtazapine (Remeron)¹ (15–45 mg at night), and trazodone¹ (50–400 mg in divided doses). Doxepin is a tricyclic medication, and because it has the potential to cause cardiac arrhythmias, it should not be used in patients with a recent myocardial infarction (MI). Patients need to have periodic cardiovascular evaluations if they use tricyclic medications long term. Antidepressants should not be used in patients with bipolar disorder without a mood stabilizer, owing to the risk of triggering a manic episode. All antidepressants have an FDA black-box warning for increased risk of suicidality in children, adolescents, and young adults under age 24. Patients need to be closely monitored.

¹Not FDA approved for this indication.

²Not available in the United States.

Lichen Simplex Chronicus

Lichen simplex chronicus (i.e., circumscribed neurodermatitis) is characterized by lichenification of skin due to chronic excessive scratching or rubbing. Clinically, it appears as plaques of thickened skin with hyperpigmentation and accentuated skin lines. The most commonly affected areas are the occipital scalp, sides of the neck, ankles, genital areas, and extensor forearms. Itch is the main symptom. The histopathologic pattern in lichen simplex chronicus is different from that of prurigo nodularis and does not show the neural hyperplasia.

The physician must rule out the underlying diseases that may cause pruritus. The treatment for lichen simplex chronicus is similar to that for prurigo nodularis. In addition to other treatments, topical tacrolimus (Protopic) has shown efficacy in some cases of lichen simplex chronicus. Short-term topical 5% doxepin cream (Zonalon) can be used for lichen simplex chronicus (see Table 2).

Trichotillomania

CURRENT DIAGNOSIS

- Hair loss is caused by repeated hair pulling, producing oddly shaped patches of alopecia with broken hair and no signs of inflammation.
- Other areas besides the scalp may be affected.
- The age of onset and underlying psychopathology should be determined.
- If patient denies hair pulling, rule out other causes of alopecia.

CURRENT THERAPY

- In children, trichotillomania is usually self-limited and parents should be reassured. Psychotherapeutic interventions are helpful.
- In adolescents and adults, first-line treatment is psychotherapy: CBT or behavioral therapy and habit reversal. Improving coping mechanisms with stress is helpful.
- Case reports and small double-blind studies have shown the efficacy of clomipramine (Anafranil)¹ and SSRIs.
- Depending on the extent of the problem, augmentation with neuroleptics can be considered, but because of the important side effect profiles of these medications, their risks and benefits should be carefully considered.
- Before using antidepressants, patients should be screened for a family history of bipolar disorder or personal history of previous manic episodes.

¹Not FDA approved for this indication.

Trichotillomania is partial hair loss caused by repeated hair pulling. Clinically, the patient has patches of alopecia with broken hair. The broken hairs are of different lengths and there is no inflammation of the scalp. The affected area has an unusual shape. A hair-pull test is negative. The hair-pull test consists of grasping between 40 and 60 hairs between the thumb and index finger and pulling them with moderate traction while moving the fingers toward the distal shaft. If less than 10% of the hair is pulled off, the test is negative. Trichotillomania can involve areas other than the scalp, and patients may pull hair in many sites. Trichotillomania can occur in any age group. In children, it is usually benign and self-limited, but in adults it usually accompanies other psychopathologies and requires psychological intervention. The lifetime prevalence rate is about 0.5% to 3.5%, and the prevalence in some reports is as high as 4.4%.

Trichotillomania was classified with impulse control disorders in the DSM-IV TR. In contrast, in the DSM-5, trichotillomania is classified with obsessive-compulsive and related disorders. If a patient denies hair pulling, other causes of alopecia, especially alopecia areata, need to be ruled out.

In children, trichotillomania may occur during periods of increased stress, such as arrival of a new sibling, parents' divorce/separation, or stressful events at school. It is usually self-limited, and parents should be reassured. In preadolescents and young adults, the diagnosis needs to be established first, followed by psychotherapeutic interventions; behavioral modification usually works well. Psychopharmacologic treatments should be reserved for last. Because of the FDA black-box warning about the increased risk of suicide and suicidal behavior with use of antidepressants in children, adolescents, and young adults, these patients should be referred to a psychiatrist if needed.

In adults, trichotillomania often accompanies other psychopathology and the treatment of the underlying illness helps to resolve the condition. Habit reversal therapy usually works better than negative feedback. Habit reversal therapy teaches the patient to monitor the behavior and the triggering factors and to replace the harmful habit with another habit. Working on increasing coping skills for stress is also helpful. Relaxation and other stress relief techniques are helpful, especially in patients with underlying anxiety. The Trichotillomania Learning Center (<http://www.trich.org>) is a good source of information for patients.

Psychotropic medications can be used if psychotherapy alone is not enough. Most reports of effective medications are based on open-label studies. In a small, double-blind comparison, clomipramine (Anafranil) 180 mg to 250 mg/day showed greater efficacy than desipramine (Norpramin).¹ There have been some open-label studies showing the efficacy of fluoxetine (Prozac),¹ but these results were not reproduced in double-blind placebo-controlled trials. Other SSRIs, such as sertraline (Zoloft),¹ fluvoxamine (Luvox), and paroxetine (Paxil),¹ have shown efficacy in case reports and open-label studies. In some augmentation trials adding haloperidol (Haldol),¹ pimozide (Orap),¹ or olanzapine (Zyprexa)¹ was beneficial for patients taking fluoxetine or clomipramine. Small studies using haloperidol or lithium¹ have shown some efficacy. Because of important side effects such as tardive dyskinesia with haloperidol and the narrow therapeutic window with lithium, it is best to use these medications judiciously. Olanzapine has been tested as monotherapy in a double-blind study and was effective. Note that before antidepressants are prescribed for these patients, it is important to screen them for bipolar disorder.

In 2009, Grant et al. evaluated N-acetylcysteine (NAC) (Acetadote),¹ a glutamatergic agent that restores extracellular glutamate concentration in the nucleus accumbens and blocks compulsive behavior, 1200 to 2400 mg/day in a double-blind placebo-controlled trial for trichotillomania for a 12-week period. Fifty-six percent of patients were much or very much improved, compared with 16% for placebo. Side effects were mild and short term, mostly affecting the gastrointestinal system (e.g., nausea, indigestion, abdominal pain) and causing headache. NAC may worsen asthma and should not be used in patients with asthma. If taken for an extended period of time, the authors recommend taking supplemental zinc, copper, and other trace minerals, as well as two to three times the typical amount of vitamin C. It is recommended to take NAC with a multivitamin plus vitamin C. In a small case series, NAC has shown efficacy in pathologic skin picking and nail biting as well.

Trichotillomania, skin picking, and nail biting can be considered as pathologic grooming behaviors. A review of available literature shows probable sufficient evidence from randomized controlled trials for the use of naltrexone (ReVia),¹ NAC, and olanzapine for trichotillomania; the SSRIs fluoxetine and citalopram for pathologic skin picking; and clomipramine for nail biting.

¹Not FDA approved for this indication.

CURRENT DIAGNOSIS

- Patients have a sensation of burning and itching in different areas of skin and mucous membranes, with no signs and symptoms of inflammation.

CURRENT THERAPY

- Rule out possible causes of abnormal sensations: infection, allergic reactions (e.g., dental fillings), vitamin and mineral deficiencies, iron deficiency or overload, diabetes, Sjögren syndrome, nerve injuries, medications, and neoplasia.
- Treat the primary cause of the abnormal sensation if found.
- In cases of idiopathic abnormal sensations, some medications may help: tricyclic antidepressants, gabapentin (Neurontin),¹ pregabalin (Lyrica),¹ SNRIs, and SSRIs.

¹Not FDA approved for this indication.

Cutaneous sensory disorders are part of chronic pain syndromes, with pain occurring in different parts of the skin or mucous membranes. Disorders include burning mouth syndrome and vulvodynia (i.e., burning and itching of the vagina).

Burning mouth syndrome is a burning sensation that happens more frequently in middle-aged women. It affects the tongue more frequently, but other parts of the mouth may be affected. It can be associated with dry mouth and a metallic taste in the mouth.

The physician should rule out local problems (e.g., dental disorders, allergic reactions, infection) and systemic problems, such as vitamin B, folate, iron, and zinc deficiencies; diabetes; autoimmune problems such as Sjögren syndrome; nerve injury; side effects of medications, including antivirals, antiretrovirals, antiepileptics, hormones, and ACE inhibitors; and medications causing dysgeusia, such as asenapine (Saphris) and eszopiclone (Lunesta).

The workup needs a thorough physical examination, medication history, and laboratory workup, as well as screening for depression and anxiety. Mood problems may result from chronic pain issues.

The primary cause needs to be treated. In idiopathic cases, therapy to help relaxation, coping-skills training, and biofeedback may help. There is no FDA-approved medication for this condition, but medications used to treat neuropathies may help. These include gabapentin (Neurontin), which can be started at 100 mg at night for 3 days and gradually increased to 100 mg three times a day. The dosage can be adjusted to 300 to 600 mg three times a day as tolerated up to a maximum of 1800 mg. Tricyclics such as amitriptyline (10–25 mg orally at bedtime, may be increased every week to a maximum dosage of 150 mg/day) can be given. SNRIs such as venlafaxine extended-release form (Effexor XR) can be given as 37.5 mg in the morning with a gradual weekly increase to the maximum of 225 mg daily, and duloxetine (Cymbalta) can be given as 30 mg daily and increased to 60 mg in 1 week; dosages over 60 mg per day are rarely more effective. Clonazepam (Klonopin) 2 to 4 mg at night may help in some cases but it is habit forming and could cause memory problems as well as increase risk of fall in elderly patients. Up to two-thirds of patients report spontaneous partial recovery within 6 to 7 years of onset.

Vulvodynia is burning and pain in the vulvar area. Infectious, neoplastic, and inflammatory causes need to be ruled out. Depression and the impact on quality of life should be evaluated.

Biofeedback and gabapentin or amitriptyline have been helpful in some cases.

Depression and anxiety lower the pain threshold, and their treatment can help patients with chronic pain syndromes to better cope with their pain and have a higher pain threshold.

Medications for Pain and Itching

Some of the psychotropic medications can be used for various dermatologic conditions, such as urticaria or postherpetic neuralgia. The older tricyclic medications have specific effects on pain or itching.

When itching is the main symptom, doxepin¹ has a much higher affinity for histamine receptors than do conventional antihistamines. It has a long half-life, and taking it once at night can control the daytime itching. The effective antipruritic dosage is usually 10 to 25 mg at night, but it could be increased at weekly intervals as needed. Amitriptyline¹ works best for disorders with pain as their main symptoms, such as burning mouth syndrome or postherpetic neuralgia. The usual dosage is 10 to 25 mg orally at bedtime, but it may be increased every week to a maximum dosage of 150 mg/day. Because tricyclic medications can affect cardiac conduction, patients need to have stable cardiovascular status. Periodic testing is required during long-term treatment. These drugs should not be used with other medications that prolong the QT interval, such as cisapride (Propulsid). They should not be prescribed during the immediate recovery period after an MI, and they should not be used at the same time as monoamine oxidase inhibitors. Patients need to be instructed to avoid driving owing to the drowsiness side effect of tricyclics.

Other medications that could help with pain symptoms include the following:

- Gabapentin (Neurontin)¹ is started at 100 mg at night, increased every 3 days to 300 mg at night, and then increased weekly to 900 to 1800 mg daily in three to four divided doses as tolerated.
- Pregabalin (Lyrica) is started with 50 mg taken orally three times daily and increased to 100 mg three times daily within 1 week based on efficacy and tolerability. If patients with postherpetic neuralgia do not experience sufficient pain relief in 2 to 4 weeks and are tolerating the medication well, the dosage can be increased to 300 mg twice daily or 200 mg three times daily (600 mg/day).
- SNRIs such as duloxetine (Cymbalta) 60 mg daily have FDA approval for diabetic neuropathy and fibromyalgia. Venlafaxine extended-release capsule (Effexor XR), which has a mechanism of action similar to that of duloxetine, can be started at 37.5 mg in the morning, with a gradual weekly increase to a maximum of 225 mg daily, for pain symptoms, though it is not FDA approved for pain treatment.
- There are some reports that SSRIs can help pain symptoms.
- Recent research has focused attention on the interaction between the pain and itch neurobiologic pathways. The potential to block different variants of opioid receptors may lead to new therapies such as novel uses of butorphanol (Stadol), a kappa-agonist that comes in the form of nasal spray.
- The substance P/neurokinin 1 (NK1) antagonist aprepitant (Emend)¹ can potentially be used for the treatment of pain.
- Another potential treatment for pruritus, nalfurafine (Remitch),³ is under testing. This is a novel derivative of the opioid receptor antagonist naltrexone. It is a selective kappa-opioid receptor agonist and has a potent antipruritic effect in different types of pruritus.
- In our experience of resistant cases of postherpetic neuralgia, applications of small amounts of the following compound cream a couple times a day on the painful area is helpful: amitriptyline 2% and ketamine 0.5% in a Vanicream base.¹

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

CURRENT DIAGNOSIS

- Patients have excessive preoccupation with an imagined defect or a slight flaw in their appearance. The problem is not perceived by, or appears slight to, others.
- Patients have rituals and repetitive behaviors in response to the appearance concern.
- Preoccupation causes clinically significant impairment in functioning and is not better accounted for by another mental illness.

CURRENT THERAPY

- Rule out other mental illnesses or causes (e.g., severe depression with bodily focus, delusional disorder, substance abuse).
- CBT and high-dose SSRIs have been shown to be effective.
- Clomipramine (Anafranil)¹ is more effective than desipramine (Norpramin).¹
- In severe cases, augmentation with an antipsychotic such as ziprasidone (Geodon)¹ has been effective in case series.

¹Not FDA approved for this indication.

Body dysmorphic disorder (BDD) is an excessive preoccupation with an imagined defect or a slight flaw in appearance. It is a severe, underrecognized problem. Patients are unwilling to discuss the symptoms owing to a sense of shame. Concerns about physical appearance vary across cultures and affect the presentation of BDD. Patients most commonly focus on the hair, skin, and nose, but they may focus on other areas of the body as well. These patients usually seek dermatology or plastic surgery help. There is a high rate of depression and suicidal ideation. More than 50% of patients experience suicidal ideation.

BDD usually starts early in the teenage years and rarely starts after age 55. Potentially patients could be between the ages of 6 and 80, but they are mostly in their 30s. Prevalence in dermatology is about 9% to 12%. Correct diagnosis and treatment are important because dermatology or surgical interventions usually are not effective. Patients are often unhappy with the results, and this may lead to litigation and suicidal ideation. Retrospective studies have shown that even when patients are satisfied with the intervention results, they focus their attention on other parts of their body.

Feusner et al. performed interesting neuroimaging studies with functional magnetic resonance imaging (fMRI) in patients with BDD compared with normal controls. Researchers studied subjects' processing of images using fMRI and showed that patients with BDD had an abnormal focus on details and tiny abnormalities and failed to process the images holistically. Studies also showed that compared with controls, patients with BDD had an activation of the amygdala, a structure that is involved in the processing of many emotions, including fear, while viewing faces. Patients usually demonstrate ritualistic grooming behavior, excessive mirror checking, and reassurance seeking. They try to camouflage the perceived defect. Some may have skin picking in an effort to get rid of a perceived imperfection. They may also compulsively tan to cover acne or pale skin.

Patients with acne and BDD usually have mild acne and often doctor shop in hopes of receiving aggressive treatments such as isotretinoin (Accutane). They also seek laser and other cosmetic treatments to treat the perceived acne scars.

Once the diagnosis is suspected, screening questionnaires should be used; also, a visual analog scale should be used by both the patient and the physician to rate the perceived defect. This could help clarify the diagnosis by showing the discrepancy between

the two ratings. Treatment consists of a combination of pharmacotherapy and CBT.

Therapy should be tailored to BDD and is different from OCD or social anxiety. It is important to show sympathy for the patient's suffering, but do not try to reassure the patient that the perceived defect does not exist. This approach will only reinforce patients' reassurance-seeking behavior and will not change their perception.

SSRIs are effective in treatment, but usually high doses for at least 12 to 14 weeks are necessary to have results. Clinical follow-up of ritualistic behaviors helps to assess the response to treatment. For resistant cases, augmentation with antipsychotics may be helpful, but these medications do not have FDA approval for this indication.

ROSACEA

Method of

Daniel J. Van Durme, MD, MPH; and Lisa M. Johnson, MD

CURRENT DIAGNOSIS

- Rosacea is most common in adults aged 30 to 50 years and can have any of four overlapping presentation types: facial flushing and erythema with telangiectasias, inflammatory papules and pustules, ocular dryness and irritation, and nasal sebaceous gland hypertrophy leading to fibrotic changes and rhinophyma.
- Common exacerbating factors include alcohol, heat, spicy foods, and sunlight.

CURRENT THERAPY

- Therapy is best chosen on the basis of severity and predominant manifestation(s).
- Avoidance of known triggers is key for all four types, especially the erythematotelangiectatic type.

CURRENT DIAGNOSIS

- Patients have excessive preoccupation with an imagined defect or a slight flaw in their appearance. The problem is not perceived by, or appears slight to, others.
- Patients have rituals and repetitive behaviors in response to the appearance concern.
- Preoccupation causes clinically significant impairment in functioning and is not better accounted for by another mental illness.

CURRENT THERAPY

- Rule out other mental illnesses or causes (e.g., severe depression with bodily focus, delusional disorder, substance abuse).
- CBT and high-dose SSRIs have been shown to be effective.
- Clomipramine (Anafranil)¹ is more effective than desipramine (Norpramin).¹

ROSACEA

Method of

Daniel J. Van Durme, MD, MPH; and Lisa M. Johnson, MD

CURRENT DIAGNOSIS

- Rosacea is most common in adults aged 30 to 50 years and can have any of four overlapping presentation types: facial flushing and erythema with telangiectasias, inflammatory papules and pustules, ocular dryness and irritation, and nasal sebaceous gland hypertrophy leading to fibrotic changes and rhinophyma.
- Common exacerbating factors include alcohol, heat, spicy foods, and sunlight.

CURRENT THERAPY

- Therapy is best chosen on the basis of severity and predominant manifestation(s).
- Avoidance of known triggers is key for all four types, especially the erythematotelangiectatic type.

- Topical antibiotics (metronidazole [Metrogel], azelaic acid [Finacea], sodium sulfacetamide, and sulfur [Sulfacet-R]) are appropriate for milder forms of papulopustular rosacea. Oral antibiotics (doxycycline [Oracea], minocycline [Minocin],¹ erythromycin [Ery-Tab],¹ azithromycin [Zithromax],¹ or metronidazole [Flagyl]¹) are used for more severe cases. Isotretinoin (Accutane, Claravis)¹ can be effective in treating very severe and refractory rosacea.
- Ocular rosacea can be treated with increased eyelid hygiene, adding topical or oral antibiotics if needed.
- Rhinophyma (sebaceous gland hypertrophy and fibrosis) needs surgical management.

¹Not FDA approved for this indication.

Rosacea is a common facial dermatosis found primarily in adults aged 30 to 50 years, particularly those of northern European or Celtic descent.

Diagnosis

Rosacea can have any of four primary manifestations, and although these overlap, most patients tend toward one predominant type. Facial erythema and flushing that also has telangiectasia is called erythematotelangiectatic type. The papulopustular type has inflammatory papules, small pustules, and occasionally small nodules. The presentation of papulopustular rosacea differs from acne vulgaris because the onset is in the 30- to 50-year-old age group instead of adolescence, and comedones are not present in papulopustular rosacea. When the sebaceous glands get markedly hypertrophic and fibrotic, this is called *phymatous type* and can lead to profound disfigurement of the nose, called rhinophyma. The ocular type involves dryness of the eyes with decreased tear production, blepharitis, and conjunctivitis.

Treatment

One key aspect of management is to have the patient maintain a careful diary for the purpose of determining and then avoiding his or her own triggers. Common triggers include alcohol, heat, certain foods, sunlight, stress, and menstruation, among others. Broad-spectrum sunblock (UVA and UVB) should be used daily. Cosmetics with a red-neutralizing green pigment can help appearance.

Topical 1% ivermectin cream (Soolantra) which is applied to the face once daily, has received approval for use in rosacea; in part, it was developed on the understanding that there is a potential etiologic role of the *Demodex* mite in the induction of rosacea. Brimonidine tartrate 0.33% gel (Mirvaso) is a selective α^2 -adrenergic receptor agonist with vasoconstrictive activity, has been approved for the treatment of nonpersistent facial erythema in adults 18 years and older with rosacea.

The erythematotelangiectatic type of rosacea is the most difficult to treat, although benefit can be found with topical antibiotics such as metronidazole 0.75% to 1% cream, lotion, or gel (Metrogel, Noritate) or azelaic acid cream (Azelex)¹ or gel (Finacea) applied once or twice daily. Sodium sulfacetamide with sulfur is made by several manufacturers, and some brands (Sulfacet-R) include a pigmentsing agent to help hide the erythema. The sulfur component can also help in cases of coexisting seborrheic dermatitis. Persistent telangiectasias can be effectively treated with laser ablation.

Papulopustular rosacea can respond to topical antibiotics, but when it is moderate to severe, oral antibiotics are indicated. Doxycycline (Adoxa)¹ 50 to 100 mg taken once or twice a day for 2 to 3 months can markedly decrease symptoms, and then the patient can switch to topical agents for long-term maintenance as needed. Minocycline (Minocin)¹ 50 to 100 mg, erythromycin¹ 250 to 500 mg, and lower-dose metronidazole (Flagyl)¹ 250 mg can each be taken once or twice a day as alternatives. Resistant cases can be treated with azithromycin (Zithromax)¹ 500 mg three times

weekly in the first month; 250 mg three times weekly in the second month; and 250 mg twice weekly in the third month. Side effects can limit longer-term use of these agents, especially metronidazole.

Patients resistant to conventional treatment can be treated with oral isotretinoin (Claravis)¹ (at low dose 0.1–0.3 or “classic” dose of 0.5–1.0 mg/kg/day) for 16 weeks. Isotretinoin has many severe side effects and is tightly regulated. Both prescribers and patients must register with the iPledge program in order to prescribe and to receive the prescriptions. See www.ipledgeprogram.com.

Ocular rosacea can often be controlled with increased eyelid hygiene, washing with warm water and baby (no-tears) shampoo twice a day along with artificial tears. Long-term consumption of omega-3 fatty acids⁷ may improve meibomian-gland dysfunction. Topical ophthalmic cyclosporine drops (Restasis)¹, applied as one drop to the eye twice daily (twelve hours apart) demonstrate statistically significant improvement in common signs and symptoms compared with artificial tears. If severe, it can be treated with topical erythromycin¹ or metronidazole ointment¹ or oral antibiotics such as tetracycline¹ or azithromycin¹. If severe, it can be treated with topical erythromycin ointment (Ilotycin)¹ or oral antibiotics. If it still persists, ophthalmology referral is necessary.

The disfigurement of rhinophyma is often of concern to patients with rosacea. They can be reassured that this is uncommon; women can be further reassured that it is much more common in men. Oral isotretinoin¹ (at the dose of 0.3 to 1 mg per kg per day for 12 to 28 weeks), may be effective in reducing nasal volume in early disease. Recurrence is likely after discontinuation, and mucinous and fibrotic changes are unresponsive to this type of therapy. Surgical techniques including laser- or light-based therapies (pulsed dye laser, intense pulsed light, carbon dioxide laser), electrosurgery, dermabrasion, tangential excision, electroscalpel, loop cautery, and scissor sculpting are effective in correcting or minimizing phymatous changes.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Method of

Gabriel P. Currie, MD; and Jose A. Plaza, MD

CURRENT DIAGNOSIS

- Serious, potentially fatal hypersensitivity reaction.
- Erythematous to purpuric or dusky macules, patches, and/or bullae on skin and mucous membranes.
- Associated prodrome and systemic illness in overwhelming majority of cases.

CURRENT THERAPY

- Rapid discontinuation of offending agent (usually a drug—see [Box 1](#)).
- Supportive care in a dedicated burn unit.

¹Not FDA approved for this indication.

- Topical antibiotics (metronidazole [Metrogel], azelaic acid [Finacea], sodium sulfacetamide, and sulfur [Sulfacet-R]) are appropriate for milder forms of papulopustular rosacea. Oral antibiotics (doxycycline [Oracea], minocycline [Minocin],¹ erythromycin [Ery-Tab],¹ azithromycin [Zithromax],¹ or metronidazole [Flagyl]¹) are used for more severe cases. Isotretinoin (Accutane, Claravis)¹ can be effective in treating very severe and refractory rosacea.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Method of

Gabriel P. Currie, MD; and Jose A. Plaza, MD

CURRENT DIAGNOSIS

- Serious, potentially fatal hypersensitivity reaction.
- Erythematous to purpuric or dusky macules, patches, and/or bullae on skin and mucous membranes.
- Associated prodrome and systemic illness in overwhelming majority of cases.

CURRENT THERAPY

- Rapid discontinuation of offending agent (usually a drug—see [Box 1](#)).
- Supportive care in a dedicated burn unit.

¹Not FDA approved for this indication.

- Meticulous wound care with avoidance of manipulation and shearing force.
- Fluid, electrolyte, and nutrition management.
- Pain control.
- Consider intravenous immunoglobulin (IVIG),¹ high-dose corticosteroids, plasmapheresis, and/or cyclosporine (Neoral, Sandimmune).¹

¹Not FDA approved for this indication.

Epidemiology

The incidence of Stevens-Johnson syndrome (SJS) is estimated at 1 to 7 cases per million person-years and for toxic epidermal necrolysis (TEN) it is 0.4 to 1.5 cases per million person-years. TEN occurs equally frequently in male and female children. However, in adults, women are more frequently affected by a ratio of 3:2 to 2:1. Those over 60 years seem to be more likely to develop TEN.

Risk Factors

It has been shown that SJS/TEN has a genetic predisposition based on the human leukocyte antigen (HLA) genotype. With this predisposition, medications are thought to cause approximately 80% of SJS/TEN cases. Other implicated etiologies include chemical exposures, mycoplasma pneumonia, viral infections, and immunizations.

Pathophysiology

The precise pathophysiology of SJS and TEN has yet to be definitively elucidated. However, it is believed that there is interplay between an inciting drug in susceptible individuals and reactive oxygen species (ROS) within keratinocytes. One theory involves the activation of cytotoxic T cells, ultimately leading to the release of granzyme B and perforin and activation the caspase cascade. Another posits that Fas-Fas ligand binding activates caspase 8, which results in nuclease activation and the widespread skin blistering that defines this disease.

Prevention

There is no known way to prevent SJS or TEN. However, the continual advances in the field of pharmacogenomics have led to the association of drug-specific associations with individual HLA antigens. For example, the strongest known HLA-disease association is carbamazepine (Tegretol)-induced SJS/TEN with the HLA-B*1502 allele among Han Chinese. Allopurinol (Zyloprim) has also been associated with HLA-B*5801.

Clinical Manifestations and Diagnosis

SJS, SJS-TEN overlap, and TEN are infrequent but severe and potentially life-threatening diseases, with some estimates of mortality rate in TEN at 30%. They tend to present with fever and flu-like symptoms 1 to 3 weeks after the use of the inciting factor. One to three days later, mucous membrane involvement develops in 90% of patients, including eyes, mouth, nose, and genitalia. The typical skin lesions appear as generalized macules with purpuric centers, ultimately progressing to large confluent bulla with epidermal detachment (Figure 1). The Nikolsky sign, which is defined as the induction of a dermal-epidermal cleavage plane when tangential pressure is applied to a blister, is generally positive. In the subsequent 3 to 5 days, separation of the epidermis yields large denuded areas with extreme pain (Figure 2). SJS, SJS-TEN overlap, and TEN are defined by the extent of epidermal involvement. At least two mucosal sites are involved. SJS is defined by less than 10% loss of epidermis, TEN is defined by greater than 30% involvement, and SJS-TEN overlap is defined by 10% to 30% involvement.

SJS, SJS-TEN overlap, and TEN are clinically different from erythema multiforme (EM) in terms of demographic characteristics,

Figure 1 Deep red macules and patches, tense and flaccid bullae, and a denuded patch on the leg.

Figure 2 Confluent bright red erythema with near-complete loss of the epidermis on the back.

recent exposure to drugs, and association with risk factors other than drugs, such as immunosuppression (especially HIV infection), collagen vascular diseases, and cancer.

Differential Diagnosis

It is important for the clinician to consider possible alternative diagnoses. These include autoimmune blistering diseases (i.e., pemphigus, pemphigoid, paraneoplastic pemphigus, linear IgA bullous dermatosis), EM, EM-like reactions, urticaria, staphylococcus scalded skin syndrome, graft-versus-host disease, and acute generalized exanthematous pustulosis.

BOX 1**Drugs Commonly Associated with Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis**

Trimethoprim-sulfamethoxazole (Bactrim) and other sulfonamide antibiotics	Oxicam—nonsteroidal antiinflammatory drugs
Allopurinol (Zyloprim)	Corticosteroids
Sertraline (Zoloft)	Nevirapine (Viramune)
Aminopenicillins	Tramadol (Ultram)
Cephalosporins	Pantoprazole (Protonix)
Quinolones	Lamotrigine (Lamictal)
Acetaminophen (Tylenol)	
Carbamazepine (Tegretol), phenytoin (Dilantin), phenobarbital, and valproic acid (Depakene)	

Treatment

The two most important steps in initial management of SJS and TEN are immediate cessation of any potential causative drug (Box 1) and early referral to a burn unit. Meticulous attention to fluids and electrolyte balances, infection risk, nutrition, and pain control are also of utmost importance. Because all epidermal and mucosal surfaces can be affected, enteral or parental feeding should be established early. Individual areas of necrotic epidermis should be gently removed and covered with a nonadherent dressing with avoidance of frequent dressing changes because they can inhibit reepithelialization. Vaseline gauze and/or mupirocin ointment (Bactroban) to open areas should be utilized. Application of a silicone dressing with silver-impregnated gauze overtop can be beneficial.

Data on the use of systemic corticosteroids are conflicting. There is concern of increased risk of sepsis and poorer wound healing with the use of corticosteroids, but there is some evidence that institution of methylprednisolone (Solu-Medrol) within the first 48 hours, before epidermal detachment, may be beneficial. There is also conflicting evidence for the use of IVIG.¹ Numerous case series have reported a decrease in mortality. If instituted, it should be instituted as early as possible at a dose of 2 to 3 g/kg over 48 to 72 hours. Other reported treatments include plasma exchange. Most analyses advocate a survival benefit using one to four sessions. Cyclosporine (Neoral, Sandimmune)¹ and cyclophosphamide (Cytosan)¹ have been used in limited circumstances and reported to be beneficial. Several case reports describe the use of tumor necrosis factor- α (TNF- α) inhibitors in the treatment of SJS/TEN. A single dose of infliximab (Remicade)¹ 5 mg/kg can be instituted if other options prove unsuccessful.

Monitoring and Complications

A severity-of-illness score for TEN has been proposed called the SCORTEN (Box 2). SCORTEN stands for “SCORE of Toxic Epidermal Necrosis.” It assigns points based on one of seven criteria, predicting mortality with increasing criteria met. This is applied on initial evaluation and the patient is not rescored.

Management in a burn unit is of critical importance. Judicious attention to fluids and electrolytes, as well as infectious risk, is mandatory. Ophthalmology and gynecology or urology should be consulted in order to prevent potential scarring and/or adhesions of the respective organ systems. Sepsis and severe fluid and electrolyte imbalances are the most common causes of death.

BOX 2**SCORTEN**

SUNBURN

Method of

Warwick L. Morison, MD

**CURRENT DIAGNOSIS**

- Sunburn appears 3 to 4 hours after exposure to sunlight or an artificial source of UV radiation such as a sunlamp.
- The redness of skin is diffuse and continuous, unlike rashes, which are often discontinuous.
- Sunburns are graded as pink, red, and blistering.

**CURRENT THERAPY**

- Prevention is the best approach to management and consists of a package of measures: avoiding over-exposure, using sunscreens, and wearing protective clothing.
- Treatment of a sunburn consists of cool baths and use of moisturizing creams.
- Topical and systemic corticosteroids do not alter the course of a sunburn.

Sunburn is a common problem, particularly in fair-skinned white persons, caused by excessive exposure to ultraviolet (UV) radiation from sunlight or artificial sources such as sunlamps. When induced by sunlight, it is mainly due to UVB (280–320 nm) radiation plus a smaller contribution from UVA (320–400 nm) radiation. Sunburn

SUNBURN*Method of*

Warwick L. Morison, MD

**CURRENT DIAGNOSIS**

- Sunburn appears 3 to 4 hours after exposure to sunlight or an artificial source of UV radiation such as a sunlamp.
- The redness of skin is diffuse and continuous, unlike rashes, which are often discontinuous.
- Sunburns are graded as pink, red, and blistering.

**CURRENT THERAPY**

- Prevention is the best approach to management and consists of a package of measures: avoiding over-exposure, using sunscreens, and wearing protective clothing.
- Treatment of a sunburn consists of cool baths and use of moisturizing creams.
- Topical and systemic corticosteroids do not alter the course of a sunburn.

Sunburn is a common problem, particularly in fair-skinned white persons, caused by excessive exposure to ultraviolet (UV) radiation from sunlight or artificial sources such as sunlamps. When induced by sunlight, it is mainly due to UVB (280–320 nm) radiation plus a smaller contribution from UVA (320–400 nm) radiation. Sunburn

is also described as erythema, and it appears 3 to 4 hours after exposure, reaches a maximum at 12 to 18 hours, and usually settles after 72 to 96 hours. In severe reactions with blistering, complete resolution can take a week or more.

Sunburns are graded as pink, red, and blistering. In contrast, thermal burns are graded by degree (first, second, and third), but this classification should not be applied to sunburns because thermal burns have quite different sequelae, such as scarring and death, which are extremely rare consequences of a sunburn. Keratoconjunctivitis, or ocular sunburn, can also be caused by UV radiation and it follows a similar time course.

There are two facets to management of sunburn: prevention and treatment. Because there is no effective treatment for an established sunburn, most emphasis should be placed on prevention.

Prevention

Skin color and the capacity of a person to tan will determine how important it is for an individual person to take preventive measures. However, even dark-skinned people can sunburn provided the exposure dose is sufficiently high. Skin color, past history of sunburn, and likely exposure should therefore be used as a guide in advising people about protection. Protection from sunlight is often equated with use of sunscreens, but this approach is too narrow, and protection should consist of a package of measures: avoiding overexposure to sunlight, using sunscreens, and wearing protective clothing.

Avoidance of Exposure

Simple avoidance of excessive exposure to a threshold dose of UV radiation is often the best advice for fair-skinned people. Scheduling outdoor activities for before 10 am and after 4 pm will avoid the peak UV irradiance period and still permit enjoyment of the outdoors. This advice should be accompanied by several warnings. Sitting in the shade or under a beach umbrella only reduces exposure by about 70%. A cloudy day is often the setting for the worst sunburns because even complete white cloud cover reduces UV exposure by only about 50%.

Clothing is not always an effective protector. If it is possible to see through a fabric, UV radiation can also penetrate to a significant extent. The geographic location of exposure must also be considered because UV radiation may be twice as intense at the equator as compared with much of continental North America.

Sunscreens

There are now a great number of sunscreens on the market, and they contain numerous active ingredients. If this is not enough to cause confusion, some are not even labeled as sunscreens: sunblocks and tanning lotions are other terms. However, the informed physician need only know four properties of a sunscreen: the sun protection factor (SPF), the spectrum of protection, the base, and whether or not it is water resistant.

The SPF is an index of the amount of protection provided by the sunscreen. For example, a fair-skinned person who normally begins to sunburn after a 10-minute exposure to sunlight should be able to tolerate up to 150 minutes of exposure after application of an SPF 15 sunscreen.

There are several provisos for this statement. To provide the stated protection, a sunscreen must be applied 10 minutes before exposure to allow binding to skin proteins to occur, and it must be applied in an adequate amount. Several studies have shown that under ideal circumstances in which sunscreen is supplied freely and the subject is observed while making the application, most people only use one half the required amount. Ordinary use probably provides much less protection. As a rough guide, one ounce of sunscreen is necessary to cover a 70-kg adult in a bathing suit; in other words, a four ounce bottle of sunscreen only provides four applications.

Sunscreens vary in the amount of the solar spectrum for which they provide protection. All sunscreens provide protection against UVB radiation and the shorter end of UVA radiation. Some sunscreens claim to provide broad-spectrum protection against UVB

and UVA radiation and contain avobenzone or titanium dioxide to protect against the longer wavelengths in the UVA spectrum. Ecamsule (Mexoryl SX), a recently approved sunscreen active, provides good absorption in the middle of the UVA spectrum; a sunscreen containing this, avobenzone, and octocrylene—an absorber of UVB radiation—provides very good broad-spectrum protection.

The base of a sunscreen is also important because it often determines whether or not a sunscreen will be used. Men usually prefer alcohol-based lotions because they dry quickly and leave a dry and nongreasy film. Women usually prefer lotions or creams because they give a moisturizing feel to the skin.

Finally, a sunscreen may be labeled water resistant or very water resistant. Because almost all outdoor pastimes involve perspiring or contact with water, a very water-resistant sunscreen should be selected.

A fair-skinned person should always use a sunscreen with an SPF 15 or higher. People who tan well and never burn are probably adequately protected with an SPF of 8 to 10. People with black or brown skin probably do not need sunscreens except for extreme occupational or social exposure.

A few myths should be dismissed. There is no effective oral sunscreen. Many have been tested and all have failed. Self-tanning preparations are not sunscreens. They do provide the appearance of a tan and are safe to use but they provide no significant protection against UV radiation.

Protective Clothing

There has been significant progress in recent years in the development, testing, and classification of UV-protective clothing. Akin to the SPF for sunscreens, such clothing is labeled with an ultraviolet protective factor (UPF), and a fabric with a UPF of 50 blocks transmission of 98% of UV radiation. A hat with a 3-inch brim all around completes the package of protection.

Protective Tanning

The proliferation of suntan parlors has generated a lot of interest in protective tanning, with much misinformation provided by the commercial interests involved. Little scientific information is available to provide a guide as to whether protective tanning is of any value in preventing the long-term hazards of excessive exposure to sunlight, namely skin cancer and premature aging of the skin. Certainly, preventive tanning using multiple suberythral doses of UV radiation can prevent sunburn, but the cost in terms of chronic damage is unknown.

Most tanning salons claim to use only UVA radiation in their tanning beds, but this claim is false. All so-called UVA tanning beds emit some UVB radiation, the most damaging wavelengths, and in addition, UVA radiation, especially in large doses, can produce the same damaging effect as UVB radiation. Furthermore, a UVA-induced tan is not very protective and at most has an SPF of 6 to 8.

A person who tans well and never burns might gain some protection from sunlight by preventive tanning without incurring too much damage. However, the risk-to-benefit ratio for people who do sunburn is probably very unfavorable.

Treatment

When a person has a sunburn, general supportive measures are the only approach to treatment. Cold compresses and cool baths with bath oil provide some relief. Frequent application of moisturizing creams help alleviate dryness. Blistering of the skin can lead to secondary infection and require use of an antibiotic cream. Rarely, an extremely severe sunburn necessitates hospitalization and management as a thermal burn.

Topical corticosteroids reduce erythema by causing vasoconstriction, but this effect is temporary and does not reduce epidermal damage. Systemic corticosteroids, even in very large doses, do not alter the course of a sunburn. Nonsteroidal antiinflammatory drugs, if given at the time of exposure or beforehand, reduce the degree of erythema over the first 24 hours but do not change epidermal damage. Of course, few people lying on the beach anticipate an excessive exposure, so they are unlikely to embark on such preventive measures.

CURRENT DIAGNOSIS

- Acute and chronic urticaria have the same features, including erythematous, edematous papules or wheals with central pallor that last less than 24 to 48 hours.
- Laboratory assessments are not recommended for acute urticaria in the absence of evidence suggesting underlying systemic illness.
- Limited laboratory studies are indicated for chronic urticaria only if there are signs of systemic disease.
- Serum measurements of C4 and C1-esterase inhibitor are the recommended initial tests if hereditary or acquired angioedema are suspected.
- Skin biopsy should be considered to rule out urticarial vasculitis if an individual lesion is painful and persists for more than 2 to 3 days with accompanying ecchymosis or petechiae.

CURRENT THERAPY

- Primary treatment of urticaria and angioedema is removal of triggering factors and initiation of therapy for symptomatic relief.
- Oral antihistamines are the cornerstones of therapy. The application of first-generation H₁-antihistamines may be limited by central nervous system and anticholinergic side effects.
- Nonsedating second generation antihistamine are often used as first line therapy.
- Systemic corticosteroids and immunosuppressive therapy, especially cyclosporine (Neoral),¹ have been used successfully in cases that are refractory to the maximum dose of antihistamines.
- Fresh-frozen plasma infusions along with standard airway precautions have been recommended for angioedema patients with laryngeal edema.
- A subcutaneous C1 esterase inhibitor injection (Haegarda) has been used successfully to prevent attack in hereditary angioedema.

¹Not FDA approved for this indication.

Urticaria, or hives, is a common cutaneous eruption that occurs in up to 25% of the general population sometime during their lives.¹ It is characterized by transient, circumscribed, pruritic, erythematous papules or plaques, often with central pallor. Individual lesions often coalesce into large wheals on the trunk and extremities that may resolve over a few hours without leaving any residual skin changes. The process is mediated by mast cells in the superficial dermis.

Angioedema is a similar process occurring in deep dermis or subcutaneous tissue. Angioedema may occur independently, accompanied by urticaria, or as a component of anaphylaxis. It is characterized by localized swelling that develops over minutes to hours and resolves within 24 to 48 hours. Common locations of angioedema include the mucosa and areas with loose connective tissue, such as the face, eyes, lips, tongue, and genitalia. Patients usually do not have pruritus, but they may have pain and a sensation of warmth. Angioedema is usually a benign process that resolves without sequelae unless it involves the larynx. African

Americans are disproportionately affected, representing up to 40% of the hospital admissions for angioedema.

Classification

Urticaria can be classified as acute or chronic, depending on the duration. Acute urticaria usually lasts for less than 6 weeks and is commonly triggered by infection, medication, insect bite, and food (Table 1). The chronic form, lasting more than 6 weeks, accounts for approximately 30% of cases of urticaria, and no clear causes can be identified in more than 80% of these cases. Stress however has been identified as a trigger in some of the cases. A significant number of patients with chronic urticaria may have persistent symptoms for more than 10 years. Approximately 40% of patients with chronic urticaria have associated angioedema, although the incidence of laryngeal edema is low.

Diagnosis

Urticaria is diagnosed clinically in most cases. A detailed history, physical examination, and complete review of systems are essential for diagnosing patients with urticaria and angioedema. The history should include the distribution and characteristics of lesions (e.g., pain, pruritus), duration of skin eruption, accompanying angioedema, airway involvement and other associated systemic symptoms (e.g., fever, arthralgia, swelling joints, refusal to walk by children). Patients should also be questioned about changes in dietary habits, stress, recent exposures, infection, and newly administered medications, including antibiotics, over-the-counter analgesia, and hormones.

Laboratory assessment is usually not helpful in diagnosing patients with acute urticaria who lack any history or clinical findings to suggest an underlying disease process. A limited number of diagnostic tests are indicated in the evaluation of patients with chronic urticaria when there is sign of systemic disease associated, such as a complete blood cell count with differential white blood cell count, an erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) determination, a thyroid-stimulating hormone (TSH) level, antithyroglobulin and antimicrosomal antibodies, antinuclear antibodies (ANA), folate, B12, ferritin, liver function test, and hepatitis B and C serologies. A detailed review of systems may help to narrow the focus of the screening test.

TABLE 1 Mechanisms in Urticaria and Angioedema

DISORDER	CAUSES
Immunoglobulin-mediated urticaria	Ig-E mediated: food, medication, insect bites, contact allergen, aeroallergens, other causes Urticaria associated with autoimmunity: antinuclear antibodies (ANAs), thyroid autoantibodies, other causes
Direct activation of mast cell degranulation	Physical stimuli: exercise, heat, cold, pressure, aquagenic, solar radiation, etc. Other agents: opiates, antibiotics (e.g., vancomycin [Vancocin]), radiocontrast, ACTH (Cortrosyn), muscle relaxants
Complement-mediated	Viral infections, parasites, blood transfusion
C1-esterase inhibitor deficiency	Genetic and acquired angioedema, paraproteinemia
Reduced kinin metabolism	Angiotensin-converting enzyme (ACE) inhibitors
Reduced arachidonic acid metabolism	Aspirin

¹Not FDA approved for this indication.

A skin biopsy of an early lesion should be performed to rule out urticarial vasculitis if the affected individual has skin lesions that are painful and last for more than 2 to 3 days with residual ecchymosis or petechiae. In patients with angioedema, prominent edema of the interstitial tissue may be demonstrated by biopsy. It is associated with antibodies against C1q, which leads to persistent complement activation and low serum C3, C4. Serum measurements of C4 and C1-esterase inhibitor are recommended initial tests if hereditary or acquired angioedema is suspected. Hereditary angioedema is caused by deficiency (type I) or dysfunction (type II) of C1-esterase inhibitor protein. A C1q level should be obtained to screen for the acquired form of angioedema if the affected individual is middle-aged.

Treatment

More than two thirds of cases of urticaria are self-limited. Spontaneous remission of chronic urticaria and angioedema is also common. The primary objective of management is to identify and discontinue the offending trigger. A patient presenting with angioedema must first be assessed for signs of airway compromise. Medical therapy is indicated for those who are symptomatic.

Antihistamines remain the first-line therapy for most patients with urticaria, because the primary complaint of pruritus is predominantly mediated by histamine released from mast cells. First-generation antihistamines such as hydroxyzine (Atarax or Vistaril 25–50 mg every 6 hours), diphenhydramine (Benadryl 25–50 mg every 6 hours), cyproheptadine (Periactin 4 mg three times daily), and chlorpheniramine¹ (Chlor-Trimeton 4 mg every 6 hours) are potent and have the quickest onset of action. However, the treatments are often limited by their sedating and anticholinergic side effects. Many first-generation antihistamines are available over the counter, providing accessible first-line therapy for patients. Patients with urticaria that lasts for several days should be considered for treatment using second-generation antihistamines such as loratadine (Claritin¹ 10 mg twice daily³), desloratadine¹ (Clarinex 5 mg twice daily³), cetirizine¹ (Zyrtec 10 mg twice daily³), levocetirizine¹ (Xyzal 5 mg daily), and fexofenadine¹ (Allegra 180 mg twice daily³). Doxepin (Sinequan),¹ an H₁- and H₂-receptor antagonist, is seven times more potent than hydroxyzine in suppression of wheal and flare responses. Because of its central nervous system side effects, combined use of doxepin with a first-generation antihistamine should be restricted. Topical 5% doxepin cream (Zonalon)¹ may help to suppress pruritus in patients with localized urticaria.

Systemic prednisone at 30 to 40 mg in a single morning dose is sufficient to suppress acute urticaria in adults. Tapering should be gradual over a 3- to 4-week period by decreasing the dosage 5 mg every 3 to 5 days to minimize rebound. Alternate-morning dosing when reaching 20 mg daily may help to minimize the steroid side effects. Methylprednisolone (Solu-Medrol 40 mg) should be given intravenously as initial therapy to patients with angioedema. This may be followed by a tapering oral course. Chronic therapy is to be avoided. Three months of treatment with cyclosporine (Neoral)¹ at 3 to 5 mg/kg can be given safely to patients who are refractory to corticosteroid therapy or have difficulty tapering their therapy. Close monitoring for hypertension and renal insufficiency is necessary during the treatment.

Leukotriene inhibitors such as zileuton (Zyflo¹ 600 mg four times daily), zafirlukast (Accolate¹ 20 mg twice daily), and montelukast (Singulair¹ 10 mg once daily) may be effective for patients with autoimmune urticaria. Successful treatment of chronic urticaria with anti-IgE (omalizumab [Xolair]¹) has been reported but the medication is approved by the FDA for moderate to severe allergic asthma only for patients above 12 years of age.

Proper management of underlying autoimmune thyroid disease or autoimmune collagen vascular diseases has been beneficial for patients with associated urticaria. Life-threatening angioedema triggered by angiotensin-converting enzyme (ACE) inhibitors has been

successfully treated with infusion of fresh-frozen plasma. Hereditary angioedema can be prevented with tranexamic acid¹ or modified androgens. Intravenous C1-esterase inhibitor (Cinryze) or icatibant (Firazyr), a bradykinin B2 antagonist, can be administered to prevent acute attacks. Subcutaneous injection of C1-esterase inhibitor (Hae-garda) has been approved by FDA in 2017 to prevent hereditary angioedema attacks. Treatments with methotrexate¹, warfarin (Coumadin),¹ plasmapheresis, and intravenous immunoglobulin (Baygam)¹ have been reported for severe, refractory¹ urticaria. These treatments are administered only by specialists on an individual basis. Non-pharmacotherapeutic means such as frequent use of skin emollients, avoidance of hot shower, scrubbing, and excessive sun exposure should also be recommended as part of management plans.

¹Not FDA approved for this indication.

VENOUS ULCERS

Method of

Jose A. Jaller, MD; and Robert S. Kirsner, MD, PhD

CURRENT DIAGNOSIS

- Venous ulcers are the most common cause of lower-extremity ulceration.
- Valvular incompetence, vein distention, muscular weakness, or a decrease in the range of motion of the ankle may lead to calf muscle pump failure.
- The mechanism of cutaneous ulceration resulting from venous insufficiency remains unknown.
- The typical location for a venous ulcer is around the medial malleolus.
- Complications of chronic venous ulcers are cellulitis and less often squamous cell carcinoma.
- Compression is the gold standard of treatment of venous disease.

CURRENT THERAPY

- Compression therapy is used to deliver a graded compression of 30 to 40 mm Hg at the ankle. Exclude arterial disease before using compression.
- Systemic medications as adjuvant therapy to compression bandages include aspirin,¹ pentoxifylline (Trental),¹ or micronized purified flavonoid fraction (Daflon 500 mg).²

¹Not FDA approved for this indication.

²Exceeds dosage recommended by the manufacturer.

A skin biopsy of an early lesion should be performed to rule out urticarial vasculitis if the affected individual has skin lesions that are painful and last for more than 2 to 3 days with residual ecchymosis or petechiae. In patients with angioedema, prominent edema of the interstitial tissue may be demonstrated by biopsy. It is associated with antibodies against C1q, which leads to persistent complement activation and low serum C3, C4. Serum measurements of C4 and C1-esterase inhibitor are recommended initial tests if hereditary or acquired angioedema is suspected. Hereditary angioedema is caused by deficiency (type I) or dysfunction (type II) of C1-esterase inhibitor protein. A C1q level should be obtained to screen for the acquired form of angioedema if the affected individual is middle-aged.

Treatment

More than two thirds of cases of urticaria are self-limited. Spontaneous remission of chronic urticaria and angioedema is also common. The primary objective of management is to identify and discontinue the offending trigger. A patient presenting with angioedema must first be assessed for signs of airway compromise. Medical therapy is indicated for those who are symptomatic.

Antihistamines remain the first-line therapy for most patients with urticaria, because the primary complaint of pruritus is predominantly mediated by histamine released from mast cells. First-generation antihistamines such as hydroxyzine (Atarax or Vistaril 25–50 mg every 6 hours), diphenhydramine (Benadryl 25–50 mg every 6 hours), cyproheptadine (Periactin 4 mg three times daily), and chlorpheniramine¹ (Chlor-Trimeton 4 mg every 6 hours) are potent and have the quickest onset of action. However, the treatments are often limited by their sedating and anticholinergic side effects. Many first-generation antihistamines are available over the counter, providing accessible first-line therapy for patients. Patients with urticaria that lasts for several days should be considered for treatment using second-generation antihistamines such as loratadine (Claritin¹ 10 mg twice daily³), desloratadine¹ (Clarinex 5 mg twice daily³), cetirizine¹ (Zyrtec 10 mg twice daily³), levocetirizine¹ (Xyzal 5 mg daily), and fexofenadine¹ (Allegra 180 mg twice daily³). Doxepin (Sinequan),¹ an H₁- and H₂-receptor antagonist, is seven times more potent than hydroxyzine in suppression of wheal and flare responses. Because of its central nervous system side effects, combined use of doxepin with a first-generation antihistamine should be restricted. Topical 5% doxepin cream (Zonalon)¹ may help to suppress pruritus in patients with localized urticaria.

Systemic prednisone at 30 to 40 mg in a single morning dose is sufficient to suppress acute urticaria in adults. Tapering should be gradual over a 3- to 4-week period by decreasing the dosage 5 mg every 3 to 5 days to minimize rebound. Alternate-morning dosing when reaching 20 mg daily may help to minimize the steroid side effects. Methylprednisolone (Solu-Medrol 40 mg) should be given intravenously as initial therapy to patients with angioedema. This may be followed by a tapering oral course. Chronic therapy is to be avoided. Three months of treatment with cyclosporine (Neoral)¹ at 3 to 5 mg/kg can be given safely to patients who are refractory to corticosteroid therapy or have difficulty tapering their therapy. Close monitoring for hypertension and renal insufficiency is necessary during the treatment.

Leukotriene inhibitors such as zileuton (Zyflo¹ 600 mg four times daily), zafirlukast (Accolate¹ 20 mg twice daily), and montelukast (Singulair¹ 10 mg once daily) may be effective for patients with autoimmune urticaria. Successful treatment of chronic urticaria with anti-IgE (omalizumab [Xolair]¹) has been reported but the medication is approved by the FDA for moderate to severe allergic asthma only for patients above 12 years of age.

Proper management of underlying autoimmune thyroid disease or autoimmune collagen vascular diseases has been beneficial for patients with associated urticaria. Life-threatening angioedema triggered by angiotensin-converting enzyme (ACE) inhibitors has been

successfully treated with infusion of fresh-frozen plasma. Hereditary angioedema can be prevented with tranexamic acid¹ or modified androgens. Intravenous C1-esterase inhibitor (Cinryze) or icatibant (Firazyr), a bradykinin B2 antagonist, can be administered to prevent acute attacks. Subcutaneous injection of C1-esterase inhibitor (Haegarda) has been approved by FDA in 2017 to prevent hereditary angioedema attacks. Treatments with methotrexate¹, warfarin (Coumadin),¹ plasmapheresis, and intravenous immunoglobulin (Baygam)¹ have been reported for severe, refractory¹ urticaria. These treatments are administered only by specialists on an individual basis. Non-pharmacotherapeutic means such as frequent use of skin emollients, avoidance of hot shower, scrubbing, and excessive sun exposure should also be recommended as part of management plans.

¹Not FDA approved for this indication.

VENOUS ULCERS

Method of

Jose A. Jaller, MD; and Robert S. Kirsner, MD, PhD

CURRENT DIAGNOSIS

- Venous ulcers are the most common cause of lower-extremity ulceration.
- Valvular incompetence, vein distention, muscular weakness, or a decrease in the range of motion of the ankle may lead to calf muscle pump failure.
- The mechanism of cutaneous ulceration resulting from venous insufficiency remains unknown.
- The typical location for a venous ulcer is around the medial malleolus.
- Complications of chronic venous ulcers are cellulitis and less often squamous cell carcinoma.
- Compression is the gold standard of treatment of venous disease.

CURRENT THERAPY

- Compression therapy is used to deliver a graded compression of 30 to 40 mm Hg at the ankle. Exclude arterial disease before using compression.
- Systemic medications as adjuvant therapy to compression bandages include aspirin,¹ pentoxifylline (Trental),¹ or micronized purified flavonoid fraction (Daflon 500 mg).²

¹Not FDA approved for this indication.

²Exceeds dosage recommended by the manufacturer.

- Other treatments, along with compression, include engineered skin, placental and skin grafts, electrical stimulation, locally derived growth factors, and venous surgery.
- The lifelong use of elastic compression stockings (30–40 mm Hg) is the mainstay of prevention.

¹Not FDA approved for this indication.

²Not available in the United States.

Ulcers resulting from venous insufficiency are the most common cause of leg ulceration. Many definitions exist for a chronic wound, which ultimately reflect the demographics, incidence, and prevalence data available. For example, although sometimes referred to as stasis ulcers, patients actually have increased blood flow locally. The Wound Healing Society classifies wounds as *acute* if they sustain restoration of anatomic and functional integrity in an orderly and timely process and *chronic* if they do not. Some of the biologic events that affect the “orderly” process include inflammation, angiogenesis (i.e., new blood vessel formation), matrix regeneration, and remodeling. The “timely” process is affected by the environment, age, pathologic process, wound location, and other factors.

Epidemiology

Venous disease affects approximately 5% of the world’s population and about 2% of the American population. It was once thought to be a disease affecting solely the elderly. The incidence increases from middle age onward. Venous leg ulceration affects 1% to 2% of adults, accounting for over 2 million lost workdays annually, and negatively impacts patients’ quality of life. Seventy percent of all leg ulcers result solely from venous disease, and an additional 20% of patients have mixed arterial and venous disease. The other 10% of leg ulcers result from a variety of causes, including neuropathy, prolonged pressure, and infectious, malignant, and inflammatory causes. A recent report that used claims data from 2013 private and governmental insurance companies revealed that wounds and ulcers had the highest direct US health care cost of all skin diseases (\$12 billion) and caused approximately 21% of all deaths related to skin condition, second only to cutaneous cancers.

Family history of venous disease, obesity, smoking, high cost of treatment, time off work, prolonged standing, and hypertension are among the factors that contribute to a strong socioeconomic impact of a country’s health care.

Pathophysiology

In the lower extremities, the venous system comprises the deep and superficial veins. Blood flows from the superficial to the deep veins through the communicating or perforating veins to ultimately reach the heart. Veins contain valves that prevent blood reflux and allow the unidirectional flow. When a healthy individual contracts the calf muscles, a high pressure develops in the deep vein system, allowing blood to flow from the deep veins to the heart. During calf muscle relaxation, the pressure difference (high pressure in the superficial veins) allows blood flow from the superficial to deep veins. If the calf muscle contraction is restricted or the one-way valves are deficient, the system fails to adequately return venous blood to the heart, leading to venous hypertension (also known as sustained ambulatory high pressure).

How does the skin ulcerate in patients with venous insufficiency? The mechanism of cutaneous ulceration as a consequence of venous insufficiency remains unknown. Several hypotheses have been reported since the beginning of the 20th century. In the early 1980s, Browse and Burnard suggested that venous hypertension could lead to endothelial distention, causing extravasation of fibrinogen into the interstitial fluid, which results in “pericapillary fibrin cuff” formation around the capillary vessels. Fibrin cuffs act as a barrier to diffusion of oxygen and nutrients, causing ischemia and ulcer formation. A few years later, Coleridge-Smith and colleagues suggested that venous hypertension could lead to decreased capillary perfusion, resulting in leukocyte trapping. The trapped leukocytes release proteolytic enzymes, which result in free radical

formation and capillary damage. The increased capillary permeability causes extravasation of fibrinogen and other metabolites, which leads to formation of a fibrin cuff around the capillaries and ultimately ischemia.

Further studies supported the presence of increased levels of monocyte aggregation. Claudy and colleagues showed that leukocyte activation caused release of tumor necrosis factor alpha (TNF- α), ultimately leading to pericapillary fibrin cuff formation. In 1993, Falanga and Eaglstein observed that fibrin cuffs were discontinuous around capillaries and therefore did not form a barrier to oxygen and nutrients causing ischemia. They also postulated the “trap” hypothesis, which suggests that venous hypertension causes endothelial cell distention leading to extravasation of macromolecules (i.e., α_2 -macroglobulin and fibrinogen) into the dermis. Moreover, α_2 -macroglobulin can bind to growth factors, such as TNF- α and transforming growth factor beta (TGF- β), making them unavailable for wound repair. Patients with venous disease may have other factors that contribute to venous ulcer formation, such as systemic alteration in fibrinolysis and arteriovenous shunting. Despite all previously conducted studies and hypotheses, further research is needed to explain the mechanism of cutaneous ulceration resulting from venous insufficiency.

Evaluation and Diagnosis

The typical location for a venous ulcer is around the medial aspect of the lower extremity near the ankle (medial malleolus) or the gaiter area. The ulcer usually begins as a blister or erosion on the skin. Ulcer borders are irregular and usually smooth. The base of the ulcer may be covered with granulation tissue, yellow slough, or both. Venous ulcers are associated with presence of pigmentation, erythema, dermatitis, edema, and induration (i.e., lipodermatosclerosis) of the surrounding skin and with varicose veins in the lower leg. Hemosiderin deposition resulting from red blood cell extravasation and iron-related stimulation of melanocytes cause the surrounding hyperpigmentation.

Lipodermatosclerosis, commonly known as an inverted bottle shape, is caused by sclerosis of the dermis and subcutaneous tissue. The presence of lipodermatosclerosis has been associated with a greater impairment of fibrinolysis in patients with venous ulcers and may be a poor prognostic factor for restriction of leg movement. Other known prognostic factors are duration and size of the ulcer and history of venous surgery. Ulcers present for longer than 6 months and larger than 5 cm² in diameter tend to be more refractory to therapy.

A diagnosis of venous ulcers may be based on clinical presentation. The findings of a lower leg ulcer associated with lipodermatosclerosis or varicose veins, or both, suggest a venous ulcer. Other common findings include atrophie blanche (i.e., porcelain white scars with telangiectasia and dyspigmentation) and dermatitis. Venous dermatitis is associated with erythema, eczema, pruritus, and scaling of the skin. Contact dermatitis surrounding the ulcer may result from the use of topical agents.

Even though venous insufficiency should be confirmed with a variety of techniques, including duplex ultrasound or plethysmography, the presence or absence of arterial disease is a more important factor dictating treatment and prognosis. Treatment with compression bandages is the mainstay of therapy and should be used cautiously in patients with arterial disease. A simple, noninvasive measurement to assess peripheral arterial disease is the ankle brachial index (ABI). This value is calculated by dividing the systolic pressure in the ankle by the systolic pressure in the arm. An ABI of less than 0.9 indicates peripheral vascular disease and represents an independent risk factor for vascular disease in other vascular beds, such as the coronary arteries. Care must be taken with diabetic or elderly patients who may have a falsely negative ABI value. All patients with an abnormal ABI value should be further evaluated. Consider a vascular consultation, magnetic resonance angiography (MRA), angioplasty, and stent bypass.

To aid in the exclusion of any underlying disease (e.g., hematologic disease, diabetes), initial laboratory tests should include complete blood cell (CBC) count with a differential count, chemistry

panel, hemoglobin A1C, prealbumin and albumin determinations, liver function tests, and levels of homocysteine, protein C and S, antithrombin III, and factor V Leiden.

Several vascular studies help in the diagnosis and severity of venous disease. Color duplex ultrasound is usually the initial study done to assess venous reflux in the lower extremities. Continuous-wave Doppler studies may yield false-negative results because it may be difficult to differentiate between the superficial and deep venous system. Air plethysmography and photoplethysmography are helpful in evaluating venous reflux and calf muscle dysfunction. Invasive venography is the gold standard to assess venous reflux, but it is used only as a last resort because of its invasive properties.

The CEAP classification was developed in 1994 by the American Venous Forum (AVF) to standardize the diagnosis and treatment of venous disease. It was based on clinical manifestations (C), etiologic factors (E), anatomic distribution of disease (A), and underlying pathophysiologic findings (P).

Complications

Main complications of long-term or chronic venous ulcers are cellulitis, osteomyelitis, and squamous cell carcinoma. A finding of exposed tendon or bone, in addition to suggesting an underlying osteomyelitis, suggests an ulcer with a nonvenous cause.

Radiographs and biopsy for histology and culture are appropriate first steps in evaluation. Consult an orthopedic surgeon for further analysis and treatment, which may include a bone biopsy and bone débridement.

Treatment

Compression is the gold standard of treatment of venous disease. After arterial disease has been excluded, reversal of the effects of venous hypertension through compression bandages and leg elevation is the cornerstone of therapy.

The goal of compression therapy is to deliver sustained graded compression with 30 to 40 mm Hg at the ankle. These bandages are applied circumferentially from the toes to the knees (involving the heel) with the foot dorsiflexed. The optimal method to deliver this pressure is through multilayered elastic compression dressings. Elastic compression dressings deliver compression during ambulation (i.e., walking) and at rest, accommodate to reduction in edema, and are superior to single-layered dressings. Inelastic compression (short-stretch compression) may deliver similar results but appear to require greater sophistication by those applying them to accomplish this. Inelastic bandages, which do not deliver compression at rest, may be advantageous in patients with arterial disease or patients who do not tolerate full compression (e.g., elderly). Patients with associated lymphatic damage may also benefit from pneumatic compression.

Systemic medication as adjuvant therapy to compression bandages, such as pentoxifylline¹ (Trental 400–800 mg three times daily³), aspirin,¹ or micronized purified flavonoid fraction (MPFF, Daflon 500 mg² [diosmin⁷ 90% and hesperidin⁷ 10%]) may be superior to compression bandages alone with regard to the rate of healing. The use of pentoxifylline as adjuvant therapy to compression in venous ulcers has been shown to be very beneficial.

Wound bed preparation was proposed as a way to help the healing process. It is a multistep process that improves the wound bed by removing necrotic and fibrinous wound tissue, increasing the amount of granulation tissue, and decreasing edema, chronic wound fluid (i.e., exudate), and bacterial burden.

Local care is best accomplished with occlusive dressings. Occlusive dressings provide a moist environment for healing. A variety of types of occlusions may be used, and the choice depends on several factors, including the location of the wound and the amount of fibrinous slough and exudate present. A fear of excessive infection with the use of occlusive dressings is unfounded. Topical

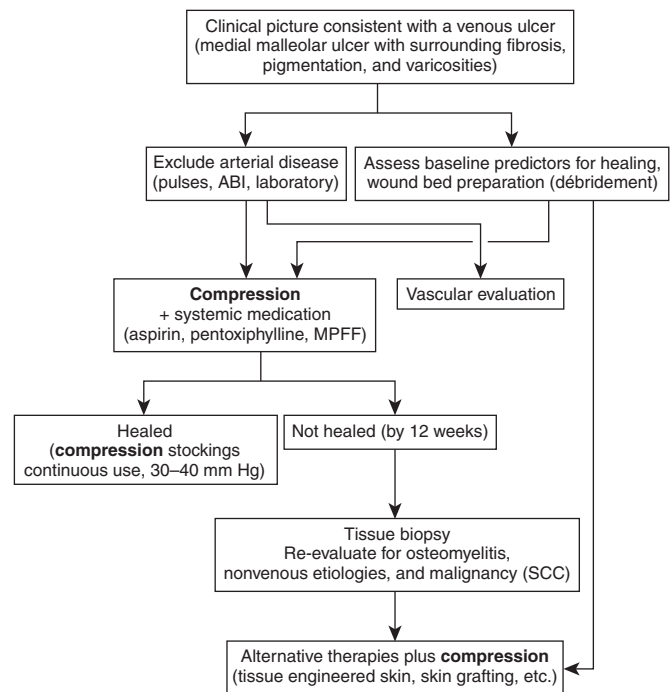

Figure 1 Simplified algorithm for the diagnosis and treatment of patients with venous ulcers. Abbreviations: ABI = ankle-brachial index; MPFF = micronized purified flavonoid fraction; SCC = squamous cell carcinoma.

antiseptics and cleansing agents should be used with caution because they may increase the time required for healing. Topical agents such as cadexomer iodine (Iodosorb), silver-impregnated dressings, and topical anesthetics are alternatives that do not prolong healing, but they should be applied directly to the wound because they may lead to skin sensitization.

Up to 50% of venous ulcers may be refractory to compression therapy alone. This refractory subset may be predicted by baseline characteristics (size and duration) and by a decrease in size with 2 to 4 weeks of treatment (Figure 1). Other available treatments include tissue-engineered skin, autologous skin, electrical stimulation, treatment with locally delivered growth factors, and venous surgery. Three categories exist for skin grafts: autograft, allogeneic (cultured), and artificial (tissue-engineered skin). Two types of autografts are full-thickness (FTSG) and split-thickness (STSG) skin grafts. The latter is commonly used by expanding it with a meshing technique.

Apligraf, a bi-layered engineered living skin composed of keratinocytes and fibroblasts from neonatal foreskin, is approved by the US Food and Drug Administration for treatment of venous leg and diabetic neuropathic foot ulcers. Surgical treatment of incompetent superficial and perforator veins along with standard of care (i.e., compression) reduce the risk of recurrence.

After healing occurs, patients with venous insufficiency are at risk for recurrence. The lifelong use of elastic compression stockings (30–40 mm Hg) is the mainstay of therapy, but early intervention after recurrence is critical. Health professionals need to understand the importance of further research to ultimately minimize the psychological, physical, and socioeconomic impact that ulcers caused by venous insufficiency have on patients and society.

VIRAL DISEASES OF THE SKIN

Method of

Sylvia L. Brice, MD

CURRENT DIAGNOSIS

Herpes Simplex Viruses 1 and 2

- Clinical: Grouped vesicles or erosions, especially in perioral or anogenital location
- Laboratory: Tzanck smear, viral culture, antigen detection, PCR, gG-based type-specific serology

Varicella-Zoster Virus

- Clinical: Papules, pustules, vesicles in diffuse (varicella) or dermatomal (herpes zoster) distribution
- Laboratory: Tzanck smear, antigen detection, viral culture, PCR

Hand-Foot-and-Mouth Disease

- Clinical: Papulovesicles on oral mucosa, hands, feet following fever, constitutional symptoms
- Laboratory: PCR

Parvovirus B19

- Clinical: “Slapped cheeks” reticular erythema on trunk or extremities following fever, constitutional symptoms; arthralgias, arthritis, purpuric eruptions; transient aplastic crisis, fetal hydrops
- Laboratory: B19 specific IgM serology, PCR

Molluscum Contagiosum

- Clinical: Few to multiple 1- to 4-mm umbilicated flesh-colored papules
- Laboratory: Histopathology if clinical appearance atypical

Orf

- Clinical: One to several solid to vesicular nodules on hands, forearms; history of exposure to sheep, goats, cattle
- Laboratory: Histopathology if clinical appearance atypical; PCR

Abbreviation: NSAID = nonsteroidal antiinflammatory drug.

CURRENT THERAPY

Herpes Simplex Viruses 1 and 2

- Acyclovir (Zovirax), valacyclovir (Valtrex), famciclovir (Famvir)
- For acyclovir resistance: foscarnet (Foscavir),¹ cidofovir (Vistide)¹

Varicella-Zoster Virus

- Acyclovir, valacyclovir, famciclovir
- For acyclovir resistance: foscarnet,¹ cidofovir¹

Hand-Foot-and-Mouth Disease

- Supportive care

Parvovirus B19

- Supportive care, IVIg (Gammagard)¹

Molluscum Contagiosum

- Surgical or chemical methods of destruction
- Immunomodulators (imiquimod [Aldara],¹ cimetidine [Tagamet]¹)

Orf

- Self-limited

¹Not FDA approved for this indication.

Abbreviation: HSV = herpes simplex virus; IVIg = intravenous immunoglobulin.

Herpes Simplex Viruses 1 and 2

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are the most closely related members of the human herpesvirus family, and the skin lesions they produce are clinically indistinguishable. Clusters of tense blisters on an erythematous base often quickly evolve into erosions or ulcerations with associated crusting. Lesions can develop at any mucocutaneous site but are typically found in the perioral or anogenital regions. Both HSV-1 and HSV-2 are transmitted by direct mucocutaneous contact with an infected host. Following viral replication in the skin or mucosa, intact viral nucleocapsids travel via sensory neurons to the corresponding dorsal root ganglia to establish latency. Later, a variety of stimuli can trigger reactivation. The virus travels back along the sensory neurons to the mucocutaneous surface to replicate and induce active or subclinical infection. In the case of subclinical infection, no active skin lesions are evident, but infectious particles are present, a state known as asymptomatic shedding. Although the viral titer is much lower than during clinically active disease, asymptomatic shedding of the virus in oral and genital secretions is thought to be responsible for the majority of cases of HSV transmission.

Primary, initial nonprimary (also known as first episode), and recurrent are terms used to further define the nature of the HSV infection. A *primary* infection refers to a patient's first infection with either type of HSV at any site. These patients are seronegative initially but subsequently develop HSV type-specific antibodies. A patient who is already infected with one HSV type and then develops an infection with the alternate type experiences an *initial nonprimary* or first-episode infection (e.g., the first episode of genital herpes in a patient with a prior history of orofacial herpes). These patients are seropositive for one type-specific HSV antibody (e.g., HSV-1) and later develop antibodies specific for the alternate HSV type (e.g., HSV-2). A *recurrent* infection is one that occurs at a site of prior infection. These patients are seropositive for HSV-1 or HSV-2, or both. Because most primary infections, whether oral or genital, are asymptomatic, the first evidence of disease often represents a recurrent or initial nonprimary infection.

Orofacial Herpes Simplex Virus Infection

Orofacial HSV, also known as herpes labialis, fever blisters, or cold sores, is commonly acquired during childhood or adolescence. Symptomatic primary disease usually takes the form of gingivostomatitis with or without additional lesions on the cutaneous perioral surfaces. Fever, malaise, and tender lymphadenopathy may also be present. In recurrent episodes, clusters of blisters erupt along the vermilion border of the lips, and subsequent erosions and crusting persist for several days up to 2 weeks. Lesions can develop anywhere in the perioral area, especially on the cheeks. In men, a viral folliculitis of the beard area (herpetic sycosis) may be mistaken for a bacterial process because it is often pustular. The presence of a prodrome and recurrence in the same site are clues to the correct diagnosis. Although recurrent intraoral lesions of HSV can occur, they are uncommon in immunocompetent persons. Exposure to

Later, a variety of stimuli can trigger reactivation. The virus travels back along the sensory neurons to the mucocutaneous surface to replicate and induce active or subclinical infection. In the case of subclinical infection, no active skin lesions are evident, but infectious particles are present, a state known as asymptomatic shedding. Although the viral titer is much lower than during clinically active disease, asymptomatic shedding of the virus in oral and genital secretions is thought to be responsible for the majority of cases of HSV transmission.

Primary, initial nonprimary (also known as first episode), and recurrent are terms used to further define the nature of the HSV infection. A *primary* infection refers to a patient's first infection with either type of HSV at any site. These patients are seronegative initially but subsequently develop HSV type-specific antibodies. A patient who is already infected with one HSV type and then develops an infection with the alternate type experiences an *initial nonprimary* or first-episode infection (e.g., the first episode of genital herpes in a patient with a prior history of orofacial herpes). These patients are seropositive for one type-specific HSV antibody (e.g., HSV-1) and later develop antibodies specific for the alternate HSV type (e.g., HSV-2). A *recurrent* infection is one that occurs at a site of prior infection. These patients are seropositive for HSV-1 or HSV-2, or both. Because most primary infections, whether oral or genital, are asymptomatic, the first evidence of disease often represents a recurrent or initial nonprimary infection.

Orofacial Herpes Simplex Virus Infection

Orofacial HSV, also known as herpes labialis, fever blisters, or cold sores, is commonly acquired during childhood or adolescence. Symptomatic primary disease usually takes the form of gingivostomatitis with or without additional lesions on the cutaneous perioral surfaces. Fever, malaise, and tender lymphadenopathy may also be present. In recurrent episodes, clusters of blisters erupt along the vermilion border of the lips, and subsequent erosions and crusting persist for several days up to 2 weeks. Lesions can develop anywhere in the perioral area, especially on the cheeks. In men, a viral folliculitis of the beard area (herpetic sycosis) may be mistaken for a bacterial process because it is often pustular. The presence of a prodrome and recurrence in the same site are clues to the correct diagnosis. Although recurrent intraoral lesions of HSV can occur, they are uncommon in immunocompetent persons. Exposure to

ultraviolet light is a common trigger factor for herpes labialis, as is fever or intercurrent infection.

Genital Herpes Simplex Virus Infection

When symptomatic, primary genital herpes often involves bilaterally distributed lesions in the anogenital area with associated fever, inguinal adenopathy, and dysuria or urinary retention. Aseptic meningitis can also occur. The lesions often persist for 2 to 3 weeks or longer. Nonprimary infections are usually less severe and have fewer constitutional symptoms. Recurrent episodes tend to be milder and shorter in duration. Often, there is a prodrome of tingling or burning followed by the development of localized vesicles that can quickly rupture, leaving nonspecific erosions or ulcerations. The lesions may be anywhere within the anogenital region but tend to recur close to the same area in subsequent episodes. The time between exposure and development of primary disease is estimated to be from 3 to 14 days. However, more often the first clinical indication of disease is a recurrence, which can occur weeks to years after the initial infection. Prior infection with HSV-1 provides some protection against acquisition of HSV-2.

Based on seroepidemiologic evidence, it is estimated that approximately 17% of the United States population aged 14 to 49 years are infected with HSV-2. In most of these persons, this disease has not been officially diagnosed and they are unaware that they are infected. Nevertheless, they experience asymptomatic shedding and unknowingly transmit the disease to sexual partners. Interrupting this cycle of transmission has become a major focus among health care providers who work with these patients. A combination of patient education and appropriate use of systemic antiviral agents may be gradually having some impact on this epidemic. Recommendations for patients with genital herpes include avoiding sex with uninfected partners when active lesions or prodromal symptoms are present and routinely using latex condoms to minimize transmission during periods of asymptomatic shedding. Chronic suppressive doses of oral antiviral agents (Table 1), including acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir), significantly reduce the frequency of clinical recurrences as well as the rate of asymptomatic shedding and may be recommended together with these other practices to reduce the risk of transmission.

Although HSV-2 is the etiologic agent in a majority of cases of genital herpes infections, an increasing number of genital herpes infections are caused by HSV-1. Symptomatic recurrences and asymptomatic shedding are less frequent with genital HSV-1 infection than with genital HSV-2 infection, and this distinction becomes important for patient counseling and prognosis.

Other Mucocutaneous Herpes Simplex Virus Infections

Eczema herpeticum, also known as Kaposi's varicelliform eruption, represents a cutaneous dissemination of HSV usually seen in patients with atopic dermatitis or other underlying skin disease. Herpetic vesicles develop over an extensive mucocutaneous surface, most often the face, neck, and upper trunk, presumably spreading from a recurrent oral HSV infection or asymptomatic shedding from the oral mucosa. Eczema herpeticum can also develop in the presence of genital HSV. As with other HSV infections, eczema herpeticum may be recurrent. In addition, patients can develop localized, recurrent HSV in previously involved areas. Because of the extensive and inflammatory nature of the process and the possible secondary bacterial infection, the underlying viral etiology may be obscured. A history of eczema and recurrent HSV in the patient and careful observation for the grouped vesicles or erosions can be key to the correct diagnosis.

Herpetic whitlow refers to HSV infection of the hand, usually one or more distal digits. Previously thought to be limited to health care professionals with exposure to oral secretions of their patients, it is now recognized that autoinoculation from orolabial or genital HSV contributes to a significant number of cases.

Herpes gladiatorum is a problem seen most commonly in athletes who participate in close contact sports such as wrestling. Typically transmitted from active herpes labialis or asymptomatic

TABLE 1 Recommendations for Systemic Antiviral Treatment of Mucocutaneous Herpes Simplex Virus Infection

EPISODE	DRUG	DOSAGE
Genital Herpes Simplex Virus		
Primary or first episode	Acyclovir	Mild to moderate: 400 mg PO tid ³ or 200 mg PO 5 ×/d × 7–10 d Severe: 5 mg/kg IV q8h × 5 d
	Valacyclovir	1 g PO bid × 7–10 d
	Famciclovir ¹	250 mg PO tid × 10 d
Recurrent episode (start at prodrome)	Acyclovir	400 mg PO tid × 5 d ³ or 800 mg PO bid × 5 d ³ or 800 mg PO tid × 2 d ³
	Valacyclovir	500 mg PO bid × 3 d or 1 g daily × 5 d
	Famciclovir	1 g PO bid × 1 d or 125 mg PO bid × 5 d
Chronic suppression	Acyclovir	>6 outbreaks per year: 400 mg PO bid or 200 mg PO tid Adjust up or down according to response
	Valacyclovir	6–10 outbreaks per year: 500 mg PO qd
	Famciclovir	≥10 outbreaks/year: 1 g PO qd ≥6 outbreaks/year: 250 mg PO bid
Orofacial Herpes Simplex Virus		
Primary or first episode	Acyclovir ¹	15 mg/kg 5 ×/d × 7 d
	Valacyclovir ¹	1 g bid × 7 d
	Famciclovir ¹	500 mg bid × 7 d
Recurrent episode (start at prodrome)	Acyclovir ¹	400 mg PO 5 ×/d × 5 d
	Valacyclovir	2 g PO bid × 1 d
	Famciclovir	1500 mg in 1 dose
Chronic suppression	Acyclovir ¹	400 mg PO bid-tid
	Valacyclovir ¹	500 mg–1 g PO qd
Orolabial or Genital Herpes Simplex Virus in Immunosuppressed Patients		
Recurrent or suppressive	Acyclovir ¹	400 mg PO tid or 5–10 mg/kg IV q8h
	Valacyclovir	500 mg–1 g PO bid
	Famciclovir	500 mg PO bid

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

shedding in oral secretions of an infected opponent, herpes gladiatorum often affects the head, neck, or shoulders and may be recurrent. In the wrestler with frequent outbreaks, chronic suppressive therapy may be recommended.

Diagnosis

Viral culture remains a common and acceptable method for diagnosing HSV infection. This method is sensitive when specimens are obtained from lesions that have not yet become too dry or crusted, usually during the first 2 to 3 days after onset. An adequate sample, obtained by unroofing the blister and swabbing the base, increases the likelihood of an accurate result. Antigen detection tests can remain positive even after lesions have dried, as long as the specimen includes epithelial cells and not just debris. For this method, a

scraping from the lesion is usually smeared on a glass slide to be sent to the laboratory. Not all antigen detection methods are designed to distinguish HSV-1 from HSV-2.

Polymerase chain reaction (PCR) is highly sensitive and has become routinely available for diagnosis of mucocutaneous HSV infections. PCR may also be useful for detection of asymptomatic shedding.

The Tzanck smear (cytologic detection) is both insensitive and nonspecific but may be of use in some clinical settings. It does not differentiate HSV types or HSV from varicella-zoster virus (VZV).

Serologic testing for HSV was previously of limited use because it could not reliably differentiate HSV-1 from HSV-2. Because they share significant genetic homology, HSV-1 and HSV-2 code for a number of common proteins that are not antigenically distinct. However, they also code for type-specific proteins that can be used to differentiate them. Current tests based on detecting type-specific viral glycoprotein G (gG-based, type-specific assays) are accurate and should be requested for this purpose. A positive HSV-2 serology may be useful in confirming the diagnosis of genital herpes in a patient with a negative viral culture or with unrecognized or asymptomatic disease. Alternatively, a negative serology can help exclude the diagnosis of HSV in a patient with chronic, nonspecific oral or genital symptoms.

Varicella Zoster Virus

VZV, another member of the human herpesvirus family, produces two specific patterns of disease in the skin. The primary infection results in varicella, also known as chickenpox, a widespread vesicular eruption usually seen in the pediatric population. Following the primary infection, VZV establishes latency in the dorsal root ganglia until some later point, when reactivation can occur. The ensuing unilateral dermatomal distribution of blisters, often preceded by neuralgic pain, is known as herpes zoster or shingles. Herpes zoster is especially common in patients older than 50 years, but it may be seen at any age. It is also seen more commonly in immunocompromised patients, such as organ transplant recipients or patients infected with HIV. Herpes zoster is no longer considered a marker for underlying cancer, and evaluation for occult malignancy in an otherwise asymptomatic patient is not indicated. A single recurrence of herpes zoster, usually in the same dermatome, may occur, but this is uncommon in immunocompetent individuals. Additional recurrences, however, suggest a dermatomal form of HSV, and laboratory assessment for this possibility may be indicated.

The most common dermatomes involved with herpes zoster are in the thoracolumbar (T3-L2) and trigeminal (V1) regions. Skin lesions typically evolve from papules to vesicles and pustules, and then to crusted erosions, before healing approximately 2 to 4 weeks after onset. The associated neuropathic pain commonly persists after the lesions have healed. Pain that continues for more than 3 months after the skin lesions resolve is referred to as post-herpetic neuralgia, one of the most common and debilitating complications of this infection.

Several clinical presentations of herpes zoster deserve additional attention. Ophthalmic zoster, with lesions along the tip, side, or base of the nose indicating involvement of the nasociliary branch of the trigeminal nerve (Hutchinson's sign), may be associated with increased risk for ocular complications. Prompt initiation of a systemic antiviral agent (Table 2) and evaluation by an ophthalmologist are recommended. Disseminated zoster, with more than a few lesions outside the primary and immediately adjacent dermatomes, can indicate visceral involvement and its associated complications. The term *zoster sine herpette* describes patients with neuropathic pain resembling zoster but without any skin lesions. The diagnosis can be supported by demonstration of increased IgG antibody titers between the acute and convalescent phases. Chronic zoster is seen predominantly in HIV-infected persons. Single or multiple warty growths can persist for weeks or months in areas of skin previously involved by typical lesions of varicella or herpes zoster. Chronic zoster is often resistant to acyclovir. Tissue biopsy and

*Continue until there are no new lesions for 48 h.

viral cultures, with further testing for antiviral resistance, may aid in assessment.

Herpes Zoster

Diagnosis

Diagnosis of herpes zoster is often made on clinical grounds alone. A Tzanck smear can provide additional support of the viral etiology. With atypical presentations, however, the diagnosis is best confirmed by real time PCR. An antigen detection method can be used if active blisters are present. Both are rapid and differentiate VZV from HSV. Viral cultures is insensitive but may be required if there is a need to assess possible antiviral resistance. Basic VZV serology is rarely useful for diagnosis.

Treatment

There are three systemic antiviral agents routinely used for the treatment of HSV and VZV infections: acyclovir, valacyclovir, and famciclovir. All three are highly effective and generally well tolerated. Because they inhibit only actively replicating viral DNA, they have no impact on latent infection. Recommendations for antiviral treatment of mucocutaneous HSV infections and herpes zoster, localized topical measures, and available formulations are outlined in Tables 1 to 5. Optimal antiviral dosage schedules for less-common HSV infections, such as herpetic whitlow, have not been determined. The doses outlined in Table 1 for either episodic or chronic suppressive therapy can be used as a guideline in these cases.

Acyclovir became available more than 25 years ago and continues to be widely used. Inside an infected host cell, acyclovir must be phosphorylated—first by a virally encoded enzyme (thymidine kinase) and then by host-cell enzymes—to the active form of the drug, acyclovir triphosphate. As a nucleotide analogue, acyclovir triphosphate is incorporated into replicating viral DNA, abruptly terminating further synthesis of that viral DNA chain. Acyclovir triphosphate also interferes with viral DNA replication by directly inhibiting viral DNA polymerase. Valacyclovir is an oral prodrug of acyclovir and has a much higher bioavailability. After ingestion, valacyclovir is rapidly metabolized to acyclovir, and the subsequent mechanism of action is as just described. Famciclovir is an oral prodrug of penciclovir (Denavir), designed for greater bioavailability. Similar to acyclovir, penciclovir must first be phosphorylated by viral thymidine kinase and then by cellular enzymes to penciclovir triphosphate. In this active form, penciclovir triphosphate interferes with viral DNA synthesis and replication by inhibiting viral DNA polymerase. Famciclovir has greater bioavailability and a longer intracellular half-life than acyclovir. For all three agents, the required activation by viral thymidine kinase and the preferential inhibition of viral DNA synthesis contribute to the highly specific antiviral activity.

If taken as recommended, acyclovir, valacyclovir, and famciclovir are generally comparable in their safety and effectiveness. Valacyclovir and famciclovir offer the convenience of less-frequent dosing. Dosing for all three should be adjusted in the presence of renal insufficiency (see Table 5).

TABLE 3 Topical Treatment Options for Mucocutaneous Herpes Simplex Virus and Varicella Zoster Virus Infections

TREATMENT	COMMENT
Cool, moist compresses using tap water or aluminum acetate 1:20 to 1:40 (Burow's solution, Domeboro, Bluboro)	Good for moist, oozing lesions to accelerate drying Apply wet dressing to involved skin and cover with a dry cloth to allow evaporation
Calamine lotion or similar shake lotion containing alcohol, menthol, and/or phenol; Aveeno colloidal oatmeal	Useful as drying and antipruritic agent May be applied after wet dressing
Bacitracin, ¹ Polysporin, mupirocin ¹ (Bactroban)	Use if there is concern for localized secondary bacterial infection
2% Viscous lidocaine, compounded suspensions ^{1,6} (e.g., Kaopectate ¹ or Maalox, ¹ diphenhydramine, ¹ lidocaine)	Useful for temporary pain relief of oral or genital mucosal involvement
Acyclovir ointment	Used together with systemic antiviral agents, may be of benefit to immunocompromised individuals for localized HSV
Penciclovir (Denavir) cream	Can decrease the duration of lesions in herpes labialis by half a day if applied every 2 h while awake for 4 days beginning at the first sign of disease
Acyclovir buccal tablet (Sitavig) 50 mg	Can decrease the duration of herpes labialis by 0.8 days if single tablet is applied within 1 hour of prodromal symptom

¹Not FDA approved for this indication.⁶May be compounded by pharmacists.

Abbreviation: HSV = herpes simplex virus.

TABLE 4 Formulations of Acyclovir, Valacyclovir, and Famciclovir

DRUG	ORAL	TOPICAL	INTRAVENOUS
Acyclovir	200, 400, 800 mg 50 mg buccal tablet	5% Ointment (5g, 15g, 30g) 5% cream (5 g)	Yes
Valacyclovir	500 mg, 1 g	No	No
Famciclovir	125, 250, 500 mg	No	No
Penciclovir (Denavir)	No	1% cream (1.5 g, 5 g)	No

20–39		125 mg q24h	125 mg q12h	500 mg q24h	
<20		125 mg q24h	125 mg q24h	250 mg q24h	
>60		1 g bid × 1 d			1500 mg single dose
40–59		500 mg bid × 1 d			750 mg single dose
20–39		500 mg single dose			500 mg single dose
<20		250 mg single dose			250 mg single dose

Although antiviral therapy does not decrease the incidence of postherpetic neuralgia, all three agents decrease the time for lesion healing and shorten the overall duration of pain if initiated within 48 to 72 hours after the onset of herpes zoster. Valacyclovir and famciclovir appear to be more effective than acyclovir for this purpose, presumably because of easier dosing. An otherwise healthy person younger than 50 years who has discrete involvement on the trunk and mild to moderate pain might benefit minimally or not at all from this intervention, especially if it is initiated after 72 hours of lesion onset. However, patients who are older than 50 years, are immunosuppressed, have involvement in the ophthalmic distribution, or have more-extensive lesions or severe pain should receive systemic antiviral therapy, even if the 72-hour deadline has expired. Adequate pain control, often requiring opiates, is also important.

The addition of systemic corticosteroids to the antiviral regimen remains controversial. There is evidence to suggest this can lessen the severity of the acute episode but does not decrease the incidence or duration of postherpetic neuralgia. Corticosteroids may be of benefit in herpes zoster complicated by facial paralysis or cranial polyneuropathy. Corticosteroids should not be used without concomitant systemic antiviral therapy.

Vaccination with a herpes zoster vaccine substantially reduces the incidence of both herpes zoster and postherpetic neuralgia. There are two herpes zoster vaccines available. The live attenuated vaccine (ZVL/Zostavax) has been in use since 2006 and is given as a single intramuscular injection. The Zoster Vaccine Recombinant, Adjuvanted (RZV/Shingrix) received FDA approval in October 2017, for immunocompetent adults 50 years and older. RZV is a non-live recombinant glycoprotein E vaccine and requires 2 doses given intramuscularly 2–6 months apart. The U.S. Advisory Committee on Immunization Practices (ACIP) currently recommends the use of RZV for immunocompetent adults aged 50 years or older for the prevention of herpes zoster and related complications. The ACIP also recommends RZV for adults aged 50 years or older who previously received the live-attenuated herpes zoster vaccine (ZVL/ZOSTAVAX) and either RZV or ZVL for adults aged 60 years or older (RZV is preferred).

Despite widespread use of these antiviral agents, antiviral resistance is rarely a problem in the immunocompetent population. However, it does arise in the setting of immunosuppression. The basis for the resistance is most commonly a mutation in the gene coding for thymidine kinase. Less often there is a mutation in the viral DNA polymerase. In either case, all three standard drugs become ineffective. Alternative antiviral agents available for treatment of acyclovir-resistant HSV and VZV infections include fos-carnet (Foscavir)¹ and cidofovir (Vistide).¹

Hand-Foot-and-Mouth Disease

Hand-foot-and-mouth disease is typically a disease of childhood. The most common etiologic agent is a nonpolio enterovirus, Coxsackie A16, and transmission is via the oral–oral or fecal–oral route. It is highly contagious. Several days after exposure, a prodrome of low-grade fever, malaise, abdominal pain, or respiratory symptoms can develop, followed by the appearance of papulovesicles on the palate, tongue, or buccal mucosa. Similar lesions can subsequently develop on the feet and hands. The eruption persists for 7 to 10 days and then resolves. Treatment is symptomatic. Nail dystrophies including onychomadesis (separation of the proximal portion of the nail plate from the nail bed) and Beau's lines (horizontal grooves in the nail plate) may be seen 2–4 weeks later.

Since 1997, outbreaks of hand-foot-and-mouth disease caused by enterovirus 71 have been reported in Asia and Australia. Although hand-foot-and-mouth disease associated with Coxsackie A16 infection is typically a mild illness, hand-foot-and-mouth disease caused by enterovirus 71 has shown a higher incidence of neurologic involvement, including fatal cases of encephalitis.

An atypical hand-foot-and-mouth disease with more widespread cutaneous involvement has been reported as associated with Coxsackievirus A6. There is a predilection for areas commonly involved in atopic dermatitis, such as the antecubital and popliteal fossae and this presentation may be confused with eczema herpeticum or VZV infection. Diagnosis of these more atypical cases may require laboratory assessment. This could include antigen detection or PCR to exclude HSV and VZV. Reverse Transcription PCR (RT-PCR) of vesicle fluid, oropharyngeal swab or stool specimen may be used to confirm the enterovirus infection.

Parvovirus B19

Cutaneous manifestations of parvovirus B19 infection include the childhood exanthem known as erythema infectiosum (fifth disease) and, less commonly, petechial or purpuric eruptions. The virus is transmitted primarily via respiratory secretions and, to a much lesser extent, through blood or blood products. The host cells for viral replication are erythroid progenitor cells, which subsequently undergo cell lysis.

A child with erythema infectiosum typically develops a low-grade fever and nonspecific upper respiratory symptoms approximately 2 days before the onset of rash. The rash has been described as having a slapped-cheeks appearance, with prominent redness over the malar eminences. This is followed by a pink-to-red lacy or reticular eruption over the trunk and extensor surfaces of the arms and legs. The rash usually lasts a week to 10 days but can transiently recur over months in response to precipitating factors such as sunlight, exercise, and bathing. Diagnosis of erythema infectiosum is usually made on clinical grounds, and treatment is symptomatic. By the time the rash appears and the diagnosis has been made, the child is no longer infectious. Much less commonly parvovirus B19 infection may manifest as a papular-purpuric eruption with edema, erythema, and patechiae in a “gloves and socks” distribution on the hands and feet.

Infection with parvovirus B19 in older adolescents and adults often manifests with arthralgias or arthritis rather than a rash. In certain patient populations, parvovirus B19 infections may be associated with complications including transient aplastic crisis, chronic anemia, and hydrops fetalis. In these less-typical presentations, serology (anti-B19 IgM or documented seroconversion) may be needed for diagnosis. Intravenous immunoglobulin (IVIg [Gamimune N]¹) is used successfully for treatment of chronic or persistent infection in immunosuppressed patients.

Molluscum Contagiosum

Molluscum contagiosum are benign umbilicated papules caused by infection with the *Molluscipoxvirus*, a member of the poxvirus family. Lesions are limited to the mucocutaneous surface and typically appear in clusters on the face, trunk, and skin fold areas in children and on thighs, lower abdomen, and suprapubic areas in sexually active adults. Large numbers of lesions in an extensive distribution may be seen in the immunosuppressed population.

Transmission routinely occurs by skin-to-skin contact with an infected host, but transmission from contaminated fomites has been reported. Autoinoculation commonly occurs. Diagnosis is usually based on clinical examination, but histopathology of atypical lesions may be used for confirmation.

Because molluscum contagiosum tends to be self-limited, treatment is not always recommended, but it can reduce the risk of autoinoculation and transmission to others. Treatment modalities are primarily aimed at destroying the lesions, similar to those used for verruca vulgaris (Table 6). In the case of sexual transmission, evaluation for other sexually transmitted diseases may be indicated.

Orf and Milker's Nodules

Orf (also known as ecthyma contagiosum) and milker's nodules are caused by the closely related *Parapoxvirus*, a member of the

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

TABLE 6 Treatment Options for Molluscum Contagiosum

TREATMENT	COMMENT
Cryotherapy (liquid nitrogen)	Freeze individual lesions for 5–10 sec Repeat PRN in 2–3 wk
Curettage	Entire lesion may be removed using a curette; this results in bleeding Removal of central core with toothpick or other pointed instrument is also effective
Cantharidin (Cantharone) ¹	Blister-inducing agent: Apply to lesion with toothpick, air dry Cover with tape or adhesive bandage Patient to wash area after 24 h (or sooner if significant pain)
Podophyllin (25% in tincture of benzoin) ¹	Cytotoxic agent: Apply to lesion with toothpick Patient to wash off after 4–6 h Contraindicated in pregnancy
Podofilox (Condylox 0.5% gel or solution) ¹	Done by patient: Apply bid for 3 consecutive d/wk × 2–4 wk Contraindicated in pregnancy
Salicylic acid/lactic acid (Occlusal, Duoofilm) ¹	Done by patient: Apply daily
Imiquimod (Aldara) 5% cream ^{1,2}	Done by patient: Apply daily 5 consecutive d/wk Leave on overnight Continue for 8–12 wk
Cimetidine (Tagamet) ¹	30 mg/kg/d PO × 6–12 wk Can boost cell-mediated immunity
Candida antigen (Candin) ¹	Intralesional injection 0.3 mL ³

¹Not FDA approved for this indication.²Not available in the United States.³Exceeds dosage recommended by the manufacturer.

poxvirus family. The virus responsible for orf is widespread in sheep and goats, whereas the virus causing milker's nodules is found in cattle. Transmission to humans is by direct contact with infected animals or recently vaccinated animals and is usually seen several days and up to 2 weeks after exposure. Preexisting skin trauma or other disruption of the normal cutaneous barrier enhances the risk of transmission. Barrier precautions and proper hand hygiene are important preventive measures.

Orf and milker's nodules most commonly appear as one to several nodules on the dorsal aspect of the hands or forearms. Lesions evolve through several clinical stages over a period of 3 to 5 weeks, ranging from solid red nodules to vesicular, exudative, or wartlike tumors. As with other poxvirus infections, lesions of orf often demonstrate central umbilication. Regional lymphadenopathy and lymphangitis are commonly seen.

Diagnosis is based on a history of exposure and clinical examination. Tissue biopsy for histopathology or electron microscopy may also be used. Orf virus infection can resemble skin lesions associated with potentially life-threatening zoonotic infections such as tularemia, cutaneous anthrax, and erysipelas. Should this be a concern, definitive diagnostic testing using PCR is available through the Centers for Disease Control and Prevention (CDC).

In general, the lesions of orf are self-limited, resolving within 4 to 6 weeks, and treatment is not routinely required. However, immunocompromised persons can develop more progressive and destructive lesions requiring therapeutic intervention such as topical cidofovir^{1,6} or imiquimod (Aldara).¹

¹Not FDA approved for this indication.⁶May be compounded by pharmacists.

WARTS (VERRUCAE)

Method of

M. Chantel Long, MD

CURRENT DIAGNOSIS

- Common warts: rough, hyperkeratotic, firm papules usually found on the extremities.
- Flat warts: small, flat, pink or flesh-colored papules on the face, arms, or legs.
- Plantar and palmar warts: callus-like lesions that disrupt skin lines on the soles or palms.
- Mosaic warts: large clusters of warts.
- Filiform warts: small, finger-like lesions on the face.
- Genital warts: flesh to brown colored, flat or exophytic, found in the anogenital region.
- Differential diagnoses: seborrheic keratoses, molluscum contagiosum, keratoacanthoma, squamous cell carcinoma, acrochordon, melanocytic melanoma, calluses, and corns.

CURRENT THERAPY

- Approximately 20% of warts spontaneously resolve within 3 months and 60% within 2 years in a healthy person.
- Salicylic acid and dimethyl ether.
- Cryotherapy.
- Cantharidin (Cantharone).^{1,6}
- Surgical removal.
- Pulsed-dye laser.
- Immunotherapy: topical imiquimod (Aldara),¹ intralesional Candida antigen (Candin).¹
- Photodynamic therapy.

¹Not FDA approved for this indication.⁶May be compounded by pharmacists.

Note: Cantharidin and Candin are not FDA approved. Aldara is approved for genital and perianal warts only.

TABLE 6 Treatment Options for Molluscum Contagiosum

TREATMENT	COMMENT
Cryotherapy (liquid nitrogen)	Freeze individual lesions for 5–10 sec Repeat PRN in 2–3 wk
Curettage	Entire lesion may be removed using a curette; this results in bleeding Removal of central core with toothpick or other pointed instrument is also effective
Cantharidin (Cantharone) ¹	Blister-inducing agent: Apply to lesion with toothpick, air dry Cover with tape or adhesive bandage Patient to wash area after 24 h (or sooner if significant pain)
Podophyllin (25% in tincture of benzoin) ¹	Cytotoxic agent: Apply to lesion with toothpick Patient to wash off after 4–6 h Contraindicated in pregnancy
Podofilox (Condylox 0.5% gel or solution) ¹	Done by patient: Apply bid for 3 consecutive d/wk × 2–4 wk Contraindicated in pregnancy
Salicylic acid/lactic acid (Occlusal, Duoofilm) ¹	Done by patient: Apply daily
Imiquimod (Aldara) 5% cream ^{1,2}	Done by patient: Apply daily 5 consecutive d/wk Leave on overnight Continue for 8–12 wk
Cimetidine (Tagamet) ¹	30 mg/kg/d PO × 6–12 wk Can boost cell-mediated immunity
Candida antigen (Candin) ¹	Intralesional injection 0.3 mL ³

¹Not FDA approved for this indication.²Not available in the United States.³Exceeds dosage recommended by the manufacturer.

poxvirus family. The virus responsible for orf is widespread in sheep and goats, whereas the virus causing milker's nodules is found in cattle. Transmission to humans is by direct contact with infected animals or recently vaccinated animals and is usually seen several days and up to 2 weeks after exposure. Preexisting skin trauma or other disruption of the normal cutaneous barrier enhances the risk of transmission. Barrier precautions and proper hand hygiene are important preventive measures.

Orf and milker's nodules most commonly appear as one to several nodules on the dorsal aspect of the hands or forearms. Lesions evolve through several clinical stages over a period of 3 to 5 weeks, ranging from solid red nodules to vesicular, exudative, or wartlike tumors. As with other poxvirus infections, lesions of orf often demonstrate central umbilication. Regional lymphadenopathy and lymphangitis are commonly seen.

Diagnosis is based on a history of exposure and clinical examination. Tissue biopsy for histopathology or electron microscopy may also be used. Orf virus infection can resemble skin lesions associated with potentially life-threatening zoonotic infections such as tularemia, cutaneous anthrax, and erysipelas. Should this be a concern, definitive diagnostic testing using PCR is available through the Centers for Disease Control and Prevention (CDC).

In general, the lesions of orf are self-limited, resolving within 4 to 6 weeks, and treatment is not routinely required. However, immunocompromised persons can develop more progressive and destructive lesions requiring therapeutic intervention such as topical cidofovir^{1,6} or imiquimod (Aldara).¹

¹Not FDA approved for this indication.⁶May be compounded by pharmacists.

Verrucae, commonly known as cutaneous warts, are benign skin growths caused by the human papillomavirus (HPV). Cutaneous warts are divided into common warts, plantar warts, flat warts, and genital warts. Common warts account for 70% of all cutaneous warts. Two-thirds of untreated common warts spontaneously regress within 2 years, but previously infected individuals have a higher rate of developing new warts than those who were never infected.

Epidemiology

It is estimated that 10% of the general population has cutaneous warts, and warts are one of the most common reasons for dermatologic visits. Transmission occurs through direct contact with an infected person or indirectly through fomites. As a result, warts are seen with greater frequency among groups of people in close contact, such as schoolchildren. Thus, warts are more common in adolescents with a frequency estimated as high as 20%. Since the extent of infection is determined by the immune response, warts are also more common in immunocompromised patients. Autoinoculation is possible by scratching the lesions, often leading to a linear pattern.

Pathophysiology

Warts are caused by HPV. More than 100 genotypes of HPV have been identified, and the virus is prevalent. HPV causes both clinical and subclinical infections and plays a role in certain cutaneous malignancies, including squamous cell carcinoma. It is found in the basal layer of the epidermis but replicates in the superficial, well-differentiated layer of the skin. The cellular proliferation gives rise to thick, hyperkeratotic lesions generally known as warts. The warts can occur anywhere on the skin or mucous membranes.

Clinical Manifestations

Most warts are asymptomatic, though patients often present with complaints of a “bump.” Usually, the warts appear flesh-colored, brown, or gray and can be flat to exophytic, giving them the classic “cauliflower” appearance. The lesions may be single or multiple and may range in size from minuscule to several centimeters in diameter. Localized irritation, pruritus, pain, or bleeding may occur. Symptoms vary based on the location and size of the lesions.

Several types of warts occur with variations in appearance, site of infection, and the specific type of HPV involved. Common warts (*verrucae vulgaris*) are white to flesh-colored, rough, hyperkeratotic, raised, and firm, usually found on the extremities. They disrupt normal skin lines on the fingers and toes and are most associated with HPV types 1, 2, and 4. Flat warts (*verrucae plana*) are caused by HPV types 3, 10, or 28 and are tan to flesh colored. They are small, 1 to 3 mm in diameter, flat, sharply demarcated growths that appear in large numbers on the face, arms, or legs. They usually occur in a linear arrangement related to local trauma, such as shaving. Butcher warts are associated with HPV type 7 and have a thick, raised, exophytic appearance. They are most common in workers who regularly handle raw meat or fish. Plantar and palmar warts (*verrucae plantaris* and *verrucae palmaris*) are hard, thickened, callus-like lesions that disrupt skin lines on the soles or palms. They are associated with HPV types 1, 2, 4, 27, and 57. They are usually flesh colored, covered with callus, and can be painful, especially when located on pressure points. If warts coalesce into a plaque, this is termed a *mosaic* wart. Filiform warts are slender, finger-like growths most commonly seen on the face, especially around the eyelids, nose, and mouth. Periungual warts are common warts impinging on and growing under toenails or fingernails. Genital warts (*condyloma acuminatum*) are flesh colored to brown, flat or exophytic lesions, occurring in anogenital regions. Mucosal papillomas are warts that occur on mucous membranes, usually in the mouth or vagina, and tend to be white in color.

Epidermodysplasia verruciformis is a rare, autosomal recessive disorder that leads to widespread reddish brown, flat papules on the trunk, hands, face, and extremities. These warts have malignant potential, especially on sun-exposed areas. It is estimated that one-

third may become malignant. These patients present in childhood. Chronically infected with multiple types of HPV, including types 3, 5, 8, 9, 12, 14, 15, 17, 19 to 25, 36 to 38, 47, 49, and 50, the warts have lifelong persistence. Another related disease is verrucous carcinoma. This is a slow-growing variant of squamous cell carcinoma that occurs in the oral mucosa, anogenital region, or plantar surface. These warts are associated with HPV types 6 and 11.

Risk Factors

Risk factors most associated with verrucae include immunosuppression and close contact. Due to their decreased immune response, immunocompromised hosts are at increased risk not only for infection, but also for malignant transformation of the warts. Pregnancy, previous wart infection, and handling raw meat or fish are also known risk factors.

Differential Diagnosis

The differential diagnosis of warts includes seborrheic keratoses, molluscum contagiosum, keratoacanthoma, squamous cell carcinoma, acrochordon, amelanocytic melanoma, porokeratosis, calluses, and corns.

Diagnosis is based on clinical findings. When the clinical appearance of the lesion is typical, no other confirmatory tests are usually necessary. Paring down the stratum corneum, or outer layer of skin, may reveal black dots, which are thrombosed or bleeding capillaries, and helps confirm the diagnosis. If needed, tissue biopsy can provide histopathologic confirmation. In immunocompromised patients, biopsy is recommended to rule out squamous cell carcinoma in any suspicious lesions, which includes large or rapidly growing, pigmented, atypical, friable, bleeding, or ulcerated lesions.

Treatment

Approximately 20% of warts spontaneously resolve within 3 months and 60% within 2 years in a healthy person. Therefore, treatment is not always necessary. Current treatments do not eradicate the virus and do not guarantee resolution. Most patients seek treatment because of the physical appearance, discomfort, or interference with daily and social functioning, especially if located on the palms, digits, or soles. The American Academy of Dermatology established reasoning for wart treatment, including the desire of the patient; for symptoms of pain, bleeding, itching, or burning; for disabling or disfiguring lesions; for large numbers or large size of lesions; for a desire to prevent spread to unblemished skin; and because of a concomitant immunocompromised condition. Immunosuppressed patients are at higher risk for developing numerous warts and require treatment to prevent progression to squamous cell carcinoma. It is often more difficult to eradicate warts in an immunosuppressed host.

Many therapeutic modalities are available for the treatment of warts. No single therapy is universally effective. Warts can resolve, recur, shrink, or grow despite therapy. It is likely that all wart therapies work by triggering an immune response to the presence of papillomavirus in the skin. Treatment of warts must be individualized and often more than one modality is needed to achieve resolution. Conservative, less painful, and less expensive treatments are preferred.

Treatment methods are divided into the categories of home remedies, over-the-counter treatments, and office-based therapies. Office-based treatments include destructive methods, surgical or laser procedures, immunologic intervention, and combination therapy.

Home Remedies

Home remedies include applications of tea tree oil,⁷ garlic extract,⁷ duct tape,¹ and hyperthermic therapy. One study comparing cryotherapy with duct tape occlusion of common warts showed

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

resolution in 85% of the children treated by occlusion, compared with 60% in the liquid nitrogen group. Proper protocol involves covering the wart with duct tape, which is left in place for 6 days. Then the site should be soaked, pared down with an emery board, and left uncovered overnight. This is repeated for a total of eight cycles. Another common home remedy is hyperthermic therapy. This involves immersing the affected area in a 45°C water bath for 30 minutes three times per week. It is a safe and inexpensive option.

Over-the-Counter Treatment

The most common over-the-counter option used by patients is one of the salicylic acid products, such as Compound W, Duofilm, Occlusal-HP, and Mediplast. These keratolytic products are offered as a solution, gel, cream, or pad in concentrations from 10% to 60%. They can be quite successful when used consistently and as directed in motivated patients. Repeated application, with pumice stone or callus file use, results in cure rates of 60% to 80%, but takes several weeks to work.

More recently, several over-the-counter wart-freezing therapies have become available. One such option is dimethyl ether, marketed as Compound W Freeze Off or Dr. Scholl's Freeze Away. These are available in aerosol form for wart treatment, which can be repeated every 2 weeks. Dimethyl ether achieves a temperature of -57°C, which is markedly higher than the -196°C temperature obtained with liquid nitrogen. This results in a more shallow depth of destruction. Because salicylic acid and dimethyl ether treatments destroy the infected epidermis and cause an immune reaction, they can be irritating and tedious, prompting many patients to seek medical care.

Office-based Treatment

Office-based treatments are largely destructive, immunomodulating, or both. Destructive treatments include cryosurgery, surgical excision, laser therapy, or repeated application of topical chemotherapy agents, such as salicylic acid, cantharidin (Cantharone),^{1,6} podophyllin (Podocon),¹ or 5-fluorouracil (Efudex).¹ The most commonly used physician office-based treatment is cryotherapy with liquid nitrogen. It can be applied by a cotton-tipped applicator or cryogun. The wart and a 1 to 2 mm margin are frozen for 10 to 30 seconds. The freeze should be repeated once after a thaw of 20 seconds. If the warts are thick, they can initially be pared down. The patient is told that a blister will result and should be left intact if possible. Treatment should be repeated every 3 to 4 weeks until normal skin markings return. Cryotherapy has demonstrated a 60% to 80% cure rate. If warts persist beyond 3 months of therapy, another method of treatment should be selected.

Another option is cantharidin (Cantharone) in a 0.7% colloidal solution. It is a chemical derived from blister beetles that is painless on application and well tolerated by children. It causes epidermal necrosis with blistering after application and occlusion for 8 hours. It is applied in the office and repeated every 4 weeks. Although not Food and Drug Administration (FDA) approved, it is a commonly used technique and can be compounded by a pharmacist. It is useful for treatment of common, periungual, and plantar warts in children, and the cure rate approaches 80%. Unfortunately, an occasional "donut wart," a ring of new warts surrounding the cleared original site, occurs.

Surgery is used for large, solitary warts, and is more direct. Large common warts of the hands or extremities are more easily treated if they are debulked surgically. This method is not recommended for plantar warts because of scarring. Surgical removal followed by electrodesiccation and curettage is effective but requires local anesthesia and can result in scarring.

Other destructive methods of wart removal usually are reserved for resistant, multiple lesions, or recalcitrant warts in immunosuppressed patients. This often requires specialty referral. Acids,

including bichloroacetic and trichloroacetic acid (Tri-Chlor),¹ should be applied by a skilled practitioner because they are known to cause pain on application, ulceration, and even scarring. Laser therapy, most often with a pulsed-dye laser (PDL) or carbon dioxide (CO₂) laser, provides selective photothermolysis of blood vessels within the wart, which compromises blood supply and results in necrosis. The PDL method is less aggressive and less painful than CO₂ vaporization. These treatments cause minimal damage to normal skin. Overall, both therapies are generally well tolerated, but local anesthesia may be necessary. Although more expensive, these methods have cure rates ranging from 45% to 90%. Photodynamic therapy (PDT) is useful for patients with multiple recalcitrant warts, especially patients who are immunosuppressed. PDT involves a topical photosensitizer applied by a trained provider. It is activated by visible light, resulting in tissue destruction. Studies of this method have been promising.

Immune modulation alone or in combination with destructive methods is helpful in treating resistant warts. The self-applied immunomodulator imiquimod (Aldara) was initially approved for treatment of genital warts. It is also used anecdotally to treat flat and common warts by inducing cytokines, including interferon production, at the site of application. A thin coat is applied at bedtime and then washed off after 6 to 10 hours. It is usually applied three times weekly and combined with cryotherapy or salicylic acid.

Intralesional immunotherapy, which includes *Candida* antigen (Candin),¹ interferon alfa-2b (Intron A),¹ bleomycin,¹ and MMR vaccine,¹ is an effective option for treatment in some patients. *Candida* antigen injection (Candin) is considered a first-line therapy in children with large or multiple warts and a second-line therapy for patients with resistant warts. It is well tolerated. *Candida* antigen is commercially available as a 1:1000 dilution. Using a 30-gauge needle and tuberculin syringe, one can inject 0.2 to 0.3 mL directly into the wart. Pretesting is unnecessary, side effects are minimal, and more than 75% of patients treated with a series of three injections have clearing of the injected and distant warts. Intralesional interferon alfa-2b (Intron A) has been used successfully to treat genital warts and warts that have not responded to conventional therapies. The clearance rate varies from 36% to 62%, but it requires multiple injections in a physician's office, is expensive, and can cause systemic adverse effects such as flu-like symptoms. Intralesional bleomycin is effective but expensive and causes severe pain. The MMR vaccine is used off-label for intralesional injection and often combined with lidocaine for comfort.

Other topical immunomodulators, such as squaric acid dibutylester (SADBE)^{1,6} or diphenycprone,^{1,6} are contact sensitizers that induce an allergic dermatitis through type IV hypersensitivity reactions. Although time consuming, treatment with SADBE is well tolerated and a good choice for recalcitrant warts in children. Other topical products available for off-label treatment include retinoids, formaldehyde compounds, and 5-fluorouracil (Efudex).¹ These agents interfere with epidermal proliferation, effect a non-specific antiviral action, or inhibit mitosis, leading to keratinocyte and viral death. All of these choices usually require specialty referral.

Oral immunomodulation with high-dose cimetidine (Tagamet)¹ has been proposed. It is postulated to enhance cell-mediated immune response. Evidence has been anecdotal. Daily doses of 30 to 40 mg/kg have been used divided twice a day to four times a day for 8 to 12 weeks.

To ensure resolution and no recurrence of warts, the patient and practitioner must often make compromises in regard to convenience, discomfort, and scarring. The factors to consider when deciding on treatment include wart location and size, patient tolerance and preference, cost, convenience, and clinician preference. Patient-applied options allow the patient greater control; however, this requires good compliance and the warts must be accessible by

TABLE 1 Treatment Regimens

DRUG	AVAILABLE AS	MECHANISM OF ACTION	DISADVANTAGES	INSTRUCTIONS
Patient Applied				
Salicylic acid (Compound W, Duofilm, Occlusol- HP, or Mediplast)	Solution, gel, lotion, cream, plaster, pad 10%–60% concentration	Keratolytic that destroys the infected epidermis while irritation stimulates an immune response	Local irritation Requires multiple applications Requires compliance Wart may need to be pared down to increase penetration	Apply nightly until clear, usually for weeks to months
Dimethyl ether (Compound W, Freeze Off, Dr. Scholl's Freeze Away)	OTC in spray canister	As above	Local irritation Requires compliance Blistering may occur	May treat every 2 weeks Total of four treatments per wart advised
Retinoids (Accutane, Retin-A, Soriatane) ¹	Soriatane (10 and 25 mg tabs), Accutane (10, 20, and 40 mg tabs), Retin-A cream/gel	Antimitotic that interferes with epidermal proliferation	Systemic with mucocutaneous dryness, elevated triglycerides, abnormal liver enzymes Avoid use in pregnancy Local irritation and dryness	Take PO daily If topical form, apply nightly
Imiquimod (Aldara) ¹	Cream 5%	Immunomodulator that mediates cytokines	Irritation, erythema, pruritus, scarring, hyperpigmentation	Apply 3 times/wk on mucosal skin Apply daily on keratinized skin
Cimetidine (Tagamet) ¹	Tablets (200, 300, 400 mg) Liquid (300 mg/5 mL)	Immunomodulator that may enhance immune response	Unclear efficacy Diarrhea Many drug-drug interactions	30–40 mg/kg daily, divided bid–qid for 8–12 weeks
Provider Applied				
Cryotherapy	Cryogun or cotton-tip application	Destroys infected dermis, induces inflammation, and leads to stimulated immune response	Pain, erythema, blistering, hypopigmentation, scarring Onychodystrophy if not careful with periungual warts	Freeze for 10–30 seconds with a 1–2 mm border, allow to thaw, then repeat May offer/need local anesthesia May repeat every 3–4 weeks
<i>Candida</i> antigen injections (Candin) ¹	1:1000 dilution	Immunomodulator	Discomfort	Intralesional injection of 0.2–0.3 mL
Trichloroacetic acid (TCA) ¹	Solution, up to 50%	Destroys infected epidermis; best for mucosal surfaces	Pain	Apply sparingly with cotton tip, air dry Repeat weekly to every other week Do not allow to “run” on normal skin Neutralize with soap or sodium bicarbonate
Cantharidin (Cantharone) ¹	Colloidal solution 0.7%, compounded	Destroys epidermis, leads to blister formation Is painless, good for kids	Avoid on face Blistering will occur	Apply with fine applicator to wart only and have patient wash off after 6–8 hr
Surgery		Surgical removal	Avoid if bleeding disorder Often requires anesthesia Scarring	Surgical excision followed by curettage and cauterization
Interferon alpha-2b (Intron A) ¹ injections		Immunomodulator	Expensive Flu-like side effects	Multiple intralesional injections several times a week Often requires specialty referral
Laser vaporization		Destroys epidermis	Expensive Requires local anesthesia	Requires specialty referral

¹Not FDA approved for this indication.

Abbreviations: bid = twice a day; OTC = over-the-counter; PO = orally; qid = four times a day.

the patient or caregiver. Provider-applied treatments are good choices for large treatment areas. Data regarding the efficacy of using more than one modality at a time are lacking. It is common practice for health care providers to combine treatment modalities. [Table 1](#) outlines current therapy regimens.

Patient Education

Counseling of patients regarding the goal and length of treatment is necessary. Patients should be educated that current treatments do not eradicate HPV, and therefore the objective of therapy is elimination of symptoms. They also need to understand that a repeated course of therapy is often required and it may take weeks to months to achieve desired results. Each treatment should be reviewed in

detail, including risks and benefits. Subsequently, the management should be tailored depending on the wart, patient, and practitioner.

ACUTE RENAL FAILURE

Method of

Kevin Schroeder, MD

CURRENT DIAGNOSIS

- Prerenal azotemia may be associated with a BUN-to-creatinine ratio $>20:1$ and a $FE_{Na} <1\%$.
- Intrarenal ARF (ATN) may be associated with a BUN-to-creatinine ratio $<20:1$ and a $FE_{Na} >1\%$.
- Postrenal ARF can manifest with frank anuria.
- Follow the trends of serum chemistries, BUN, creatinine, and urine output on a daily basis.

Abbreviations: ARF = acute renal failure; ATN = acute tubular necrosis; BUN = blood urea nitrogen; FE_{Na} = fractional excretion of sodium.

CURRENT THERAPY

- Hemodynamic support and maintenance of euvoletic state
- Correction of electrolyte and acid-base imbalances
- Removal of all offending agents and correction of underlying causes
- Adjustment of all medications for decreased glomerular filtration rate
- Renal replacement when needed on an individual basis

Epidemiology and Definitions

Acute renal failure (ARF), increasingly called acute kidney injury, is a clinical syndrome that can include decreased urine output, retention of nitrogenous metabolic waste products normally excreted by the kidney, retention of sodium and extracellular fluid resulting in peripheral and sometimes central edema, and various electrolyte and acid-base disturbances that may be associated with elevations in the blood urea nitrogen (BUN) and serum creatinine concentrations. Typically these changes occur rapidly over hours to days. Acute renal failure may further be described by the decrement in urine output: polyuric failure, indicating greater than 3 L urine output per 24 hours; nonoliguric failure, indicating 0.4 to 3L urine output per 24 hours; oliguric failure, indicating less than 400 mL urine output per 24 hours; and anuric failure, with less than 50 mL urine output per 24 hours.

Currently accepted definitions of ARF include a rise in the serum creatinine concentration by more than 0.5 mg/dL or a relative increase in the serum creatinine concentration by more than 25% for patients with preexisting chronic kidney disease (CKD) and a reduction in the glomerular filtration rate (GFR) by 50%. Note that these definitions are very operational and based on laboratory data readily available to practicing physicians, but consensus regarding a single, more sensitive measure of ARF is lacking.

Traditionally, ARF has been subclassified mechanistically into three categories. *Prerenal azotemia* refers to conditions that cause a fall in GFR because of reduced glomerular perfusion pressure. *Intrinsic renal failure* refers to conditions that directly damage any of the four main structural components of the kidney, including the afferent and efferent arterioles, glomeruli, tubules, and interstitium. *Postrenal failure* commonly refers to any condition that causes obstruction of either the upper or lower urinary tract. From a practical standpoint, clinicians must also consider the situation in which ARF occurs (in an ambulatory patient, at hospital admission, during hospitalization, or after discharge) and the rapidity of deterioration, because some diagnoses are more likely depending on the clinical context.

The reported incidence of ARF varies by clinical situation and patient population, occurring in about 2% of all inpatient admissions. Varying definitions of disease and methodologic characteristics of epidemiologic studies also affect the reported incidence. General surgical patients undergoing nonemergent, noncardiac surgery had ARF at a reported incidence of 0.8%, and critically ill surgical patients undergoing noncardiac surgery experienced ARF at a rate nearly 80 times higher. Several scoring systems have been developed to predict the risk of ARF in patients undergoing cardiac surgery, which can vary from 5% to 25%. General medicine patients can experience ARF during a hospitalization at a rate of up to 7%, but the incidence may be in the 30% to 50% range for patients in critical care units. It may be possible that the true incidence of ARF in the United States will increase substantially as the Baby Boom generation enters its seventh decade.

Despite advances in medical technology, pharmacotherapeutics, and dialysis modalities in the critical care setting, mortality associated with ARF remains largely untouched at 20% to 80%. Recent studies have detected an increased mortality with even a slight rise in serum creatinine (increase <0.5 mg/dL). ARF adds to length of stay by about 4 days and can easily increase the cost of admission by more than \$10,000.

Classification

Causes of ARF (Box 1) are elucidated chiefly from the history and physical examination. In particular, the history should focus first on symptoms causing volume depletion, second on symptoms relating to obstruction, and third on systemic symptoms including unexplained malaise, weight loss, fever, sinopulmonary bleeding, joint pain or swelling, rashes, myalgias, and neuropathies. All these factors must be considered in light of the patient's comorbid conditions, especially cardiovascular disease, hypertension, diabetes, liver disease, and peripheral vascular disease. Medications including antihypertensives, diuretics, analgesics, and over-the-counter supplements should be reviewed carefully. The physical examination serves to confirm the patient's volume status (e.g., frank hypotension or orthostatic change in blood pressure with tachycardia), to identify signs of cardiovascular disease and cardiopulmonary decompensation, to assess the status of the urinary bladder, and to detect signs of systemic disease. In addition to routine serum chemistries, BUN, and serum creatinine levels, all patients with nonanuric ARF must have a urinalysis. The clinician must observe the urine sediment for the presence of protein, blood, dysmorphic red cells, and cellular and noncellular casts. Finally, for oliguric

patients, calculation of the fractional excretion of sodium (FE_{Na}) might prove useful. Serologic testing regarding acute glomerulonephritis should be obtained when the history and physical examination suggest sufficient pretest probability.

Prerenal Azotemia

Prerenal azotemia is the most common cause of ARF among patients admitted to general medicine services. It is commonly observed in cases of volume depletion or decreased effective arterial blood volume. These include profuse emesis or diarrhea, hemorrhage, and overzealous diuresis, especially in the face of poor oral intake. In these cases, peripheral and central edema is often absent. Decompensated CHF, decompensated cirrhosis leading to the hepatorenal syndrome, and the nephrotic syndrome all lead to effective decreases in circulating arterial volume. Commonly, patients with these conditions have peripheral edema and sometimes central edema with low albumin states. In the former case, diuretics often improve not only the heart failure but also the renal dysfunction concomitantly. Recalling the principles of vascular autoregulation (Figure 1), the clinician must realize that the

kidneys of elderly patients and patients with chronic hypertension are especially susceptible to intravascular volume changes. This is particularly true when patients are medicated with angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, nonsteroidal antiinflammatory drugs and cyclooxygenase-2 inhibitors, and calcineurin inhibitors, all of which effectively paralyze the kidney's ability to regulate glomerular perfusion.

Typical laboratory findings in prerenal azotemia include an elevated BUN:creatinine ratio ($>20:1$) and a FE_{Na} of less than 1%. However, if the patient had been taking diuretics, the FE_{Na} may be falsely elevated. Metabolic alkalosis and hypokalemia might or might not be present. The urinalysis is expected to show a high specific gravity with no blood, no protein, and bland sediment; there may be a few hyaline casts. Clinically, pure prerenal azotemia often responds quickly to restoration of euolemia with increased urine output and a falling creatinine within 24 hours. Therapy for prerenal azotemia should be aimed at restoring clinical euolemia and eliminating the cause of the azotemia. Infusion of isotonic saline is the norm, with supplemental oral rehydration where possible, and use of colloids or blood products when needed. In the

Figure 1 Principle of vascular autoregulation.

case of decompensated left heart failure with pulmonary embarrasment, it is often necessary to employ an inotrope (e.g., dobutamine [Dobutrex]) in combination with a diuretic, whereas with hepatorenal syndrome, combinations of midodrine (Proamatine)¹ and octreotide (Sandostatin)¹ have been employed with some success.

Intrinsic renal failure may be subdivided into diseases that affect the renal microvasculature, glomeruli, tubules, and interstitium. Although the pharmacologic effects of certain medications (e.g., angiotensin-converting enzyme inhibitors [ACEIs] and nonsteroidal antiinflammatory drugs [NSAIDs]) directly affect the renal microvasculature, renal dysfunction associated with their use physiologically produces a prerenal picture. However, cholesterol emboli syndrome and small vessel vasculitis represent two diseases whose impact on the renal microvasculature is pathologic. In the former case, cholesterol-laden debris dislodged from the abdominal aorta or aortic arch showers distal vascular beds. The classic scenario involves a patient who, having recently undergone an endovascular procedure, presents with abdominal colic, ARF, livedo reticularis, and evidence of ischemic toes. Depending on the size of the embolus, the patient can have frank intestinal or renal infarction or an acutely ischemic lower extremity, necessitating emergent intervention. Eosinophiluria and hypocomplementemia may be noted. The elevation in creatinine can progress in a stepwise fashion for several days to weeks after the original event. Magnetic resonance imaging (MRI) can show evidence of wedge-shaped infarcts in the renal parenchyma. Optimal therapy with regard to antiplatelet agents versus anticoagulants remains uncertain.

Glomerular Disease

Glomerular disease accounts for roughly 10% of ARF among hospitalized patients. The hallmarks of rapidly progressive acute glomerulonephritis (RPGN) include an active urine sediment (dysmorphic red blood cells [RBCs] and cellular casts), hypertension, some edema, and a rapid decline in renal function over days. World Health Organization (WHO) class IV systemic lupus erythematosus (SLE) nephritis, anti-neutrophil cytoplasmic antibodies (ANCA)-mediated disease, and anti-GBM (glomerular basement membrane) disease are examples. Serologic testing is often useful, but a renal biopsy is almost always indicated for definitive diagnosis. Treatment usually involves some combination of corticosteroids and cytotoxic medications. Because of the severe increase in morbidity and mortality when these diseases are untreated, RPGN should be considered a medical emergency, with prompt attempts to diagnose and treat. It is important to recognize that whereas diseases that primarily manifest as the nephritic syndrome commonly cause ARF, entities associated more with a nephrotic-syndrome

picture—including membranous disease, minimal change disease, or focal sclerosis—can certainly produce ARF as well. This usually occurs in the setting of massive nephrotic-range proteinuria (10–20 g/24 hours) and associated marked hypoalbuminemia.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) accounts for fully 50% of ARF among hospitalized patients; depending on the scenario, this figure can rise to as much as 75%. ATN has three common causes: ischemic, toxic, and septic. ATN has been described by its phases: Injury, during which time the insult causes direct damage to the tubules, is manifested as a progressive increase in the serum creatinine and possibly the development of oliguria. In the plateau phase, the creatinine, urinary output, and volume status are relatively stable. Recovery is marked by a spontaneous decline in serum creatinine and increase in urinary output, perhaps even into a polyuric range. The time course of ATN from injury to recovery is variable. Depending on the severity of the injury and the preexistence of renal disease, ATN can reverse within 1 to 3 weeks, although a small percentage of patients with ATN remain dialysis dependent after months. ATN is typically associated with a loss of urinary concentration, elevated urinary sodium excretion, and an elevated FE_{Na} of greater than 2%. The BUN and creatinine tend to rise proportionally. The urinary sediment can reveal tubular epithelial cell casts that have a coarsely granular or muddy-brown appearance.

Ischemic ATN typically occurs during periods of prolonged hypotension and represents an evolution of prerenal azotemia. Ischemic ATN is commonly observed to varying degrees after cardiovascular and major orthopaedic or trauma surgery. Careful attention must be paid to urine output and volume status. High-dose diuretics may be employed to avoid pulmonary edema, and if a suboptimal response is seen, the dosage should be doubled after the first dose. Patients who rapidly become oliguric have a high mortality rate, which is unaffected by diuretics and can therefore require early initiation of dialysis. Specific risk factors for developing ischemic ATN in the postoperative setting include advanced age (older than 70 years), preexisting CKD, diabetes, emergent surgery, preexisting vascular disease, and the need for valvular, particularly aortic valve, heart surgery in addition to bypass grafting. The degree and duration of intraoperative hypotension as well as time spent on cardiopulmonary bypass can also play roles.

Toxic ATN is proximal tubular cell death as a consequence of drugs or other endogenous chemicals. Drugs that classically cause toxic ATN include aminoglycosides, amphotericin B (Fungizone), radiocontrast, platinum-based chemotherapy, and NSAIDs. Endogenous chemicals known to cause toxic ATN include uric acid, myoglobin, and heme. Clinically, it is worthwhile noting that although the onset of ATN after a single dose of NSAID or iodinated radiocontrast material may be rapid (24–72 hours) especially in volume-depleted patients, in the case of aminoglycosides the onset of injury may be a bit slower, consistent with cumulative dose exposure. In general, ATN is best avoided by limiting the dose of potentially toxic medications (e.g., once-daily dosing of aminoglycosides), maintenance of adequate volume status, and close attention to the serum creatinine and urinary output.

In the case of radiocontrast agents, low osmolar and isosmolar agents are thought to be less toxic, and dose limitation (or elimination) to less than 100 mL are helpful strategies. Although prospective randomized, controlled trial data are inconclusive, and meta-analyses are equivocal, in cases of elective contrast exposure it remains common practice at many centers to administer *N*-acetylcysteine (Mucomyst)¹ in a dosage of 600 mg orally every 12 hours on the day before and the day of exposure. This, along with intravenous fluid administration for up to 6 hours before elective procedures (some authors use bicarbonate-containing solutions), seem to be reasonably safe, low-cost measures that can offer

some protection against ATN in patients with known renal disease. After contrast-enhanced procedures, serum creatinine should be measured daily in hospitalized patients and at 48 hours after the procedure in outpatients.

Septic ATN often manifests in the critical care setting in patients with multisystem organ failure. Patients are typically hypotensive with either Gram-positive or Gram-negative bacteremia and anuria, often with severe acidemia. Unlike patients with prerenal azotemia whose urine output responds to volume resuscitation, patients with septic ATN do not produce urine in response to substantial volume resuscitation (Table 1). The clinical picture is difficult to distinguish from ischemic ATN, because the two disease processes can coexist. Clinically, ischemic and toxic ATN are thought to show signs of resolution within 14 days of removal of the insult, whereas the sequelae of septic ATN can persist for one or several months after the infection, requiring prolonged hospitalization and dialysis support. Mortality in this setting can be as high as 80%, and patients who survive their initial illness are particularly susceptible to nosocomial infections, catheter-related bacteremia, and malnutrition.

Interstitial Disease

Interstitial disease represents the third most common cause of ARF among hospitalized patients after prerenal azotemia and ATN. Acute interstitial nephritis is usually the effect of either drugs or pyelonephritis. In the case of medications, key diagnostic points include a delayed onset after medication exposure, as much as 7 days, and the co-incidence of fever and a central rash in about 30% of patients. The diagnosis may be suspected in the presence of sterile pyuria, eosinophiluria, and eosinophilia. Because the disease is of nonglomerular and nontubular origin, the urine sediment should be relatively bland, with minimal hematuria or proteinuria. Renal biopsy confirming the presence of increased numbers of eosinophils in the interstitium remains the gold standard. Antibiotics that are particularly notorious for causing acute interstitial nephritis include penicillins, particularly methicillin (Staphcillin); sulfa-containing drugs; rifampin (Rifadin); and quinolones. Typically, cessation of the suspected agent results in improved renal function within 5 days; however, in severe, prolonged cases, a course of corticosteroids can hasten improvement. Importantly, if the patient is re-exposed to the offending agent, acute interstitial nephritis can develop much more rapidly.

Obstructive Disease

Obstructive renal disease, although relatively uncommon, should be highly suspected in any patient with otherwise unexplained anuria, especially in those with a known pelvic malignancy or recent pelvic surgery. Obstruction of the lower tract and bladder outlet is more prevalent among elderly men with prostatic

hypertrophy and diabetics with autonomic nervous dysfunction. Upper-tract obstruction can be seen in cases of retroperitoneal fibrosis, uroepithelial malignancy, and nephrolithiasis. Certain systemic processes including tumor lysis syndrome, myeloma cast nephropathy, and ethylene glycol overdose can all cause an intratubular obstruction due to massive crystal and cast deposition within the kidney.

Clinically, obstruction of the bladder outlet may be diagnosed and treated via placement of a Foley catheter. Bladder scans, ultrasounds, and measurement of the pre- and postvoid residual bladder volumes are also important but not always immediately necessary. Bilateral upper tract obstruction requires intervention in the form of bilateral percutaneous nephrostomy tubes or internal double-J stent placement via cystourethroscopy. Patients with severe obstruction may be significantly hyperkalemic at presentation, requiring prompt treatment. Fortunately, if the obstruction is relieved in a timely fashion, the hyperkalemia usually dissipates without emergent dialysis.

Treatment

Management of hospitalized patients is generally supportive. Specific measures include a thorough daily review of the medication list to ensure that all possible toxic medications have been eliminated and that all drugs excreted via the kidneys have been dose adjusted for the level of renal dysfunction. The patient's volume status should be assessed frequently, with appropriate adjustments in intravenous fluids or diuretics. Similarly, electrolytes, BUN, and creatinine should be checked daily. In general, hospitalized patients should remain hospitalized until the clinical course has at least stabilized and close outpatient follow-up is ensured. Outpatients with acute renal failure can require urgent hospitalization if the cause is not immediately apparent and reversible, or if significant hyperkalemia or volume overload exists, or if the patient has significant comorbidities.

The decision to initiate renal replacement therapy is made by the nephrologist on a patient-by-patient basis. Some absolute clinical indications for dialysis exist, such as severe hyperkalemia; peaked T waves or prolongation of the QRS complex by electrocardiogram; volume overload or acidosis refractory to medical therapy; certain intoxications or electrolyte abnormalities; and symptomatic uremia with pericarditis, neurologic changes, or bleeding diatheses. Depending on the clinical setting, the two most common are hyperkalemia and volume overload; rarely will the nephrologist let ARF with either of these conditions progress to the point of cardiac arrhythmia or intubation undialyzed.

Patients who require urgent or emergent dialysis can typically be dialyzed via standard intermittent hemodialysis. This method is more effective for acute correction of electrolyte, toxin, and acid-base aberrations as well as pulmonary edema. Controversy exists as to the proper dose of dialysis for patients with ARF, particularly those in the critical care setting. Clinical practice varies by center, but studies have shown a survival benefit favoring daily hemodialysis to keep the BUN less than 100 mg/dL.

Continuous renal replacement therapy (CRRT) or continuous veno-venous hemofiltration is usually reserved for critically ill patients, particularly those with hypotension requiring vasopressor support or those with sufficiently poor cardiac performance and volume overload who cannot tolerate acute intravascular volume shifts associated with conventional hemodialysis.

Acute peritoneal dialysis, although certainly a viable modality, is practiced much less commonly in the United States partly due to the widespread availability of hemodialysis.

Emerging Issues

In clinical practice, the diagnosis and treatment of ARF rest on the ability to recognize it in a timely fashion. The two universally available indicators—urinary output and serum creatinine measurement—are limited in their sensitivity and specificity; however, new urinary and plasma biomarkers are emerging that can allow earlier identification of ARF. Urinary neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), and interleukin-18

(IL-18), in combination with plasma NGAL and cystatin C measurements, are all currently being evaluated in ARF clinical trials. These assays hold the promise of earlier detection and perhaps more specific anatomic localization of the injury within the kidney. Whether these biomarkers are used alone, serially, or in combination as an acute kidney injury panel remains to be seen as they transition from primarily clinical trial–based application to widespread clinical use. Questions regarding their ability to help predict which patients with ARF will spontaneously recover renal function and which will require dialysis remain to be answered.

Nephrotoxicity associated with gadolinium-containing contrast media has risen to the front of discussion among radiologists and nephrologists. Originally thought to be non-nephrotoxic, gadolinium has been implicated in a number of well-documented cases. Perhaps more striking are the mounting reports of gadolinium-related nephrogenic systemic fibrosis, which is characterized by brawny epidermal fibrotic plaques developing over several weeks after exposure. It is important to recognize that other organs including the subcutaneous tissues, skeletal musculature, lungs, and heart may be involved. Although the pathogenesis of this disease has not been fully elucidated, epidemiologically 90% of cases have been described among end-stage renal disease patients requiring dialysis, and fully 10% have occurred among patients with CKD stages 3 and 4. Because there is no cure for this disease and its clinical consequences are potentially devastating, clinicians now must consider the risk-to-benefit ratio of exposing a patient to gadolinium-enhanced MRI procedures and weigh that risk against the well-established risk of iodinated contrast used in CT scans.

CHRONIC KIDNEY DISEASE

Method of

Kashif Abad, MD; and Mark Unruh, MD MS

CURRENT DIAGNOSIS

- The estimated glomerular filtration rate (eGFR) is the generally accepted, best index of kidney function. Normal eGFR varies according to age, sex, and body size; in young adults, it is approximately 125 mL/min per 1.73 m² and declines with age.
- Chronic kidney disease (CKD) is defined as GFR < 60 mL/min/1.73 m² as well as elevated markers of kidney damage. The most common marker of kidney damage is urine albumin.

- The most common method to access GFR is serum creatinine combined with CKD-EPI equation. If possible, determine the underlying cause of CKD and consider referral to a nephrologist for management if GFR < 30 mL/min/1.73 m²

CURRENT THERAPY

- Initiate treatment to delay or prevent disease progression, including an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin receptor blocker (ARB) to reduce blood pressure to < 130/80 mm Hg and urine total protein excretion to as low as possible but at least < 1 g/day.
- Prevent or treat biochemical or clinical abnormalities including serum potassium, calcium, bicarbonate, calcium, phosphorous, parathyroid hormone, and hemoglobin.
- Evaluate for presence of comorbid conditions such as hypertension, diabetes, and cardiovascular disease.

Chronic kidney disease is the term used to describe patients with decrease in glomerular filtration rate (GFR) or kidney damage such as albuminuria; there are different levels of CKD. CKD has been classified by cause, kidney function, and severity of albuminuria. *Kidney damage* is defined as structural or functional abnormalities of the kidney, initially without decreased GFR, which over time can lead to decreased kidney function. Markers of kidney damage include abnormalities in the composition of the blood or urine or abnormalities in imaging tests. *End-stage renal disease (ESRD)* or *kidney failure* is the term used to describe patients who have advanced renal failure requiring renal replacement therapy (i.e., either hemodialysis/peritoneal dialysis or transplantation). CKD has been associated with higher costs of care and risk of death.

Most chronic kidney disease demonstrates an inexorable progression. The rate of decline could be estimated as much as 7–10 mL/min/year in those with an untreated diabetic nephropathy. Electrolyte homeostasis, causes of progressive decline in function, and manifestations of kidney failure are similar enough across the different pathologies that we can think of common underlying routes to progression, symptoms, and hopefully amelioration of CKD. These interventions often do not reverse kidney disease; rather, they slow the progression of kidney disease. Therefore earlier diagnosis and treatment may delay kidney death so that a patient can avoid undergoing dialysis, transplantation, and the complication of kidney failure.

Prevalence of Chronic Kidney Disease

Estimates are that there are 30 times as many subjects with chronic kidney disease as compared to ESRD. Approximately 14.7% of the US adult population is thought to have some form of chronic kidney disease. Of note, the majority of those with stage 1 and 2 kidney disease may not even be aware of their kidney disease. Furthermore, more than 75 million are thought to have an increased risk of developing CKD. Only a fraction of patients understand that they have CKD, so it is crucial that to convey this to them so that they can take steps to slow the progression of CKD.

Risk Factors for CKD

The non-modifiable risk factors are important for risk stratification by screening and for understanding the pathophysiology of CKD progression (Table 1). These risk factors include ethnicity, which is a risk factor for many kidney diseases. For example, African-American patients with diabetes have a two-to-three-fold higher risk of developing kidney failure compared to white patients. Modifiable risk factors are important for both understanding disease progression and as a possible option for prevention or therapy.

(IL-18), in combination with plasma NGAL and cystatin C measurements, are all currently being evaluated in ARF clinical trials. These assays hold the promise of earlier detection and perhaps more specific anatomic localization of the injury within the kidney. Whether these biomarkers are used alone, serially, or in combination as an acute kidney injury panel remains to be seen as they transition from primarily clinical trial–based application to widespread clinical use. Risk Factors for CKD

The non-modifiable risk factors are important for risk stratification by screening and for understanding the pathophysiology of CKD progression (Table 1). These risk factors include ethnicity, which is a risk factor for many kidney diseases. For example, African-American patients with diabetes have a two-to-three-fold higher risk of developing kidney failure compared to white patients. Modifiable risk factors are important for both understanding disease progression and as a possible option for prevention or therapy.

TABLE 1 Risk Factors for the Development or Progression of Kidney Disease

Albuminuria
Hypertension
Episodes of acute kidney injury
Underlying cause of kidney disease (e.g., diabetic nephropathy)
Obesity
Hyperlipidemia
Smoking
High-protein diet
Metabolic acidosis
Hyperphosphatemia
Hyperuricemia
Hyperglycemia

For example, the heavy consumption of analgesics has been associated with the development of kidney failure. The number of patients that develop kidney disease and at risk for developing kidney disease will increase with the increasing prevalence of diabetes and aging of the population.

Approach to the Diagnosis of Chronic Kidney Disease

In clinical practice, the serum creatinine and blood urea nitrogen (BUN) concentrations are commonly used as indicators of GFR. The laboratory measurement of creatinine and urea is accurate and reliable, although normal values may vary slightly from lab to lab. Creatinine production varies with muscle mass, and therefore changes in lean body weight influence the serum creatinine level. For example, a body builder may have an elevated Cr but normal renal function and vice versa for a cachectic elderly woman with muscle atrophy. When using the plasma creatinine to assess GFR, it is also important to keep in mind the semi-logarithmic relationship between the serum creatinine concentration and GFR. Kidney Disease International Global Outcomes (KDIGO) Guideline on Chronic Kidney Disease currently recommends using the Chronic Kidney Disease Epidemiology (CKD-EPI) 2009 creatinine equation: The CKD-EPI equation is currently the most accurate way to estimate GFR from serum creatinine.

CKD-EPI CREATININE EQUATION:

$$\text{GFR} = 141 \times \min(S_{\text{Cr}}/\kappa, 1)^{\alpha} \times \max(S_{\text{Cr}}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 [\text{if female}] \times 1.159 [\text{if black}]$$

where: S_{Cr} is serum creatinine in mg/dL,
 κ is 0.7 for females and 0.9 for males,
 α is -0.329 for females and -0.411 for males,
 \min indicates the minimum of S_{Cr}/κ or 1, and
 \max indicates the maximum of S_{Cr}/κ or 1.

Formulas derived from studies of large groups of patients—such as those by Cockcroft and Gault and the Modification of Diet in Renal Disease (MDRD) in which GFR was correlated with other factors (e.g., body weight, age, and serum albumin)—are sufficiently accurate to use for clinical purposes.

The recent classification of CKD includes a measure of albuminuria. A spot albumin/creatinine ratio serves as a very important biomarker. Higher levels of albuminuria are linked to progression of CKD, higher frequency of acute kidney injury, higher rates of dialysis, and higher risk of death.

There are novel estimating equations that use a range of new biomarkers to estimate kidney function. The most widely used is Cystatin C, which can be used to estimate GFR in patients with extremes of age or body habitus. Cystatin C is a low-molecular-weight cysteine protease inhibitor produced in all nucleated cells and has a constant level of production but rises with poor renal function. Hence, Cystatin C may serve to improve the estimates of GFR in a number of settings. However, Cystatin C levels

have been associated with thyroid levels and inflammation, so providers should interpret this biomarker with caution in these settings.

Management of Chronic Kidney Disease

Staging of CKD

The purpose of CKD staging is to guide management, including stratification of risk for progression and complications of CKD. Staging of CKD should be done according to [Figure 1](#) and [Table 2](#) and based on:

- Cause of disease
- Six categories of eGFR (G stages)
- Three levels of albuminuria (A stages)

The GFR is the generally accepted best index of kidney function. Chronic kidney disease (CKD) is defined as GFR less than 60 mL/min per 1.73 m² as well as markers of kidney damage. In the United States the most common marker of kidney damage is urine albumin. Other markers are kidney cysts or pathologic changes in the kidney, for example. The severity of CKD is also determined by the level of GFR.

CKD Stage 3 (moderately decreased GFR)

Stage 3 CKD (a GFR of 30 to 59 mL/min per 1.73 m²) has been subdivided into GFR stages 3a (G3a – GFR 45 to 59 mL/min per 1.73 m²) and 3b (G3b – GFR 30 to 44 mL/min per 1.73 m²) to more accurately reflect the continuous association between lower GFR and risk for mortality and adverse kidney outcomes.

CKD Stage 4 (Severely decreased GFR)

GFR 15–29 mL/min per 1.73 m²

CKD Stage 5 (Kidney failure)

G5 – GFR <15 mL/min per 1.73 m² or treatment by dialysis

Referral to a nephrologist is recommended when eGFR <30 mL/min per 1.73 m² and/or urine albumin creatinine ratio is >300 mg/g, with earlier referral recommended in specific cases. Early referral to a nephrologist is associated with improved outcomes once patients initiate dialysis.

General Approach to Treatment of Chronic Kidney Disease

Treatment of CKD is divided according to modalities that are specific to the underlying disorder and those that are used to treat all patients with CKD.

The physician treating the patient with CKD has two goals: preventing or delaying progression of CKD and alleviating the electrolyte and hormonal abnormalities that can lead to symptoms or complications. The provider can use the CKD classification system shown in [Figure 1](#) to educate patients and highlight the need for adhering to strategies to slow the rate of CKD progression.

Strategies to Slow Progression of CKD

Since we have a better understanding of the progression of kidney disease, we can effectively slow progression. Rather than losing 10 mL/min/year of kidney function as an untreated Type 1 diabetic, those with adequate disease control can forestall the need for dialysis by slowing the rate of progression anywhere from 2 to 6 mL/min/year. This makes a dramatic difference to the individual and to society in terms of quality of life and costs to the health care system. Treat the underlying cause by identifying reversible factors such as volume depletion, uncontrolled hypertension, obstructive uropathy and nephrotoxins.

Blood Pressure Management

In addition to the use of an ACE-I or ARB, management of hypertension in CKD first entails salt-depleting therapy with a salt-restricted diet and diuretic therapy ([Table 3](#)). Patients frequently require additional therapy to combat the enhanced vasoconstriction and to attempt to slow the rate of CKD progression. The KDIGO Blood Pressure guidelines have recommended a target blood pressure of <130/80 for those with advance kidney disease.

Prognosis of CKD by GFR and Albuminuria Categories: KDIGO 2012				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to mildly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min/ 1.73 m ²) Description and range	G1	Normal or high	≥90			
	G2	Mildly decreased	60-89			
	G3a	Mildly to moderately decreased	45-59			
	G3b	Moderately to severely decreased	30-44			
	G4	Severely decreased	15-29			
	G5	Kidney failure	<15			

Very dark gray (G1/G2 and A1): low risk (if no other markers of kidney disease, no CKD); Light gray (G3a and A1; G1/G2 and A2): moderately increased risk; Medium gray (G3b and A1; G3a and A2; G1/G2 and A3): high risk; Medium dark gray (G4/G5 and A1; G3b/G4/G5 and A2; G3a/G3b/G4/G5 and A3): very high risk.

Figure 1 Prognosis of CKD by GFR and albuminuria.

Among patients with diabetes and CKD, these guidelines recommended a blood pressure target <140/90 based largely on results from the ACCORD study. Lastly, there is a real opportunity to improve care due to gaps in awareness, treatment, and control of BP among patients with CKD. Although BP treatment has been shown to slow progression of CKD, there is a substantial number of CKD patients with poor BP control. Around 30% of CKD patients are not aware of their BP. Of those that are aware, substantial portions are untreated. Few of those that are treated, are controlled. Only one-fifth of the patients with CKD stages 3–4 have awareness, treatment, and control of BP.

Angiotensin- Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme inhibitors (ACE-Is) and angiotensin receptor blockers (ARBs) are preferred anti-hypertensive agents for the treatment of blood pressure among patients with CKD, particularly patients with albuminuria. Ang II plays a key role in the progression of glomerulosclerosis, and there is a large amount of experimental data in both animals and people that blocking AngII mitigates progressions. This is thought to be due to a reduction in the glomerular capillary hypertension, reduction in proteinuria, and a diminution of the Ang II fibrosing effects. ACE-I and ARB both are likely to delay progression of kidney disease and have cardiovascular benefits. Some studies have examined the possibility of using both together in treatment of chronic kidney disease, with

results suggesting more harm than benefit owing to higher rates of hyperkalemia and acute kidney injury among patients receiving dual therapy. The ACE/ARBs substantially delay progression of kidney failure. There does not appear to be a point where you should discontinue ACE/ARB medications unless after starting these medicines there is a significant rise in creatinine. When an ACE-I or ARB causes a rise in creatinine >30%, the agent should be held to investigate potential renal artery stenosis or volume depletion.

Dietary Protein Restriction

The role of dietary protein restriction in renoprotective strategies for CKD patients remains controversial. Kidney Disease Improving Global Outcomes (KDIGO) suggests daily restriction in protein intake to 0.8 g/kg for CKD patients, although a very-low-protein diet has been associated with increased mortality over the long term. One study had shown a benefit with nuts and other healthy protein foods in reducing the progression and mortality from CKD.

In spite of the fact that inconclusive results of the largest controlled clinical trial done to investigate protein restriction in CKD, the Modified Diet in Renal Disease (MDRD) study, a benefit of moderate protein restriction was suggested by a long-term follow-up analysis. Several prior and subsequent studies and meta-analyses appear to support the role of low protein in retarding progression of CKD and delaying initiation of maintenance dialysis therapy.

Overall, most experts believe that, despite the absence of observed benefit in the MDRD trial, systematic reviews suggest that protein

TABLE 2 Chronic Kidney Disease Classification Based on Glomerular Filtration Rate and Albuminuria

GFR STAGES	eGFR (mL/min/ 1.73m ²)	TERMS
G1	>90	Normal or high
G2	60–89	Mildly decreased
G3a	45–59	Mildly to moderately decreased
G3b	30–44	Moderately to severely decreased
G4	15–29	Severely decreased
G5	<15	Kidney failure (add D if treated by dialysis)

ALBUMINURIA STAGES	ALBUMIN/ CREATININE RATIO (MG/G)	TERMS
A1	<30	Normal to mildly increased
A2	30–300	Moderately increased
A3	>300	Severely increased

*Chronic kidney disease is defined as either GFR ≤ 60 mL/min/1.73 m² for ≥ 3 months or structural or functional abnormalities manifested by presence of markers of kidney damage in blood, urine, or imaging studies.[†] Uremic symptoms include nausea, vomiting, anorexia, metallic taste, pericarditis, peripheral neuropathy, central nervous system changes including difficulty with concentration, and seizures.

restriction may be beneficial, and the balance of evidence suggests a benefit of moderate dietary protein restriction. Limiting protein intake is also associated with favorable laboratory and metabolic effects, including reduction of blood urea nitrogen levels, uremic toxins, and acid load, in addition to reduced phosphorus load with better control of metabolic bone disorders. Protein restriction may be particularly effective in diseases characterized by hyperfiltration, such as diabetes and certain glomerulopathies.

In patients with CKD, a balanced and individualized dietary approach based on low-protein diet should be carefully monitored, with periodic follow-up for adequate caloric intake and surveillance to optimize protein malnutrition with body weight as well as serum albumin.

Avoid Nephrotoxic Medications

Avoid nephrotoxins and note that both prescription and over-the-counter medications can have deleterious kidney effects. The most concerning nephrotoxins over the counter are NSAIDs, antacids, proton pump inhibitors, and a number of herbal medications (licorice, Cat's Claw). Several prescription medications can be deleterious to the kidney. Noteworthy are the calcineurin inhibitors such as cyclosporine (Sandimmune) and tacrolimus (Prograf), which cause progressive renal insufficiency. We know this because solid-organ transplants have a high rate of kidney failure. Other medications such as aminoglycosides and amphotericin (Fungi-zone) or the use of IV contrast have detrimental effects on the hospitalized patient.

Clinical Manifestations of Kidney Failure

P. A. Piorry coined the word *urémie* in 1847 to indicate problems caused by "contaminating the blood with urine." The basic abnormality is the presence of waste products that are not being eliminated by the kidney. In current use, the term *uremia* reflects a clinical syndrome associated with loss of kidney function. Uremic symptoms in advanced CKD result both from kidney excretory failure (retention of urea, certain hormones, polyamines, trace elements, serum proteases, so-called "middle molecules," pyridine derivatives, B₂ microglobulin, etc.) and from the loss of metabolic and endocrine functions normally performed by the kidney. Uremia is thought to be in part due to protein intake, since a low-protein diet mitigates some of the symptoms. While we know that some of the uremic toxins are partially dialyzable, the exact etiology of uremia remains unknown.

Uremia also relates a loss of metabolic and endocrine functions normally performed by the intact kidney. Hence, kidney failure is a multisystem disorder (see Table 4). The measurement of kidney function can be variable, and that degree of variability makes it difficult to use as the only factor in clinical decision making. Therefore, as CKD progresses, clinicians tend to regularly assess the subjective symptoms associated with uremia. In particular, uremia has been described in the following systems: neurologic (sleep, memory), GI (appetite, nausea, dysgeusia), and dermatologic (itching). If the severity of these symptoms cannot be managed by symptomatic therapy, then that would be an indication for starting dialysis. Furthermore, if a dialysis patient has these symptoms, it may reflect an inadequate treatment, and the dialysis dose will have to be increased. Of note, the usual physical signs of kidney failure can be rapidly assessed during an exam: blood pressure, pericardial rub, edema, and crackles on lung exam.

TABLE 3 Recommendations for the Treatment of Patients With CKD

BLOOD PRESSURE CONTROL IN CKD		MAINTAIN BLOOD PRESSURE < 130/80 mm Hg < 140/90 FOR DIABETIC CKD	
Reduce proteinuria by administering angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs)		Decrease urine protein excretion as low as possible, at least < 1 g/day	
Control phosphate concentration with phosphate binders, using non-calcium-containing binders when possible		Maintain serum phosphate toward the normal range in CKD	
Maintain vitamin D level by administration of vitamin D analogs		Maintain 25-OH vitamin D levels at 30 ng/mL by administration of cholecalciferol (D ₃) or ergocalciferol (D ₂)	
Prevent hyperparathyroidism with vitamin D analogs or calcimimetics		Maintain parathyroid levels between 150–600 (2–9 × normal)	
Correct anemia with erythropoiesis-stimulating agents and iron replacement as needed		Maintain hemoglobin between 10 and 11 mg/dL. Keep iron saturation (iron/TIBC) > 20%	
Administer diuretics to control hypertension and volume overload		Maintain euvolemia when possible	
Control serum potassium with dietary restriction, diuretics, and/or potassium exchange resin as necessary		Maintain serum potassium < 5.0 mEq/L	
Prevent malnutrition with adequate calories and protein intake		Maintain protein intake between 0.6 and 1 g/kg in CKD and between 1 and 1.3 g/kg on dialysis	
Control metabolic acidosis with administration of sodium bicarbonate or sodium citrate		Maintain serum bicarbonate > 22 mEq/L but < 26 mEq/L	

TABLE 4 Signs and Symptoms of Kidney Failure

CARDIOVASCULAR COMPLICATIONS	
Hypertension	
Ischemic cardiac disease	
Pericardial disease	
Congestive heart failure	
Hematologic Abnormalities	
Anemia	
Bleeding tendency	
Neuropsychiatric Abnormalities	
Peripheral neuropathy	
CNS disturbances

Carpal Tunnel Syndrome	
	ENDOCRINE DISORDERS
	Secondary hyperparathyroidism
	Glucose intolerance (uremic diabetes)
	Hyperlipidemia
	Sexual dysfunction/infertility
	Immunologic Defects
	Lymphocytopenia, leukopenia
	Decreased antibody responses
	Decreased cell-mediated response
	Increased susceptibility to infection
	Dermatologic Abnormalities
	Pruritus, uremic pigmentation, uremic frost, calciphylaxis, nail changes
	Gastrointestinal Abnormalities
	Anorexia, nausea, vomiting
	Upper tract disease: gastritis, duodenitis,

Measures Designed to Treat Comorbidity in Kidney Disease

Anemia (Table 5)

Anemia may be managed in patients with CKD by first ruling out other causes of anemia such as GI bleeding and iron deficiencies. Iron deficiency is common in patients with CKD and may be evaluated with a total iron saturation (TSAT) and ferritin. Low ferritin (<100ng/mL) and TSAT (<20) in patients with moderate to advanced CKD indicate an absolute iron deficiency. Iron deficiency may be treated using the oral or intravenous route. After iron stores are restored, if the anemia persists and other causes are ruled out, then a erythropoiesis-stimulating agent (ESA) such as erythropoietin (Procrit, Epogen) may be used. For CKD patients, the uses of ESAs are shown to reduce the need for blood transfusions and modestly improve quality of life. The risks of ESA use include an increase in cardiovascular events, hypertension, and cancer progression. For CKD patients the recommendations are to initiate therapy if the Hgb are below 10g/dL with an individualized decision for a target based on risks and benefits. In many cases, providers target a hemoglobin between 10 mg/dL and 11 mg/dL and avoid exceeding levels >12 mg/dL.

Metabolic Acidosis

Metabolic acidosis develops in CKD when the eGFR drops below 30 mL/min. Recent studies have linked metabolic acidosis in CKD to protein wasting, loss of bone, and sympathetic activation. Observational studies have also linked metabolic acidosis to a higher rate of CKD progression and increased risk of death. There are a large number of ongoing studies testing whether oral sodium bicarbonate supplementation in CKD preserves renal function, and bicarbonate supplementation has been widely adopted for metabolic acidosis in CKD. A standard dose used in clinical trials for CKD patients has been sodium bicarbonate 0.5 mEq/kg/day. The supplemental bicarbonate may be titrated up or down depending on serum bicarbonate and symptoms. If bicarbonate is not tolerated by patients, then clinicians could try Shohl's solution (citric acid/sodium citrate), as

TABLE 5 Factors to Consider in the Management of Patients With CKD

Contributors to the loss of kidney function
Hypertension
Diabetes mellitus
Dietary salt intake
Proteinuria
Metabolic acidosis
Complications of chronic kidney disease
Anemia
Platelet dysfunction
Abnormal bone and mineral metabolism (e.g., secondary hyperparathyroidism)
Lipid abnormalities (elevated cholesterol and triglycerides)
Metabolic acidosis
Volume overload
Electrolyte disturbances (e.g., hyperkalemia)
Cardiovascular disease

citrate is converted to bicarbonate by the liver. Currently, a reasonable target serum bicarbonate for patients with moderate to advanced CKD would be >22mEq/L and <26mEq/L.

Divalent Ion Metabolism

CKD is associated with abnormalities of divalent ions (Ca^{++} , P) and of the hormones that regulate the concentration of these minerals in body fluids. It is of note that the dysregulation of these divalent ions has also attracted attention as a possible source of cardiovascular disease, since those with CKD are found to have calcium deposition and a calcification of heart valves. Lastly, failed management of divalent ions may lead to calcific uremic arteriopathy, or calciphylaxis. Calciphylaxis is a rare syndrome characterized by the development of painful nodules in the soft tissue that indurate and ulcerate. This disorder has no uniformly effective treatment and has a high mortality rate. Serum phosphorus is controlled by administration of phosphate binders usually starting with calcium citrate (Citracal) or acetate (PhosLo). If these are not successful or if patients have elevated serum calcium levels, then sevelamer (Renagel) or lanthanum (Fosrenol) can be used alone or in combination with calcium binders. Physicians should aim to maintain serum phosphorus levels between 2.7 and 4.6 mg/dL in CKD stage 3 and 4 and between 3.5 and 5.5 mg/dL in CKD stage 5. Defining the target PTH level in the setting of CKD remains a challenge because of end-organ resistance to PTH. Parathyroid hormone levels should be maintained between 150 and 600 pg/mL ($2-9 \times$ normal) in end-stage renal disease and patients on dialysis. Suppression of parathyroid hormone secretion can be achieved by administration of various vitamin D analogs in combination with calcimimetic agents such as cinacalcet (Sensipar). Serum calcium levels should be monitored closely. Low 25-OH vitamin D levels have been documented in a large number of individuals both with and without renal failure. In patients with renal impairment this can contribute to the abnormal 1,25-OH vitamin D levels. Measurement of 25-OH vitamin D levels should be obtained in all patients with CKD and estimated GFR less than 60 mL/min/1.73 m². If levels are below 30 ng/mL, ergocalciferol (D_2) or cholecalciferol (D_3) should be given at sufficient doses to maintain it above this level.

Hyperkalemia

The clinical consequence of hyperkalemia includes cardiac toxicity, muscle weakness, and death. The target potassium concentration for patients with CKD should remain in the normal range, and patients should be monitored during treatment with ACEIs or ARBs. Management of a high serum potassium in patients with CKD should include a low-potassium diet. If there is a sudden

increase, it may be due to use of salt substitutes, large amounts of juice, or eating high-potassium foods. It may be helpful to get a nutrition consult to help the patient maintain a low-potassium diet and have a nutritionist be aware of differences in diverse foods, since both noni and coconut juice are high in potassium. In addition, review medications for those associated with hyperkalemia and consider decreasing the dose of ACEI or ARB. Diuretics also may be used to decrease serum potassium levels in CKD, with loop diuretics the most widely used for patients with an eGFR < 30 mL/min. Lastly, potassium binding agents may be used to control serum potassium levels in patients with advanced CKD. The potassium exchange resin, sodium polystyrene sulfonate (Kayexalate), or one of the newer exchange resins patiromer (Veltassa) decreases serum potassium levels.

Volume Overload

Sodium retention contributes to hypertension and edema among patients with CKD. In order to adequately address volume overload, both the intake and sodium excretion may need to be addressed in patients with CKD. Patients should adhere to a low-sodium diet, which is often complicated by other dietary restrictions (low-potassium, low-phosphate, ADA diet). Given the complexity of diet in CKD, use of a nutritionist with expertise in kidney-related diets can help both volume overload and the other complications of CKD. In addition to sodium restriction, patients may need to use a diuretic for blood pressure and volume management. In the setting of an eGFR < 30 mL/min, loop diuretics are often used to address volume overload. The loop diuretics such as furosemide (Lasix) should be dosed frequently enough to maintain a negative sodium balance. If the loop diuretic at higher doses is not adequately addressing volume overload, then an additional distal tubule diuretic such as metolazone (Zaroxolyn) may be used to increase urinary sodium excretion. It should be noted that increasing sodium excretion may cause acute kidney injury of CKD patients, particularly in the setting of ACEI/ARB and other diuretics. In this case, the patients will often respond to reducing the diuretic dose with close monitoring.

Chronic Kidney Disease–Mineral Bone Disorder (CKD-MBD)

Chronic kidney disease–mineral bone disorder (CKD-MBD) is a systemic disorder of mineral and bone metabolism associated with CKD due to hyperphosphatemia from diminished kidney phosphorus excretion and hypocalcemia due to impaired kidney production of active 1, 25-(OH)₂D leading to secondary hyperparathyroidism. Elevations in serum fibroblast growth factor 23 (FGF23), metabolic bone disease, soft tissue calcifications, and other metabolic derangements are associated with morbidity and mortality in CKD. The management of CKD-MBD is complex due to homeostatic system and multiple treatment options without definitive randomized trials. The ideal strategy should be normalizing serum calcium, phosphate, PTH, and metabolic acidosis while minimizing the risks associated with the therapies. The various treatment options for hyperphosphatemia and secondary hyperparathyroidism include dietary phosphorus restriction, phosphate binders, calcitriol (Rocaltrol) or other active vitamin D analogues, calcimimetics, adequate hemodialysis, and parathyroidectomy. The optimal PTH level in the setting of CKD remains a challenge and has not been prospectively determined. KIDIGO guidelines recommend that PTH be kept between two to nine times the upper limit of normal for the assay.

Cardiovascular Disease

While >10 million American adults are estimated to have a GFR < 60 mL/min (i.e., CKD 3 or worse), far fewer are on dialysis or have received a transplant. Why is there a disparity between the number receiving renal replacement therapies and the number with CKD? Most patients with CKD die from cardiovascular disease (CVD) prior to requiring dialysis or transplantation. On dialysis, the risk of death from CVD remains 10–100 times higher than the general population. A 25-year-old man on hemodialysis has

approximately the same risk of dying from heart disease as an 80-year-old without CKD. Traditional risk factors account for only a portion of the CVD risk associated with CK. Traditional risk factors include age, diabetes, lipids, hypertension, and smoking, among others. Many nontraditional risk factors are believed to play a role in increasing CVD risk in CKD. Some of these risk factors are anemia, volume overload, hyperparathyroidism, calcium/phosphate disturbances, uremia, and malnutrition/inflammation often associated with CKD. The exact role these nontraditional risk factors play is an actively researched area. In general, consider patients with CKD high-risk patients for CVD, and CKD is considered by some to be a coronary equivalent. Data indicate that patients with lower GFRs (<45 mL/min) and microalbuminuria/proteinuria carry a very high CVD risk (~equivalent to a prior history of coronary disease). This is important when seeing a patient in the emergency room for chest pain or when evaluating a patient pre-operatively for surgery, etc. Treatment focuses on optimizing management of known CVD risk factors and being alert for harbingers of active CVD. Those caring for CKD patients must address CVD risk management. Primary prevention focuses on blood pressure, exercise, +/- aspirin, +/- statins. The data available for cardiovascular risk management is limited in part owing to the exclusion of patients with significant CKD in many large studies. Hence, the utility of ASA and statins (if any) in this setting is not well established. CKD patient's often present with atypical symptoms of CVD, a high index of suspicion is important.

MALIGNANT TUMORS OF THE UROGENITAL TRACT

Method of
Peter E. Clark, MD

CURRENT DIAGNOSIS

Carcinoma of the Prostate

- Average-risk patients can be offered screening with prostate-specific antigen (PSA) testing and digital rectal examination (DRE) at 55 years of age, high-risk patients with a strong family history, and African American patients at age 40 years.
- Patients with an elevated PSA or abnormal DRE are referred for discussion regarding risks, benefits, and alternatives to biopsy of the prostate.
- Diagnosis is made with transrectal ultrasound-guided biopsy of the prostate.
- Staging with bone scanning is done for patients with high-grade tumors (Gleason grade 4 or 5), PSA levels greater than 20 µg/mL, elevated alkaline phosphatase levels, or bone pain.

Renal Cell Carcinoma

- Hematuria is the single most common sign, occurring in up to 60% of cases. Flank pain and a palpable mass can also occur, but the classic triad of hematuria, flank pain, and a palpable abdominal mass is present in only 10% of cases. Other common signs and symptoms are fever, anemia, thrombocytosis, hypercalcemia, and an elevated sedimentation rate.
- Most tumors are asymptomatic and are detected incidentally on radiographic imaging (renal ultrasonography, computed tomography [CT] scanning, or magnetic resonance imaging).

Benign Renal Tumors

- Angiomyolipomas have a characteristic appearance of fat within the lesion on CT scans.
- Angiomyolipomas may occur sporadically or as part of the tuberous sclerosis complex.
- Tuberous sclerosis is characterized by benign tumors within the cerebellum, mental retardation, epilepsy, and adenoma sebaceum. Angiomyolipomas occur in half of these patients and are typically bilateral and multifocal, making management more challenging.
- Oncocytomas are benign renal tumors that account for 5% to 10% of solid renal lesions.
- Oncocytomas can be more round and of uniform density, or they may have a central scar or spoke-wheel appearance on CT scan. However, no feature can reliably distinguish these tumors from a malignant renal tumor.
- Oncocytomas should be diagnosed only histologically; they are characterized by eosinophilic granular, mitochondria-laden cells.
- In general, a non-fat-containing, solid renal mass should be considered malignant until proven otherwise.

Tumors of the Renal Pelvis and Ureter

- Tumors arising in the renal pelvis account for 10% of all renal tumors and approximately 5% of all urothelial carcinomas.
- Ureteral tumors account for 25% of upper tract urothelial carcinomas.
- These tumors are more common in men than in women.
- Cigarette smoking is strongly associated with an increased risk, as are analgesic abuse and cyclophosphamide (Cytosan).
- The most common presenting symptom is hematuria.
- Diagnostic work-up usually includes CT urography, urinary cytology, and cystoscopy.
- Cytologic examination of the urine has a high specificity but poor sensitivity, particularly for low-grade lesions.
- Between 3% and 5% of patients with bladder cancer have associated upper tract urothelial carcinoma. This risk is

increased in patients with carcinoma in situ (CIS) or high-grade disease, in whom the risk can be as high as 20%.

- Patients with upper tract urothelial carcinoma have a 30% to 70% risk of developing bladder cancer.

Urothelial Carcinoma of the Bladder

- Painless, gross hematuria is the most common presenting symptom.
- Twenty percent of patients present with only microscopic hematuria.
- Irritative voiding symptoms such as frequency, urgency, or dysuria may also suggest a malignancy, particularly CIS.
- Patients with suspected bladder cancer should undergo an evaluation of their upper tracts (typically by CT), cystoscopy, and cytologic examination of the urine (or another urine-based tumor marker study).
- Transurethral biopsy or resection confirms the diagnosis.
- Ninety percent of bladder cancers are urothelial carcinoma, and 75% are non-muscle-invasive (superficial) at presentation.

Urethral Carcinoma

- Urethral carcinoma is the only urologic malignancy that is more common in females than in males.
- Fifty percent of cases are associated with urethral stricture.
- Urethral carcinoma may manifest as hematuria, obstructive voiding, or a palpable mass.
- Transurethral biopsy is usually required for diagnosis.

Penile Cancer

- Squamous cell carcinoma of the penis occurs most commonly in the sixth decade of life.
- Symptoms are related to ulceration, necrosis, suppuration, and hemorrhage of the penile lesion.
- The diagnosis is established by biopsy.
- Clinical evaluation of patients with penile cancer includes physical examination with palpation of the inguinal region, chest radiography, CT of the abdomen and pelvis.

Testicular Cancer

- Testicular cancer is relatively rare overall, but it is the most common malignancy in men between the ages of 15 and 35 years, with 8090 new cases occurring annually.
- Testicular cancer often manifests as a painless, enlarging testicular mass.
- Malignant tumors of the testis can be divided into those originating from the germinal cells (seminomatous and nonseminomatous germ cell tumors), rare tumors from the supporting cells (Leydig cells and Sertoli cells), and rare metastases from another primary site.
- Ninety-five percent of tumors originating in the testis are germ cell tumors. Fewer than 10% of all germ cell tumors arise from extragonadal primary sites such as the mediastinum or retroperitoneum.
- Human β -chorionic gonadotropin and α -fetoprotein are accurate and relatively specific tumor markers for testicular cancer.

CURRENT THERAPY

Carcinoma of the Prostate

- Potentially curative treatment is generally offered to men with at least a 10-year life expectancy.
- Treatment options for clinically localized T1c and T2 tumors include active surveillance/watchful waiting, radiation therapy (external irradiation and brachytherapy), cryotherapy, High Intensity Focused Ultrasound (HIFU) and surgery (open and laparoscopic).
- Treatments for locally advanced tumors (T3/T4) or high-risk cancer patients include surgery and external irradiation in combination with androgen-deprivation therapy (ADT).

- Treatment for patients with metastatic disease (N1–2 or M1) includes initial ADT and later potentially chemotherapy, alternate forms of ADT, or immunotherapy.
- Follow-up includes history, physical examination, and monitoring of prostate-specific antigen at least every 6 months for 2 years and then annually. Any abnormalities may be more fully evaluated with appropriate imaging.

Renal Cell Carcinoma

- Treatment for localized masses is almost always surgical excision via radical or partial nephrectomy. Both operations may be performed with an open or a laparoscopic approach.
- Partial nephrectomy should be attempted in patients who have a solitary kidney, bilateral disease, or renal insufficiency. Partial nephrectomy is the preferred operation for patients who have lesions 4 cm or smaller and a normal contralateral kidney, with local recurrence rates of less than 5%.
- Minimally invasive approaches including percutaneous radio-frequency ablation and cryotherapy are acceptable alternatives to carefully selected patients.
- Up to 25% of patients have metastatic disease at diagnosis. Sites of metastasis, in decreasing frequency, include lungs, lymph nodes, liver, bone, and adrenal gland.
- Chemotherapy and radiation therapy provide little to no survival benefit, with radiation only palliating painful metastases.
- The mainstay of treatment in the past was immunotherapy, with 5-year survival rates of 10% to 20%. Immunotherapy now relies on high dose IL-2 (interleukin-2, Prolekin). In select cases and more recently the checkpoint inhibitor nivolumab (Opdivo) for second line therapy.
- Modern therapies for advanced or metastatic RCC include targeted therapies such as the oral tyrosine kinase inhibitors such as sunitinib (Sutent), pazopanib (Votrient), axitinib (Inlyta), and sorafenib (Nexavar), and the mammalian target of rapamycin (mTOR) inhibitors, temsirolimus (Torisel) and everolimus (Afinitor).
- Evidence suggests improved survival for those undergoing nephrectomy before systemic immunotherapy for metastatic disease.

Benign Renal Tumors

- For angiomyolipomas, management should be individualized. With asymptomatic lesions smaller than 4 cm, observation with annual imaging is reasonable.
- For patients with a symptomatic angiomyolipoma or one larger than 4 cm, surgical excision should be considered, although angioembolization is another option. Angioembolization can be used to stabilize a patient with acute hemorrhage secondary to an angiomyolipoma.

Tumors of the Renal Pelvis and Ureter

- Distal ureteral tumors can be managed with distal ureterectomy and ureteroneocystostomy.
- High-grade, multifocal, or high-stage tumors are optimally treated by nephroureterectomy with removal of a cuff of bladder at the ureteral orifice.
- Laparoscopic nephroureterectomy is the preferred surgical approach, allowing for complete tumor removal and often quicker convalescence.
- Carefully selected patients, especially those who have bilateral disease or a functionally solitary kidney, can be managed with endoscopic tumor ablation.

Urothelial Carcinoma of the Bladder

- Treatment depends on tumor stage.
- Superficial (Ta) low-grade cancers are managed with transurethral resection, with or without a single, immediate postresection instillation of a chemotherapeutic agent, typically mitomycin-C (Mutamycin).
- Carcinoma in situ or high-grade stage Ta tumors that involve the lamina propria (stage T1) and recurrent tumors are managed

with transurethral resection and intravesical agents such as thiotepa (Thioplex), doxorubicin (Adriamycin), and mitomycin-C¹ or intravesical bacillus Calmette-Guérin (Tice BCG).

- Bladder surveillance is mandatory, because the recurrence rate in the bladder can be as high as 50% at 5 years.
- Surveillance protocols vary but typically include cystoscopy and urinary tumor studies (usually cytology) every 3 months for the first 2 years, semiannually in years 3 to 5, and annually thereafter.
- Periodic evaluation of the upper tracts should be performed, usually by computed tomographic (CT) urography.
- Superficial disease that progresses or is refractory to conservative management, as well as tumors that invade the bladder muscle (stages T2–T4), is best managed by radical cystectomy and urinary diversion.
- Urinary diversion may be either incontinent (conduit) or continent (orthotopic or continent cutaneous).
- Five-year recurrence-free survival rates are 60% to 85% after cystectomy for organ-confined disease (stages T2a–T2b). For extravesical disease (stages T3a to T4), the 5-year survival rate decreases to 40% to 60%; for node-positive disease it is less than 30%.
- Patients with T2–T4 disease should be strongly considered for combination therapy with surgery plus chemotherapy, either in the neoadjuvant or the adjuvant setting. Recent randomized trials have suggested an approximately 5% survival advantage for neoadjuvant chemotherapy plus surgery, compared with surgery alone.
- Patients with M1 disease are usually treated with chemotherapy.
- The standard regimen over the past decade has been MVAC: methotrexate (Trexall),¹ vinblastine (Velban),¹ doxorubicin (Adriamycin), and cisplatin (Platinol); however, durable complete response rates are less than 15%.
- Newer agents such as gemcitabine (Gemzar)¹ along with cisplatin appear to offer similar response rates and reduced toxicity.
- The checkpoint inhibitor atezolizumab (Tecentriq) is now approved as immunotherapy for patients who have failed first line chemotherapy.

Urethral Carcinoma

- Treatment of the primary tumor is surgical excision and varies based on the location and stage of the tumor.
- In men, urethrectomy can be performed via a perineal incision.
- Proximal tumors of the bulbar urethra are often managed with cystoprostatectomy and en bloc urethrectomy.
- Among women, for tumors of the proximal urethra and tumors with extension into adjacent structures, cystectomy with en bloc urethrectomy and anterior vaginectomy along with pelvic lymphadenectomy is usually required.
- Radiation therapy is also reported to provide local control in selective cases.

Penile Cancer

- Small penile cancers limited to the prepuce can be treated by circumcision alone.
- Partial penectomy is used to treat smaller (2–5 cm) distal penile tumors. The remaining penis should be long enough to permit voiding in the standing position. The 5-year cure rate for patients treated with partial penectomy is 70% to 80%.
- Larger distal penile lesions and proximal tumors require total penectomy and perineal urethrostomy. If the scrotum, pubis, or abdominal wall is involved, radical en bloc excision may be necessary.
- Many patients have inguinal lymphadenopathy at presentation. However, inguinal lymph node enlargement before excision of the primary tumor may be the result of infection and not metastatic disease. Therefore clinical assessment of the inguinal region should be delayed 4 to 6 weeks.

- If inguinal lymphadenopathy persists or with high-risk features, there is a high likelihood of metastatic disease, and ilioinguinal lymphadenectomy should be performed. The procedure is performed on the contralateral side if the initial side contains tumor and could be simultaneously performed or staged on inpatients with high risk disease.
- Irradiation of the primary tumor and regional lymph nodes is an alternative to surgery in patients with small (≤ 2 cm), low-stage tumors.
- Mohs' surgery is another alternative for small lesions (≤ 2 cm).

Testicular Cancer

- All patients with suspected testicular tumors should undergo a radical orchiectomy through an inguinal approach and early, high ligation of the spermatic cord.
- Serum tumor markers should be measured before surgery and are used for disease staging and to monitor for recurrence.
- Radiographic staging should include, at a minimum, a CT scan of the abdomen and pelvis and chest radiography.
- Seminoma is the most common histologic form of germ cell tumor and generally carries a better prognosis than other variants. Standard therapy for low-stage (T1, 2a, or 2b) disease is orchiectomy with active surveillance, short course chemotherapy, or adjuvant radiation therapy to the retroperitoneum. Relapse is relatively rare, occurring in 4% of patients with stage 1 and 10% of patients with stage 2 disease. Relapses after radiation therapy can be salvaged in more than 90% of cases through systemic chemotherapy. The long-term cure rate for low-stage seminoma is approximately 99%.
- Nonseminomatous germ cell tumors (NSGCTs) include embryonal cell carcinomas, choriocarcinomas, yolk sac carcinomas, teratomas, and mixed germ cell tumors. As with pure seminoma, the cure rate for low-stage NSGCTs is high ($>95\%$) in patients with stage 1 disease.
- Surveillance, retroperitoneal lymph node dissection (RPLND), and adjuvant chemotherapy are standard treatment options for stage 1 NSGCT.
- RPLND is a major abdominal operation in which lymph nodes from the retroperitoneum are removed, from the renal hilum down to the level of the common iliac artery, with lateral margins being confined by the ureters.
- Adjuvant chemotherapy after RPLND should be considered if any lymph node is larger than 2 cm in diameter, if at least six nodes are involved, or if there is extranodal invasion.
- Patients with persistently increased concentrations of α -fetoprotein, human β -chorionic gonadotropin, or both but without other clinical evidence of disease after orchiectomy usually have systemic disease and are treated with chemotherapy.
- Approximately one third of patients require up-front chemotherapy. Those with clinical stage 2c disease (or higher), primary retroperitoneal germ cell tumors, or mediastinal seminomas treated with radiation therapy should undergo systemic, cisplatin-based, multiagent chemotherapy.
- Postchemotherapy RPLND for seminoma is typically reserved for patients with residual masses larger than 3 cm. For NSGCT, some groups reserve postchemotherapy RPLND for patients who do not have substantial tumor shrinkage ($>90\%$ shrinkage of retroperitoneal nodes and no residual nodes >1.5 cm) and those with teratomatous elements in the primary tumor. Others advocate surgery for all patients with initial bulky retroperitoneal disease. All agree that a clear, residual mass after chemotherapy in the setting of NSGCT warrants postchemotherapy RPLND.
- Multimodal therapy has allowed 90% to 95% of testicular cancer patients to be cured, even in the face of metastatic disease.

[†]Not FDA approved for this indication.

Carcinoma of the Prostate

Prostate cancer is the most common noncutaneous solid malignancy among men in the United States, and it is second only to lung cancer with respect to cancer-related death. In 2008, there were an estimated 186,320 new cases of prostate cancer and 28,660 deaths due to this disease. Because prostate cancer is predominantly a disease of the elderly, its incidence may be expected to rise over time as the US population ages.

There is a familial predisposition to prostate cancer, which is more common among those with a first-degree relative who also has the disease, and it appears to be more common among African American men than among Caucasian men. Environmental factors that have been associated with an increased risk of prostate cancer include a high-fat Western-style diet, as compared with a high-soy Asian diet, and low levels of vitamin D.

Hereditary prostate cancer is relatively rare but may account for up to 40% of tumors among young men with the disease. One of several genes found in families with hereditary prostate cancer is hereditary prostate cancer 1 (*HPC1*), which is located on the long arm of chromosome 1. Translocations leading to fusion of two genes (*TMPRSS2:ERG* gene fusion) has also been implicated in a large number of sporadic prostate cancers.

Diagnosis

The vast majority of prostate cancers are adenocarcinomas. There is a large discrepancy between the risk of finding incidental prostate cancer at autopsy (estimated to be as high as 75% by age 80 or older) and the risk of having the disease clinically diagnosed (lifetime risk, approximately 1 in 6). Most men with early-stage prostate cancer diagnosed in the modern era have no specific disease-related symptoms. Benign prostatic hypertrophy is often found in association with prostate cancer and is also more common in men as they age, but there is no known causal relationship between the two. Prostate cancer can rarely manifest with pelvic pain, bladder outlet obstruction, or ureteral obstruction from locally advanced disease or with bone pain from distant metastatic disease.

The advent and widespread use of the serum prostate-specific antigen (PSA) test as a screening tool for prostate cancer has resulted in a stage migration, with most men now diagnosed with early-stage disease. This has been associated with better recurrence-free survival rates after definitive local therapy. Certain groups, such as the American Urologic Association and the American Cancer Society, have advocated that physicians offer screening with a serum PSA determination and digital rectal examination for men older than 55 years of age and for African American men and those with a family history of prostatic cancer starting at age 40 years. However, these recommendations are not uniformly accepted; the US Preventive Services Task Force recently gave a grade D recommendation for routine screening with PSA for prostate cancer. It is generally accepted that the decision to screen for prostate cancer should be made in individuals with at least 10 years of life expectancy.

Serum PSA is specific for the prostate but is not specific for cancer. It is secreted by both benign and malignant prostatic epithelial cells. The PSA may be elevated in men with a variety of prostate-related conditions, such as prostatitis, benign prostatic hypertrophy, urinary tract infection, or prostatic cancer. Until recently, a PSA level lower than 4.0 ng/mL was considered normal, and in younger men a value of greater than 2.5 ng/mL could perhaps be considered abnormal. More recently, it has become clear that there is no true cutoff value for PSA. Instead, the association between PSA and prostate cancer risk is a continuum. Even at a PSA of essentially zero, there is still a 6% chance of having prostate cancer on biopsy.

The majority of the serum PSA is bound to protease inhibitors such as α_1 -antichymotrypsin, whereas a fraction is unconjugated or free. The relative proportion of free serum PSA can be used to improve the specificity of PSA for diagnosis of prostate cancer by biopsy. Benign prostatic hypertrophy is associated with a higher proportion of free PSA, and patients with greater 25% free serum PSA are less likely to harbor prostate cancer. The precise cutoff

point associated with prostate cancer is controversial and ranges from 10% to 20% or higher. Development of new tests to improve PSA specificity, such as measurement of complexed PSA or early pro-forms of PSA, is an area of ongoing investigation.

The most common method used to diagnose prostate cancer is a transrectal ultrasonography (TRUS)-guided prostate biopsy. TRUS allows for accurate localization of the zonal anatomy of the prostate and can accurately measure its size. It therefore acts as a guide for the biopsy, because prostatic cancers typically reside in the peripheral zone, and biopsies are concentrated within that zone. Although prostate cancer can manifest as hypoechoic lesions on TRUS, the tumors usually are not visible. TRUS lacks both sensitivity and specificity and should not be used as a screening test.

The most common grading system used to estimate the degree of tumor differentiation is the Gleason grading system. The two most common Gleason grade patterns (on a scale of 1 to 5) are summed to give a score between 2 and 10. Tumors with Gleason scores between 2 and 6 are well differentiated and have a better prognosis, whereas those with Gleason scores between 8 and 10 are poorly differentiated and have a worse prognosis. Gleason score 7 is associated with intermediate differentiation and prognosis. The majority of cancers found in the modern era are well to intermediately differentiated (Gleason score 5 to 7).

Staging of prostatic cancer defines the local, regional, and distant extent of disease. The tumor-node-metastasis (TNM) staging system is the most commonly used method. The most common clinical stage in the modern era is that of nonpalpable tumors detected because of a concerning PSA result (stage T1c). The primary staging modality for local disease is the digital rectal examination. This may be supplemented by pelvic magnetic resonance imaging in selected cases where there is significant concern for locally advanced disease based on the digital rectal examination. Although PSA only roughly correlates with the overall disease burden, bone metastasis is quite uncommon among patients whose PSA value is less than 20 ng/mL. Therefore a radionucleotide bone scan in the absence of symptoms is not required routinely if the PSA value is less than 10 ng/mL and the Gleason sum is 7 or less. Computed tomography (CT) scanning is not routinely used, because grossly positive nodes are detected rarely with a clinically localized tumor.

Lymph node staging is important in selecting patients for therapy. CT scanning may show enlarged lymph nodes in patients with high-volume or high-grade primary tumor but has poor sensitivity and specificity. Laparoscopic pelvic lymphadenectomy can provide adequate sampling of the pelvic lymph nodes in those patients not selecting surgery. More commonly, lymph node dissection is performed concomitantly at the time of radical prostatectomy.

Treatment

There is no one optimal treatment for clinically localized prostatic cancer, so therapy must be individualized. Among men with a life expectancy of less than 10 years, observation alone may be appropriate. Carefully selected men with low-risk prostate cancer may choose active surveillance rather than curative treatment but must be rigorously monitored for evidence of worsening disease.

Surgery and radiation therapy are the most commonly used curative modalities. For low-risk, organ-confined tumors, the 15-year disease-free survival rates are greater than 90% among patients treated with surgery. Moreover, the survival outcome is similar after radiation therapy and after surgery. However, properly done prospective, randomized comparisons among similarly staged patients have not been done. Radiation therapy can be delivered as external-beam radiotherapy or as brachytherapy using radioactive seeds (iodine 125 or palladium 103) implanted directly into the prostate. Cryotherapy (i.e., freezing of the prostate) is another approved treatment for men with prostatic carcinoma that is becoming more widely accepted as an alternative treatment option. More recently, High Intensity Focused Ultrasound (HIFU) has been approved for use in the United States, although experience with this modality in the US is limited compared to Europe.

Radical prostatectomy, or surgical removal of the prostate, may be performed via an open incision or by a laparoscopic

technique. Traditionally, an open surgery is performed through an anterior, retropubic approach or, less commonly, through a perineal incision. Laparoscopic and, in particular, robot-assisted radical prostatectomy is being performed with increasing frequency. The benefits of a robot-assisted approach may include reduced blood loss, sooner return to normal function, and possibly better functional outcomes and better surgical margin rates (although the latter two have not been definitively demonstrated to this point). In patients who were sexually active before therapy, preservation of the neurovascular bundles is often undertaken in an attempt to maintain postoperative sexual function. For patients with organ-confined disease, the prognosis is excellent, with a life expectancy similar to that of men without prostatic cancer. For those patients with positive surgical margins or positive lymph nodes on final pathology, consideration can be given to delivering, respectively, adjuvant irradiation or androgen-deprivation therapy (ADT).

Serum PSA should rapidly become undetectable after radical prostatectomy, because, in theory, all PSA-producing tissue has been removed. After radiation therapy or cryotherapy, the PSA is expected to reach low levels over time and then remain stable. An increasing serum PSA is evidence of tumor recurrence. There is controversy about when to initiate ADT in men with a rising PSA level after treatment.

Prostatic cancer, at least initially, is an androgen-sensitive disease. Therefore the primary first-line treatment for metastatic prostate cancer is ADT. Suppression of serum testosterone can be achieved by orchiectomy (i.e., surgical castration). Alternatively, medical castration may be considered. Luteinizing hormone-releasing hormone analogues effectively suppress testosterone to the castrate range within 1 month after administration by suppressing central nervous system secretion of luteinizing hormone. There is increasing awareness that ADT can be associated with significant long-term morbidity, including vasomotor reflex changes (hot flashes), loss of libido, erectile dysfunction, osteoporosis, anemia, muscle wasting, gynecomastia, and possibly cognitive changes and increased risk of cardiovascular disease. The choice to use ADT must, therefore, be carefully balanced based on the individual patient's overall risk of prostate cancer-related morbidity and mortality versus ADT-related morbidity.

Most patients with metastatic disease initially respond to ADT, but almost inexorably the disease progresses despite ongoing ADT, to become castration resistant prostate cancer (CRPC). At that point, the median survival time is less than 2 years. The standard chemotherapy for CRPC is docetaxel (Taxotere) plus prednisone, and prospective randomized trials have demonstrated a modest survival benefit among patients so treated. An alternative for asymptomatic or minimally symptomatic men with metastatic CRPC include sipuleucel-T (Provenge), a novel cellular immunotherapy-based intervention, abiraterone acetate (Zytiga) and enzalutamide (Xtandi). Several options now exist for men with metastatic CRPC who have failed prior docetaxel therapy including cabazitaxel (Jevtana), abiraterone acetate (Zytiga), enzalutamide (Xtandi), and Radium-223 dichloride (Xofigo). Another approved drug is mitoxantrone (Novantrone) for palliative relief of symptomatic bone pain from CRPC. Radiation therapy can be used effectively to palliate focal sites of bone metastases. The mechanisms by which prostatic carcinoma escapes hormonal control and becomes castrate resistant represent an area of ongoing intensive research.

Tumors of the Renal Parenchyma

Malignant tumors of the renal parenchyma are of either primary or metastatic origin. Primary renal tumors may be benign or malignant. The most common tumor of primary renal cell carcinoma (RCC) is conventional (clear cell) RCC; other tumor types, such as papillary, chromophobe, collecting duct, and medullary carcinomas and sarcomas, occur infrequently. The most common benign renal tumors are angiomyolipomas and oncocytomas. The latter, in particular, are generally indistinguishable from malignant lesions on radiographic imaging. Metastatic lesions (e.g., from lung,

breast, melanoma, or ovary) may occur, and primary lymphoma may be present in the kidney.

Renal Cell Carcinoma

RCC is the most common primary neoplasm of the kidney, accounting for more than 85% of all primary renal tumors. There were an estimated 54,390 newly diagnosed cases of RCC in the United States in 2008, and an estimated 13,010 people died of this disease. RCC represents approximately 3% of all adult malignancies and usually manifests between 40 and 60 years of age, although it can be found in younger age groups. It has a 2:1 male-to-female preponderance and in both sporadic and familial forms is associated with aberrations of the von Hippel–Lindau (VHL) gene and protein.

RCC is thought to arise from cells of the proximal convoluted tubule. The most consistent genetic aberration found in most cases of sporadic, conventional RCC are aberrations in the *VHL* gene. No specific agent has been implicated as the cause of RCC, although tobacco products are associated with an approximately twofold increased risk of being diagnosed with the disease. Patients, and particularly younger patients, with end-stage renal disease who develop acquired cystic disease of the kidney also have an increased risk of RCC. Between 1% and 2% of these patients develop RCC, so annual renal ultrasonography is reasonable as a screening tool in this population, with confirmatory studies such as CT for complex or suspicious lesions.

Diagnosis

The most common sign associated with RCC in 29% to 60% of cases is hematuria. The classic triad of flank pain, hematuria, and a palpable abdominal mass is relatively rare, occurring in fewer than 10% of cases. Other common symptoms and signs include fever, anemia, hypercalcemia, thrombocytosis, and elevated erythrocyte sedimentation rate, lactate dehydrogenase, or alkaline phosphatase. Currently, there are no reliable, commercially available tumor markers for RCC. Most often, these tumors are incidentally diagnosed on radiographic imaging performed for unrelated or nonspecific purposes.

The most commonly used staging system for RCC is the TNM staging system. It allows for a distinction between venous involvement and nodal invasion and stratifies the extent of each stage. RCC can involve the renal vein and vena cava and may even extend into the right atrium. Locally, it can directly invade surrounding structures such as the adrenal gland and colon. Five-year survival rates range from 80% to 90% for stages T1 N0 M0 (<7 cm) and T2 N0 M0 (>7 cm), 40% to 60% for stage T3 N0 M0, and 10% to 20% for N1–3 and M1 disease.

Treatment

Surgical excision of the tumor is the primary treatment for RCC. The classic procedure was a radical nephrectomy, in which the kidney was removed en bloc within Gerota's fascia and the ipsilateral adrenal gland and lymph nodes. This was routinely performed as an open procedure (flank, transabdominal, or thoracoabdominal incision). Adrenalectomy is now generally reserved for upper-pole tumors, very large tumors, or lesions that directly extend into the adrenal gland. Although these operations are increasingly performed through a laparoscopic approach, an open approach is usually preferred if there is extensive involvement of the inferior vena cava. In rare cases with supradiaphragmatic tumor extension within the cava, cardiopulmonary bypass may be required for tumor extraction.

A partial nephrectomy has become a standard approach for surgical excision of renal parenchymal tumors, particularly for individuals with solitary kidneys, those with bilateral masses, and those with compromised renal function. It has become the preferred operation for patients who have lesions of 4 cm or smaller and a normal contralateral kidney, because local recurrence rates are less than 5%, and partial (rather than radical) nephrectomy is associated with a lower long-term risk of chronic renal failure. As with radical nephrectomy, there is a growing

experience with laparoscopic approaches to partial nephrectomy. There are also several, minimally invasive approaches that are being utilized with increasing frequency including radiographically guided, percutaneous thermal tumor ablation using radio-frequency ablation or cryotherapy. These modalities are typically reserved for older patients or poor surgical candidates.

Up to 25% of patients initially present with metastatic disease. Sites of metastasis of RCC, in decreasing frequency of occurrence, include lung, lymph nodes, liver, bone, and adrenal gland. Chemotherapy and irradiation have little to no survival benefit, with radiation therapy only palliating painful metastases. The mainstay of treatment in the past was immunotherapy, with 5-year survival rates of 10% to 20%. Modern therapies for advanced or metastatic RCC now include the so-called targeted therapies, such as the oral tyrosine kinase inhibitors, sunitinib (Sutent), pazopanib (Votrient), axitinib (Inlyta), and sorafenib (Nexavar), and the mammalian target of rapamycin (mTOR) inhibitors, temsirolimus (Torisel) and everolimus (Afinitor). More recently the checkpoint inhibitor nivolumab (Opdivo) has been approved for use in metastatic RCC. Evidence suggests improved survival among those patients who undergo nephrectomy before systemic immunotherapy.

Benign Renal Tumors

Although they are not as frequent as malignant tumors, benign solid masses are also seen in the kidney. Angiomyolipomas can often be diagnosed radiographically based on the appearance of fat by CT scan. They can occur sporadically or as part of an inherited familial syndrome, tuberous sclerosis. The latter entity is characterized by mental retardation, benign tumors of the cerebellum, epilepsy, adenoma sebaceum, and angiomyolipomas. Approximately 50% of patients with tuberous sclerosis develop angiomyolipomas, most of which are bilateral and multifocal. The management of angiomyolipoma is controversial and should be individualized. Asymptomatic tumors smaller than 4 cm can generally be observed with annual radiographic imaging. Symptomatic lesions (bleeding, pain, rapid growth) and lesions larger than 4 cm should be considered for surgical excision, although angiobolization is another option. Acute hemorrhage from an angiomyolipoma can often be managed or at least stabilized by angiobolization.

Oncocytomas are the most common solid, benign renal tumors and account for 5% to 10% of solid renal lesions. Although these lesions tend to have a more uniform density than RCC and can have a characteristic central scar or spoke-wheel appearance on CT, there is no radiographic feature that reliably distinguishes an oncocytoma from a malignant renal lesion. Oncocytoma is therefore a diagnosis that should be made only on histologic analysis. The tumors characteristically exhibit eosinophilic, granular cells packed with mitochondria. Oncocytomas are thought to arise from the distal portion of the renal tubule.

Metastatic Renal Lesions

The most common primary malignancy to metastasize to the kidney is lung cancer, although cancers of the ovary, breast, or bowel, melanoma, and lymphoma can do so as well. Lymphoma of the kidney is almost always a manifestation of systemic disease. The management is therefore grounded in systemic chemotherapy, with surgery reserved for palliative symptom relief. However, approximately 15% of renal lymphomas manifest with a solitary renal mass as the sole radiographic manifestation. These lesions can be challenging to manage and difficult to distinguish from RCC preoperatively.

Tumors of the Renal Pelvis and Ureter

Approximately 10% of all renal tumors originate in the renal pelvis rather than the renal parenchyma. These account for 5% of all urothelial carcinomas (the majority of which arise in the bladder). Of the upper tract urothelial carcinomas, approximately one fourth arise in the ureter and the remainder in the renal pelvis. Urothelial carcinoma of the upper urinary tract is more common in men than in women and more common in whites than in blacks.

Environmental exposures associated with a higher risk of developing upper tract urothelial carcinoma include analgesic abuse, cyclophosphamide (Cytoxan), and a strong association with tobacco abuse.

Among patients with bladder cancer, approximately 3% to 5% develop upper tract urothelial carcinoma. This can increase to as high as 20% among those with carcinoma in situ (CIS) or high-grade disease. Conversely, approximately 30% to 70% of patients with a history of upper tract urothelial carcinoma go on to develop bladder cancer. As a consequence, these patients require ongoing periodic cystoscopic surveillance. The incidence of bilateral upper tract tumors is 2% to 5%. Other histologic tumor types that can manifest in the upper urinary tract include squamous cell carcinoma (SCC) and adenocarcinoma. Although they are rare, the risk is increased among patients with a history of recurrent, refractory urinary tract infections or staghorn calculi.

Diagnosis

The most common presenting symptom for upper tract urothelial tumors is hematuria. For patients with adequate renal function, the evaluation for hematuria includes CT urography, urinary cytology (or another urinary-based tumor marker), and cystoscopy. Urinary cytology has a high specificity but a generally poor sensitivity, particularly for low-grade disease. Other urinary tumor markers, such as NMP-22, and fluorescent in situ hybridization approaches typically have better sensitivity but are not as specific. A retrograde ureteropyelogram may be helpful in patients with poor renal function who cannot receive intravenous contrast agents. In general, if a suspicious mass is seen on CT or other imaging, a ureteroscopy is typically performed with biopsy or brushings to establish the diagnosis. The TNM system is the standard for staging.

Treatment

Disease isolated to the distal ureter is most often managed with distal ureterectomy and ureteroneocystostomy. High-grade or high-stage disease and multifocal disease isolated to one side are optimally managed in most cases by excision of that upper tract system via a radical nephroureterectomy, including excision of the distal portion of the ureter and complete excision of the ureteral orifice together with a cuff of bladder. Traditionally, these procedures were done via open incisions (one or two separate incisions, depending on the surgeon), but laparoscopy is increasingly being used to decrease patient morbidity and improve surgical recovery. In selected patients who have low-grade, low-stage disease with a small overall disease burden, an endoscopic approach using laser or electrocautery to destroy the tumors may be considered. This is also a strong consideration for those patients with bilateral disease or involvement of a functionally solitary renal unit. Most often, retrograde endoscopic approaches via ureteroscopy are employed, although in highly selected cases antegrade percutaneous approaches can be used.

Carcinoma of the Bladder

Urothelial Carcinoma of the Bladder

Bladder carcinoma is the fifth most common malignancy in the United States, with more than 68,810 new cases diagnosed annually. It is almost three times more common in men than in women, in whom it is the fourth most common cancer. Because of its propensity to recur, particularly in patients with superficial disease, it is the second-most prevalent cancer. High-grade bladder cancer is a deadly disease and is the fifth most common cause of cancer deaths among men. There is a well-established relationship between the development of bladder cancer and a variety of carcinogens. Perhaps the most widespread factor is tobacco abuse. Cigarette smoking is thought to account for up to half of all bladder cancers in men. Bladder cancer is also associated with other, less frequent occupational exposures, such as in the rubber and oil refinery industries. It is also associated with exposure to the chemotherapeutic agent, cyclophosphamide (Cytoxan); exposed patients have up to a ninefold

increased risk of developing bladder cancer, most likely related to a urinary metabolite of cyclophosphamide, acrolein.

Approximately 90% of bladder malignancies are urothelial carcinomas. Of these, the majority (70%) are papillary, 10% are sessile, and 20% demonstrate mixed morphology. Although roughly three quarters of bladder cancer patients present with non-muscle invasive, or superficial, disease, approximately 20% to 25% progress to muscle invasion over time. Nevertheless, 80% to 90% of patients with muscle-invasive disease had it at initial presentation. A strong correlation exists between tumor grade and stage; most well-differentiated tumors are superficial, and most poorly differentiated tumors are invasive. CIS is a poorly differentiated urothelial carcinoma that grows as a sheet confined to the urothelium. CIS may be found as a solitary or multifocal process and is associated with invasive carcinoma in 25% of cases, where it portends a poor prognosis. Between 10% and 20% of patients treated with cystectomy for diffuse or refractory CIS are found to have microscopic muscle-invasive disease.

Diagnosis

Gross painless hematuria is the most common presenting sign of bladder cancer. However, approximately 1 in 5 patients have only microscopic hematuria. Other symptoms that can be indicative of urothelial carcinoma (in particular, CIS) include irritative voiding symptoms such as frequency, urgency, and dysuria. Patients who present with symptoms and signs concerning for urothelial carcinoma should undergo an evaluation that includes cystoscopy, urinary tumor marker study (typically, urinary cytology), and evaluation of the upper tracts (typically by CT urography). The diagnosis is usually confirmed at the time of transurethral resection or biopsy.

Treatment

The management options for urothelial carcinoma are heavily dependent on the stage and grade of disease. The TNM system is recommended for staging. For most non-muscle invasive, low-grade tumors, transurethral resection, with or without a single, immediate instillation of a chemotherapeutic agent such as mitomycin-C (Mutamycin),¹ is all that is required. This must then be followed by careful, ongoing surveillance by cystoscopy, urinary tumor studies (typically cytology), and periodic upper tract imaging. For patients with high-grade disease (including CIS) and tumors that superficially invade the lamina propria (stage T1) or are rapidly recurrent tumors, adjuvant treatment with intravesical agents such as thiotepa (Thiopex), doxorubicin (Adriamycin), and mitomycin-C (Mutamycin)¹ or intravesical bacillus Calmette-Guérin (Tice BCG) may be indicated. In the United States, the most frequently used agent for this purpose, particularly for CIS, is intravesical BCG.

Patients with superficial disease must undergo regular surveillance, because the recurrence rate is as high as 50% at 5 years. Surveillance protocols vary but typically include cystoscopy and urinary tumor studies (usually urinary cytology) every 3 months for 2 years, then every 6 months for 3 years, and annually thereafter. Periodic evaluation of the upper tracts, typically by CT urography, is warranted, because there is a 3% to 5% incidence of development of upper tract urothelial carcinoma among patients with bladder urothelial carcinoma.

The risk of disease progression in patients with low-grade, low-stage (Ta) urothelial carcinoma is less than 5% to 10%. This risk increases as the stage and grade of the tumor increase. Patients who have muscle-invasive disease (stage T2 or higher), either at presentation or with progression after therapy for superficial disease, are best treated by radical cystectomy and urinary diversion. A thorough pelvic lymphadenectomy should be performed at the time of surgery. The precise limits of dissection for the lymphadenectomy remain somewhat controversial, although the latest data suggest that patients who have more lymph nodes removed fare better.

High-grade bladder cancer is a potentially lethal disease. There are an estimated 14,100 deaths due to bladder cancer annually.

¹Not FDA approved for this indication.

Among patients with organ-confined (pT2a-pT2b), muscle-invasive disease who undergo cystectomy, the 5-year recurrence-free survival rates are between 60% and 85%. For patients undergoing radical cystectomy who have extravesical extension of their disease (pT3-pT4 disease), the 5-year recurrence-free survival rates are lower, 40% to 60%. Patients with lymph node-positive disease fare the worst, with 5-year recurrence-free survival rates of 20% to 30%.

Patients with muscle-invasive bladder cancer should be considered for multimodal therapy (i.e., chemotherapy in addition to surgery). The standard regimen over the past decade has been MVAC: methotrexate (Trexall),¹ vinblastine (Velban),¹ doxorubicin (Adriamycin), and cisplatin (Platinol). This can be delivered either before surgery (neoadjuvant) or in the postsurgery setting (adjuvant). There is level 1 evidence to support MVAC chemotherapy combined with cystectomy for muscle-invasive bladder cancer, although the survival benefit across studies is only on the order of 5% to 10%. Newer agents, such as gemcitabine (Gemzar)¹ along with cisplatin, appear to offer similar response rates and reduced toxicity and are often used currently in lieu of MVAC. Cytotoxic chemotherapy produces response rates of 50% to 70% in patients with advanced or metastatic disease; however, the durable, long-term, complete response rates at 5 years are no more than 15% across series. The checkpoint inhibitor, atezolizumab (Tecentriq) had recently been approved in the second line for the systemic treatment of metastatic bladder cancer.

Urinary diversion may be accomplished after cystectomy in several ways, but the fundamental categories are incontinent and continent forms. Incontinent forms of diversion include ileal and colon conduits, both of which require that the patient wear an external collection appliance. Continent forms of diversion include the continent cutaneous diversion, which requires creation of a low-pressure reservoir (often of colon) and a catheterizable efferent limb with an associated valve mechanism to prevent urine leakage. More recently, emphasis has shifted to continent diversions in which the low-pressure reservoir is anastomosed to the native urethra. These orthotopic neobladders may be crafted from colon or ileum and offer the opportunity to avoid any external collection devices and, usually, any need for catheterization. Such devices may improve patients' quality of life after surgery, although this has not been formally demonstrated in a randomized trial.

Adenocarcinoma of the Bladder

Adenocarcinomas account for fewer than 2% of bladder cancers. They can be found in three settings: as primary lesions in the bladder, as metastases or local extensions from another site, or as primary urachal carcinomas. They are typically invasive and poorly differentiated and carry a poor prognosis. Adenocarcinomas may be found in association with bladder augmentation cystoplasties and are the most common form of bladder cancer in patients born with bladder exstrophy. The treatment of choice is typically radical cystectomy, pelvic lymphadenectomy, and urinary diversion.

Squamous Cell Carcinoma of the Bladder

SCC accounts for approximately 6% of bladder cancers in the United States but more than 75% of bladder cancers in Egypt. SCC is associated with chronic bladder inflammation from a variety of sources. These include chronic indwelling Foley catheters, recurrent or refractory bladder infections, and bladder diverticula or stones. In Egypt, approximately 80% of SCCs are associated with *Schistosoma haematobium* infestation. These bilharzia-associated SCCs of the bladder tend to occur in patients 10 to 20 years earlier than in the United States.

SCC of the bladder often carries a poor prognosis and is usually best treated by radical cystectomy. After surgery, this form of bladder cancer has a higher propensity for local recurrence, compared with urothelial carcinomas. SCC of the bladder is typically resistant

to cytotoxic chemotherapy, particularly the regimens frequently used for urothelial carcinoma. The benefit of neoadjuvant radiation therapy before cystectomy remains to be proven, at least for the non-bilharzial SCC typically found in the United States.

Urethral Carcinoma

Diagnosis

Urethral carcinoma is unusual in that it is more common in women than in men. It is a disease of the elderly, typically occurring after 60 years of age. The etiology remains to be determined, but approximately half of the cases are associated with urethral stricture disease. In women, there is an association with urethral malakoplakia and urethral caruncles. The usual presenting symptom in this circumstance is a papillary or fungating urethral mass and hematuria. A number of scenarios warrant a more thorough evaluation for possible urethral carcinoma, including a palpable urethral mass, an obstruction that does not respond to conventional management, development of a urethral abscess or fistula, presence of microscopic or gross hematuria, and the development of inguinal adenopathy.

Treatment

The primary treatment of urethral carcinoma is most often surgical excision, with the approach and the extent of surgery driven by both gender and the location of the mass relative to the sphincteric complex (likelihood of postoperative continence). For example, cystectomy with en bloc urethrectomy and anterior vaginectomy along with pelvic lymphadenectomy is usually required for tumors located in the proximal urethra or tumors with extension into adjacent structures. In selected cases, radiation therapy can provide local control. In locally advanced disease, multimodality treatment with chemotherapy and either surgical excision or radiation therapy provides the optimal chance for long-term cure, although there is no standard regimen to date.

Penile Cancer

Diagnosis

Penile cancer is relatively rare in the United States. Penile carcinoma has been associated with retained phimotic foreskin and poor personal hygiene. It is rare among men who are circumcised before puberty and occurs most commonly in the sixth decade of life. The symptoms relate directly to the mass itself and can include ulceration, pain, necrosis, foul odor, hemorrhage, and suppuration of the lesion. The clinical evaluation of patients with penile cancer involves a thorough physical examination including of the phallus and careful attention to palpation of the inguinal lymph nodes. Additional studies may include radiographic testing with chest radiography, CT scan of the abdomen and pelvis, and bone scan.

Treatment

Treatment is usually dictated by the tumor stage (TNM system), size, and location. Small tumors that are confined to the prepuce can often be managed by circumcision alone. Smaller tumors on the distal shaft can be treated by partial penectomy, provided that a normal tissue margin can be achieved and there is enough penile length remaining to permit voiding in the standing position. Among patients treated by partial penectomy, the 5-year recurrence-free survival rate is 70% to 80%. Large lesions and tumors on the proximal shaft may require total penectomy and perineal urethrostomy to achieve adequate local tumor control. If there is involvement of local structures such as the scrotum or pubis, radical en bloc resection may be required. Achieving negative margins is critical, because local recurrence of the disease can rarely be salvaged by radiation or chemotherapy.

Although many patients have inguinal lymphadenopathy at presentation, inguinal lymph node enlargement before excision of the primary tumor may be the result of infection and not metastatic disease. Clinical assessment of the inguinal region is therefore typically delayed for 4 to 6 weeks. Lymphadenopathy that persists or develops de novo raises the strong possibility of lymph node metastases, and an ilioinguinal lymphadenectomy should be

¹Not FDA approved for this indication.

performed. If inguinal lymphadenopathy resolves, lymph node dissection may not be necessary. It is often necessary to perform bilateral inguinal lymphadenectomy, particularly in patients with high-risk disease, for whom this should be considered regardless of the presence or absence of palpable nodes. Radiation of the primary tumor and regional lymph nodes is an alternative to surgery in carefully selected patients with small (≤ 2 cm), low-stage tumors. Similarly, Mohs' surgery is an option for small tumors, particularly ones at the base that otherwise might require a total penectomy.

Testicular Cancer

Malignant tumors of the male gonads can be divided into neoplasms originating from the germinal cells, rare tumors from the supporting cells (Leydig cells and Sertoli cells), and rare metastases from another primary site. The germinal neoplasms include seminomatous and nonseminomatous germ cell tumors (NSGCTs). Ninety-five percent of tumors originating in the testis are germ cell tumors. Fewer than 10% of all germ cell tumors arise from extragonadal primary sites such as the mediastinum and retroperitoneum. Testicular cancer is relatively rare overall, but it is the most common malignancy in men between the ages of 15 and 35 years, with 8090 new cases occurring annually.

Testicular cancer represents one of the great success stories in modern medicine. The mortality rates for testis cancer have decreased from more than 50% before the 1970s to less than 10% in the modern age. This is the result of a variety of advances, including more effective multiagent chemotherapy, improved surgical techniques, and better methods to diagnose and monitor the disease (e.g., CT scans, tumor markers). Testicular cancer currently serves as a paradigm for the multimodal treatment of malignancies.

Germ cell tumors are substantially more prevalent in Caucasians than in African Americans, by a margin of at least 5:1. Indeed, a report from the US military indicated a relative incidence of 40:1. The exact etiology of germ cell tumors is not fully understood. Familial clustering has been demonstrated, particularly among siblings. Two conditions associated with a higher risk for germ cell tumors are cryptorchidism and Klinefelter's syndrome, the latter associated with disease arising from the mediastinum. Orchidopexy for cryptorchidism does not appear to reduce the risk of neoplasia, but it does improve the ability to monitor the testis.

Diagnosis

A painless testicular mass in a patient of the appropriate age group should be considered a primary testicular tumor until proven otherwise. A substantial number of testicular tumors manifest with less specific symptoms, including diffuse testicular pain, swelling, hardness, or some combination of these findings. A tumor can be difficult to distinguish from an infectious epididymo-orchitis. However, because the latter is more common than a testicular tumor, a short trial of antibiotics is often undertaken. If symptoms do not abate or the findings do not revert to normal within 2 to 4 weeks, testicular sonography is indicated to identify any underlying testicular mass. A radical inguinal orchiectomy with early, high ligation of the spermatic cord at the internal ring is required for all patients with a suspected testicular tumor.

Testicular cancers typically first spread to regional, retroperitoneal lymph nodes below the level of the renal vessels. The primary nodal landing zone for right-sided tumors lies between the aorta and the inferior vena cava (interaortocaval nodes), whereas for left-sided tumors it is lateral to the aorta (para-aortic). Other frequent sites of metastases include the left supraclavicular lymph nodes and the lungs. Standard initial metastatic evaluation should include a CT scan of the abdomen and pelvis and chest radiography. Enlarged lymph nodes (>1 – 2 cm) in the primary lymphatic drainage areas (landing zones) of the affected side are involved by metastatic disease in approximately 70% of cases. CT imaging of the chest is required if mediastinal, hilar, or lung parenchymal disease is suspected. Serum tumor markers should be measured before orchiectomy and should include human β -chorionic gonadotropin (β -hCG), α -fetoprotein (AFP), and the less-specific marker, lactate dehydrogenase.

Treatment

All suspected testicular tumors should be treated with a radical orchiectomy through an inguinal approach and early, high ligation of the spermatic cord. β -hCG and AFP are relatively specific tumor markers for testicular cancer. They have substantially improved the ability to monitor the disease and to intervene early in the event of recurrence. They, along with lactate dehydrogenase, should be measured before orchiectomy. AFP production is restricted to NSGCTs, specifically tumors that contain at least a component of embryonal carcinoma or yolk sac tumor. Patients with an increased AFP and pure seminoma on pathologic examination of the orchiectomy specimen are still considered to have an NSGCT. Increased serum β -hCG can occur with seminomatous and nonseminomatous tumors. Increased concentrations of β -hCG are seen in 40% to 60% of patients with metastatic NSGCT and in 15% to 20% of patients with metastatic seminomas. Lactate dehydrogenase is less specific but has independent prognostic value in patients with advanced germ cell tumors. Serum lactate dehydrogenase is increased in approximately 60% of patients with NSGCT and in 80% of those with seminomatous germ cell tumors.

Persistently elevated concentrations of AFP and β -hCG, even in the absence of radiographic or clinical findings, implies active disease and is sufficient cause to initiate systemic therapy, provided that false-positive elevations have been ruled out. The serum half-life of β -hCG is 5 to 7 days, and that for AFP is 30 hours. A slow decrease in serum levels after orchiectomy also implies metastatic disease.

Seminoma is the most common histologic form of germ cell tumor and generally carries a better prognosis than other variants. Standard therapy for low-stage (T1, 2a, or 2b) disease is orchiectomy followed by active surveillance, chemotherapy, or radiation therapy to the retroperitoneal and possibly the ipsilateral pelvic lymph nodes, depending on clinical stage and patient preference. Relapse is relatively rare, occurring in 4% of patients with stage 1 and 10% of patients with stage 2 disease. Relapses can be salvaged in more than 90% of cases by systemic chemotherapy. The long-term cure rate for low-stage seminoma is approximately 99%.

NSGCTs include embryonal cell carcinomas, choriocarcinomas, yolk sac carcinomas, teratomas, and mixed germ cell tumors. As with pure seminoma, the cure rate is high ($>95\%$) in patients with stage 1 disease. Retroperitoneal lymphatic metastases may be found in 20% of patients who have no lymphatic or vascular invasion or invasion into the tunica albuginea, spermatic cord, or scrotum at the time of orchiectomy, even if CT scans are negative for lymphadenopathy. There are three options for low-stage NSGCT after orchiectomy in the absence of radiographic evidence of lymphadenopathy and with normalized serum tumor markers: surveillance, two cycles of chemotherapy, and nerve-sparing retroperitoneal lymph node dissection (RPLND). Patients with clinical stage 1 disease but embryonal histology or the presence of lymphovascular invasion or extension beyond the tunica albuginea have a higher risk of relapse ($>30\%$) with surveillance and should be considered for primary RPLND.

Although RPLND is a major abdominal operation, it offers the best way to control disease within the retroperitoneum. Lymph nodes are removed from the level of the renal hilum caudad to the level of the aortic bifurcation. The lateral margins are the ureters. Historically, this operation was associated with loss of ejaculatory function due to ligation of the sympathetic nerve fibers in the region. With modern, nerve-sparing techniques, ejaculatory function can be preserved in more than 95% of patients. Patients with persistently elevated AFP or β -hCG after orchiectomy most likely have metastatic disease, even in the absence of radiographically detectable lesions. These patients usually should go on to systemic chemotherapy first, rather than RPLND or two cycles of chemotherapy.

Clinical stage 2 NSGCTs can be managed by either RPLND or primary chemotherapy, depending on several factors. Those patients who are without marker elevation, are asymptomatic, and have small-volume retroperitoneal-only disease can be offered

primary RPLND. Those with persistently elevated tumor markers, symptomatic disease, or more bulky retroperitoneal disease usually undergo systemic chemotherapy. Local recurrence in the retroperitoneum after a properly performed RPLND is rare (<10%).

Adjuvant chemotherapy after RPLND should be considered if any lymph node is more than 2 cm in diameter, if six or more nodes are involved, or if there is extranodal invasion. Cure rates are not different in those who do or do not receive adjuvant chemotherapy, but the former group require fewer cycles of chemotherapy and fewer additional surgeries.

Approximately one third of patients require up-front chemotherapy. Those patients with clinical stage 2c disease (or higher), primary retroperitoneal germ cell tumor, or mediastinal seminomas treated with radiation therapy should all undergo systemic, cisplatin-based, multiagent chemotherapy.

Postchemotherapy RPLND for seminoma is typically reserved for patients with residual masses more than 3 cm in size or a positive PET scan. For NSGCT, this issue is more controversial. Some groups reserve this treatment for patients who do not have substantial tumor shrinkage (>90% shrinkage of retroperitoneal nodes and no residual nodes >1.5 cm) and for those with teratomatous elements in the primary tumor. Others advocate surgery for all patients with initial bulky retroperitoneal disease, regardless of the response to chemotherapy. All agree that a clear residual mass after chemotherapy in the setting of NSGCT warrants a postchemotherapy RPLND.

The first successful combination chemotherapy regimens for testicular cancer included cisplatin, vinblastine, and bleomycin (Ble-NOXane) and resulted in complete remission in 70% to 80% of patients with metastatic disease. Studies have shown that prolonged maintenance chemotherapy is unnecessary, and etoposide (VePesid) has largely replaced vinblastine (because it is less toxic and probably more efficacious). Serious adverse effects of chemotherapy include neuromuscular toxic effects, myelosuppression, bleomycin-induced pulmonary fibrosis, Raynaud's phenomenon, and secondary malignancy.

Leydig cell tumors are generally benign tumors that make up between 1% and 3% of all testicular tumors. The majority of cases occurs in men aged 20 to 60 years old, although roughly one fourth are diagnosed before puberty. After radical orchiectomy, the prognosis is usually good, with recurrences rarely reported.

Gonadoblastoma is a rare tumor that occurs almost exclusively in patients with a history of gonadal dysgenesis. They account for fewer than 1% of all testicular neoplasms and can occur at any age from infancy to beyond 70 years, although most patients are diagnosed before age 30. Initial management is with radical orchiectomy. Because of a 50% incidence of bilateral disease, a contralateral gonadectomy is generally warranted. The prognosis after orchiectomy is usually excellent.

Lymphoma is the most common secondary neoplasm of the testicle and the most common testicular neoplasm in men older than 50 years of age, with a median age at presentation of 60 years. Although survival is often poor for patients with bilateral disease and those presenting with lymphoma at other sites who later experience a testicular relapse, the prognosis is substantially better for patients presenting with primary testicular lymphoma confined to the testicle.

PRIMARY GLOMERULAR DISEASES

Method of

Manuel Praga, MD, PhD; and Enrique Morales, MD, PhD

CURRENT DIAGNOSIS

- Clinical presentations of glomerular diseases range from asymptomatic urinary abnormalities (proteinuria, microhematuria) to severe forms of rapidly progressive glomerulonephritis (gross hematuria, edema, acute renal function worsening, hypertension).
- Secondary causes of glomerular disease should be excluded by means of history, physical examination, and appropriate laboratory tests.
- Renal biopsy establishes the diagnosis and classification of primary glomerular diseases.

CURRENT THERAPY

- Appropriate treatment should be instituted as early as possible.
- Blood pressure should be lower than 130/80 mm Hg (<125/75 mm Hg in patients with proteinuria >1 g/24 h).
- Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are indicated in most cases of chronic proteinuric glomerular diseases due to their antiproteinuric, antihypertensive, and renoprotective effects.
- Specific therapy of primary glomerular diseases includes steroids, anticalcineurinic agents, and cytotoxics. Due to the potential risks of these therapies, the likelihood of progression and the presence of chronic irreversible parenchymal damage must be carefully assessed.
- Primary or idiopathic glomerular diseases comprise a wide variety of glomerular histologic lesions, with different clinical presentations and variable prognosis. Although some entities portend a favorable long-term prognosis, a considerable fraction of untreated patients who have other glomerular entities reach end-stage renal failure.

Clinical Presentation and Diagnosis

The clinical manifestations of primary glomerular diseases are very variable, ranging from asymptomatic urinary abnormalities to severe forms of rapidly progressive glomerulonephritis. The different clinical presentations are summarized and defined in [Box 1](#).

Most milder forms of glomerular diseases are diagnosed by a positive dipstick test for microhematuria or proteinuria. All these patients should have quantitative estimations of proteinuria (24-hour proteinuria or protein-to-creatinine ratio in a random sample of urine), urinary microscopic examination, and serum creatinine. Glomerular disorders can be the renal manifestation of systemic diseases of different causes (e.g., malignancies, infections, autoimmune disorders), as discussed later. Therefore medical history and physical examination should carefully investigate data suggesting such diseases. In addition to general laboratory analysis and assessment of renal morphology (renal echography), more specific determinations should be performed in all patients with suspected glomerular diseases: protein electrophoresis, serum levels of immunoglobulins, serum complement fractions C3 and C4, antinuclear antibody (ANA), anti-DNA antibodies, antineutrophilic cytoplasmic antibodies (ANCA), and tests for hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV infections.

Renal biopsy is the conclusive method for establishing the diagnosis and classification of primary glomerular disorders. Indications for renal biopsy include the nephrotic syndrome in adults

primary RPLND. Those with persistently elevated tumor markers, symptomatic disease, or more bulky retroperitoneal disease usually undergo systemic chemotherapy. Local recurrence in the retroperitoneum after a properly performed RPLND is rare (<10%).

Adjuvant chemotherapy after RPLND should be considered if any lymph node is more than 2 cm in diameter, if six or more nodes are involved, or if there is extranodal invasion. Cure rates are not different in those who do or do not receive adjuvant chemotherapy, but the former group require fewer cycles of chemotherapy and fewer additional surgeries.

Approximately one third of patients require up-front chemotherapy. Those patients with clinical stage 2c disease (or higher), primary retroperitoneal germ cell tumor, or mediastinal seminomas treated with radiation therapy should all undergo systemic, cisplatin-based, multiagent chemotherapy.

Postchemotherapy RPLND for seminoma is typically reserved for patients with residual masses more than 3 cm in size or a positive PET scan. For NSGCT, this issue is more controversial. Some groups reserve this treatment for patients who do not have substantial tumor shrinkage (>90% shrinkage of retroperitoneal nodes and no residual nodes >1.5 cm) and for those with teratomatous elements in the primary tumor. Others advocate surgery for all patients with initial bulky retroperitoneal disease, regardless of the response to chemotherapy. All agree that a clear residual mass after chemotherapy in the setting of NSGCT warrants a postchemotherapy RPLND.

The first successful combination chemotherapy regimens for testicular cancer included cisplatin, vinblastine, and bleomycin (Ble-NOXane) and resulted in complete remission in 70% to 80% of patients with metastatic disease. Studies have shown that prolonged maintenance chemotherapy is unnecessary, and etoposide (VePesid) has largely replaced vinblastine (because it is less toxic and probably more efficacious). Serious adverse effects of chemotherapy include neuromuscular toxic effects, myelosuppression, bleomycin-induced pulmonary fibrosis, Raynaud's phenomenon, and secondary malignancy.

Leydig cell tumors are generally benign tumors that make up between 1% and 3% of all testicular tumors. The majority of cases occurs in men aged 20 to 60 years old, although roughly one fourth are diagnosed before puberty. After radical orchiectomy, the prognosis is usually good, with recurrences rarely reported.

Gonadoblastoma is a rare tumor that occurs almost exclusively in patients with a history of gonadal dysgenesis. They account for fewer than 1% of all testicular neoplasms and can occur at any age from infancy to beyond 70 years, although most patients are diagnosed before age 30. Initial management is with radical orchiectomy. Because of a 50% incidence of bilateral disease, a contralateral gonadectomy is generally warranted. The prognosis after orchiectomy is usually excellent.

Lymphoma is the most common secondary neoplasm of the testicle and the most common testicular neoplasm in men older than 50 years of age, with a median age at presentation of 60 years. Although survival is often poor for patients with bilateral disease and those presenting with lymphoma at other sites who later experience a testicular relapse, the prognosis is substantially better for patients presenting with primary testicular lymphoma confined to the testicle.

- Blood pressure should be lower than 130/80 mm Hg (<125/75 mm Hg in patients with proteinuria >1 g/24 h).
- Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are indicated in most cases of chronic proteinuric glomerular diseases due to their antiproteinuric, antihypertensive, and renoprotective effects.
- Specific therapy of primary glomerular diseases includes steroids, anticalcineurinic agents, and cytotoxics. Due to the potential risks of these therapies, the likelihood of progression and the presence of chronic irreversible parenchymal damage must be carefully assessed.
- Primary or idiopathic glomerular diseases comprise a wide variety of glomerular histologic lesions, with different clinical presentations and variable prognosis. Although some entities portend a favorable long-term prognosis, a considerable fraction of untreated patients who have other glomerular entities reach end-stage renal failure.

Clinical Presentation and Diagnosis

The clinical manifestations of primary glomerular diseases are very variable, ranging from asymptomatic urinary abnormalities to severe forms of rapidly progressive glomerulonephritis. The different clinical presentations are summarized and defined in [Box 1](#).

Most milder forms of glomerular diseases are diagnosed by a positive dipstick test for microhematuria or proteinuria. All these patients should have quantitative estimations of proteinuria (24-hour proteinuria or protein-to-creatinine ratio in a random sample of urine), urinary microscopic examination, and serum creatinine. Glomerular disorders can be the renal manifestation of systemic diseases of different causes (e.g., malignancies, infections, autoimmune disorders), as discussed later. Therefore medical history and physical examination should carefully investigate data suggesting such diseases. In addition to general laboratory analysis and assessment of renal morphology (renal echography), more specific determinations should be performed in all patients with suspected glomerular diseases: protein electrophoresis, serum levels of immunoglobulins, serum complement fractions C3 and C4, antinuclear antibody (ANA), anti-DNA antibodies, antineutrophilic cytoplasmic antibodies (ANCA), and tests for hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV infections.

Renal biopsy is the conclusive method for establishing the diagnosis and classification of primary glomerular disorders. Indications for renal biopsy include the nephrotic syndrome in adults

BOX 1 Clinical Presentations of Glomerular Diseases**Nephrotic Syndrome**

- Proteinuria >3.5 g/d in adults and >40 mg/h/m² in children
- Hypoalbuminemia
- Hyperlipidemia
- Edema

Nephritic Syndrome

- Hypertension
- Oliguria
- Edema
- Hematuria (usually macroscopic)
- Red cell casts
- Non-nephrotic proteinuria
- Mild and nonprogressive GFR decrease

Rapidly Progressive Glomerulonephritis

- Acute or subacute progressive worsening of renal function
- Hematuria (usually macroscopic)
- Red cell casts
- Proteinuria (usually <3.5 g/d)
- Blood pressure often normal

Persistent Asymptomatic Urinary Abnormalities

- Non-nephrotic proteinuria (<3.5 g/d in adults and <40 mg/h/m² in children)
- Persistent microscopic hematuria

Recurrent Macroscopic Hematuria

- Bouts of gross hematuria, usually triggered by infections
- Persistent microhematuria between the episodes of gross hematuria

Chronic Renal Insufficiency

- Persistent proteinuria and/or microhematuria
- Hypertension
- Small kidneys

Hypocomplementemia

The C3 and C4 fractions of serum complement are characteristically reduced in some types of glomerular diseases. This is an important clue for diagnosis.

Abbreviation: GFR = glomerular filtration rate.

BOX 2 Main Histologic Findings of Primary Glomerular Diseases**Minimal Change Disease**

- Normal glomeruli on light microscopy
- Negative immunofluorescence and diffuse effacement of epithelial foot processes on electron microscopy

Focal and Segmental Glomerulosclerosis

- Focal (some glomeruli) and segmental (parts of affected glomeruli) scarring of the glomerular tuft

Membranous Nephropathy

- Thickening of glomerular capillary walls with projections of glomerular basement membrane ("spikes")
- Subepithelial immune deposits detected by immunofluorescence and electron microscopy

Membranoproliferative Glomerulonephritis

- Increase of mesangial cells and mesangial matrix
- Widening (double contoured appearance) of capillary loops
- IgG, C3, and IgM on immunofluorescence and subendothelial (type I) or intra-GBM (type II) deposits on electron microscopy

IgA Nephropathy

- Predominant deposition of mesangial IgA on immunofluorescence
- Proliferation of mesangial cellularity and mesangial matrix on light microscopy
- Mesangial electron-dense deposits on electron microscopy

Acute Postinfectious (Diffuse Proliferative)**Glomerulonephritis**

- Marked hypercellularity due to mesangial and endothelial cell proliferation and glomerular influx of neutrophils
- Hump-like subepithelial dense deposits on electron microscopy

Crescentic Glomerulonephritis

- Cellular or fibrocellular crescents in a variable percentage of glomeruli
- Immunofluorescence pattern distinguishes the main three types:
 - Type I: Linear IgG staining of the GBM (anti-GBM disease)
 - Type II: Granular deposits along GBM (immune complex deposition)
 - Type III: Negative immunofluorescence (pauci-immune glomerulonephritis)

Abbreviation: GBM = glomerular basement membrane; Ig = immunoglobulin.

(except cases attributed to diabetic nephropathy) and steroid-resistant nephrotic syndrome in children, rapidly progressive nephritis, persistent nephritic syndrome with deteriorating renal function, and, usually, recurrent macroscopic hematuria. The need for renal biopsy in patients with asymptomatic urinary abnormalities should be individualized. The most characteristic pathologic findings of the main primary glomerulonephritis are summarized in [Box 2](#), and their commonest clinical presentations are summarized in [Box 3](#).

Treatment**Conservative Therapy**

Hypertension is a common finding in patients with primary glomerulonephritis. Current guidelines recommend blood pressure targets lower than 130/80 mm Hg in these patients and lower than 125/75 mm Hg in patients with proteinuria greater than 1 g/24 hours. Any antihypertensive drug or drug combinations are useful, and they should be selected on the basis of the patient's characteristics. However, blockade of the renin-angiotensin system either with an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin receptor blocker (ARB) should be the main basis of antihypertensive treatment because of their demonstrated renoprotective effect (slowing or preventing loss of renal function) in patients with chronic renal diseases. The beneficial effects of ACEIs and ARBs appear to be similar and are also observed in proteinuric patients with normal blood pressure. Renal protection induced by ACEIs and ARBs is closely related to the significant reduction in

proteinuria that these agents induce. The level of proteinuria is the best way to monitor the efficacy of ACEIs and ARBs. Aldosterone antagonists (spironolactone, eplerenone) have also shown a remarkable antiproteinuric efficacy. Nevertheless, serum creatinine and potassium should be monitored after ACEI, ARB, or antialdosteronic agents are initiated, particularly in patients with reduced renal function.

Hyperlipidemia is a common finding in patients with glomerular diseases, particularly in those with the nephrotic syndrome. Prospective clinical studies have demonstrated that treatment of hyperlipidemia decreases proteinuria and prevents renal function loss. Statins such as atorvastatin (Lipitor) (10–40 mg after the evening meal) are the most commonly used lipid-lowering drugs. A level of LDL cholesterol lower than 100 mg/dL is recommended. Weight loss in obese patients induces a significant reduction in proteinuria, and smoking should be strictly forbidden, because smoking is associated with a more rapid progression toward renal failure in any type of renal disease.

All these measures (blood pressure lowering, treatment with ACEIs or ARBs, treatment of hyperlipidemia, weight loss, cessation of smoking) are also beneficial for the global cardiovascular

BOX 3**Commonest Presentations of the Main Primary Glomerular Diseases****Minimal Change Disease**

- Nephrotic syndrome

Focal and Segmental Glomerulosclerosis

- Nephrotic syndrome in more than two thirds of patients
- Non-nephrotic proteinuria in the remaining patients
- Renal insufficiency (20%–40%), hypertension (50%), and microhematuria (40%)

Membranous Nephropathy

- Nephrotic syndrome in >80% of patients
- Non-nephrotic proteinuria in the remaining patients

Membranoproliferative Glomerulonephritis

- Nephrotic syndrome in 50%
- Nephritic syndrome in 20%–30%
- Asymptomatic urinary abnormalities in 20%–30%
- Hypocomplementemia is common.

IgA Nephropathy

- Asymptomatic urinary abnormalities (microhematuria \pm proteinuria) in >75%
- Intercalated recurrent or isolated episodes of macroscopic hematuria in >40%
- Nephritic or nephrotic syndrome in <10%

Acute Postinfectious Glomerulonephritis

- Nephritic syndrome
- Hypocomplementemia

Crescentic Glomerulonephritis

- Rapidly progressive glomerulonephritis

Abbreviation: Ig = immunoglobulin.

risk that is significantly higher in proteinuric patients (mainly in those with renal insufficiency) than in the normal population.

The complications of the nephrotic syndrome require specific treatment. Edema is usually managed with a low-sodium diet plus furosemide (Lasix) in doses carefully adjusted to the severity of edema. Daily weight measurement is very important, because excessive diuretic doses can lead to volume depletion and functional worsening of renal function. In resistant cases, combinations of different types of diuretics (furosemide plus a thiazide diuretic, or furosemide plus a potassium-sparing diuretic such as spironolactone [Aldactone] in patients with hypokalemia) are needed. More severe cases require albumin infusions followed by high-dose intravenous furosemide (although intravenous albumin [Albuminar]¹ increases proteinuria) or even removal of fluids by hemodialysis. Nephrotic patients are at increasing risk for thrombotic events. Prophylactic treatment (subcutaneous low-molecular-weight heparin) is indicated in conditions of high risk, such as immobilization.

Specific Therapy

Box 4 summarizes the immunosuppressive treatment of primary glomerular diseases.

Minimal Change Disease

Minimal change disease (MCD) is most common in children but also causes 10% to 15% of nephrotic syndrome in adults. Corticosteroid therapy is a very effective treatment for MCD. For children, the dose of prednisone is 60 mg/m²/day and for adults 1 mg/kg/day (up to 80 mg/day). About 75% of patients respond (complete proteinuria disappearance) within 2 weeks, and more than 90% respond within 8 weeks, but adults show in general a slower response than children. Initial steroid dose is continued for 4 weeks and then changed to alternate-day prednisone (40 mg/m² on alternate days) or to daily prednisone, slowly tapering off over 6 to

BOX 4**Immunosuppressive Treatment of Primary Glomerular Disease****Minimal Change Disease****First Line**

- Steroids

Second Line

- Cytotoxics (frequent relapsers)
- Anticalcineurinics or mycophenolate mofetil (CellCept)¹ (steroid-dependent)

Focal Segmental Glomerulosclerosis**First Line**

- Steroids
- ACEIs
- ARBs

Second Line

- Anticalcineurinics
- Mycophenolate mofetil¹
- Rituximab (steroid dependent)

Membranous Nephropathy**First Line**

- Anticalcineurinics
- Steroids plus cytotoxics
- ACEIs
- ARBs

Second Line

- Mycophenolate mofetil
- Intramuscular ACTH (Synacthen)^{1,2}
- Rituximab (Rituxan)¹

Membranoproliferative Glomerulonephritis

- Steroids
- ACEIs
- ARBs

IgA Nephropathy**First Line**

- ACEIs
- ARBs

Second Line

- Steroids
- Fish oil

Acute Postinfectious Glomerulonephritis

- Conservative therapy

Crescentic Glomerulonephritis**Type I (anti-GBM)**

- Steroids
- Cyclophosphamide (Cytoxan)¹
- Plasmapheresis

Type II and III Induction

- Steroids
- Cyclophosphamide¹
- Plasmapheresis in severe acute renal failure
- Rituximab in ANCA-positive type III crescentic GN

Maintenance

- Low-dose steroids
- Azathioprine (Imuran)¹

²Not available in the United States.

Abbreviations: ACEI = angiotensin-converting enzyme inhibitor; ACTH = adrenocorticotrophic hormone; ARB = angiotensin receptor blocker; GBM = glomerular basement membrane; Ig = immunoglobulin.

10 weeks. Keeping patients on steroids for more than 3 months is associated with a lower 1-year relapse rate.

Up to 75% of children and many adults have nephrotic syndrome relapses. Isolated relapses are re-treated with steroids as in the first episode. Frequent relapsers (two or more relapses within a 6-month period) are treated with a low-dose steroid course plus cyclophosphamide (Cytoxan) (1.5–2 mg/kg/day) or chlorambucil (Leukeran)¹ (0.1–0.2 mg/kg/day) in an 8-week course. After these short-term cytotoxic courses, a considerable fraction of patients remain free of proteinuria for prolonged periods, with a low rate of serious complications. Longer or repeated courses can induce severe side effects and are not recommended.

The response of steroid-dependent patients (reappearance of the nephrotic syndrome during or immediately after steroid withdrawal) to cytotoxics is poorer than that of frequent relapsers. Steroid-dependent patients and frequent relapsers unresponsive to cytotoxics are commonly treated with cyclosporine (Neoral)¹ given in an initial dose of 3 to 4 mg/kg in two divided doses, then adjusting for serum levels of 100–175 ng/mL. Most steroid-dependent patients transform into cyclosporine-dependent, and the risk of cyclosporine-induced nephrotoxicity should be considered. Mycophenolate mofetil (MMF, CellCept)¹ (600 mg/m²/12 h in children, 500–1000 mg/12 h in adults) is a very useful alternative. Rates of response and relapse are similar to those of cyclosporine, but tolerance is better and there is no risk of nephrotoxicity. Therapy with cyclosporine or MMF if the patient responds is continued for up to 12 months before slow and careful tapering. Rituximab¹ (four weekly intravenous doses of 375 mg/m²) has been used in some patients with steroid-dependent nephrotic syndrome and frequent relapsers, inducing a significant decrease in the number of relapses in many of them. However, randomized controlled trials or observational studies with longer follow-up are needed.

Less than 10% of MCD patients are steroid resistant. Because most of them subsequently have focal segmental glomerulosclerosis (FSGS) on biopsy, their therapeutic approach is the same as for FSGS.

Focal and Segmental Glomerulosclerosis

Causes of secondary FSGS (obesity, reflux nephropathy, reduction in renal mass) should be carefully excluded. Treatment with an ACEI or ARB is the first option in patients with non-nephrotic proteinuria or in patients with nonaggressive nephrotic syndrome (proteinuria <5 g/day, serum albumin >3 g/dL, normal renal function), mainly if hypertension coexists. Patients with severe nephrotic syndrome or nephrotic proteinuria after ACEI or ARB introduction should be treated with prednisone 1 mg/kg/day. Several retrospective studies have shown that steroid treatment maintained for at least 6 months is followed by more than 50% partial or complete remissions. However, in responsive patients, proteinuria starts to decrease after 2 to 3 months of treatment.

If proteinuria did not show significant changes within this period, introduction of an anticalcineurinic agent together with steroid tapering is recommended. Cyclosporine (doses and blood levels as in MCD) has been the most commonly used drug, and prospective studies have shown more than 70% partial or complete remission after 6 months of treatment. Tacrolimus (Prograf)¹ (0.05–0.10 mg/kg/day in two divided doses, then adjusted for serum levels of 4–7 ng/mL) is proved to be effective in some cyclosporine-resistant FSGS cases.

In patients with complete or partial response to cyclosporine or tacrolimus, these drugs should be maintained at the lowest effective doses for at least 1 year before slowly tapering off. In some patients resistant to steroids and cyclosporine, or in those with mild degrees of renal insufficiency, MMF¹ (same doses as in MCD) has decreased proteinuria and stabilized renal function for prolonged periods in some patients, but there are no prospective controlled studies. Sirolimus (Rapamune)¹ has induced complete (19%) or partial (38%) remission in a series of patients, although other

studies have failed to confirm these beneficial effects and have shown a remarkable number of serious side effects.

About 20% to 25% of children with aggressive forms of FSGS have mutations in the genes coding for several podocyte proteins, mainly podocin. Most of these patients are unresponsive to any kind of treatment.

Membranous Nephropathy

More than one-third of MGN patients have a spontaneous remission, and most remissions take place during the first 2 years of the disease. Conservative therapy should be maintained during the first 9 to 12 months, unless renal function starts to deteriorate. ACEIs or ARBs, or both, can induce partial remission (non-nephrotic proteinuria) in a considerable percentage of cases.

In patients with an aggressive presentation (massive nephrotic syndrome and deteriorating renal function), a 6-month course of alternating monthly prednisone 0.5 mg/kg/day with a month of chlorambucil¹ 0.2 mg/kg/day or cyclophosphamide¹ 2 mg/kg/day is recommended. Other clinicians simultaneously use prednisone starting with 1 mg/kg/day and tapering off over 6 months plus chlorambucil or cyclophosphamide for 14 weeks.

In patients maintaining normal renal function and persistent nephrotic proteinuria beyond 9 to 12 months, immunosuppressive therapy should be initiated, mainly in the presence of markers of poor outcome, which include male gender, older age, and proteinuria persistently higher than 8 g/day after ACEI or ARB treatment. Alternating prednisone and chlorambucil (as indicated earlier), prednisone and cyclophosphamide, and cyclosporine¹ 3–4 mg/kg/day, targeting blood levels of 100–175 ng/mL are beneficial, inducing complete or partial remission in most patients.

Side effects (diabetes, bone necrosis, infections) are more serious with steroids plus cytotoxic treatments; trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim) (80 mg/400 mg/day) should be concurrently administered for *Pneumocystis jirovecii* prophylaxis. Cyclosporine, administered for 6 months, is followed by approximately 50% of recurrences after drug withdrawal.

No studies comparing anticalcineurinic and cytotoxics have been published for MGN. Tacrolimus,¹ another anticalcineurinic agent, can also induce partial response in more than 80% of treated patients, although recurrence after withdrawal is the same (50%) as with cyclosporine. A recent randomized pilot trial reported that tetracosactide (Synacthen),^{1,2} an analogue of ACTH (1 mg IM twice a week for 1 year) induced remissions in the same percentage as a regimen of steroids plus cyclophosphamide.

Uncontrolled studies reported that MMF¹ (1000–2000 mg/day) reduced proteinuria and stabilized renal function in some MGN patients unresponsive to other therapies. Rituximab (Rituxan),¹ a monoclonal antibody against CD20-lymphocytes, has induced complete (15%–20%) or partial (35%–40%) remission in several series of patients, although no prospective controlled studies have been published. On the other hand, rituximab has been effective to avoid nephrotic syndrome relapse after tacrolimus withdrawal in patients successfully treated with this drug but showing anticalcineurin dependence.

Membranoproliferative Glomerulonephritis

The incidence of idiopathic membranoproliferative glomerulonephritis (MPGN) has progressively decreased over the last decades, being currently an uncommon disease in developed countries. Most cases of MPGN are now secondary to HCV infection and concurrent cryoglobulinemia. No prospective studies about the treatment of idiopathic MPGN have been carried out in the last several years. Uncontrolled series of patients suggested that prolonged (>2 years) prednisone treatment is beneficial in terms of proteinuria reduction and renal survival. Prospective randomized trials with aspirin¹ and dipyridamole (Persantine)¹ showed a significant reduction in proteinuria some decades ago, but later analysis did not demonstrate long-term benefits on renal survival.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

²Not available in the United States.

Conservative therapy, including ACEIs and ARBs, should be prescribed in all cases. In patients with the nephrotic syndrome after an observation period or in those with more aggressive presentations (deteriorating renal function, crescents), a 6- to 12-month course of prednisone could be indicated. Some small series of patients suggested that cyclophosphamide¹ is effective in aggressive cases of MPGN, but conclusive evidence is lacking.

MMF has been suggested as a possible therapeutic alternative, based on some observational studies. In MPGN with isolated deposits of C2 on immunofluorescence (so-called C3 glomerulopathy), a dysregulation in the complement system has been demonstrated, and eculizumab, a specific inhibitor of the complement system, has been effective in some cases.

Immunoglobulin A Nephropathy

As in all types of primary glomerular diseases, the aggressiveness of therapeutic approaches in patients with immunoglobulin A (IgA) nephropathy should be graded according to the severity of the presentation. In patients with microhematuria and normal renal function, only regular follow-up is required. If slowly increasing proteinuria appears, an ACEI or ARB, or a combination of both drugs, should be started, even in the absence of hypertension, targeting for proteinuria less than 1 g/day and blood pressure lower than 125/75 mm Hg.

In patients with increasing proteinuria greater than 1–1.5 g/day in spite of these measures, other therapies should be contemplated. Steroids were proven to be beneficial in patients with normal renal function and proteinuria greater than 1 g/day in a prospective randomized trial: methylprednisolone (Solu-Medrol) pulses, 1 g/day for 3 days in the beginning of months 1, 3, and 5, and oral prednisone 0.5 mg/kg every other day for 6 months reduced proteinuria and increased renal survival in comparison with untreated patients.

Treatment with fish oil supplements¹ in this type of patient remains controversial. Although eicosapentaenoic acid (1.8 g/day) or docosahexaenoic acid (1.2 g/day) demonstrated beneficial effects in some trials, these effects were not reproduced in others.

In patients with more aggressive presentations (proteinuria and deteriorating renal function), a prospective trial demonstrated that prednisone 40 mg/day tapering to 10 mg/day within 2 years plus cyclophosphamide¹ 1.5 mg/kg/day for 3 months followed by azathioprine (Imuran)¹ 1.5 mg/kg/day for at least 2 years significantly improved renal survival in comparison with untreated patients.

MMF (1000–2000 mg/day) has been tested by means of several randomized controlled trials in IgA nephropathy, obtaining disparate results. Although some studies suggested a positive influence, others have failed to confirm these results.

Acute Postinfectious (Diffuse Proliferative) Glomerulonephritis

As in MPGN, the incidence of diffuse proliferative glomerulonephritis has drastically decreased in recent years in developed countries. The prognosis is generally good, and signs and symptoms of the disease (nephritic syndrome) resolve sporadically within 2 to 6 weeks in a great majority of cases. Treatment should be focused on adequate control of blood pressure, salt restriction, and diuretics to prevent fluid excess and the risks of cardiac failure. The triggering infection should be investigated and treated if it has not disappeared spontaneously.

Some patients present with more aggressive courses, developing progressive renal insufficiency. In these cases, crescents involving a large proportion of glomeruli can be observed in a second biopsy. No controlled studies have been carried out in these aggressive cases, but some series of patients recommend high-dose intravenous pulse steroid, followed by oral prednisone 1 mg/kg/day, tapering off over 2 to 3 months. There is no evidence that more aggressive immunosuppressive therapy is beneficial.

Crescentic Glomerulonephritis

Treatment of crescentic glomerulonephritis (CGN) should be promptly instituted because of the rapid transformation of cellular crescents into irreversible fibrotic crescents that collapse the glomerular tufts. Prognosis of type I (anti-GBM disease) CGN is poorer than that of types II and III, particularly in the presence of oligoanuria, dialysis requirement, or a large fraction of glomeruli with crescents.

Treatment of type I CGN includes steroids, cyclophosphamide,¹ and plasmapheresis. Pulse intravenous methylprednisolone (500–1000 mg daily for 3–4 days) is followed by oral prednisone (1 mg/kg/day for 3–4 weeks, then slowly tapering off over 6 months). Oral cyclophosphamide (2 mg/kg/day) is usually maintained for 2 to 3 months. Plasmapheresis (daily or alternate-day 4-liter exchanges) using albumin as replacement fluid or fresh frozen plasma if bleeding risk is high is usually performed for 2 to 3 weeks. The duration of plasmapheresis, as well as the intensity and the duration of immunosuppressive therapy, should be guided by the clinical status and the titers of anti-GBM antibodies. In patients without pulmonary hemorrhage and with very advanced renal involvement (massive presence of glomerular fibrotic crescents), aggressive immunosuppression is not indicated.

The precise etiology of type II CGN (e.g., systemic lupus erythematosus, cryoglobulinemia) should be identified and the therapy guided by the diagnosis. If no apparent diagnosis is available, treatment is similar to that for type III (pauci-immune) CGN.

Induction treatment of type III CGN consists of steroids (oral prednisone, 1 mg/kg/day for 3–4 weeks, slowly tapered to a maintenance dose of 10–20 mg) and intravenous monthly pulses of cyclophosphamide (initial dose 0.5 to 1 g/m², adjusted for renal function and age), which has proved to be as effective and less toxic than oral administration. Once remission is achieved (recovery of renal function, absence of extrarenal symptoms), usually within 3 to 6 months, cyclophosphamide is replaced by azathioprine¹ 1 to 2 mg/kg/day for 12 to 18 months plus prednisone 5 to 10 mg daily or every other day. Positive titers of ANCA, particularly p-ANCA, can indicate more prolonged, low-dose, maintenance treatment, because the risk of recurrence is high. Plasmapheresis (similar to that in type I CGN) is proven to add benefits in type III CGN manifesting with severe renal failure. In two recent trials, rituximab (375 mg/m² per week for 4 weeks) was as effective as cyclophosphamide as induction therapy in ANCA-positive vasculitis. Interestingly, rituximab was more effective than cyclophosphamide in relapsing cases. Although not tested in prospective trials, MMF¹ (1500–3000 mg/day) has been shown effective and well tolerated, even as induction therapy in some series of patients.

¹Not FDA approved for this indication.

PYELONEPHRITIS

Method of

Patricia D. Brown, MD

CURRENT DIAGNOSIS

- Abrupt onset of fever, flank pain, and costovertebral angle tenderness with or without symptoms of cystitis are classic presenting features.
- Patients with lower UTI symptoms or laboratory evidence of UTI accompanied by flank pain, fever, or signs of systemic toxicity such as GI complaints should be managed as having APN.
- Urinalysis with microscopic examination should be performed in all patients with suspected APN. Absence of pyuria is strong evidence against the diagnosis.
- A urine culture should be obtained in all patients with APN. Blood cultures should be obtained in those who are hospitalized.
- Patients should be categorized into those with uncomplicated and those with complicated infections.

Abbreviation: APN = acute pyelonephritis; GI = gastrointestinal; UTI = urinary tract infection.

CURRENT THERAPY

- Hospitalization is recommended for patients unable to tolerate oral intake, those with severe pain, and those with signs of severe sepsis. Hospitalization is generally recommended for patients with complicated infections and for all pregnant women.
- Parenteral regimens for hospitalized patients include an aminoglycoside, third-generation cephalosporin, or fluoroquinolone, with oral switch therapy selected on the basis of culture and susceptibility data.
- Initial empiric therapy for outpatients is a fluoroquinolone.
- Imaging is not recommended for patients with uncomplicated infections. Pre- and postcontrast computed tomographic scans should be obtained in those who fail to respond within 72 hours to appropriate antibiotic therapy.

Acute pyelonephritis (APN) is a urinary tract infection (UTI) that involves the renal parenchyma, also referred to as *upper tract UTI*. Most episodes of APN occur as a result of ascending infection from the bladder; patients with APN might or might not have symptoms of concomitant cystitis. Rarely, pyelonephritis occurs secondary to hematogenous seeding of the kidney as a result of infection elsewhere, most commonly endocarditis due to *Staphylococcus aureus* or disseminated fungal infection.

Epidemiology

Surprisingly little is known about the epidemiology of APN. Similar to cystitis, APN (and hospitalization for APN) is more common in women than men; men have been reported to have higher in-hospital mortality. In contrast to cystitis, risk factors for pyelonephritis are not well defined. A study of nonpregnant women 18 to 49 years of age found risk factors for APN included factors known to be risk factors for acute cystitis, including frequency of sexual intercourse, recent UTI, diabetes, and maternal UTI history. The incidence of bacteremia in patients with APN is reported to be 11% to 53% in various studies; risk factors for bacteremia are not well established. In one study, age greater than 65 years, vomiting, pulse greater than 110 beats per minute, segmented neutrophils greater than 90%, and pyuria with greater than 50 leukocytes per high-powered field were independent risk factors for bacteremia in women with uncomplicated APN.

BOX 1

Factors Associated With Complicated Pyelonephritis

- Diabetes
- Foreign body (catheter, stent)
- Health care–associated infections
- Immunocompromise
- Incomplete voiding (detrusor muscle dysfunction due to neurologic disease or medications)
- Infections due to multidrug-resistant pathogens
- Obstruction (including stones)
- Pregnancy
- Recent history of instrumentation
- Renal failure
- Renal transplant recipient
- UTI in a male patient
- Vesicoureteral reflux

Abbreviation: UTI = urinary tract infection.

Similar to lower UTI, APN can be further classified into complicated or uncomplicated infection. The factors that make an episode of APN a complicated UTI are outlined in [Box 1](#).

Clinical Presentation

The classic presenting features of APN include abrupt onset of fever, flank pain, and costovertebral angle tenderness with or without symptoms of lower UTI including dysuria, urgency, and frequency. Unfortunately, there is no single constellation of signs or symptoms that is pathognomonic for APN. When localization studies have been performed on patients with symptoms of acute cystitis, 30% to 50% have been shown to have APN. Women who present with symptoms that have been present more than 7 days and those with a recent history of UTI are more likely to have APN. Flank pain is reported in approximately one-half of patients with APN but also occurs in almost 20% of patients with cystitis. Fever is present in one half of patients with APN, but less than 5% of patients with cystitis. Nausea, vomiting, and diarrhea occur commonly in patients with APN, and gastrointestinal (GI) symptoms can dominate the presenting complaints.

In general, patients who present with lower urinary tract symptoms or laboratory evidence of urinary tract infection accompanied by fever, flank pain or tenderness, or signs of systemic toxicity, such as GI symptoms, should be treated for APN.

The diagnosis can be particularly challenging in the frail elderly patient, because symptoms such as frequency, urgency, and incontinence are often chronic in this patient population and unrelated to active UTI. Change in mental status may be the only presenting complaint. Because the prevalence of bacteriuria in this patient population is high, particularly among those with chronic indwelling catheters, UTI must be a diagnosis of exclusion.

Acute pelvic inflammatory disease can have a presentation similar to APN. Pelvic examination should be performed on all sexually active women to exclude this diagnosis.

The differential diagnosis of APN is outlined in [Box 2](#).

Diagnosis

Urinalysis, ideally with microscopic examination, using a clean-catch, midstream specimen, should be performed in all patients with suspected APN. Pyuria is a key finding in the diagnosis of UTI, and the absence of pyuria is strong evidence against a diagnosis of APN. Direct microscopic examination under high power of the urinary sediment from a centrifuged specimen should reveal more than 10 leukocytes per high-powered field. The presence of white blood cell (WBC) casts is highly specific for localization of the infection to the kidney, but it is inadequately sensitive to exclude the diagnosis of APN. The dipstick test for leukocyte esterase is used as a rapid screening test to detect significant pyuria; the sensitivity is reported to be 75% to 96%, with a specificity of 94% to 98%. Because of the lower range of the reported sensitivity of the

- Appendicitis
- Cholecystitis
- Diverticulitis
- Gastroenteritis
- Herpes zoster
- Musculoskeletal pain, including vertebral disorders
- Ovarian cysts, tumors
- Pancreatitis
- Perforated viscus
- Pelvic inflammatory disease
- Pneumonia
- Renal stones, renal vein thrombosis, renal infarction

dipstick test, microscopic examination to exclude significant pyuria should be obtained in patients with suspected APN.

The presence of nitrite in the urine, detected by a dipstick test, has a reported sensitivity of 35% to 85% and a specificity of 92% to 100% for UTI. Microscopic examination of a gram-stained, centrifuged urine specimen revealing at least one bacterium per oil-immersion field correlates with more than 10^5 colony-forming units (cfu)/mL of bacteria, with a sensitivity of 95%. Although this is the standard definition of significant bacteriuria, it has been shown that women with UTI can have levels of bacteriuria as low as 10^2 cfu/mL.

Although the microbiology of APN has remained predictable, significant changes in antimicrobial susceptibility patterns have occurred. Therefore, in contrast to recommendations for acute uncomplicated cystitis, a urine culture should be obtained in all patients with suspected APN. The need to obtain blood cultures has been debated, because blood cultures rarely yield a pathogen different from what was isolated from the urine. Bacteremia has been reported in 11% to 53% of patients hospitalized with APN. Bacteremic patients have a longer length of stay, and one recent report suggests that this is due to a longer time to resolution of fever. Many experts continue to recommend that blood cultures be obtained as part of the diagnostic evaluation of patients who are ill enough to require hospitalization; blood cultures are not necessary for those who will be managed as outpatients.

The role of diagnostic imaging in the management of APN is discussed later. In some cases with an atypical presentation, imaging may be helpful to confirm the diagnosis of APN. In this setting, pre- and postcontrast computed tomography (CT) is the imaging procedure of choice in adults.

Microbial Etiology

Most cases of APN are caused by *Escherichia coli*. Other enterobacteriaceae, including *Klebsiella* species and *Proteus* species, are also occasionally implicated. Other gram-negative pathogens such as *Pseudomonas*, *Serratia*, *Enterobacter*, and *Acinetobacter* should be considered in health care-associated infections. *Enterococcus* is an uncommon pathogen in community-acquired infections, but it must be considered in health care-associated infections, including vancomycin-resistant enterococci. Other gram-positive pathogens include *Streptococcus agalactiae* and *Staphylococcus* species. Although a common cause of acute cystitis in young women, *Staphylococcus saprophyticus* is a rare cause of pyelonephritis; the finding of *Staphylococcus aureus* in a urine culture should always prompt a search for an extrarenal source of infection that might have served as a source of hematogenous seeding. A Gram stain of the urine is a simple and rapid test to exclude a gram-positive pathogen as the etiology of APN and guide the initial selection of empiric therapy.

The emergence of resistance to trimethoprim-sulfamethoxazole (TMP-SMX [Bactrim]) among *E. coli* has had a major impact on the approach to initial empiric antimicrobial therapy for APN. It is clear that the prevalence of resistance varies depending on

geographic region, and clinicians often do not have access to meaningful local resistance data. Recent reports of increasing fluoroquinolone resistance among uropathogens are of great concern, although overall resistance rates in North America remain low. Also concerning is the increasing prevalence of extended-spectrum β -lactamase (ESBL) *E. coli* and *Klebsiella* species, although these are mainly a concern in health care-associated infections in the U.S. Risk factors for infection with ESBL-producing organisms are poorly defined however recent infection or colonization with an ESBL-producing organism should be considered a risk factor for this pathogen. Other potential risk factors include older age, frequent antibiotic use in the preceding year and recent APN in patients with underlying diabetes.

Treatment

The first decision in the management of patients with APN is whether or not the patient requires hospitalization. Although prospective randomized trials are lacking, several retrospective studies as well as several prospective nonrandomized trials suggest that outpatient management is safe for many patients. Hospitalization should be considered for patients who cannot tolerate oral intake or who have severe pain or signs of severe sepsis. A strategy of initial management in the emergency department or an observation unit with an initial dose of parenteral antibiotic therapy, intravenous fluids, and symptomatic treatment of nausea and pain may be used in select patients to avoid hospital admission. Patients who will be treated as outpatients should have a stable social situation and the ability to contact the physician and return promptly if their symptoms worsen. Hospitalization is generally recommended for patients with complicated infections. Most experts believe that pregnant women with APN should always be hospitalized.

There are surprisingly few prospective randomized trials of the treatment of pyelonephritis. For patients who require hospitalization, parenteral therapy with an aminoglycoside, a third-generation cephalosporin, or a fluoroquinolone is recommended. At my institution we discourage fluoroquinolones for this indication because there are other effective alternatives and we wish to minimize the use of these very broad-spectrum agents in the hospital setting. Although resistance to TMP-SMX among uropathogenic *E. coli* appears to have leveled off and might actually be decreasing, this agent should not be used for empiric therapy of APN. If a ESBL-producing organism is suspected, empiric therapy should include a carbapenem. Because risk factors for ESBL-producing organisms are not well defined, consideration for coverage of these pathogens should be given in all patients with APN who have severe sepsis or septic shock.

If a gram-positive pathogen is suspected or suggested by the results of urine Gram stain, ampicillin or ampicillin-sulbactam (Unasyn) with or without an aminoglycoside can be used. Patients should receive intravenous therapy until they are clinically improving and able to reliably tolerate oral intake; oral therapy can be chosen based on the results of urine culture and susceptibility data. TMP-SMX, a fluoroquinolone, and ampicillin are all potential candidates for oral switch therapy. The narrowest spectrum, least expensive agent to which the isolated pathogen is susceptible should be chosen. Despite in vitro susceptibility data, first- and second-generation cephalosporins have a poor track record in the treatment of APN and are generally not recommended, with the exception of pyelonephritis in pregnancy.

Bacteremic patients might take longer to respond but do not require more prolonged parenteral therapy. The total duration of therapy for pyelonephritis is generally 14 days. Seven days of therapy with ciprofloxacin for uncomplicated APN has been shown to be effective as has 5 days of therapy with high-dose (750 mg daily) levofloxacin, and these regimens are endorsed by the current guidelines. Longer courses of therapy may be required for select patients with complicated pyelonephritis. For outpatients, initial empiric therapy with a fluoroquinolone is recommended, with adjustment of therapy, if needed, based on the results of urine culture. All of the currently available fluoroquinolones can be used, with the exception of moxifloxacin (Avelox),

BOX 3**Antimicrobial Therapy for the Management of Acute Pyelonephritis****Parenteral Regimens**

- Ampicillin 2 g q4h–q6h
- Ampicillin-sulbactam (Unasyn) 3 g q6h
- Ceftriaxone (Rocephin) 2 g q24h
- Ciprofloxacin (Cipro) 400 mg q12h
- Gentamicin (Garamycin) 3–5 mg/kg q24h
- Levofloxacin (Levaquin) 500 mg q24h

Oral Regimens

- Amoxicillin 500 mg q8h
- Ciprofloxacin 500 mg q12h
- Ciprofloxacin XR 1000 mg q24h
- Levofloxacin 250 mg q24h
- Trimethoprim-sulfamethoxazole DS (Bactrim DS) 160/800 mg q12h

which does not achieve adequate levels in the urine. Although it is useful in the treatment of cystitis, norfloxacin (Noroxin) is not recommended for the treatment of APN because it does not achieve sustained tissue or serum levels. Suggested antimicrobial dosing regimens for APN are outlined in [Box 3](#).

Imaging

Imaging is generally not needed in patients with uncomplicated APN. For patients with complicated infections (e.g., history of stones, prior renal surgery), renal ultrasound with abdominal plain films is considered an acceptable alternative to excretory urography. For patients with diabetes or other immunocompromise and for patients who fail to respond after 72 hours of appropriate antibiotic therapy, pre- and postcontrast CT is the imaging procedure of choice.

Follow-up

Most patients will respond to appropriate antibiotic therapy. Follow-up urine cultures to document microbiological response are not recommended in patients who have responded clinically.

RENAL CALCULI

Method of

William J. Somers, MD; and Tia D. Chaffin, RN

**CURRENT DIAGNOSIS**

- Renal calculi can present acutely or more often are discovered as an incidental finding on an unrelated radiologic study.

- Ureteral calculi present with either acute onset of excruciating flank pain or a gradual onset preceded by generalized abdominal discomfort.
- Renal colic pain can radiate from the ipsilateral flank to the lower abdomen, often mimicking pain from cholecystitis, appendicitis, or ovarian conditions such as torsion or ruptured ovarian cysts.
- Physical examination will reveal an anxious patient experiencing sharp, excruciating costovertebral pain. Pain commonly occurs in waves. Percussion of the flank reveals exquisite tenderness. The patient cannot find a comfortable resting position.
- Computed tomography (CT) scan without intravenous contrast (CT stone protocol) is the definitive diagnostic study. Abdominal plain film and renal ultrasonography are not as accurate as CT.
- Urinalysis may demonstrate either microscopic or gross hematuria. Pyuria in the absence of bacteriuria is common and does not always indicate infection.
- Nausea, vomiting, and low-grade fever are common. Temperature over 101°F suggests infection and is an acute urologic emergency.

**CURRENT THERAPY**

- Asymptomatic renal stones can be managed electively with observation or surgical intervention.
- Once the acute episode is controlled with intravenous analgesics and the patient is discharged from the emergency department, ureteral obstruction can be managed with oral analgesics, liberal oral fluid intake, and expectant observation if the patient is afebrile and the stone is 5 mm or less in size.
- A follow-up renal ultrasound should be obtained 2 weeks after the first presentation of symptoms. If hydronephrosis persists or if the stone has not passed, the patient should be referred to a urologist.
- Fever and/or leukocytosis regardless of a clean urine sample indicates possible pyonephrosis, a surgical emergency, and the patient should be hospitalized for definitive treatment.
- Patients who are calcium stone formers should be encouraged to maintain a low-sodium, low-protein, normal-calcium diet and increase oral intake of fluids to 2 L daily.
- Patients who are recurrent calcium stone formers should be offered thiazide diuretics in addition to maintaining the dietary measures to limit stone formation.
- Patients who form uric acid stones should be encouraged to maintain a liberal oral intake of fluids and try to maintain an alkaline urine with potassium citrate (Urocit-K).

Epidemiology

The incidence of urinary tract stone disease has more than doubled in the last three decades, including an increase in the pediatric population. Causes include change in diet to higher salt and animal protein intake, high rates of obesity, and warmer climates. Currently about 10% of men and 7% of women will experience an episode of urolithiasis in their lifetime. Caucasian males have the highest rate of stone disease, whereas African-American females have the lowest rate. The incidence of renal stones rises between 20 and 60 years of age and then begins to decrease. The peak age for urinary tract stones is between 40 and 60 years. Without medical treatment, there is a 50% likelihood of recurrence of urolithiasis. The annual expenditure in the United States for treatment of urinary tract stones exceeds \$5 billion, making it a significant social and economic burden.

Risk Factors

The most significant correlation with stone formation is low urine output. This can be attributed to poor fluid intake or living or working in higher temperatures. The risk of kidney stones in the

Epidemiology

The incidence of urinary tract stone disease has more than doubled in the last three decades, including an increase in the pediatric population. Causes include change in diet to higher salt and animal protein intake, high rates of obesity, and warmer climates. Currently about 10% of men and 7% of women will experience an episode of urolithiasis in their lifetime. Caucasian males have the highest rate of stone disease, whereas African-American females have the lowest rate. The incidence of renal stones rises between 20 and 60 years of age and then begins to decrease. The peak age for urinary tract stones is between 40 and 60 years. Without medical treatment, there is a 50% likelihood of recurrence of urolithiasis. The annual expenditure in the United States for treatment of urinary tract stones exceeds \$5 billion, making it a significant social and economic burden.

Risk Factors

The most significant correlation with stone formation is low urine output. This can be attributed to poor fluid intake or living or working in higher temperatures. The risk of kidney stones in the

United States increases from the West to the East and from the North to the South. The region with the highest prevalence of kidney stones has been labeled the “stone belt.” It applies to the region in the Southeast United States that includes Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, South Carolina, Tennessee, and Virginia. Other significant risk factors for urolithiasis include previous history of stone disease and family history of stone disease. Physical abnormalities of the urinary tract can increase stone formation. Systemic risk factors include hyperparathyroidism, intestinal disorders, bariatric surgery, diabetes, hypertension, obesity, frequent urinary tract infections, urinary retention, gout, and spinal cord injury. Dietary risk factors include diets high in sodium, high in animal protein, low in citrus, high in oxalate, or low in calcium. Contrary to popular belief, water quality, source, and hardness do not affect the likelihood of stone formation. Stones are more likely to form in patients with very high or very low urinary pH levels, hypercalciuria, hyperuricosuria, hyperoxaluria, or hypocitruria.

Pathophysiology

Urine exists in four states: *undersaturated*, in which no crystals will form; *metastable*, in which concentration of salts is high but urine inhibitors prevent supersaturation; *saturated*, where salts, when added, will not dissolve; and *supersaturated*, which is an unstable solution and crystals can form spontaneously. Urine is generally in a supersaturated state.

The major theory describing stone formation begins with spontaneous crystallization in a supersaturated urine. This tiny crystal nucleus then attaches to a cell membrane in the collecting tubule. This nidus then attracts other crystals and cell debris, forming a tiny calcification that gradually grows larger as these particles continue to adhere to the mass. Some of these calcifications break off and proceed to the collecting system. If this transit time is slow, the crystal may remain in place indefinitely. Calcium oxalate is the most common type of stone.

Another theory suggests that spontaneous crystallization occurs at damaged sites along the nephron. These crystals arise from the damaged cell wall, remain fixed in place, and attract further crystal accumulation. Initial cell damage is believed to occur from high calcium oxalate levels. Some studies implicate oxalate as the sole cause for renal tubule cell damage. Pak showed that the calcium oxalate concentration is four times higher in urine than its solubility in water. This higher concentration then has an adverse effect on the cells. This is an interesting but as yet unproved theory.

Historically Randall’s plaques were believed to provide a base for crystal nucleation in the collecting system. These plaques are located in the loop of Henle just below the urothelium in the renal papillae. As they grow they erode through the urothelium, forming a nidus for crystal attachment and growth. These plaques are often seen during ureteroscopic examination of the renal collecting system.

Since a supersaturated salt solution will spontaneously generate crystal formation, there must be some inherent factors that inhibit crystal formation. Citrate, magnesium, and pyrophosphates are the major stone inhibitors naturally found in urine. Citrate is the major inhibitor. Citrate complexes with calcium, reducing its availability and thus preventing spontaneous precipitation of calcium oxalate, as well as inhibiting the calcium crystal nucleation. Magnesium binds to oxalate and reduces its availability to bind with calcium.

Other inhibitors such as Tam-Horsfall proteins have been identified, but their role is not fully understood.

Calcium Stones

Calcium stones are the most common type of stone in the United States. Calcium stone formers all present with hypercalciuria, which is the first step in stone formation. About 10% of calcium is absorbed in the colon, while 30% to 40% is absorbed in the small intestine. The kidney filters 270 mmol of calcium daily and absorbs all but approximately 4 mmol of it. The active form of vitamin D is the most potent stimulator of intestinal calcium absorption. Calcium transport is regulated at three sites: intestine,

bone, and kidney. Low calcium intake stimulates increased calcium absorption, which stimulates parathyroid hormone (PTH). PTH regulates the conversion of 25-hydroxyvitamin D to 1,25-(OH)₂D₃ or calcitriol. PTH also stimulates the mobilization of calcium from bone through the action of osteoclasts and increases the absorption of calcium by renal tubules.

The classic model for hypercalciuria describes three types:

1. Absorptive: the most common form, occurring in 55% of stone formers, and caused by an increase in intestinal absorption of calcium. Absorptive hypercalciuria can be categorized as type 1, in which urinary calcium remains high despite a low-calcium diet, and type 2, in which urinary calcium is normalized on a low-calcium diet.
2. Resorptive: identified in approximately 5% of stone formers and usually seen in patients with hyperparathyroidism. Excessive PTH secretion causes increased production of calcitriol (1,25-(OH)₂vitamin D₃), which causes increased intestinal absorption of calcium. These patients present with hypercalciuria, hypercalcemia, and reduced phosphatemia. Patients with serum calcium levels above 10 should be evaluated for hyperparathyroidism.
3. Renal: commonly called renal leak hypercalciuria and due to a defect in calcium reabsorption in the proximal tubule. It is characterized by high fasting urine calcium levels, normal serum calcium levels, and elevated PTH.

Other causes of hypercalcemia include sarcoidosis, granulomatous diseases, malignancy, and glucocorticoid use. Malignancy is the most common cause of hypercalcemia in hospitalized patients. Of the malignancies, lung and breast are most common. It is believed the tumors produce cytokines and other factors, which cause bone destruction through the action of osteoclasts, resulting in bone destruction and subsequent hypercalcemia. Glucocorticoids stimulate the release of PTH. Nephrolithiasis is common in patients with Cushing syndrome.

Oxalate

Oxalates cause increased urinary saturation of calcium oxalate, which in turn can cause calcium oxalate stone formation. Primary hyperoxaluria is an autosomal recessive disorder responsible for end-stage renal failure before the age of 15 in 50% of young patients. Normally glycopyrates are converted to glycine, but in these children they are converted to oxalates. Combined liver and kidney transplants are the primary treatment for them.

Enteric hyperoxaluria is the most common cause of acquired hyperoxaluria. It is associated with chronic diarrheal conditions, loss of large segments of small bowel, and intrinsic bowel disease. Loss of fat absorption in these patients results in increased oxalate absorption. Oxalate readily binds to calcium, which can ultimately initiate stone formation.

Renal Tubular Acidosis

Renal tubular acidosis (RTA) describes a defect in urinary acidification resulting in a metabolic acidosis. Hypokalemia, elevated urine pH, hypocitraturia, and hypercalciuria can lead to stone formation. There are three types of RTA. Patients with type 1 or distal RTA are at high risk for stone formation. Calcium phosphate stones are found in patients with type 1 RTA, which should prompt the physician to conduct further diagnostic testing. Treatment can decrease the rate of stone formation. Type 2 or proximal RTA is not associated with nephrolithiasis. Type 4 RTA is not commonly associated with stones, but they can occur.

Uric Acid Stones

Uric acid stones are unique in that they can be dissolved medically. Uric acid is the end product of purine metabolism. Humans lack the enzyme uricase, which is the final step in the metabolism of uric acid to allantoin. Uric acid is not readily soluble in normally acidic urine. Hyperuricosuria is found in patients with gout, type 2 diabetes, and Lesch-Nyan syndrome. Alkalinizing urine is the primary treatment for asymptomatic uric acid renal stones.

Prevention

The time-honored key to prevention for all stones is increased water intake. Multiple studies have shown that increasing oral intake of fluids to produce a 2- to 2.5-liter daily urine output is the most efficient and least expensive way to prevent most stones. Additional measures include a low-salt diet, limiting protein, and avoiding foods with high oxalate content.

When available, the stone should be analyzed to provide a diagnosis and a specific plan tailored to the type of stone and underlying pathologic cause if present. A complete medical history should be obtained, which can identify an underlying cause such as hyperparathyroidism, Cushing syndrome, type 2 diabetes, antiviral medication, and so forth. The American Urological Association has published guidelines for prevention and management of nephrolithiasis, which are summarized later.

Common misconceptions about the type of fluid patients should be drinking include avoiding alcohol, coffee, colas, wine, and beer. Only one study reported a decrease in the recurrence rate when patients avoided colas, but the rate was so low it was not clinically significant. In general, there is no definite consensus on avoidance of certain fluids or the selection of certain fluids to help prevent recurrent calcium oxalate stones.

Contrary to popular belief, a low-calcium diet is associated with an increase in calcium oxalate stones. It is believed that low calcium intake results in increased oxalate absorption from the gut and higher levels of urinary oxalate. Recommendations suggest daily calcium intake of 1 to 2 g. A low-sodium diet has been shown to decrease urinary calcium excretion, but in general compliance with a low-sodium diet is difficult. A high-oxalate diet has been shown to increase stone recurrence. Patients should be counseled to limit foods high in oxalate. Oxalate content of various foods is readily available through online searches. Here again a 1- to 2-g daily intake of calcium seems to offset the risk of stone recurrence in these patients with high urinary oxalate levels. Calcium supplements in older women may lead to higher risk of stone disease, but there are conflicting reports. If a patient is taking supplements, baseline 24-hour urine collections should be obtained to monitor urinary calcium levels and make dietary adjustments as needed. Since urinary citrate is a stone inhibitor, patients should be encouraged to add fruits and vegetables to their diet. There is no hard evidence that drinking lemonade or adding lemon to tap water prevents recurrent stone formation. Animal protein intake contributes to an acidic urine, which promotes stone formation. Patients should limit their weekly intake of meats, cheese, eggs, and fish.

There are no definitive studies demonstrating a beneficial effect of reducing purine intake in lowering uric acid stone formation. But in general, patients with recurrent calcium or uric acid stones and a diet high in purines may benefit from reducing their intake of high-purine foods. These include various seafood, shellfish, water fowl, organ meats, game meats, pork, and poultry. Simply restricting red meats without limiting other high-purine foods is not beneficial.

For those patients who have failed dietary measures or those who continue to form stones after altering their diets, medical therapy is indicated.

Thiazide diuretics are the gold standard for prevention of recurrent calcium oxalate stones. Chlorthalidone¹ 25 mg daily, hydrochlorothiazide¹ 50 mg daily, and indapamide¹ 2.5 mg daily are all well tolerated (patients should be monitored for hypokalemia). Potassium citrate (Urocit-K) 10 to 20 mEq daily can be prescribed for patients with recurrent calcium oxalate stones, uric acid stones, and cystine stones. Sodium citrate is an alternate choice but risks creating a higher urinary calcium load. A baseline 24-hour urinary citrate level and follow-up study 6 months later will determine if therapy is effectively raising urinary citrate levels. Uric acid stones can be dissolved with aggressive urinary alkalization using potassium citrate. Patients with hyperuricosuria and recurrent calcium oxalate or uric acid stones should be offered allopurinol (Zyloprim) 300 mg daily. Patients with cystine stones should be

managed with high fluid intake, urinary alkalization with potassium citrate, and reduction in sodium and protein intake. Thiol drugs should be prescribed if dietary measures fail. Alpha-mercaptopropionyl glycine (tiopronin, Thiola) 800 mg daily in three divided doses is the treatment of choice. An alternative preparation, d-penicillamine (Cuprimine), is associated with more severe side effects and should be a second-line choice.

Struvite stones occur in the presence of chronic urinary infection. Treatment of the stone with sterilization of the urinary tract is the best option. If surgery is not an option, suppressive antibiotic therapy may help.

According to one recent study, only one in three patients will follow recommendations to prevent recurrent stones.

Clinical Manifestations and Diagnosis

Nonobstructing renal or bladder stones may be found incidentally on imaging studies for other ailments or disease surveillance. A patient may present with only micro or gross hematuria, recurrent urinary tract infections, or a decrease in renal function. Most patients seek medical attention when the stone progresses into the ureter, causing some degree of obstruction. The patient may present with significant back or side pain that varies in intensity and often comes in waves. The pain may radiate to the groin or lower abdomen. The patient is often unable to get comfortable in any one position and may pace the floor. Urinary symptoms may include hematuria, dysuria, frequency, urgency, or difficulty urinating. If infection is also present, patients may present with cloudy or foul-smelling urine, fever, chills, and flank pain. Nausea and vomiting may also be present. If the stone has passed into the bladder neck or urethra, the patient may present with inability to urinate or urinating small amounts of urine. Some patients may present with vague symptoms of aching flank pain at times.

When a patient presents with symptoms of a possible urinary tract calculi, a complete medical history should be obtained, including any previous kidney stones or family history of kidney stones. Patients should be asked about systemic disorders increasing stone formation risk, as well as factors such as diet, fluid intake, and professional work conditions including high climate or increased perspiration at work.

A CT scan without intravenous contrast is the most accurate way of diagnosing renal and ureteral stones and is the first choice. An abdominal plain film is an unreliable and inaccurate diagnostic tool. It should never be ordered in an acute situation. Small 1- to 2-mm stones are difficult to see on plain films. Uric acid stones, cystine stones, and triamterene stones are radiolucent and are not visible on plain films. Renal ultrasound is a good tool to identify and follow hydronephrosis but does not accurately identify renal stones and cannot be used to follow ureteral stones. It too does not play a role in the acute situation. A CT stone protocol is readily available in medical centers and outpatient facilities. It can be performed in less than 15 minutes, and no preparation is required. Diagnosis is instantaneous and accurate. Intravenous pyelography is no longer considered an appropriate study. Magnetic resonance imaging (MRI) can be used to diagnose ureteral stones in pregnant females, but interpretation is dependent on the experience of the radiologist and his or her familiarity with the technique. It is not frequently used for this purpose.

Differential Diagnosis

Asymptomatic nephrolithiasis is usually discovered as an incidental finding on an unrelated radiologic study. Intense renal shadowing on abdominal ultrasound is suggestive for renal stone. A calcification overlying the renal shadow can suggest renal stone, but the differential diagnosis includes arterial calcifications, stomach or intestinal contents, calcified lymph nodes, renal cell tumors, and cholelithiasis. Pelvic calcifications seen on plain films can be ascribed to phleboliths, ovarian calcifications, prostate calcifications, appendoliths, vascular calcifications, and bladder stones. Plain films should not be expected to provide an accurate diagnosis. Unless the renal stone is obstructing the renal pelvis, it does not cause pain. Patients who present with back pain and

¹Not FDA approved for this indication.

nonobstructing renal stones should not be treated for renal colic. Further diagnostic evaluation is indicated.

In contrast to asymptomatic renal stones, ureteral stones almost always present with dramatic onset of excruciating pain. The diagnosis is almost instantaneous. Renal colic is localized to either cost-overtebral area. Nausea and vomiting are common. Pain is not relieved by changing position. As the stone progresses distally, the pain can mimic multiple acute abdominal conditions. The differential diagnosis of right lower quadrant abdominal pain includes:

- Acute appendicitis
- Ovarian conditions (e.g., rupture, ectopic pregnancy)
- Incarcerated inguinal hernia
- Cholecystitis
- Testicular torsion
- Diverticulitis, but very rarely

The differential for left lower quadrant pain is the same as for right lower quadrant pain with the exception of appendicitis and cholecystitis for obvious reasons. Diverticulitis is more commonly seen in the descending colon than in the ascending colon.

Treatment

Renal Stones

Asymptomatic renal stones pose a dilemma: whether to treat or not. One of the largest retrospective studies evaluated the natural history of these stones based on their location and size. Over 3 years of active observation, the study found that 60% of stones remained asymptomatic, 7% passed spontaneously, and 20% were operated on for pain. Less than 30% of the stones caused renal colic. Most of the studies determined that lower pole stones did not pass spontaneously but grew in size more quickly than stones in the upper collecting system. These upper pole stones also passed more spontaneously. Patients should be offered treatment of renal stones if larger than 5 mm and in the upper pole of the kidney. Lower pole stones can be followed if the patient is not anxious to have treatment or if the stone has been present for years without a change in size or location. Stones 10 mm or larger should be treated regardless of position. These stones could pass spontaneously and will require emergency surgery. All Staghorn calculi should be treated unless comorbidities prevent surgical intervention. Autonephrectomy is the ultimate outcome for untreated staghorn calculi.

Once a decision is made to treat a renal stone, the next step is to decide which method is best for the patient. Factors to consider are the size of the stone, stone composition, location, number of stones, and body habitus. Extracorporeal shock wave lithotripsy (ESWL) is not recommended for stones larger than 20 mm. Stones between 10 and 20 mm can be treated but may require multiple ESWL treatment sessions. Percutaneous nephrostolithotomy (PNL) is the best choice for these larger stones. All staghorn and partial staghorn calculi should be treated with PNL. For stones less than 10 mm, ESWL is a good choice if the stone is visible on plain film and the patient is not morbidly obese. Most ESWL units cannot propel shockwaves into the kidney if the distance from the treatment head to the stone is more than 10 cm. ESWL should not be used on very dense stones with Hounsfield units greater than 800. These stones either will not fracture or will require multiple ESWL sessions. ESWL may not be successful for treating radiolucent stones such as uric acid stones, cysteine stones, and indinavir stones. In these cases flexible ureteroscopy using holmium laser energy is the treatment of choice. ESWL for lower pole stones of any size is not as successful as flexible ureteroscopy with laser energy. ESWL can fracture these stones, but the spontaneous clearance rate of the fragments is only 60%.

Medical dissolution treatment should be offered to patients with uric acid or cystine stones. Unfortunately compliance with a medical and dietary regimen is dismal and most will need surgical intervention.

Ureteral Stones

It is generally accepted that stones less than 5 mm will pass spontaneously over 3 months. Most stones pass sooner than that.

The following is a general guide for treatment of the acute episode:

- CT stone protocol to identify the number, size, and location of the stone(s).
- Intravenous narcotic and antiemetic if necessary.
- Urinalysis to evaluate for bacteria. Pyuria and hematuria are common and not signs of infection. If bacteria are present obtain culture and begin empiric antibiotics.
- Abdominal plain film. If the stone is visible, this will provide a way to follow the stone.
- Complete blood count, electrolytes.
- Hydronephrosis will be present but does not dictate treatment.
- Once pain is controlled, the patient is able to tolerate PO fluids, and laboratory tests are acceptable, the patient can be discharged with oral narcotics and an alpha-blocker. Oxycodone 5 mg PO every 4 to 6 hours is a good choice for pain control. Tamsulosin (Flomax)¹ 4 mg PO daily has been shown in many studies to assist in spontaneous stone passage. It can be prescribed to women as well.

Patients with any of the following signs and/or symptoms should be admitted and urologic consultation obtained as soon as possible:

- Fever and leukocytosis, or signs of sepsis
- Solitary kidney
- Uncontrolled pain or vomiting
- Bilateral ureteral stones
- Stones larger than 5 to 7 mm
- Ureteropelvic junction stones larger than 5 mm

The choice to insert a ureteral stent depends on the urologist and his or her assessment of the situation. There are no strict rules and the choice is left to the discretion of the urologist.

Once the patient is discharged, he or she should be encouraged to drink as much fluid as possible and strain the urine for the stone. If the stone is visible on plain film, the patient should return to the office in 2 weeks for a renal ultrasound and abdominal plain film. If the stone is progressing and the patient is not experiencing significant pain, observation can continue. If the renal sonogram demonstrates increasing hydronephrosis, urologic consultation is indicated.

If the stone has not passed within 30 days, a urologic consultation should be obtained. It is not uncommon for patients to pass the stone and not see it in the urinary stream. Renal sonography is very useful to identify resolution of the hydronephrosis in these cases.

Once the patient collects the stone, it should be sent for analysis. A follow-up renal sonogram should be obtained 6 to 8 weeks after passage to identify any residual silent hydronephrosis. If hydronephrosis is present, urologic consultation should be obtained.

Complications

The most serious complication of nephrolithiasis is pyonephrosis, infected urine behind an obstructing stone. This is a urologic emergency requiring immediate drainage of the obstructed kidney. A percutaneous nephrostomy is the quickest way to achieve drainage.

Stones can become lodged in the ureter and remain asymptomatic. They eventually become impacted. The urothelium surrounds and covers the stone, trapping it in place over time. Silent hydronephrosis continues until the kidney eventually becomes atrophic and nonfunctioning. This is the reason either a CT or renal sonogram must be obtained 6 to 8 weeks after the patient passes a stone or is no longer symptomatic.

Failure to identify treatable conditions such as hyperparathyroidism, hyperuricemia, and cystinuria contributes to recurrent stone formation and morbidity associated with stone passage.

Surgical complications from ureteroscopy include pain, hemorrhage, infection, ureteral perforation, and ureteral avulsion. Ureteral avulsion should never occur and is the most feared

¹Not FDA approved for this indication.

complication by every urologist. Ureteral stents can usually manage any other ureteral complication.

Complications from ESWL include hemorrhage, perirenal hemorrhage, failure to disintegrate the stone, and retained stone fragments. Some studies have shown an association between uncomplicated ESWL and delayed onset of diabetes and hypertension.

Monitoring

Patients with stones should have yearly radiologic studies for at least the first 5 years after they present with a stone. There is a 50% chance they will develop another stone during that time. CT is the most accurate, but abdominal plain films are useful if the stones are visible. There is no place for renal sonography for monitoring patients. If the stone burden increases over time, urologic consultation should be obtained.

If a 24-hour urine collection is obtained and dietary or medical treatment is recommended, the metabolic evaluation should be repeated 6 months later to determine if the plan is effective. Not surprisingly, most patients will not comply with the recommendations. Periodic 24-hour metabolic evaluations every few years are a good way to remind patients to self-monitor their fluid intake and modify their diets if necessary.

TRAUMA TO THE GENITOURINARY TRACT

Method of

Bahaa S. Malaeb, MD; and Yooni Yi, MD

The genitourinary tract is involved in 3% to 10% of trauma cases. The kidney, followed by the bladder and urethra, are the most commonly involved genitourinary organs. In most cases, injury to the genitourinary tract is not isolated, and the initial evaluation of the urologic injuries should emphasize the context of the patient's associated injuries that might be more pressing or life-threatening. Still, early involvement of the urologist is prudent to help plan further interventions. The spectrum of genitourinary injuries is widespread, and management can range from immediate repair to temporization with delayed reconstruction. The goal of a urologist in the trauma setting is to establish urinary drainage in order to optimize kidney function, minimize hemorrhage, and control urinary extravasation to reduce associated complications such as infection or ileus.

Renal Trauma

Renal injury occurs in 1% to 5% of all trauma cases. Blunt impact accounts for the majority of renal injuries (90%–95%) and causes damage secondary to direct organ injury or disruption of the kidney from its attachments (e.g., renal hilum and ureteropelvic junction). Penetrating trauma most commonly is caused by stabbing or gunshot wounds. The damage from penetrating injury can be limited to the tract of the stab wound, or it can be more extensive secondary to necrosis from energy transfer and the blast effect of high-velocity bullets. The history is crucial in the diagnosis of renal

Figure 2 American Association for the Surgery of Trauma grading system for traumatic renal injuries: grade I, renal contusion and subcapsular hematoma; grade II, cortical laceration and perirenal hematoma; grade III, laceration into medulla or segmental renal artery thrombosis without a parenchymal injury; grade IV, laceration involving the collecting system, with or without a devascularized segment and contained vascular injury; grade V, renal artery thrombosis, avulsion of the renal pedicle, and shattered kidney. (From McAninch JW [ed]: *Traumatic and Reconstructive Urology*. Philadelphia, WB Saunders, 1996.)

injury and should include the mechanism of trauma as well as any preexisting kidney disease or condition that might contribute to worsening renal function. Hematuria has a very poor correlation with degree of injury, because disruption of the ureteropelvic junction, arterial disruption or thrombosis, and other severe injuries can exist in a setting with no hematuria.

The American Association for the Surgery of Trauma (AAST) classifies renal injuries into five grades (Figures 1 and 2):

- Grade 1: Nonexpanding subcapsular hematoma/contusion with absence of parenchymal injury
- Grade 2: Less than 1 cm laceration into the renal cortex, not extending into the collecting system, with a nonexpanding hematoma confined to the perirenal fascia
- Grade 3: Greater than 1 cm laceration, extending through the renal cortex and medulla but not the collecting system
- Grade 4: Laceration extending to the collecting system with urinary extravasation or a segmental vascular injury with contained hematoma; renal artery thrombosis
- Grade 5: Shattered kidney or renal pedicle avulsion

Renal injury should be suspected in any trauma patient who has a penetrating injury with gross or microscopic hematuria (>2 red

complication by every urologist. Ureteral stents can usually manage any other ureteral complication.

Complications from ESWL include hemorrhage, perirenal hemorrhage, failure to disintegrate the stone, and retained stone fragments. Some studies have shown an association between uncomplicated ESWL and delayed onset of diabetes and hypertension.

Monitoring

Patients with stones should have yearly radiologic studies for at least the first 5 years after they present with a stone. There is a 50% chance they will develop another stone during that time. CT is the most accurate, but abdominal plain films are useful if the stones are visible. There is no place for renal sonography for monitoring patients. If the stone burden increases over time, urologic consultation should be obtained.

If a 24-hour urine collection is obtained and dietary or medical treatment is recommended, the metabolic evaluation should be repeated 6 months later to determine if the plan is effective. Not surprisingly, most patients will not comply with the recommendations. Periodic 24-hour metabolic evaluations every few years are a good way to remind patients to self-monitor their fluid intake and modify their diets if necessary.

TRAUMA TO THE GENITOURINARY TRACT

Method of

Bahaa S. Malaeb, MD; and Yooni Yi, MD

The genitourinary tract is involved in 3% to 10% of trauma cases. The kidney, followed by the bladder and urethra, are the most commonly involved genitourinary organs. In most cases, injury to the genitourinary tract is not isolated, and the initial evaluation of the urologic injuries should emphasize the context of the patient's associated injuries that might be more pressing or life-threatening. Still, early involvement of the urologist is prudent to help plan further interventions. The spectrum of genitourinary injuries is widespread, and management can range from immediate repair to temporization with delayed reconstruction. The goal of a urologist in the trauma setting is to establish urinary drainage in order to optimize kidney function, minimize hemorrhage, and control urinary extravasation to reduce associated complications such as infection or ileus.

Renal Trauma

Renal injury occurs in 1% to 5% of all trauma cases. Blunt impact accounts for the majority of renal injuries (90%–95%) and causes damage secondary to direct organ injury or disruption of the kidney from its attachments (e.g., renal hilum and ureteropelvic junction). Penetrating trauma most commonly is caused by stabbing or gunshot wounds. The damage from penetrating injury can be limited to the tract of the stab wound, or it can be more extensive secondary to necrosis from energy transfer and the blast effect of high-velocity bullets. The history is crucial in the diagnosis of renal

Figure 1 Computed tomography scan demonstrating large right perirenal hematoma and thrombosed posterior segmental artery. This was classified as a grade IV renal injury.

Figure 2 American Association for the Surgery of Trauma grading system for traumatic renal injuries: grade I, renal contusion and subcapsular hematoma; grade II, cortical laceration and perirenal hematoma; grade III, laceration into medulla or segmental renal artery thrombosis without a parenchymal injury; grade IV, laceration involving the collecting system, with or without a devascularized segment and contained vascular injury; grade V, renal artery thrombosis, avulsion of the renal pedicle, and shattered kidney. (From McAninch JW [ed]: *Traumatic and Reconstructive Urology*. Philadelphia, WB Saunders, 1996.)

injury and should include the mechanism of trauma as well as any preexisting kidney disease or condition that might contribute to worsening renal function. Hematuria has a very poor correlation with degree of injury, because disruption of the ureteropelvic junction, arterial disruption or thrombosis, and other severe injuries can exist in a setting with no hematuria.

The American Association for the Surgery of Trauma (AAST) classifies renal injuries into five grades (Figures 1 and 2):

- Grade 1: Nonexpanding subcapsular hematoma/contusion with absence of parenchymal injury
- Grade 2: Less than 1 cm laceration into the renal cortex, not extending into the collecting system, with a nonexpanding hematoma confined to the perirenal fascia
- Grade 3: Greater than 1 cm laceration, extending through the renal cortex and medulla but not the collecting system
- Grade 4: Laceration extending to the collecting system with urinary extravasation or a segmental vascular injury with contained hematoma; renal artery thrombosis
- Grade 5: Shattered kidney or renal pedicle avulsion

Renal injury should be suspected in any trauma patient who has a penetrating injury with gross or microscopic hematuria (>2 red

blood cells per high-power field), a blunt injury with gross hematuria, or a blunt injury with microscopic hematuria and shock (systolic blood pressure <90 mm Hg). In addition, imaging of the urinary tract should be obtained in children who have more than 50 red blood cells per high-power field even in the absence of hypotension.

In a stable patient, radiographic evaluation should consist of computed tomographic (CT) scanning with intravenous contrast and delayed images showing opacification of the collecting system and ureters. In the absence of a CT scan in a patient who is transported directly to the operating room for exploration, an intraoperative single-film intravenous pyelogram can be performed to confirm that two functioning kidneys are present; however, the poor quality of the images makes them unreliable for staging purposes.

Kidney exploration is indicated for the unstable patient in whom renal injury is thought to be the reason for a life-threatening and persistent hemorrhage. Another absolute indication for renal exploration and revascularization is renal artery hilar avulsion or renal artery thrombosis, if bilateral or in a solitary kidney. In patients undergoing exploratory laparotomy for associated injuries, renal exploration should be performed only in the presence of an expanding or pulsatile hematoma. Exploration of a nonexpanding, nonpulsatile hematoma is associated with a higher rate of nephrectomy and should be avoided. Almost all other injuries can be managed conservatively or with minimally invasive methods.

Nonoperative management consists of supportive care with intravenous hydration, antibiotics, bedrest, and serial measurements of hemoglobin and hematocrit. Patients can ambulate after they are clinically stable, gross hematuria has resolved, and the hemoglobin and hematocrit have been relatively constant over 24 hours.

Routine early follow-up imaging for grades 1 to 3 blunt renal injury is unnecessary. Any imaging should be motivated by a change in the patient's clinical situation or laboratory values. Grade 4 renovascular injuries can be followed up clinically. Follow-up imaging is indicated for patients with grade 4 or 5 injuries with urinary extravasation to assess for worsening urinoma or hematoma that might require further intervention. Additionally, there should be periodic monitoring of blood pressure following renal trauma.

Ureteral Trauma

Trauma to the ureter is rare, most likely because of its retroperitoneal and bony pelvis location, its relatively small caliber, and its mobility. The etiology of ureteric trauma is mostly iatrogenic (75% of all ureteric injuries); 73% of iatrogenic injuries occur secondary to gynecologic procedures, and the remainder are divided between general surgery and urologic procedures. Ureteral injury should be suspected in all cases of penetrating trauma to the abdomen, especially with high-velocity projectiles, because of the blast effect.

The AAST has classified ureteric injuries into five grades of severity:

- Grade 1: Hematoma only
- Grade 2: Injury involving less than 50% of the circumference of the ureter
- Grade 3: Injury involving more than 50% of the circumference of the ureter
- Grade 4: Complete transection with less than 2 cm of devascularization
- Grade 5: Complete transection with more than 2 cm of devascularization

The diagnosis usually is made intraoperatively if a high suspicion of ureteric injury is present or postoperatively by imaging obtained for investigation of fistula formation or clinical signs of upper tract obstruction. Hematuria is not a sensitive marker for ureteral injury, therefore lack of hematuria does not portend a lack of ureteral injury. For noniatrogenic injuries, imaging should be obtained in patients who had rapid deceleration or penetrating injuries to

Figure 3 Intravenous pyelogram demonstrating extravasation of urine from right mid-ureter.

the flank. Imaging modalities used are usually intravenous pyelography, CT scanning with intravenous contrast and delayed images, and retrograde pyelography. Findings indicative of ureteral injury include contrast extravasation, ureteral narrowing, and delayed peristalsis (Figure 3). Alternatively, the ureters may be interrogated intraoperatively by using direct inspection, by injecting intravenous methylene blue¹ and watching for leakage of dye, or by passing a ureteral catheter (if it passes easily, an injury is unlikely).

Grade 1 and 2 injuries can be managed initially by placement of a ureteral stent. If grade 2 or 3 injuries are identified immediately during exploration for a suspected ureteric injury, they can be managed by primary closure of the ureteric injury over an internal stent and placement of a nonsuction abdominal drain, as long as there is no associated thermal injury or necrosis. Grade 3 to 5 injuries usually require débridement of nonviable ends with reanastomosis over an internal ureteral stent or more complicated surgical procedures involving mobilization of the bladder and reimplantation of the ureter into the bladder. The type of ureteral repair depends on the amount of devitalized tissues and the location of the injury (proximal, middle, or distal ureter). Ureteroureterostomy, transureteroureterostomy, ureterocalicostomy, renal autotransplantation, ureteroneocystostomy with or without Boari flap or psoas hitch, and bowel interposition are all treatment options for various degrees of ureteral injuries.

Bladder Trauma

Blunt trauma accounts for 67% to 86% of bladder injuries resulting from external trauma, and up to 97% of those patients have associated pelvic fractures. The most common cause of blunt trauma is motor vehicle crashes. Penetrating trauma accounts for 14% to 33% of traumatic bladder injuries. The incidence of iatrogenic injury varies by procedure but is highest for hysterectomy and other obstetric and gynecologic procedures (up to 61 per 1000 cases). In cases of blunt trauma, injury should be suspected in patients who have pelvic fractures, suprapubic pain and inability to void, ileus, absent bowel sounds, or abdominal distention. For

¹Not FDA approved for this indication.

Figure 4 Intraperitoneal bladder rupture. Note contrast extravasating from the dome of the bladder and outlining the small intestine as well as the left colon.

iatrogenic injuries, any urine in the field, visible laceration in bladder, or gas distention of the urinary drainage bag in laparoscopic surgery warrants further investigation. It is important to delineate whether a bladder injury involves intraperitoneal or extraperitoneal rupture. Intraperitoneal rupture occurs at the level of the bladder dome, where the muscular support is weakest (Figures 4 and 5).

The diagnostic test of choice is a CT cystogram, in which the bladder is filled with contrast to capacity (350–400 mL instilled by gravity). In children, the volume instilled is 60 mL plus 30 mL per year of age up to a maximum of 300 mL. Passive filling of the bladder by clamping of the catheter is associated with unacceptably high rates of false-negative tests. Plain film cystography is an alternative, but a single anteroposterior film is insufficient; post-drainage films and, preferably, oblique views should be obtained as well. In both settings, retrograde urethrography should be performed, if there is a suspicion of urethral injury, before placement of a Foley catheter.

Figure 5 Extraperitoneal bladder rupture seen on computed tomographic cystogram.

Figure 6 Retrograde urethrogram diagnostic of partial bulbar urethral transection resulting from straddle injury.

Most extraperitoneal bladder ruptures can be managed with Foley catheter drainage for 7 to 10 days. Bladder neck involvement, concomitant vaginal or rectal injuries, presence of bone fragments in the bladder, or bladder wall entrapment necessitates surgical intervention. Intraperitoneal ruptures should be managed with surgical exploration because of the associated ileus and peritonitis caused by urine leak. In contrast, all penetrating bladder injuries should be explored and repaired because of the risk of necrosis and nonhealing. Bladder repair is performed with a multiple-layer closure and catheter drainage for 7 to 10 days.

Urethral Trauma

Traumatic injury to the urethra occurs in 10% of patients who sustain a pelvic fracture. Female urethral injuries are very rare. The male urethra is anatomically divided into a posterior part (prostatic and membranous urethra) and an anterior part (bulbous urethra, penile/pendulous urethra, and fossa navicularis). Injury to the anterior urethra occurs mostly from blunt trauma, penetrating injuries, or instrumentation. Posterior urethral injuries are usually associated with pelvic fractures but can occur secondary to blunt, penetrating, or iatrogenic injury.

Classic signs of urethral injury include blood at the meatus, a high-riding prostate on rectal examination, and perineal or scrotal ecchymosis. Imaging is indicated with any of these signs. The imaging study of choice is a retrograde urethrogram, and it should be performed before placement of a urethral catheter is attempted. In the absence of any signs, the diagnosis is most frequently made when retrograde urethrography is performed to investigate difficulty with urethral catheter placement (Figure 6).

The AAST grading system does not distinguish between anterior or posterior injury but classifies urethral injuries as follows:

- Grade 1: Contusion and blood at the meatus with normal urethrogram
- Grade 2: Stretch injury with no extravasation of contrast
- Grade 3: Partial disruption with contrast extravasating at the injury site but still reaching the bladder
- Grade 4: Complete disruption with contrast not reaching the bladder; urethral defect of less than 2 cm
- Grade 5: Complete disruption with urethral defect greater than 2 cm or complex injury involving the bladder neck, prostate, rectum, or vagina

Grade 1 and 2 injuries can be managed conservatively by placement of a urethral catheter. Management of grade 3 urethral injury should initially emphasize stabilization of the patient, because extensive bleeding could be present in cases of severe injury to the pelvis. Placement of a catheter may be attempted even if there is a suspicion of partial urethral injury. If this is met with difficulty, a suprapubic tube may be placed.

In cases of complete disruption, evidence supports early endoscopic realignment performed within the initial hospitalization if the patient is stable. This involves endoscopic passage of a guidewire across the defect and placement of a catheter over the

guidewire, with the purpose of reestablishing urethral continuity. An alternative method is placement of a suprapubic tube and delayed reconstruction; the latter approach is associated with a 100% rate of stricture formation. Early endoscopic alignment has been shown to decrease the rate of stricture formation and the severity of strictures when they do occur, compared with suprapubic tube placement and delayed urethral reconstruction. Immediate open repair is rarely indicated unless complex injury extends into the bladder, rectum, or vagina and the patient is undergoing surgery for associated injuries. Immediate exploration is recommended for anterior urethral injuries associated with penetrating trauma or penile fractures.

Trauma to the External Genitalia

Injury to the scrotum is most frequently secondary to blunt trauma and can cause subcutaneous hematoma, hematocele, or testicular injury. Scrotal swelling and patient discomfort can make separation of testicular injury from extratesticular scrotal trauma difficult on physical examination. Therefore, one should have a low threshold for further investigation with ultrasound. A heterogeneous echo pattern in the testicular parenchyma on ultrasonography suggests testicular injury (Figure 7). Visualization of a tear in the tunica albuginea is less accurate. Ultrasound studies additionally provide information about any compromise in testicular blood flow.

Scrotal exploration should be performed whenever testicular injury is suspected. If the tunica is ruptured and there is extrusion of seminiferous tubules, the extruded tubules should be débrided, hemorrhage controlled, and the tunica closed. Testicular salvage rates are high (90%) when the scrotum is explored acutely but drop by half if exploration is delayed. Another indication for scrotal exploration is a large hematocele; evacuation of the hematoma can decrease the morbidity associated with protracted recovery and resolution of the hematoma and can occasionally identify a manageable source of bleeding. Scrotal exploration should also be performed in cases of inconclusive ultrasound findings or whenever the clinical suspicion for testicular injury is high.

Trauma to the penis can range in severity from a contusion to complete amputation. In cases of penile amputation, stabilization of the patient is important, and the need for transfusion should be addressed. Immediate microimplantation is the management technique of choice if available. The severed penile fragment should be immediately placed in normal saline and bag over ice to help preserve the fragment for reimplantation. Penile fracture occurs after blunt injury to the erect penis, usually incurred during sexual intercourse. Patients often report a “crack” or a “pop” followed by severe pain and detumescence. Penile fractures involve rupture of

the tunica albuginea. The hematoma is usually limited to the penis, unless the injury also involves Buck’s fascia, causing ecchymosis and bruising that involves the scrotum as well. It is important to rule out associated urethral injury, which occurs in 10% of the cases. Surgical exploration, closure of the fascial defect, and repair of any associated urethral injury should be done acutely.

In females, blunt trauma to the vulva is rare. Injuries to genitalia can be associated with sexual assault and must be evaluated in that context. Consequently, vaginal smears should be taken, and the vagina should be thoroughly inspected with a speculum and with the patient under anesthesia.

Trauma resulting in skin loss, such as burns, large abrasions, and avulsions, should be explored and débrided in an effort to stage the injury and decrease the risk of complications such as Fournier’s gangrene and urinoma. Delayed reconstruction can be performed after stabilization and proper delineation of viable versus nonviable tissues. The reconstructive options include mobilization of local flaps or skin grafts.

An understanding of the mechanism of injury is important to establish clinical suspicion of urologic trauma. Radiologic imaging is essential in making the correct diagnosis and managing it appropriately. Early diagnosis minimizes patient morbidity.

Studies of prospective design are clearly lacking for urologic trauma. Consolidation of the experience of major trauma institutions nationwide in a consortium for multi-institutional protocols could be the answer to this lack of prospective data.

URETHRAL STRICTURE DISEASE

Method of

Hadley Wyre, MD; and Sable Shew, MD

CURRENT DIAGNOSIS

- Perform a thorough history and physical examination, delineating past trauma, instrumentation, and sexual history, as well as a complete genitourinary examination.
- Patients with urethral stricture will commonly present with obstructive symptoms of weak urinary stream, straining to urinate, and even frank urinary retention.
- In-office testing consists of urinalysis and urine culture for evaluation of infection, as well as uroflowmetry and postvoid residual bladder ultrasound to evaluate urine flow rate and emptying ability.
- Retrograde urethrogram remains the gold standard for diagnosis of urethral stricture disease.

guidewire, with the purpose of reestablishing urethral continuity. An alternative method is placement of a suprapubic tube and delayed reconstruction; the latter approach is associated with a 100% rate of stricture formation. Early endoscopic alignment has been shown to decrease the rate of stricture formation and the severity of strictures when they do occur, compared with suprapubic tube placement and delayed urethral reconstruction. Immediate open repair is rarely indicated unless complex injury extends into the bladder, rectum, or vagina and the patient is undergoing surgery for associated injuries. Immediate exploration is recommended for anterior urethral injuries associated with penetrating trauma or penile fractures.

Trauma to the External Genitalia

Injury to the scrotum is most frequently secondary to blunt trauma and can cause subcutaneous hematoma, hematocele, or testicular injury. Scrotal swelling and patient discomfort can make separation of testicular injury from extratesticular scrotal trauma difficult on physical examination. Therefore, one should have a low threshold for further investigation with ultrasound. A heterogeneous echo pattern in the testicular parenchyma on ultrasonography suggests testicular injury (Figure 7). Visualization of a tear in the tunica albuginea is less accurate. Ultrasound studies additionally provide information about any compromise in testicular blood flow.

Scrotal exploration should be performed whenever testicular injury is suspected. If the tunica is ruptured and there is extrusion of seminiferous tubules, the extruded tubules should be débrided, hemorrhage controlled, and the tunica closed. Testicular salvage rates are high (90%) when the scrotum is explored acutely but drop by half if exploration is delayed. Another indication for scrotal exploration is a large hematocele; evacuation of the hematoma can decrease the morbidity associated with protracted recovery and resolution of the hematoma and can occasionally identify a manageable source of bleeding. Scrotal exploration should also be performed in cases of inconclusive ultrasound findings or whenever the clinical suspicion for testicular injury is high.

Trauma to the penis can range in severity from a contusion to complete amputation. In cases of penile amputation, stabilization of the patient is important, and the need for transfusion should be addressed. URETHRAL STRICTURE DISEASE

Method of

Hadley Wyre, MD; and Sable Shew, MD

CURRENT DIAGNOSIS

- Perform a thorough history and physical examination, delineating past trauma, instrumentation, and sexual history, as well as a complete genitourinary examination.
- Patients with urethral stricture will commonly present with obstructive symptoms of weak urinary stream, straining to urinate, and even frank urinary retention.
- In-office testing consists of urinalysis and urine culture for evaluation of infection, as well as uroflowmetry and postvoid residual bladder ultrasound to evaluate urine flow rate and emptying ability.
- Retrograde urethrogram remains the gold standard for diagnosis of urethral stricture disease.

CURRENT THERAPY

- In the acute setting of urinary retention, the ideal management would be placement of a suprapubic tube to avoid manipulation of the stricture; however, dilation and catheter placement may be appropriate or necessary in some patients.
- Depending on the patient, goals of care should be delineated regarding treatment of stricture disease; that is, definitive therapy versus chronic management of stricture symptoms.
- Endoscopic treatments are available and include urethral dilation and direct visualization internal urethrotomy; however, repeat attempts at these approaches have a low long-term success rate.
- Surgical management includes both anastomotic and augmentation urethroplasty—both of which are more invasive than endoscopic approaches but are known to have improved long-term patency rates.

Urethral stricture disease affects 0.6% of the male population and can be classified in multiple ways: anterior versus posterior, benign versus malignant, extrinsic versus intrinsic, and congenital versus acquired. The urethra is a conduit for urine from the bladder to outside of the body. In males, the anterior urethra (region encircled by corpus spongiosum) begins at the meatus and includes the fossa navicularis, penile urethra, and bulbar urethra—strictures here are the result of scarring of the urethral epithelium and surrounding spongy tissue, termed spongiofibrosis. As this scarring narrows the urethral lumen, symptoms become noticeable. Typically, the urethral lumen must narrow to less than 14 French for this scarring to be the cause of any voiding symptoms. Anterior urethral stricture can be secondary to iatrogenic injury, infections, penile/perineal trauma, pelvic fractures, and self-instrumentation. In the posterior urethra, including the membranous urethra, prostatic urethra, and bladder neck, narrowing is termed contracture or stenosis and is the result of a distraction injury sustained during pelvic trauma or prior surgical procedures of the prostate (Figure 1).

Diagnosis

Often patients with strictures will present with obstructive voiding symptoms including weak or intermittent stream, postvoid dribbling, straining to urinate, or overt urinary retention. Nonobstructive symptoms include postvoid fullness, urinary tract infections, and pelvic pain. A thorough history, including a detailed social/sexual history, and physical examination should be done, and

any prior trauma to or instrumentation of the genitourinary tract noted. The physical examination should be comprehensive, with the genital examination examining for palpable strictures in the anterior urethra.

Laboratory workup should include urinalysis and urine culture for evaluation of infection, as well as a basic metabolic panel to evaluate for any renal function compromise. It is possible to perform an assessment of voiding symptoms in a clinic setting with the use of postvoid ultrasound and uroflowmetry. Once the patient has voided to completion, an ultrasound measurement of postvoid residual urine volume can objectively estimate the patient's ability to evacuate and alert the provider to overt retention. Uroflowmetry is the measurement of flow rate of urine—findings that suggest significant stricture include an elongated voiding time and a low maximal flow rate, essentially flattening the flow curve to a plateau appearance.

The gold standard in urethral stricture diagnosis remains the retrograde urethrogram. Radiocontrast is administered via catheter in a retrograde fashion, filling the urethra and opacifying it—this study is especially helpful for evaluating the length, location, and severity of strictures in the anterior urethra. Additionally, an antegrade study, or voiding cystourethrogram, can be performed to allow for visualization of the bladder neck, prostatic urethra, and membranous urethra. In addition to cystoscopic evaluation for direct visualization of the stricture, ultrasound of the penis/perineum can be used to further delineate characteristics of the stricture. Biopsy is occasionally performed to rule out malignancy as a cause of the stricture (Figure 2).

Acute Treatment

Acutely, the main complication from a urethral stricture is frank urinary retention, which may be associated with a decline in renal function. Typically a urethral catheter cannot be placed because of obstruction from the stricture. In the setting of overt urinary retention, a suprapubic tube is often placed at the bedside or in the operating room to allow for rapid decompression of the urinary system without manipulating the stricture. There are times where suprapubic tube placement may not be possible, and it is therefore reasonable to dilate the stricture and place a urethral catheter to drain the urine. However, manipulation of the stricture can lead to an increase in the length of the stricture and complexity of the eventual repair.

Long-Term Treatment

Multiple modalities exist for the treatment of urethral stricture disease, with varying success rates and complication rates. A thorough discussion between the patient and provider, considering the patient's goals for either cure or symptom management, life expectancy, and stricture qualities, is vital to ensuring that an

Figure 1 Anatomy of male urethra. (A) Penile urethra. (B) Bulbar urethra. (C) Prostatic urethra. White arrow by A=fossa navicularis; white arrow between B and C=membranous urethra.

Figure 2 Bulbar urethral stricture visualized on retrograde urethrogram.

appropriate care plan is developed. Prior to proceeding with any treatment, it is essential to evaluate the urethra proximal to and distal to the stricture with the modalities mentioned earlier; this is to ensure removal of all affected tissue and prevent recurrence.

Conservative management with urethral dilation is appropriate as a first attempt at treatment of a short stricture with minimal spongiofibrosis, with the ultimate goal of stretching rather than tearing tissue to open the lumen without increasing the scarring present. Direct visualization internal urethrotomy (DVIU) is opening of a stricture—by laser, cold knife, or hot knife—to release the scar and allow the urethra to heal at a larger diameter over a catheter. Long-term success rates for DVIU have been reported at 20% to 30% for short strictures with minimal spongiofibrosis. It is important to note that the success rate of repeat DVIU is close to 0%, and after failure, the patient should be referred for definitive surgical repair.

Surgical management includes operations to excise the scar and perform urethral anastomosis, and tissue transfer reconstruction with harvesting of distant tissue—typically oral mucosa—for urethral augmentation. Anastomotic urethroplasty is best for short strictures, 1 to 2 cm in length, while augmentation urethroplasty can be utilized for much longer defects. For any type of urethral reconstruction, resticture is the most common complication, as well as sexual dysfunction and ejaculatory dysfunction. Other treatment options include long-term suprapubic tube drainage, perineal urethrostomy, and urinary diversion, depending on each patient's individual case and discussion with the patient's surgeon. Regardless of modality, clinicians should monitor patients for symptomatic recurrence of strictures.

URINARY INCONTINENCE

Method of

Simon Patton, MD; and Renee Bassaly, DO

CURRENT DIAGNOSIS

- Urinary incontinence is broadly categorized as stress urinary incontinence or urgency urinary incontinence.
- The diagnosis can often be determined by a careful history and physical examination but can be aided with noninvasive methods such as a bladder diary.
- It is important to rule out any other potential causes of incontinence including urinary tract infection, urinary retention, or medication side effect.

CURRENT THERAPY

- Modest weight loss has been shown to help both forms of incontinence and is an important first-line therapy.
- Urgency urinary incontinence can initially be managed with lifestyle modifications including timed voiding and avoidance of bladder irritants, as well as physical therapy. Further options include medications (anticholinergics or B₃ agonists).
- Third-line therapy for urgency urinary incontinence includes sacral neuromodulation, botulinum toxin injections, and tibial nerve stimulation.
- Stress urinary incontinence can be managed conservatively with home Kegel exercises or formal pelvic floor training with physical therapy. Mechanical urethral support using a disposable tampon-like device or incontinence pessary is another non-invasive option.
- Surgical management of stress urinary incontinence is midurethral slings, principally using synthetic mesh. I would include Burch and autologous sling.

Epidemiology

Urinary incontinence is a very common problem particularly in the female population, with incidence roughly twice that of male patients (30% vs. 17%). The exact incidence may be difficult to know, however, because this is a sensitive subject that patients may not volunteer unless solicited. The annual cost of treating incontinence is estimated to be \$24 billion, and annually 260,000 women undergo surgery for stress incontinence.

Risk Factors

Risk factors vary between genders. Women are at greater risk due to anatomic differences, principally a shorter urethral length. Other risk factors include increased age, parity, obesity, diabetes, smoking, and pelvic radiation. In male patients a history of prostate surgery or an enlarged prostate are potential risk factors. Urinary tract symptoms including incontinence may represent manifestations of neurologic disorders including history of stroke, multiple sclerosis, or spinal cord injury.

Pathophysiology

The bladder consists of a smooth muscular reservoir (the detrusor muscle), two inlets (the ureters), and an outlet (the urethra). Urine from the kidneys enters the bladder via the ureters and exits via the urethra, which is itself a muscular tube consisting of smooth and striated muscle. Bladder function has two phases: storage and emptying. During the storage phase, the bladder collects urine; this phase involves relaxation of the detrusor muscle and contraction of the urethral muscle, all of which is under sympathetic and voluntary control. The emptying phase involves relaxation of the urethral muscles and contraction of the detrusor, which is mediated by the parasympathetic system. Under normal circumstances, emptying is voluntarily initiated in the adult.

In women, the bladder and urethra are supported by the anterior vaginal wall, which, in turn, is suspended by connective tissue attachments from the pelvic floor muscles. Continence is maintained when the urethral closure pressure exceeds the detrusor pressure. Adequate support from the anterior vaginal wall is required to maintain this relationship during periods of increased intraabdominal pressure. Consequently, urinary continence depends on the relative relaxation of the detrusor, the contraction of urethral muscles, and the support of the anterior vaginal wall. Incontinence can ensue when these relationships are disrupted.

Prevention

The pelvic floor musculature plays an important role in the maintenance of continence, and as such, pelvic floor physical therapy directed at these muscles has been shown to improve continence

appropriate care plan is developed. Prior to proceeding with any treatment, it is essential to evaluate the urethra proximal to and distal to the stricture with the modalities mentioned earlier; this is to ensure removal of all affected tissue and prevent recurrence.

- Surgical management of stress urinary incontinence is midurethral slings, principally using synthetic mesh. I would include Burch and autologous sling.

Epidemiology

Urinary incontinence is a very common problem particularly in the female population, with incidence roughly twice that of male patients (30% vs. 17%). The exact incidence may be difficult to know, however, because this is a sensitive subject that patients may not volunteer unless solicited. The annual cost of treating incontinence is estimated to be \$24 billion, and annually 260,000 women undergo surgery for stress incontinence.

Risk Factors

Risk factors vary between genders. Women are at greater risk due to anatomic differences, principally a shorter urethral length. Other risk factors include increased age, parity, obesity, diabetes, smoking, and pelvic radiation. In male patients a history of prostate surgery or an enlarged prostate are potential risk factors. Urinary tract symptoms including incontinence may represent manifestations of neurologic disorders including history of stroke, multiple sclerosis, or spinal cord injury.

Pathophysiology

The bladder consists of a smooth muscular reservoir (the detrusor muscle), two inlets (the ureters), and an outlet (the urethra). Urine from the kidneys enters the bladder via the ureters and exits via the urethra, which is itself a muscular tube consisting of smooth and striated muscle. Bladder function has two phases: storage and emptying. During the storage phase, the bladder collects urine; this phase involves relaxation of the detrusor muscle and contraction of the urethral muscle, all of which is under sympathetic and voluntary control. The emptying phase involves relaxation of the urethral muscles and contraction of the detrusor, which is mediated by the parasympathetic system. Under normal circumstances, emptying is voluntarily initiated in the adult.

In women, the bladder and urethra are supported by the anterior vaginal wall, which, in turn, is suspended by connective tissue attachments from the pelvic floor muscles. Continence is maintained when the urethral closure pressure exceeds the detrusor pressure. Adequate support from the anterior vaginal wall is required to maintain this relationship during periods of increased intraabdominal pressure. Consequently, urinary continence depends on the relative relaxation of the detrusor, the contraction of urethral muscles, and the support of the anterior vaginal wall. Incontinence can ensue when these relationships are disrupted.

Prevention

The pelvic floor musculature plays an important role in the maintenance of continence, and as such, pelvic floor physical therapy directed at these muscles has been shown to improve continence

in both postmenopausal women and younger postpartum women, at least in the short term. Physical therapy in the male population has not been studied as a prevention strategy. One modifiable risk factor for incontinence is obesity, and even a modest weight loss of 10% has been shown to help improve continence status.

Clinical Manifestation

Urinary incontinence can be a sign, symptom, as well as a diagnosis. Urinary incontinence falls into two broad categories: stress incontinence and urge incontinence. Stress urinary incontinence occurs when urethral closure pressure cannot increase sufficiently to compensate for a sudden increase in intraabdominal pressure, as from laugh, cough, or Valsalva maneuver. Urgency urinary incontinence occurs when an unintended bladder contraction creates an insuppressible urge to void, leading to urinary leakage. When patients have signs or symptoms of both stress and urge incontinence, it is referred to as *mixed urinary incontinence*.

Diagnosis

Diagnosis rests principally on a careful history and physical examination. A thorough history is important to solicit what causes a patient to leak. Leakage with laughing, coughing, sneezing, exercise, or similar exertion would likely be stress urinary incontinence. Leakage associated with an urge that is difficult to defer is likely urgency urinary incontinence. If patients have both symptoms, then they likely have mixed urinary incontinence. If a patient complains of symptoms of mixed incontinence, a careful history to determine which is most bothersome is important. If the patient has difficulty knowing what has caused their leakage, a 3-day bladder diary recording liquid consumed, times and amounts voided, and leakage events with associated symptoms can help with diagnosis and treatment.

Other pertinent components to a thorough history include surgery to the spinal cord, bladder neck, or pelvic floor, which may lead to obstruction; neurologic disease (e.g., multiple sclerosis or a spinal cord lesion); or psychiatric disease (e.g., dementia, which may limit the ability to recognize a need to void). Musculoskeletal function, with emphasis on mobility, should be reviewed. A detailed medication history will identify any medications that may affect urine output or bladder function. It is important to also elicit any other symptoms that may coexist with incontinence and signal pelvic floor dysfunction, including nocturia, fecal incontinence, or constipation.

After a thorough history, a detailed physical examination is necessary. A focused genitourinary examination includes inspection of the external genitalia. Eliciting reflexes from the S2-S4 nerve roots will help determine whether there is any neurologic component. In female patients, perform a pelvic examination and look for any prolapse or pelvic masses and note whether any atrophy is present. Palpation of the urethra allows for evaluation of any urethral masses or possible diverticula. Lastly, assessment of pelvic floor musculature is important, evaluating for any pain or discomfort in the levator ani muscles and assessing the patient's ability to perform a proper Kegel exercise. In males, performance of a digital rectal examination is recommended to evaluate for any prostatic masses or hypertrophy.

The physical examination provides an opportunity for diagnosis as well; asking the patient to cough or perform a Valsalva maneuver allows for the direct visualization of stress incontinence if present. Additionally, this provides an opportunity in female patients to evaluate for prolapse and assess urethral mobility. Historically, this was done by placing a cotton swab in the urethra to observe for hypermobility seen with >30 degrees of mobility on strain from baseline. However, because of patient discomfort, this test is not routinely performed. After completing the physical examination, one must perform a urinalysis to rule out any infectious etiology and at times perform a post-void residual (either with a bladder scan or with catheterization) to evaluate for any possible voiding dysfunction. If the patient has a more complex history because of prior urologic surgery, neurologic disease, or is difficult to

diagnose on history and physical alone, then complex urodynamic testing may be indicated.

Differential Diagnosis

The differential diagnosis for urinary incontinence includes stress urinary incontinence, urgency urinary incontinence, and a mixture of the two as mentioned above. Other causes of undesired leakage of urine include overflow (due to urinary retention), functional (due to impaired mobility or mental capacity), as well as a fistula or diverticulum. A patient with a fistula most commonly presents with the complaint of constant persistent urinary leakage. In the industrialized world these generally form after genitourinary surgery, whereas in developing countries trauma from childbirth is the primary cause. A diverticulum may present with a painful anterior vaginal wall mass as well as irritative voiding symptoms such as urinary frequency, urgency, dysuria, and postvoid dribbling. Other causes of lower urinary tract symptoms such as urgency, frequency, and dysuria include urinary tract infection, uncontrolled diabetes, or urinary tract malignancy.

Therapy

Stress Urinary Incontinence

Nonsurgical options for treatment of stress urinary incontinence include strengthening of the pelvic musculature through Kegel exercises and mechanical support of the urethra. Kegel exercises may be performed by the patient at home, although some patients may have difficulty identifying the muscles to perform them properly. Formal training with a pelvic floor physical therapist can help the patients learn to identify the muscles (sometimes using biofeedback devices) and contract them appropriately. Proper contraction of the levator ani muscles provides improved support for the bladder and urethra and helps decrease leakage.

Mechanical support of the urethra and bladder neck can be accomplished using an incontinence pessary or a disposable incontinence tampon. Pessaries are ring-shaped silicone devices with a knob that is meant to sit under the urethra. Patients are fitted for the correct size in the office. Patients must be followed up for at 3 to 6 month intervals to ensure the pessary has not caused any erosions or excoriations. This can be avoided by teaching patients how to insert and remove the pessary themselves or prescribing a vaginal estrogen cream in postmenopausal patients. A disposable option is available over the counter as well. It comes in three sizes, and the patients can fit themselves at home with the starter pack. Once they find the correct size, it can be placed when the patient desires and may be kept in place for up to 8 hours. Some patients choose this option if they only have stress incontinence during certain times (i.e., exercise).

If conservative therapies do not adequately address their complaints, surgical options are available. The general principle of restoring support to the urethra is the same as in conservative therapies. This can be accomplished by placing a sling under the urethra. The sling material can be lightweight polypropylene mesh or fascia (either autologous or cadaveric). The most commonly used type is the synthetic mesh and it is placed either retropubically or through the obturator membrane. Both methods have been shown to have a high rate of satisfaction with a low complication rate.

Stress incontinence in men is much less common but can also be treated with slings placed at the bulbar urethra. Artificial urinary sphincters can also be implanted that compress the urethra and can be controlled by the patient.

Urgency Urinary Incontinence

Lifestyle modifications are a good first-line therapy for patients with urgency urinary incontinence. Drinking an appropriate amount of fluids and avoiding foods and beverages that are known to irritate the bladder can provide significant relief. Additionally, performing timed voiding can help retrain the bladder. Formal training with a pelvic floor physical therapist has also been shown to significantly decrease incontinence episodes. It is important to note, however, that just performing Kegel exercises is often not adequate in these

patients and can in fact worsen their symptoms if they already have tightly held, nonrelaxing pelvic floor musculature.

Pharmacologic therapy consists of anticholinergic medications or beta 3 agonists. Anticholinergic medications target the muscarinic receptors on the bladder; however, they are not specific and can cause significant dry mouth, dry eyes, and constipation, side effects that lead to a high discontinuation rate. Patients are unable to take this class of medication if they have closed-angle glaucoma. Additionally, there have recently been some concerns raised about long-term use leading to cognitive decline. The beta 3 agonists also work to slow down detrusor contractions but do so by targeting a different receptor. They have been shown to raise blood pressure and so are precluded in patients with uncontrolled severe hypertension; all patients should routinely check their blood pressure after starting one of these medications.

Third-line therapies for urgency urinary incontinence include sacral neuromodulation, tibial nerve stimulation, and intradetrusor injection of botulinum toxin A. Sacral neuromodulation has been approved by the Food and Drug Administration for this indication, as well as fecal incontinence and voiding dysfunction. It consists of a lead placed in the S3 foramen and connected to a pacemaker-like device that is implanted in the adipose of the buttocks. Patients are then able to control some of the settings (including program and amplitude) from an external device. The sacral nerve roots can also be stimulated via the tibial nerve. Treatments involve a small, acupuncture-sized needle placed in the tibial nerve followed by 30 minutes of stimulation. These are carried out at weekly treatments for 12 weeks followed by monthly maintenance therapy. Botulinum toxin A, a neurotoxin that works by decreasing the presynaptic release of acetylcholine, can be injected directly into the detrusor muscle. A risk of this treatment is urinary retention, which requires that patients be able to perform self-catheterization.

Mixed Urinary Incontinence

If a patient presents with components of both stress and urgency, eliciting first which symptom is the most bothersome allows for appropriate tailoring of treatment. It is important to remind

patients that even a modest weight loss of 10% can help reduce bothersome urinary symptoms by up to 60%. As noted above, physical therapy can help address both type of incontinence as a valuable first-line therapy.

Overflow Incontinence

If a patient is diagnosed with overflow incontinence, then management is directed at maintaining an empty bladder through self-catheterization. In male patients, if the retention is due to prostatic hypertrophy, then pharmacologic therapy with α -agonists or 5 α reductase inhibitors may be warranted. If medication fails to improve their symptoms, then surgical treatment with ablation (microwave or radiofrequency) or resection is indicated.

Complications

Urinary incontinence can cause significant morbidity in terms of financial as well as psychological burdens on patients. In addition to causing rashes and skin breakdown, incontinence also leads to depression, isolation, anxiety, depression, and increased risk of falls. Incontinence is one of the leading causes of institutionalization in the elderly. As the population ages, the incidence of incontinence will continue to increase, making its diagnosis and treatment increasingly important.

BACTERIAL INFECTIONS OF THE MALE URINARY TRACT

Method of

John N. Krieger, MD

CURRENT DIAGNOSIS

- UTIs include a wide clinical spectrum.
- Infection at any site in the urinary tract places the entire system at risk.
- The critical clinical issue is to distinguish uncomplicated (medical) from complicated (surgical) infections.
- Anatomic evaluation and imaging studies are seldom indicated for adult patients with uncomplicated UTIs.
- Well-documented UTIs in boys require urologic investigation because of the high prevalence of structural urinary tract abnormalities.
- We recommend culture and sensitivity testing of urine specimens for any male patient with symptoms or signs suggesting a UTI to document the infection and to guide therapy in an era of increasing antimicrobial resistance.
- We discourage routine screening of urine cultures in long-term care patients who have no localizing signs or symptoms suggesting a UTI.

CURRENT THERAPY

- The optimal goal of therapy is to eliminate the infecting organism from the urinary tract.
- Antimicrobial therapy alone is less effective for patients with complicated UTIs than for patients with uncomplicated UTIs.
- Managing patients with complicated UTIs often requires anatomic evaluation and imaging studies.
- For patients with complicated UTIs it is often necessary to eliminate or control predisposing factors.
- Rapid eradication of the infection can limit the potential for infection of adjacent structures.
- Ensure elimination of the infection by repeating urine cultures.
- A prolonged course of antimicrobial therapy might prove necessary for patients with persistent infections.

Urinary tract infections (UTIs) include a wide clinical spectrum whose common denominator is bacterial invasion of the genitourinary organs and tissues. UTI can involve any part of the urinary tract from the renal cortex to the urethral meatus. UTI can predominate at a single site, such as the bladder (cystitis), prostate (prostatitis), epididymis (epididymitis), kidneys (pyelonephritis), or perinephric space (perinephric abscess). When any of its parts has become infected, the entire urinary tract is placed at risk for bacterial invasion.

The great majority of UTIs occur by the ascending route. Bacteria from the fecal flora colonize the perineum and then ascend via the urethra to involve the bladder, the ureter, and the kidneys. On occasion, hematogenous dissemination results in bacterial seeding of the urinary tract. Classic examples of such hematogenous infection are genitourinary tuberculosis or staphylococcal infection of a renal cyst (historically known as a renal carbuncle). On rare occasions, the urinary tract is involved by infection from contiguous structures. For example, patients with diverticulitis or appendicitis occasionally develop abscesses or fistulas that involve the urinary tract.

Distinguishing Complicated from Uncomplicated Infections

The first step in patient evaluation is to distinguish uncomplicated (medical) infections from complicated (surgical) infections. Uncomplicated UTIs occur in the absence of underlying structural, functional, or neurologic disorders of the urinary tract. Uncomplicated UTIs usually respond promptly to appropriate antimicrobial therapy. Anatomic evaluation and imaging studies are seldom indicated in patients with uncomplicated UTIs.

Complicated UTIs occur when the urinary tract has been repeatedly invaded by bacteria, leaving residual inflammation, in some cases accompanied by obstruction, stones, foreign bodies, or neurologic conditions that interfere with urinary drainage. Antimicrobial therapy alone is markedly less effective in complicated UTIs than in uncomplicated UTIs. Managing patients with complicated infections often requires anatomic evaluation and imaging studies. An important differential point is that patients with complicated UTIs tend to have persistence of bacteria within the urinary tract in the face of antimicrobial agents to which the bacteria appear to be sensitive in laboratory tests. Often, it is necessary to correct an underlying obstructive lesion, improve voiding, drain an abscess, or remove a stone or foreign body to clear the infection.

Total elimination of the infecting organism from the urinary tract represents the ideal goal of UTI therapy. This is a realistic goal for patients with uncomplicated UTIs. However, achieving this goal can prove difficult in patients with complicated UTIs whose underlying abnormalities cannot be corrected. For example, it is often impossible to achieve long-standing resolution of bacteriuria in patients who require indwelling catheters or who have functional obstruction of their voiding mechanisms. In such cases, resolution of symptoms directly related to UTI is the only practical therapeutic goal.

Natural History

During infancy, the incidence of symptomatic UTIs is higher in boys than in girls. In part, this has been related to male circumcision status. It appears that bacteria can adhere to the prepuce of uncircumcised boys, providing access to the urinary tract. Neonatal circumcision reduces the UTI rate in boys by about 90%. After the neonatal period, symptomatic UTIs in boys and men are distinctly uncommon until middle age. This contrasts dramatically with UTI rates in girls and women, who experience increasing rates of both symptomatic and asymptomatic infections, with a marked increase following initiation of sexual activity, then a continued

gradual rise with increasing age. Asymptomatic bacteriuria is also distinctly unusual in male patients compared with female patients.

Well-documented UTIs in boys mandate thorough urologic investigation. This is because of the high prevalence of structural urinary tract abnormalities in boys with UTIs. Often, UTI represents the key diagnostic presentation for major abnormalities of the urinary tract. For example, vesicoureteral reflux of urine, posterior urethral valves, and other major structural abnormalities often manifest initially with bacterial UTIs. Early diagnosis and appropriate therapy offer the best chance for preservation of maximal kidney function. Unfortunately, the developing kidneys are especially susceptible to continued scarring that can progress despite appropriate treatment.

Structural urinary tract abnormalities remain a major cause of renal failure in children. Morbidity may be minimized by appropriate evaluation and therapy. The optimal radiologic approach for children with UTI is controversial. The traditional choice for evaluation of a boy with a UTI is the combination of renal ultrasound to evaluate the upper urinary tract plus a voiding cystourethrogram to evaluate the lower urinary tract. Voiding cystourethrography should be obtained after resolution of the initial infection, because dilation of the upper urinary tract may be exaggerated after a recent UTI. More recent approaches focus on confirming the diagnosis of acute pyelonephritis before invasive imaging is considered, starting with a renal and bladder ultrasound, then nuclear medicine scan in selected cases. This has been termed the *top down approach*. In my opinion this is an attractive, evidence-based approach to minimize unnecessary interventions and to improve compliance with recommended testing.

Because UTIs are unusual in young men, there are few well-done natural history studies in this population. In young men with UTIs who have no obvious neurologic or structural abnormalities, sexual intercourse, particularly among homosexual men or heterosexual men who practice insertive anal intercourse, may be a risk factor. The overall contribution of these practices to bacterial UTIs in men is uncertain.

Traditional urologic teaching is to recommend thorough evaluation for structural abnormalities in such patients, including radiographic studies and cystourethroscopy. However, our published experience suggests that previously healthy college-age men with well-documented UTIs have a low rate of structural genitourinary tract abnormalities. A uroflow study and postvoid residual urine determination by ultrasound are adequate to screen for structural abnormalities in young men whose UTIs resolve. We reserve imaging studies and cystoscopy for patients at risk for significant abnormalities on the basis of these screening studies and a thorough physical examination. Recent studies indicate that bacterial pathogens require an exceptional repertoire of virulence factors to cause UTIs in previously healthy young men. The other major risk factors for UTIs in men are instrumentation of the urinary tract and bacterial prostatitis.

Diagnosis and Localization

Accurate diagnosis is prerequisite for appropriate UTI therapy. Therefore, we recommend culture and sensitivity testing of urine specimens from any male patient with symptoms or signs suggesting a UTI. In patients who do not have obstructive lesions, stasis, stones, or foreign bodies, recurrent and persistent bacterial UTIs are often related to bacterial prostatitis. Segmented localization cultures can be used to differentiate cystitis and urethritis from bacterial prostatitis. The procedure should be carried out at a time when the patient does not have bacteriuria.

My procedure for lower urinary tract localization is outlined briefly. After cleaning the glans with sterile water, the first-void urine (initial 5–10 mL of voided urine) is collected in a sterile container. Next, a midstream specimen is obtained. The patient is asked to stop voiding. Prostatic fluid is expressed by digital rectal prostate massage. The post–prostate massage urine (next 5–10 mL voided after the massage) is then collected. Culture and sensitivity testing are then carried out on each of these four specimens. It is critical to ensure that the clinical microbiology laboratory is aware

of the purpose of these studies so that they will evaluate low concentrations of uropathogens that may be present in the localization cultures.

Diagnosis of chronic bacterial prostatitis can be made if the post–prostate-massage urine specimen or the expressed prostatic secretion contains a 10-fold or greater increase in the concentration of the uropathogen compared with that in the first-void urine specimen. In patients with well-documented bacterial prostatitis, the causative organism is identical to the uropathogen causing recurrent UTI episodes.

It is important to recognize that only a small minority of men presenting with symptoms of prostatitis fit into the acute or chronic bacterial prostatitis categories. The great majority of patients with symptoms of prostatitis are classified in the chronic prostatitis/chronic pelvic pain category. In contrast to the recognized benefit of therapy for patients with acute and chronic bacterial prostatitis, the role of antimicrobial therapy and other treatments has not been defined for men with symptoms of chronic prostatitis/chronic pelvic pain syndrome.

Treatment

There are three keys to successful UTI therapy. First, eliminate or control predisposing factors, if possible. For example, we are often asked to manage resistant UTIs in long-term care patients with indwelling catheters. One approach is to change their bladder management from a chronic indwelling catheter to an intermittent self- or assisted-catheterization program. Other examples include removing or correcting obstructing lesions, stones, or strictures to improve drainage of the urinary tract. These measures may be successful in eliminating the focus of infection, even with no antimicrobial therapy. Second, eradicate the infection as soon as possible to prevent colonization of the prostate and other structures. Third, ensure resolution of the UTI by obtaining cultures during or immediately after therapy and at follow-up 1 to 2 months after therapy.

Uncomplicated Infections

Uncomplicated infections generally manifest with symptoms of bacterial cystitis, such as the combination of urinary frequency, urgency, dysuria, nocturia, suprapubic discomfort, low-back pain, or hematuria. Systemic symptoms of fever, chills, and rigor are absent. Urine culture confirms the diagnosis, with *Escherichia coli* representing the most common pathogen. Uncomplicated infections, including those introduced by a single or short course of indwelling urethral catheterization, generally respond promptly to a short course of antimicrobial therapy. The infection can persist and become difficult to eradicate if the prostate becomes colonized or if the patient has a stone or structural abnormality of the urinary tract. Thus, an effort should be made to eliminate predisposing factors while routine therapy is guided by in vitro susceptibility tests.

I prefer oral therapy with one of the agents listed in [Table 1](#). In the Pacific Northwest, bacteria causing UTIs have developed substantial resistance to trimethoprim–sulfamethoxazole (Bactrim). Therefore, I usually initiate empiric therapy with a quinolone. Nitrofurantoin (Macrochantin) remains highly effective and is an attractive alternative drug. In general, I recommend that the duration of therapy be at least 2 weeks, although only limited data address this point in male patients. Recent increases in antimicrobial resistance in many areas, especially multi-drug resistant organisms, including extended spectrum beta-lactamase producing bacteria has led us to add fosfomycin (Monurol) to our oral therapies in selected patients with resistant *E. coli* infections.

Complicated Infections

Patients with systemic signs or those with a history of structural or neurologic abnormalities merit anatomic and functional investigation of the urinary tract. Antimicrobial therapy alone might fail to cure infection, and urosepsis can develop unless there is specific management of the underlying problem. My initial choice for evaluating these patients is usually computed tomography (CT) with IV contrast. If a renal or retroperitoneal abscess is suspected,

TABLE 1 Oral Antimicrobial Agents Prescribed for Urinary Tract Infections In Men

AGENT	DOSAGE
Fluoroquinolones	
Ciprofloxacin (Cipro)	250–500 mg bid
Ciprofloxacin extended release (CiproXR)	500–1000 mg qd
Levofloxacin (Levaquin, Levaquin LEVA-pak)	250–750 mg qd
Ofloxacin (Floxin)	200–400 mg bid ³
Norfloxacin (Noroxin)	400 mg bid
Combination Agents	
Trimethoprim–sulfamethoxazole (Bactrim, Septra, Bactrim DS, Septra DS)	160 mg trimethoprim, 800 mg sulfamethoxazole bid
Amoxicillin–clavulanate (Augmentin)	500–875 mg amoxicillin, 125 mg clavulanate bid
Other Antimicrobials	
Trimethoprim (Proloprim)	100–200 mg bid
Nitrofurantoin monohydrate (Macrobid)	100 mg bid
Nitrofurantoin (Macrochantin)	50–100 mg qid

³Exceeds dosage recommended by the manufacturer.

CT scanning has proved superior to the other modalities for diagnosis. The exception is that I prefer transrectal ultrasound for evaluation of possible prostatic abscesses.

Prolonged courses of therapy are indicated for patients with persistent infections. Often, I use 3 to 4 months of therapy in this situation. In patients with chronic bacterial prostatitis, elderly patients, or those in nursing homes, continuous therapy may be necessary to suppress bacteriuria, even though eradication can prove impossible. Thus, for patients with recurrent or complicated infections, I recommend an attempt to eradicate the focus of infection, following thorough evaluation of the urinary tract. The therapy is usually with the drugs listed in Table 1. My first choice for curative therapy is usually a quinolone. For patients with persistent or frequently relapsing infections, I consider long-term therapy (months or years) using low dosages of antimicrobial drugs for prophylaxis or suppression. In this situation, my choice is usually either trimethoprim–sulfamethoxazole or nitrofurantoin.

Prostatitis

Acute and chronic bacterial prostatitis can manifest with local urinary tract symptoms characteristic of bacterial cystitis or with systemic signs and symptoms. Acute bacterial prostatitis can manifest with the sudden onset of chills, fever, malaise, and low back and perineal pain, as well as difficulty with urination. On rectal examination, the prostate is tense and exquisitely tender. Excessive palpation can induce septicemia.

For patients who require hospitalization, my initial choice is the combination of a β -lactam drug with an aminoglycoside until the results of antimicrobial sensitivity testing are available. Following parenteral therapy, the patient is managed with continued antimicrobial therapy for at least 4 weeks, usually employing a quinolone. Patients with acute bacterial prostatitis usually respond well to a variety of antimicrobial agents that penetrate an acutely inflamed prostate. Many of these agents are not effective in chronic bacterial prostatitis.

In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is often insidious in onset. Patients usually have recurrent symptomatic UTIs and, sometimes, recurrent episodes of acute

prostatitis. Between symptomatic episodes, patients may be totally asymptomatic. Diagnosis depends on the localization cultures described earlier. Treatment must be prolonged, because diffusion of many antimicrobial agents into the uninfamed prostate is poor.

My initial choice is usually a quinolone, with trimethoprim–sulfamethoxazole as a second-choice agent. Other agents may be indicated based on culture and susceptibility test results.

It is important to avoid confusing bacterial prostatitis with chronic prostatitis/chronic pelvic pain syndrome. This is the most common category of symptomatic prostatitis. A critical distinguishing point is that patients with chronic prostatitis/chronic pelvic pain syndrome do not have bacteriuria and they have negative bacterial localization cultures. Most do not benefit from repeated courses of antimicrobial therapy.

Long-Term Care Patients

My approach to managing UTI differs in long-term care patients, including those with incontinence and indwelling urinary catheters or other devices. In such patients, chronic asymptomatic bacterial colonization should not be treated. It is impossible to sterilize the urine permanently in such men. Furthermore, resistant organisms will likely emerge, making subsequent therapy difficult. I treat such patients only if they develop acute symptoms referable to the urinary tract or before genitourinary tract procedures. I strongly recommend against obtaining screening cultures in long-term care patients because these cultures often lead to unnecessary therapy that selects resistant bacterial flora. Further, there is evidence that bacterial colonization with relatively benign strains can inhibit establishment of symptomatic infections caused by more-virulent bacteria. If UTI treatment is necessary for a patient who requires an indwelling catheter, then it is best to change the catheter before starting treatment.

Patients in long term care with recurrent symptomatic episodes can be challenging. The best option is to work to eliminate predisposing factors to the extent possible. For example, substituting clean intermittent catheterization for an indwelling urethral catheter may help resolve recurrent symptomatic episodes.

BENIGN PROSTATIC HYPERPLASIA

Method of

Judd W. Moul, MD; and Brian M. Whitley, MD

Epidemiology

Benign prostatic hyperplasia (BPH) was generally a topic only of interest to urologists up to about 20 years ago, when several classes of medical therapy became available. Once widespread direct-to-consumer medical advertising hit the airwaves, the public's lexicon included "BPH," and men and their families were being educated about it. When combined with the aging population, the obesity epidemic, and subsequent health consequences, we have a very important disease process. As other countries improve their standards of living, BPH has become one of the most common health conditions of the aging man worldwide.

From a practical standpoint, BPH and its symptoms are very uncommon before the age of 40 years. By ages 60 years and 85 years, the histologic prevalence of BPH at autopsy is 50% and 90%, respectively. The symptoms of BPH are now referred to as lower urinary tract symptoms (LUTS). At age 70 years, about 40% of men report LUTS and by age 75 years, the incidence of LUTS increases to 50%.

The diagnosis and treatment of BPH has always been in the realm of the specialty of urology, and this remains the case. However, as more medical and surgical therapies have been introduced and prostate-specific antigen (PSA) testing for prostate cancer has become commonplace, urologists are working more closely with internists, family physicians, generalists, and physician extenders to jointly manage these patients.

Pathophysiology

Even though BPH is common, we know very little about the true pathophysiology. However, we do know that men who were castrated before puberty do not develop BPH, and we also know that it is a progressive disease of aging. Before the 1980s, BPH was generally thought of as a static condition of a gradually growing prostate gland that caused progressive bladder outlet obstruction. In fact, it was common to use the "donut hole" analogy with patients, explaining to them that the prostate is like a donut surrounding the bladder neck and outlet. With aging and prostate growth, the donut hole gets smaller, causing progressive obstruction. In the era when transurethral resection of the prostate (TURP) was the only effective treatment, this simple static explanation was sufficient.

From the 1980s onward, our understanding has advanced to recognize that BPH has both a static obstructive and a dynamic component under neural control. The donut hole now has to have electrical wires attached to it with the ability to adjust the current. In addition, the contribution of the bladder to LUTS has been well recognized as a key contributor to the dynamic component of BPH and LUTS.

The static growth and proliferation of the periurethral tissue into BPH is under androgenic stimulation. Specifically, the main male hormone testosterone is converted to the more active metabolite dihydrotestosterone (DHT) by the enzyme 5 α -reductase in the prostatic stromal and epithelial cells of the prostate. 5 α -Reductase

occurs in two forms, type 1 and type 2. Only type 2 is present in the prostate and genitalia. This is critical for the understanding of one of the two main classes of medical therapy for BPH, the 5 α -reductase inhibitors (5-ARIs), medications that block the conversion of testosterone to DHT.

The dynamic component of BPH and LUTS is based on autonomic input to the smooth muscles in the lower urinary tract, including the bladder, prostate, and urethra. These areas have a large concentration of α_1 -adrenergic receptors that, when stimulated by various stressors, cause increasing smooth muscle tone. This increased smooth muscle tone leads to increased urethral resistance and contributes to the bladder outlet obstructive symptoms of BPH. This physiology leads to the basis for the other main class of drugs to treat BPH, the α_1 -adrenergic blockers.

Symptoms

LUTS include urinary frequency, decreased force and caliber of the urinary stream, hesitancy, straining to void, urgency, and nocturia. The severity can range from the stoic man who refuses to acknowledge any symptoms to the man in frank urinary retention. Most urologists now use a standardized patient self-administered questionnaire, such as the International Prostate Symptom Score (IPSS) (Figure 1). This is very useful to elicit symptoms and bother in a typical male population with suboptimal health-seeking behavior.

It is now very common for men to be referred to urology for a collection of age-related issues including elevated PSA, LUTS, BPH, or erectile dysfunction (ED). Commonly, the PSA or ED brings the patient to the attention of the health care system for the first time in years and may be the first opportunity to influence men on healthy living and health maintenance as they enter middle or older vulnerable ages. Recognizing this, all health care providers should keep this in mind and try to perform a broader men's health assessment while the patient is captive.

Diagnosis

The diagnosis of BPH is generally made based on symptoms or the IPSS standardized patient-self-administered questionnaire combined with a digital rectal examination, PSA blood test, urinalysis, and, in some cases, a cystoscopy. The differential diagnosis can include urinary tract infection (UTI), prostatitis, urinary stones in the lower urinary tract, urethral stricture disease, neurogenic or overactive bladder, prostate or bladder cancer, and even congestive heart failure. Some common medications, such as over-the-counter cold medicines containing α -adrenergic agents, can exacerbate LUTS and can even put a man into acute urinary retention if he has underlying BPH.

A properly performed digital rectal examination is critical to master in the diagnosis of BPH. Because the posterior prostate gland is located adjacent to the rectum and about 3 to 5 cm internal to the anus, the experienced clinician can gain valuable information. I prefer the patient to bend over the examining table with toes pointed slightly inward, the knees bent slightly forward and the forehead and arms resting on the table. The examiner uses a liberally lubricated gloved index finger to palpate the posterior side of the prostate for size estimate and for any induration or nodularity that might indicate the presence of prostate cancer. In this case, referral to an urologist is mandatory.

The size of the prostate is measured either by estimating the weight in grams or the volume in cubic centimeters. Models have been developed to teach clinicians how to gauge size and consistency. In general, a normal size prostate is 20 to 25 g (or cm³) in middle-aged men. A size of 25 to 30, 30 to 50, and greater than 50 g (or cm³) is a general guide to mild, moderate, and severe BPH. However, size does not necessarily correlate to symptoms, and both symptom score and size estimate should be reported. The size gauges the histologic condition and the symptoms indicate the LUTS and the bother index, which are both important for individualized treatment.

The laboratory assessment should include a urinalysis to rule out hematuria. Like an abnormal digital rectal examination, a urinalysis that shows persistent red blood cells should prompt referral to

BENIGN PROSTATIC HYPERPLASIA

Method of

Judd W. Moul, MD; and Brian M. Whitley, MD

Epidemiology

Benign prostatic hyperplasia (BPH) was generally a topic only of interest to urologists up to about 20 years ago, when several classes of medical therapy became available. Once widespread direct-to-consumer medical advertising hit the airwaves, the public's lexicon included "BPH," and men and their families were being educated about it. When combined with the aging population, the obesity epidemic, and subsequent health consequences, we have a very important disease process. As other countries improve their standards of living, BPH has become one of the most common health conditions of the aging man worldwide.

From a practical standpoint, BPH and its symptoms are very uncommon before the age of 40 years. By ages 60 years and 85 years, the histologic prevalence of BPH at autopsy is 50% and 90%, respectively. The symptoms of BPH are now referred to as lower urinary tract symptoms (LUTS). At age 70 years, about 40% of men report LUTS and by age 75 years, the incidence of LUTS increases to 50%.

The diagnosis and treatment of BPH has always been in the realm of the specialty of urology, and this remains the case. However, as more medical and surgical therapies have been introduced and prostate-specific antigen (PSA) testing for prostate cancer has become commonplace, urologists are working more closely with internists, family physicians, generalists, and physician extenders to jointly manage these patients.

Pathophysiology

Even though BPH is common, we know very little about the true pathophysiology. However, we do know that men who were castrated before puberty do not develop BPH, and we also know that it is a progressive disease of aging. Before the 1980s, BPH was generally thought of as a static condition of a gradually growing prostate gland that caused progressive bladder outlet obstruction. In fact, it was common to use the "donut hole" analogy with patients, explaining to them that the prostate is like a donut surrounding the bladder neck and outlet. With aging and prostate growth, the donut hole gets smaller, causing progressive obstruction. In the era when transurethral resection of the prostate (TURP) was the only effective treatment, this simple static explanation was sufficient.

From the 1980s onward, our understanding has advanced to recognize that BPH has both a static obstructive and a dynamic component under neural control. The donut hole now has to have electrical wires attached to it with the ability to adjust the current. In addition, the contribution of the bladder to LUTS has been well recognized as a key contributor to the dynamic component of BPH and LUTS.

The static growth and proliferation of the periurethral tissue into BPH is under androgenic stimulation. Specifically, the main male hormone testosterone is converted to the more active metabolite dihydrotestosterone (DHT) by the enzyme 5 α -reductase in the prostatic stromal and epithelial cells of the prostate. 5 α -Reductase

occurs in two forms, type 1 and type 2. Only type 2 is present in the prostate and genitalia. This is critical for the understanding of one of the two main classes of medical therapy for BPH, the 5 α -reductase inhibitors (5-ARIs), medications that block the conversion of testosterone to DHT.

The dynamic component of BPH and LUTS is based on autonomic input to the smooth muscles in the lower urinary tract, including the bladder, prostate, and urethra. These areas have a large concentration of α_1 -adrenergic receptors that, when stimulated by various stressors, cause increasing smooth muscle tone. This increased smooth muscle tone leads to increased urethral resistance and contributes to the bladder outlet obstructive symptoms of BPH. This physiology leads to the basis for the other main class of drugs to treat BPH, the α_1 -adrenergic blockers.

Symptoms

LUTS include urinary frequency, decreased force and caliber of the urinary stream, hesitancy, straining to void, urgency, and nocturia. The severity can range from the stoic man who refuses to acknowledge any symptoms to the man in frank urinary retention. Most urologists now use a standardized patient self-administered questionnaire, such as the International Prostate Symptom Score (IPSS) (Figure 1). This is very useful to elicit symptoms and bother in a typical male population with suboptimal health-seeking behavior.

It is now very common for men to be referred to urology for a collection of age-related issues including elevated PSA, LUTS, BPH, or erectile dysfunction (ED). Commonly, the PSA or ED brings the patient to the attention of the health care system for the first time in years and may be the first opportunity to influence men on healthy living and health maintenance as they enter middle or older vulnerable ages. Recognizing this, all health care providers should keep this in mind and try to perform a broader men's health assessment while the patient is captive.

Diagnosis

The diagnosis of BPH is generally made based on symptoms or the IPSS standardized patient-self-administered questionnaire combined with a digital rectal examination, PSA blood test, urinalysis, and, in some cases, a cystoscopy. The differential diagnosis can include urinary tract infection (UTI), prostatitis, urinary stones in the lower urinary tract, urethral stricture disease, neurogenic or overactive bladder, prostate or bladder cancer, and even congestive heart failure. Some common medications, such as over-the-counter cold medicines containing α -adrenergic agents, can exacerbate LUTS and can even put a man into acute urinary retention if he has underlying BPH.

A properly performed digital rectal examination is critical to master in the diagnosis of BPH. Because the posterior prostate gland is located adjacent to the rectum and about 3 to 5 cm internal to the anus, the experienced clinician can gain valuable information. I prefer the patient to bend over the examining table with toes pointed slightly inward, the knees bent slightly forward and the forehead and arms resting on the table. The examiner uses a liberally lubricated gloved index finger to palpate the posterior side of the prostate for size estimate and for any induration or nodularity that might indicate the presence of prostate cancer. In this case, referral to an urologist is mandatory.

The size of the prostate is measured either by estimating the weight in grams or the volume in cubic centimeters. Models have been developed to teach clinicians how to gauge size and consistency. In general, a normal size prostate is 20 to 25 g (or cm³) in middle-aged men. A size of 25 to 30, 30 to 50, and greater than 50 g (or cm³) is a general guide to mild, moderate, and severe BPH. However, size does not necessarily correlate to symptoms, and both symptom score and size estimate should be reported. The size gauges the histologic condition and the symptoms indicate the LUTS and the bother index, which are both important for individualized treatment.

The laboratory assessment should include a urinalysis to rule out hematuria. Like an abnormal digital rectal examination, a urinalysis that shows persistent red blood cells should prompt referral to

International Prostate Symptom Score (I-PSS)

Patient Name: _____ Date of birth: _____ Date completed: _____

a urologist for cystoscopic and upper urinary tract assessment. A urinalysis suggesting UTI should be followed up with a urine culture. If the patient presents in acute or chronic urinary retention and especially if there is a high postvoid or postcatheter residual bladder volume, a serum creatinine and blood urea nitrogen should be obtained. Severe BPH sometimes causes hydronephrosis and renal insufficiency, and rarely it causes renal failure. In-office bladder ultrasound scanners are very useful to quickly assess residual urine.

Contemporary diagnosis of BPH involves obtaining a PSA result. The latest guidelines from the American Urological Association (<http://www.auanet.org>) regarding the use of PSA testing are very helpful. Although the traditional upper limit of normal for PSA testing has been 4.0 ng/mL, recent guidelines base more on changes in PSA levels over time, considering that most men with BPH will have prior PSA results. In the specific setting of using PSA to help manage BPH, the best data come from the PLESS trial (Proscar

Long-Term Efficacy and Safety Study), where a PSA of 0 to 1.3 ng/mL, 1.4 to 3.2 ng/mL, and greater than 3.2 ng/mL was associated with small, medium, and large prostate glands (assuming prostate cancer has been ruled out) and predicted therapeutic response to finasteride (Proscar) (see later section).

Treatment

Treatment of BPH is always individualized to the patient and involves evaluation of symptoms and bother along with objective findings from examination and laboratory results. Current treatments range from periodic monitoring without treatment to treatment of extreme cases with open enucleative surgery.

Active Surveillance and Watchful Waiting

For many men, especially those with lower symptom scores and little bother, annual monitoring with digital rectal examination, PSA, urinalysis and symptom assessment are all that is required. Many

men are happy to be reassured that they do not have clinically significant prostate cancer and are glad to hear that no immediate treatment is necessary.

Complementary and Alternative Medicine

The use of complementary and alternative medicine supplements is very common and physicians should ask patients about their use just as they ask about prescription medications. There are now many “prostate” and “men’s health” supplements containing a variety of chemicals that include zinc¹, saw palmetto⁷, vitamin E,¹ vitamin D¹, and selenium⁷, among others. Aside from a few European clinical trials of saw palmetto, the use of supplements to help BPH is speculative. One challenge is quality assurance of dose and ingredients of these agents that are not FDA-regulated. Although not for BPH, the NIH-funded SELECT trial (Selenium and Vitamin E Cancer Prevention Trial) to determine whether vitamin E or selenium, or both, would prevent prostate cancer is illustrative. Neither supplement had any effect on prostate cancer (or BPH to our knowledge). With the lack of robust trial data for the plethora of supplements, the evidence-based medicine answer to patients is clear.

Medical Therapy

α-Blocker Medications

The use of α -adrenergic blocking oral agents to treat BPH has been commonplace since the 1980s. These agents are directed at the dynamic component of BPH and LUTS by relaxing the smooth muscle tissue in the bladder neck and prostate. In simple terms, they relax the bladder outlet, resulting in better urinary flow.

Initial agents, such as prazosin (Minipress)¹, were not selective blockers and were also used to treat hypertension. Furthermore, these early agents were not long-acting and had to be taken multiple times per day, which severely limited their practical clinical utility. The next generation in the class were doxazosin (Cardura) and terazosin (Hytrin), which were longer-acting agents only dosed once a day. However, they were not selective and also lowered blood pressure, so titration was necessary. The third and current generation agents are selective blockers that treat BPH but do not lower blood pressure when used at recommended doses. The three in this class are tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo).

In general, clinicians use α -blockers in men with smaller prostate glands (≤ 30 – 35 g or cm^3), in younger men, and in patients where rapid effect is needed. Side effects of this class include headache, dizziness, asthenia, drowsiness, and retrograde ejaculation. Alfuzosin is reported to have the lowest rate of retrograde ejaculation. α -Blockers lower urinary tract muscular relaxation properties and are also now employed for ureteral urinary calculi (kidney stones) to facilitate spontaneous passage. α -Blockers are often used to treat prostatitis as well. In this setting, the agents can relieve dysfunctional voiding that contributes to some cases of prostatitis.

5 α -Reductase Inhibitors

The 5 α -reductase inhibitors have been available since the early 1990s. Finasteride (Proscar) was the first agent in this class (5 mg/daily) and is a type 1 inhibitor. Dutasteride (Avodart; 0.5 mg/daily) is a type 1 and type 2 inhibitor and was approved in 2002. Both drugs prevent the conversion of testosterone to the more active metabolite dihydrotestosterone in the prostate. This inhibition results in involution of BPH tissue and prostate shrinkage. On average, most men achieve 20% to 40% reduction in prostate size after at least 6 months of use. In general, these agents are most effective in men with prostate glands more than 30 g (or cm^3). Both drugs lower PSA levels by about 50% after 6 months of use. This is critical to take into account when screening for prostate cancer. If the PSA level does not fall by one-half and the patient has been compliant with medication, the patient should be referred to a urologist for a workup. In follow-up of men, PSA is generally

doubled in assessing risk for prostate cancer. However, the use of PSA velocity or doubling-time and other prostate cancer screening tools are still valid as long as the effect on PSA is appreciated.

There are two key clinical trials that are important. The MTOPS trial (Medical Therapy of Prostate Symptoms) showed that the combination of an α -blocker (doxazosin) and a 5 α -reductase inhibitor (finasteride) was more effective than either alone or placebo in treatment of BPH and LUTS. The PCPT (Prostate Cancer Prevention Trial) showed that finasteride¹ lowered the rate of prostate cancer by 25% over placebo in a large 7-year study. Recently, the REDUCE trial (Reduction by Dutasteride of Prostate Cancer Events) confirmed the prostate chemoprevention benefit of this class of drugs, showing that dutasteride also lowered the rate of prostate cancer by 23% over placebo. In 2010, the FDA ruled that dutasteride would not be approved for prostate cancer prevention, citing safety concerns in this prevention setting. In 2013, the long term follow up of the PCPT showed that there was no excess mortality associated with long-term finasteride use compared to placebo, proving the long-term safety of this therapy.

Urologists also use 5 α -reductase inhibitors to treat chronic hematuria due to an enlarged prostate and sometimes prescribe these agents before transurethral resection of the prostate (TURP) to lessen surgical bleeding.

Minimally Invasive Procedures

In the past 35 years, a series of minimally invasive procedures have appeared in practice with the goals of reducing prostatic obstruction while preserving sexual function with normal erections and ejaculation. Balloon dilation, transurethral microwave therapy (TUMT), and transurethral needle ablation (TUNA) have all fallen from favor due to lack of durable effect in improving lower urinary tract symptoms. Two newer minimally invasive procedures have, however, shown durability in multi-year randomized clinical trials. The prostatic urethral lift procedure (UroLift) utilizes small, permanently implanted anchors placed cystoscopically that physically retract and compress the obstructing lobes of the prostate and can provide near-immediate improvement in flow rates and symptom scores. Alternatively, the Rezum thermal ablation procedure utilizes radiofrequency-generated water vapor (103°C) injected cystoscopically into the prostate tissue resulting in gradual resorption of treated prostate tissue and significant improvements in flow rates and symptom scores over the course of weeks following the procedure. Both procedures carry the benefits of very low rates of ED and retrograde ejaculation, but it remains unknown whether either procedure will provide long-lasting relief of lower urinary tract symptoms similar to more invasive surgical procedures. High-intensity focused ultrasound was granted FDA approval in 2015 for ablation of prostate tissue but has not gained wide use for BPH management and is more frequently utilized in the treatment of prostate cancer.

Surgical Therapy

Transurethral resection of prostate (TURP) remains the gold-standard treatment for men who have failed to improve on medical therapy, who dislike or are intolerant of medication side effects, or who have developed urinary retention, renal failure secondary to BPH, or large bladder calculi. TURP is associated with relatively low rates of incontinence and erectile dysfunction; however, retrograde ejaculation is an expected permanent outcome for most men undergoing this surgery. Evolutions of the traditional TURP procedure now utilize saline irrigation, thereby reducing the risk of hyponatremia during the procedure. Several laser technologies (Greenlight, Holmium, or Thulium) utilized for enucleation or vaporization of prostate tissue have resulted in reduction in hospital stay, transfusion rates, and catheter duration compared to TURP. Finally, for men with severe BPH and very large glands (>150 grams), simple prostatectomy performed robotically or via small suprapubic incision remains a valuable and highly

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

¹Not FDA approved for this indication.

effective surgical treatment. As with radical prostatectomy used for prostate cancer, open or robotic prostatectomy for BPH should be performed by urologic surgeons who are highly experienced in this area.

EPIDIDYMITIS AND ORCHITIS

Method of

Robin A. Walker, MD

CURRENT DIAGNOSIS

- Subacute or gradual onset of scrotal pain and swelling that occasionally radiates to lower abdomen. Typically unilateral; however, inflammation can spread to opposite testicle.
- Fever and urinary tract symptoms (e.g., dysuria, frequency, urgency, hematuria) may be present.
- Testicle should be in normal position with cremasteric reflex intact (rule out torsion).
- Pain is relieved by elevation of testicle (Prehn sign).
- Ultrasound with Doppler is readily available and has high sensitivity and specificity for ruling out testicular torsion; however, referral to urology should not be delayed if torsion is suspected.
- Urinalysis should be obtained, preferably on first-void urine.
- Send urine for culture, especially when sexually transmitted disease (STD) is not suspected.
- Nucleic acid amplification assays for *Gonorrhea* and *Chlamydia* can be run on urine or urethral specimens.

CURRENT THERAPY

- Sexually active men 14 to 35 years old: ceftriaxone (Rocephin)¹ 250 mg IM once and doxycycline (Vibramycin)¹ 100 mg twice daily for 10 days. Azithromycin (Zithromax)¹ 1 g PO for one dose may be substituted for doxycycline if compliance is questionable.
- Oral cephalosporins and fluoroquinolones are no longer recommended for gonococcal infections.
- For older men or when enteric organisms are thought to be the most likely cause: levofloxacin (Levaquin)¹ 500 mg orally twice daily for 10 days, or ofloxacin (Floxin)¹ 300 mg orally twice daily for 10 days.

- Cultures, if obtained, should be followed and treatment adjusted accordingly.
- Patients should follow up in 2 to 3 days. Pain should improve in 1 to 3 days with treatment. Failure to improve should elicit re-evaluation of the diagnosis and therapy, and consideration should be given to other causes such as a testicular tumor/cancer, abscess, infarction, and tuberculosis (TB) or fungal pathogens.
- Sexual partners should be referred for evaluation and treatment if there was intercourse in the preceding 60 days from onset of symptoms.
- Education should occur regarding prevention of STDs.

¹Not US Food and Drug Administration (FDA) approved for this indication.

Epidemiology

Epididymitis is most common in males 18 to 35 years of age, but can occur in all ages. There are approximately 600,000 cases per year in the United States, and these accounted for 1 in 144 outpatient visits in men (2002 data).

In men 35 years of age or younger who are sexually active, the most common pathogens are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In those older than 35, the cause is most likely urinary tract pathogens such as *Escherichia coli*. In men who perform insertive anal intercourse, coliform bacteria are common causative agents. Other less common pathogens include TB, fungal infections, and viruses. Cytomegalovirus has been identified as a cause in patients with HIV.

In boys ages 2 to 13 the incidence is approximately 1.2 per 1000 and is most commonly a postinfectious inflammatory reaction to pathogens such as enteroviruses, adenoviruses, and mycoplasma pneumonia. If a bacterial pathogen is isolated, a urologic workup for any anatomic abnormalities is warranted.

Other uncommon noninfectious causes of epididymitis include vasculitides and medications such as amiodarone (Pacerone).

Orchitis is less common than epididymitis and is most often associated with concurrent epididymitis, occurring in approximately 60% of men with epididymitis. In prepubertal boys, orchitis is usually a sequela of mumps infection. Between 20% and 30% of men with mumps develop orchitis.

Risk Factors

The predominant risk factor for epididymitis is unprotected sexual intercourse. Additionally, trauma from strenuous physical activity, bicycle or motorcycle riding, and prolonged sitting can predispose to epididymitis. Risk factors in prepubertal boys and men over age 35 are related to anatomic abnormalities (e.g., prostatic obstruction, posterior urethral valves, meatal stenosis), recent instrumentation, or urogenital tract surgery (e.g., vasectomy). In prepubertal boys, recent infections can predispose to a postinfectious inflammatory reaction in the epididymis.

Pathophysiology

Infective epididymitis is usually caused by retrograde ascent of pathogens, most commonly bacterial. Noninfectious epididymitis can be autoimmune or can be associated with known syndromes (e.g., Behçet disease) or a side effect of medications, most notably amiodarone (Pacerone). If symptoms last longer than 3 months, the patient meets the diagnostic criteria for chronic epididymitis.

Clinical Manifestations

The typical presentation is subacute onset of unilateral scrotal pain. Any acute onset of pain requires careful consideration of possible testicular torsion. The pain in epididymitis can radiate to the lower abdomen. Fever and urinary tract symptoms such as increased frequency, dysuria, and hematuria are frequently present. The cremasteric reflex is preserved and the testicle should be in its normal anatomic position. The epididymis is tender, swollen, and often indurated. Pain is relieved on testicular elevation (Prehn sign). Over

effective surgical treatment. As with radical prostatectomy used for prostate cancer, open or robotic prostatectomy for BPH should be performed by urologic surgeons who are highly experienced in this area.

Epidemiology

Epididymitis is most common in males 18 to 35 years of age, but can occur in all ages. There are approximately 600,000 cases per year in the United States, and these accounted for 1 in 144 outpatient visits in men (2002 data).

In men 35 years of age or younger who are sexually active, the most common pathogens are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In those older than 35, the cause is most likely urinary tract pathogens such as *Escherichia coli*. In men who perform insertive anal intercourse, coliform bacteria are common causative agents. Other less common pathogens include TB, fungal infections, and viruses. Cytomegalovirus has been identified as a cause in patients with HIV.

In boys ages 2 to 13 the incidence is approximately 1.2 per 1000 and is most commonly a postinfectious inflammatory reaction to pathogens such as enteroviruses, adenoviruses, and mycoplasma pneumonia. If a bacterial pathogen is isolated, a urologic workup for any anatomic abnormalities is warranted.

Other uncommon noninfectious causes of epididymitis include vasculitides and medications such as amiodarone (Pacerone).

Orchitis is less common than epididymitis and is most often associated with concurrent epididymitis, occurring in approximately 60% of men with epididymitis. In prepubertal boys, orchitis is usually a sequela of mumps infection. Between 20% and 30% of men with mumps develop orchitis.

Risk Factors

The predominant risk factor for epididymitis is unprotected sexual intercourse. Additionally, trauma from strenuous physical activity, bicycle or motorcycle riding, and prolonged sitting can predispose to epididymitis. Risk factors in prepubertal boys and men over age 35 are related to anatomic abnormalities (e.g., prostatic obstruction, posterior urethral valves, meatal stenosis), recent instrumentation, or urogenital tract surgery (e.g., vasectomy). In prepubertal boys, recent infections can predispose to a postinfectious inflammatory reaction in the epididymis.

Pathophysiology

Infective epididymitis is usually caused by retrograde ascent of pathogens, most commonly bacterial. Noninfectious epididymitis can be autoimmune or can be associated with known syndromes (e.g., Behçet disease) or a side effect of medications, most notably amiodarone (Pacerone). If symptoms last longer than 3 months, the patient meets the diagnostic criteria for chronic epididymitis.

Clinical Manifestations

The typical presentation is subacute onset of unilateral scrotal pain. Any acute onset of pain requires careful consideration of possible testicular torsion. The pain in epididymitis can radiate to the lower abdomen. Fever and urinary tract symptoms such as increased frequency, dysuria, and hematuria are frequently present. The cremasteric reflex is preserved and the testicle should be in its normal anatomic position. The epididymis is tender, swollen, and often indurated. Pain is relieved on testicular elevation (Prehn sign). Over

time, scrotal wall erythema and a reactive hydrocele may appear and infection can spread from the epididymis to the testicle (orchitis), as well as to the opposite testicle.

Epididymitis secondary to noninfectious causes tends to have a more gradual onset of symptoms.

Viral orchitis from mumps is characterized by abrupt onset of unilateral testicular pain with swelling that typically occurs between 4 and 7 days after the development of parotitis. About 75% of patients with orchitis will also have fever and one third will complain of dysuria.

Diagnosis

Diagnosis can be made by a careful history and physical examination; however, laboratory testing can help confirm epididymitis. Urine should be obtained for analysis and culture, preferably from a first-void sample. The presence of leukocyte esterase and 10 or more white blood cells (WBCs) per high-power field is suggestive for urethritis, helping to differentiate from testicular torsion.

Nucleic acid amplification tests for *N. gonorrhoeae* and *C. trachomatis* should be run on all sexually active men 35 years of age or younger and those over 35 who are at increased risk. These can be run on urine or urethral samples. A Gram stain of urethral discharge should demonstrate 5 or more WBCs per high-power field. Gonococcal infection is established by the presence of WBCs containing intracellular gram-negative diplococci. Depending on risks, consideration should be given to testing for the presence of other STDs.

Color Doppler ultrasound is a readily available study with a sensitivity and specificity for testicular torsion ranging between 89% and 100%. However, imaging should not delay immediate referral to a specialist if torsion is clinically suspected.

Differential Diagnosis

- Testicular torsion: duration less than 6 hours, absence of cremasteric reflex, diffuse testicular tenderness. Elevation of the testis usually exacerbates discomfort.
- Orchitis: testicular tenderness and swelling, normal cremasteric reflex.

Therapy/Treatment

In sexually active men ages 14 to 35, empiric treatment should be started for suspected epididymitis before laboratory results are available. The current recommended regimen is ceftriaxone (Rocephin)¹ 250 mg IM once plus doxycycline (Vibramycin)¹ 100 mg orally twice daily for 10 days. If compliance is questionable or the patient is allergic to doxycycline, azithromycin (Zithromax)¹ 1 g orally once can be substituted. The Centers for Disease Control and Prevention (CDC) no longer recommends fluoroquinolones or oral cephalosporins for the treatment of gonococcal infections.

For men 35 years of age or older, and when a coliform pathogen is suspected, treatment consists of levofloxacin (Levaquin)¹ 500 mg orally for 10 days or ofloxacin (Floxin)¹ 300 mg orally twice daily for 10 days.

Most patients can be treated in the outpatient setting. Inpatient treatment is recommended for suspicion of abscess, intractable pain, signs of sepsis, or failure of outpatient care. Symptomatic care consists of pain control with supportive garments, analgesics, rest, and cold packs.

Orchitis, when not associated with epididymitis infection, is typically treated in a supportive manner with hot or cold packs, rest, nonsteroidal antiinflammatory drugs, and scrotal elevation. Symptoms from viral-associated orchitis typically resolve in 3 to 10 days.

Complications

Complications include sepsis, abscess formation, extension of infection, and infertility.

¹Not FDA approved for this indication.

ERECTILE DYSFUNCTION

Method of

Maurice Duggins, MD

The 1992 National Institutes of Health (NIH) Consensus Development Conference on Impotence defined *erectile dysfunction* (ED) as “any male patient with an inability to achieve an erect penis as part of the overall multifaceted process of male sexual function.” Compared to the previous term of *impotence*, the NIH definition is more descriptive, more inclusive, and less pejorative. Impotence suggests that a man is unable to perform sexually, whereas ED allows for better understanding of the varying degrees of sexual dysfunction that can result in ED. The NIH conference also highlighted that many men with ED were not diagnosed, probably because of embarrassment in discussing the issue. In the decades since the consensus conference, widespread advertising of ED therapies has encouraged more men to discuss ED with their physicians.

Epidemiology

According to the most recent survey, about 18 million men in the United States over age 20 are affected by ED. The prevalence ranges from 20% to above 50% with increasing age. The prevalence is also increased threefold in men with diabetes. Because not all patients report ED or seek therapy, the true prevalence may be significantly higher. A large study in which family physicians screened for and investigated ED symptoms found that nearly half of male patients over 40 had problems, with the prevalence strongly linked to age, diabetes, and cardiovascular disease. According to current estimates, over 152 million men worldwide experience ED. This estimate is projected to reach over 300 million by 2035 and may be even higher due to increasing levels of diabetes and obesity.

In about 80% of patients, an organic cause can be identified for ED. The remaining 20% are attributed to psychogenic causes. Although traditionally organic and psychogenic have been regarded as distinct types of ED, cases with organic causes are often confounded by psychogenic factors.

Besides the personal and emotional burden, ED is one of the most costly urologic conditions. Treatment costs in the United States are estimated at \$328 million annually. Even with insurance, a patient may spend from \$119 to \$30,000 for ED therapy in 1 year.

Risk Factors

Risk factors for ED include age, cardiovascular disease, diabetes, psychiatric disorders, unhealthy lifestyle choices, low education level, and pelvic trauma or surgery. Many men have multiple risk factors. As men age, libido decreases, probably due to decline in testosterone levels. Cardiovascular diseases encompass vascular damage associated with diabetes, hypertension, coronary heart disease, and dyslipidemia. Any history of psychological or psychiatric problems including depression, anxiety, sexual abuse, or stress predisposes to developing ED. Endocrine conditions also indicate

time, scrotal wall erythema and a reactive hydrocele may appear and infection can spread from the epididymis to the testicle (orchitis), as well as to the opposite testicle.

Epididymitis secondary to noninfectious causes tends to have a more gradual onset of symptoms.

ERECTILE DYSFUNCTION

Method of

Maurice Duggins, MD

The 1992 National Institutes of Health (NIH) Consensus Development Conference on Impotence defined *erectile dysfunction* (ED) as “any male patient with an inability to achieve an erect penis as part of the overall multifaceted process of male sexual function.” Compared to the previous term of *impotence*, the NIH definition is more descriptive, more inclusive, and less pejorative. Impotence suggests that a man is unable to perform sexually, whereas ED allows for better understanding of the varying degrees of sexual dysfunction that can result in ED. The NIH conference also highlighted that many men with ED were not diagnosed, probably because of embarrassment in discussing the issue. In the decades since the consensus conference, widespread advertising of ED therapies has encouraged more men to discuss ED with their physicians.

Epidemiology

According to the most recent survey, about 18 million men in the United States over age 20 are affected by ED. The prevalence ranges from 20% to above 50% with increasing age. The prevalence is also increased threefold in men with diabetes. Because not all patients report ED or seek therapy, the true prevalence may be significantly higher. A large study in which family physicians screened for and investigated ED symptoms found that nearly half of male patients over 40 had problems, with the prevalence strongly linked to age, diabetes, and cardiovascular disease. According to current estimates, over 152 million men worldwide experience ED. This estimate is projected to reach over 300 million by 2035 and may be even higher due to increasing levels of diabetes and obesity.

In about 80% of patients, an organic cause can be identified for ED. The remaining 20% are attributed to psychogenic causes. Although traditionally organic and psychogenic have been regarded as distinct types of ED, cases with organic causes are often confounded by psychogenic factors.

Besides the personal and emotional burden, ED is one of the most costly urologic conditions. Treatment costs in the United States are estimated at \$328 million annually. Even with insurance, a patient may spend from \$119 to \$30,000 for ED therapy in 1 year.

Risk Factors

Risk factors for ED include age, cardiovascular disease, diabetes, psychiatric disorders, unhealthy lifestyle choices, low education level, and pelvic trauma or surgery. Many men have multiple risk factors. As men age, libido decreases, probably due to decline in testosterone levels. Cardiovascular diseases encompass vascular damage associated with diabetes, hypertension, coronary heart disease, and dyslipidemia. Any history of psychological or psychiatric problems including depression, anxiety, sexual abuse, or stress predisposes to developing ED. Endocrine conditions also indicate

potential risk for ED. Thyroid or gonadal diseases put men at especially high risk. Lifestyle choices associated with ED include being sedentary, obese, smoking, and abuse of either illicit substances (e.g., cocaine) or alcohol. Lower education levels are also associated with higher prevalence of ED. The correlation between ED and surgery or trauma to the pelvis is not surprising. Patients undergoing pelvic or prostatic radiation, transurethral resection of the prostate (TURP), or radical prostatectomy are at increased risk for ED.

Pathophysiology

Sexual performance in men has four stages: libido (desire), erection (arousal or engorgement), ejaculation, and detumescence. Problems in any stage can result in male sexual dysfunction. The basic mechanical or primary focus of erectile dysfunction is in stage 2. Erection is a complex neuroendocrine psychophysiological event. Erection can occur during sleep, indicating that sexual stimulation is not required.

Nitric oxide (NO) is essential for erection. The release of NO in the cells of the corpus cavernosa following parasympathetic stimulation leads to the conversion of guanylate cyclase to cyclic guanosine monophosphate (cGMP). This causes smooth muscle relaxation that permits the influx of blood causing engorgement of the penis. This mechanism also slows the outflow of venous blood from the penis thus enhancing penile engorgement. Other contributors to vasodilation during erection include vasoactive intestinal peptide (VIP) and prostaglandins E1 and E2 (PGE1 and PGE2).

Prevention

The prevention of ED is mainly directed at modifying risk factors. Patients should be encouraged to quit smoking to reduce vascular damage. Regular exercise, weight management, reducing or stopping alcohol, and abstaining from illicit drugs are important in preventing ED. Family physicians can review medications to identify those with potential to induce ED. Similarly, family physicians can work with patients to identify and manage psychological, hormonal, or neurologic conditions associated with ED.

Clinical Manifestation

Not all men readily admit to ED. Some patients assume that sexual dysfunction is part of the aging process. Others may be embarrassed by the topic. It is important for physicians to anticipate and proactively ask about ED, especially in men with risk factors. In addition to medical conditions such as hypertension, diabetes, or depression, men dealing with difficult personal relationships or major life stresses such as divorce, illness of spouse or partner, bereavement, or work-related stress should be asked about sexual function and ED.

Diagnosis

Establishing the diagnosis of ED begins with a comprehensive history and physical examination. The patient should be asked about risk factors as well as any sexual concerns. The interview must be open, welcoming, and nonjudgmental. Sexual problems can be identified and documented using validated questionnaires such as the International Index of Erectile Function Questionnaire (IIEF), the Sexual Encounter Profile (SEP), or the Global Assessment Questions (GAQ). Though these tools are helpful, they are not necessary to make the diagnosis. Their usefulness may be noted when assessing the patient's response to therapy. A history of sudden, situational, or complete immediate loss of erection during sexual activity (but otherwise experiencing normal erections while awake) may indicate a psychogenic source. Conversely, gradual onset of poor or absent erections suggests an organic cause of ED. The history should address symptoms of conditions associated with ED, especially diabetes, hypertension, cardiovascular disease, and depression or other psychological problems. Medications should be reviewed.

The physical examination should include the genitalia and the cardiac, vascular, endocrine, and neurologic systems. Any

anatomic anomaly may be significant. The testicles, penis, and prostate should be palpated and any atrophy or abnormality noted. The cardiovascular examination should document any findings of heart failure or problems in perfusion.

Differential Diagnosis

Erectile dysfunction may be primary or a manifestation of another medical problem. Endocrinopathies such as hypogonadism, thyroid disorders, and hyperprolactinemia must be ruled out. Drug abuse, alcoholism, renal disease, spinal cord injury, multiple sclerosis, and prostate diseases may all masquerade as ED. Stress-related conditions and sleeping disorders such as sleep apnea should be considered. The condition may also be an adverse effect of medication.

Therapy

In addition to modifying risk factors and any exacerbating conditions, several strategies are available to treat ED. The principal current options are behavioral therapy, medication, hormone replacement or supplement, assistive devices, and surgery.

Phosphodiesterase type 5 (PDE5) inhibitor medications have become the most reliable and acceptable oral therapy for treating ED. This class of medication includes sildenafil (Viagra), vardenafil (Levitra), avanafil (Stendra), and tadalafil (Cialis). The mechanism of action is identical, but the drugs differ in pharmacokinetic properties. Both sildenafil and vardenafil have an action window of 4 to 6 hours whereas tadalafil is effective for up to 36 hours. The common adverse effects with this group of medications are limited to brief headache, flushing, dyspepsia, rhinitis, and vision changes. They are contraindicated with the use of nitrates. Because the onset of action varies with PDE5 inhibitors, they should be taken on an empty stomach at least 1 hour before sexual activity. Trazodone (Desyrel)¹ may be helpful in men whose ED has significant depression/anxiety basis. Yohimbine⁷ has fallen out of favor because of its low level of predictable erection response coupled with its adverse side effects.

Testosterone replacement is most appropriately used in hypogonadal patients. The oral formulation is not highly recommended or used in the United States. Gels, patches, and injections are preferred methods of administering testosterone. Testosterone may be used with PDE5 inhibitors. Potential adverse effects include exacerbation of sleep apnea, prostatic hyperplasia, and the unmasking of occult prostate cancer. Care must also be given to avoiding gel-skin contact with women and children. Testosterone should never be used in men with normal testosterone levels, as well as those with breast or prostate cancer.

Other medications are administered as injectable or intraurethral suppositories. Alprostadil (Caverject), papaverine¹, vasoactive intestinal polypeptide (VIP)⁵, and phentolamine¹ began as individual penile injections and evolved into combination injections over time. These are usually given initially by a urologist to quantify the optimal safe dose that is required for a full erection. The lowest effective dose is the goal of titration.

Vacuum-assisted devices are effective and have the benefit of being considered the most cost-effective therapy for ED. They are not, however, convenient or acceptable for some patients and/or their sexual partners. These devices draw blood into the penis and then maintain the erection with the use of a special constrictive band placed at the base of the penis to prevent the blood from leaving the penis. These devices should never be used in patients with blood dyscrasias or sickle cell anemia.

Surgical therapies are mainly limited to correction of a traumatic penile injury, repair of Peyronie's deformity or other abnormality, or prosthesis insertion. Some surgical interventions attempt arterial revascularization. Procedures for venous revascularization are considered experimental therapy for ED. Prostheses can be rigid,

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

⁷Available as dietary supplement.

malleable, or inflatable. They are mostly inserted as a final and permanent treatment for ED.

No therapy for ED is complete without counseling. This may be limited to a physician-patient discussion on appropriate and responsible use of therapy plus self-education or physician-directed readings on ED; however, referral to a psychiatrist and/or psychologist may be appropriate. Psychosexual counseling in addition to medication has been shown to benefit patients suffering from ED and should be seen as an integrative part of overall therapy.

Complementary and alternative therapies do not have enough data to support recommendation at this stage. Many treatments are promoted as nutritional cures and have not been scientifically evaluated or have insufficient evidence to support use. Ginkgo biloba⁷, ginseng⁷, human chorionic gonadotropin (HCG)⁷, and L-arginine⁷ are some of the popular supplements advertised for ED. Patient should be asked about use of these therapies, and those patients who choose to continue use should be monitored for adverse effects and potential drug-drug interactions.

Monitoring

Monitoring is based on patient needs and the therapy selected. The PDE5 inhibitors may only need routine follow-up to assess efficacy and to make dosage adjustments. Warning and education on appropriate response to priapism should be discussed with the patient. Signs of hemodynamic changes should also be reviewed such as dizziness, arrhythmias, tachycardia, or syncope. These occur less often with PDE5 inhibitors and most commonly with injectable therapies. Patients taking testosterone replacement may need annual prostate examinations and blood testing to monitor hormone, liver enzymes, hemoglobin, and prostate-specific antigen (PSA) levels. The frequency of testing should be increased for those patients at higher risk for prostate cancer such as African Americans and those with a family history of prostate cancer.

Complications

Complications from ED and its treatment must always be considered and appropriately addressed. They include depression, anxiety, schizoid behavior, and deviant or violent behavior. Sildenafil can cause a blue or green halo visual effect. Musculoskeletal pain is a common side effect of vardenafil and tadalafil. The PDE5 inhibitors should never be taken with nitrates or other vasodilators because severe or fatal hypotensive response may occur. Priapism may result from any of the medicated forms of therapy. Hormonal replacement therapy can lead to elevated liver enzymes, exacerbation of sleep apnea, and either prostatic hypertrophy or enhanced growth of prostate cancer. Pain, hematomas, or plaques may occur as a result of penile injections. Topical agents can cause skin irritation, urethral bleeding, or dysuria. ED has a significant effect on patients' families, self-esteem, and quality of life; therefore patients, their partners, and family members should be treated with respect and compassion.

⁷Available as dietary supplement.

PROSTATITIS

Method of

Charles R. Powell, MD

CURRENT DIAGNOSIS

- The workup for prostatitis begins with a thorough history and physical, as well as a urinalysis and urine culture. Diagnosis is based on symptoms (Figure 1) and tenderness on digital rectal examination. There is a controversial role for prostate massage and culture of expressed prostatic secretions.
- Urinalysis and midstream urine culture are important to distinguish bacterial from nonbacterial causes but are not necessary for the diagnosis of prostatitis.
- Prostatitis is categorized as acute or chronic. It has been further characterized by the National Institutes of Health (NIH) into four categories: acute bacterial, chronic bacterial, chronic pelvic pain syndrome (also called chronic nonbacterial prostatitis), and asymptomatic (Table 1).
- Chronic prostatitis is defined as duration longer than 3 months and typically manifests with pelvic pain and lower urinary tract symptoms.

CURRENT THERAPY

- The majority of prostatitis falls under the category of chronic prostatitis/chronic pelvic pain syndrome, and monotherapy has not proven effective.
- Fluoroquinolone antibiotics are first-line therapy for acute and chronic bacterial prostatitis.
- Trimethoprim/sulfamethoxazole (Bactrim)¹ can be considered first-line therapy, but local antibiotic resistance patterns should be considered before empiric treatment.
- First-generation cephalosporins, doxycycline (Vibramycin), tetracycline, azithromycin (Zithromax),¹ and clarithromycin (Biaxin)¹ are all second-line agents.
- Acute prostatitis may require inpatient admission and intravenous (IV) antibiotics depending on severity and presence of sepsis. Urinary retention may require suprapubic tube urinary drainage as a Foley catheter may worsen prostate inflammation.
- The role of antibiotics in the treatment of chronic pelvic pain syndrome is less clear. Treatment directed at specific phenotypes has improved outcomes recently. The UPOINT treatment philosophy has garnered much interest in the urologic community and is used to phenotype subjects and to direct multimodal therapy.

Complications from ED and its treatment must always be considered and appropriately addressed. They include depression, anxiety, schizoid behavior, and deviant or violent behavior. Sildenafil can cause a blue or green halo visual effect. Musculoskeletal pain is a common side effect of vardenafil and tadalafil. The PDE5 inhibitors should never be taken with nitrates or other vasodilators because severe or fatal hypotensive response may occur. Priapism may result from any of the medicated forms of therapy. Hormonal replacement therapy can lead to elevated liver enzymes, exacerbation of sleep apnea, and either prostatic hypertrophy or enhanced growth of prostate cancer. Pain, hematomas, or plaques may occur as a result of penile injections. Topical agents can cause skin irritation, urethral bleeding, or dysuria. ED has a significant effect on patients' families, self-esteem, and quality of life; therefore patients, their partners, and family members should be treated with respect and compassion.

⁷Available as dietary supplement.

PROSTATITIS

Method of

Charles R. Powell, MD

CURRENT DIAGNOSIS

- The workup for prostatitis begins with a thorough history and physical, as well as a urinalysis and urine culture. Diagnosis is based on symptoms (Figure 1) and tenderness on digital rectal examination. There is a controversial role for prostate massage and culture of expressed prostatic secretions.
- Urinalysis and midstream urine culture are important to distinguish bacterial from nonbacterial causes but are not necessary for the diagnosis of prostatitis.
- Prostatitis is categorized as acute or chronic. It has been further characterized by the National Institutes of Health (NIH) into four categories: acute bacterial, chronic bacterial, chronic pelvic pain syndrome (also called chronic nonbacterial prostatitis), and asymptomatic (Table 1).
- Chronic prostatitis is defined as duration longer than 3 months and typically manifests with pelvic pain and lower urinary tract symptoms.

CURRENT THERAPY

- The majority of prostatitis falls under the category of chronic prostatitis/chronic pelvic pain syndrome, and monotherapy has not proven effective.
- Fluoroquinolone antibiotics are first-line therapy for acute and chronic bacterial prostatitis.
- Trimethoprim/sulfamethoxazole (Bactrim)¹ can be considered first-line therapy, but local antibiotic resistance patterns should be considered before empiric treatment.
- First-generation cephalosporins, doxycycline (Vibramycin), tetracycline, azithromycin (Zithromax),¹ and clarithromycin (Biaxin)¹ are all second-line agents.
- Acute prostatitis may require inpatient admission and intravenous (IV) antibiotics depending on severity and presence of sepsis. Urinary retention may require suprapubic tube urinary drainage as a Foley catheter may worsen prostate inflammation.
- The role of antibiotics in the treatment of chronic pelvic pain syndrome is less clear. Treatment directed at specific phenotypes has improved outcomes recently. The UPOINT treatment philosophy has garnered much interest in the urologic community and is used to phenotype subjects and to direct multimodal therapy.

¹Not FDA approved for this indication.

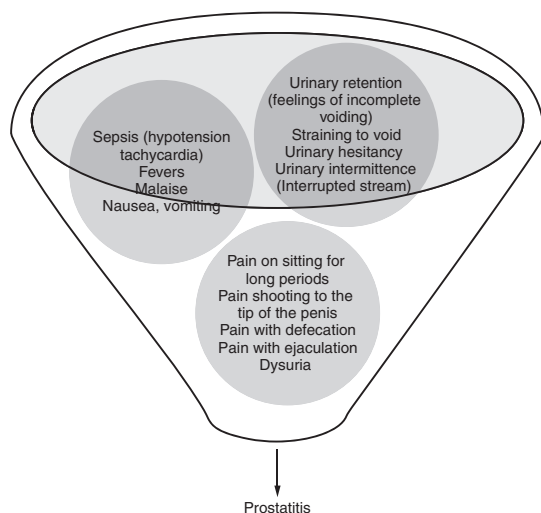

Figure 1 Symptoms associated with prostatitis.

TABLE 1 National Institutes of Health Consensus Classification of Prostatitis

CATEGORY	DESCRIPTION
I. Acute bacterial prostatitis	Acute infection of the prostate gland with positive urine or semen cultures. Symptoms present for less than 3 months.
II. Chronic bacterial prostatitis	Chronic infection of the prostate gland with positive urine or semen cultures. Symptoms present for greater than 3 months.
III. Chronic pelvic pain syndrome	Chronic pelvic pain in the absence of bacterial infection localized to the prostate. Symptoms present for greater than 3 months.
A. Inflammatory	Significant white blood cell (WBC) count in the prostatic secretions, urine, or semen.
B. Noninflammatory	Insignificant WBC count in the prostatic secretions, urine, or semen.
IV. Asymptomatic prostatitis	WBC count elevated or bacteria in the prostatic secretions, urine, semen, or histologic specimens of prostate tissue.

Epidemiology

The prevalence of prostatitis is approximately 8.2% (range 2.2%–9.7%). It accounts for 8% of visits to urologists and up to 1% of visits to primary care physicians. In 2000, the estimated cost to diagnose and treat prostatitis was \$84 million, not including pharmaceutical spending.

Risk Factors

The risk factors for prostatitis include urinary tract infection, elevated postvoid residual (urinary retention), recent history of prostate biopsy, urinary catheterization, unprotected anal intercourse, recent urethral instrumentation such as cystoscopy, and condom catheter use.

Pathophysiology

Prostatitis is commonly associated with infection but can also describe noninfectious chronic pelvic pain, as well as asymptomatic histologic evidence of sterile inflammation. The causes for acute and chronic bacterial prostatitis include prior genitourinary infections such as epididymitis/orchitis, infection resulting from prostate needle biopsy, and recent urinary tract infection. Other

predisposing factors include obstruction of urine from urethral stricture, benign prostatic hypertrophy (BPH), or neurogenic causes. A causative organism can be found in <10% of prostatitis cases. The causative organisms include *Escherichia coli* (most common at 65%–80% of infections), *Pseudomonas aeruginosa*, *Serratia* species, *Klebsiella* species, and *Enterobacter aerogenes*. Gram-positive organisms include enterococci. Organisms isolated from patients with recent history of lower urinary tract instrumentation or manipulation exhibit more resistance to ciprofloxacin (Cipro) and cephalosporins. For these patients ciprofloxacin is often inadequate. A combination of cephalosporins and aminoglycosides is appropriate. Patients with a history of HIV infection should prompt investigation for atypical pathogens. The cause of chronic pelvic pain syndrome/chronic nonbacterial prostatitis (NIH category 3) is less well understood, as is asymptomatic prostatitis (NIH category 4).

Prevention

Prophylactic antibiotic dose before urologic procedures, particularly prostate needle biopsy, according to the American Urological Association Best Practice Statement for Urologic Surgery (<http://www.auanet.org>). Preprocedure rectal swabs to assess resistance patterns are now considered in select cases where resistance is more likely, such as prior antibiotic exposure.

Clinical Manifestations

Figure 1 details some symptoms of prostatitis, separated by domain.

Diagnosis

Diagnosis of acute and chronic bacterial prostatitis is primarily based on history, physical examination, urine culture, and urine specimen testing before and after prostatic massage. If acute bacterial prostatitis is suspected prostatic massage should not be performed because this might be harmful. Sexually active men younger than 35 years and older men who engage in high-risk sexual behaviors should be tested for *Neisseria gonococcus* and *Chlamydia trachomatis* as well. The presence of leukocytes in the semen, first-voided urine, midstream urine, expressed prostatic secretions, or post-prostatic massage urine did not correlate with symptoms when studied in a prospective manner. Bacterial localization studies, such as the Meares-Stamey four-glass test, are useful in subcategorizing type 3 chronic pelvic pain syndrome but have unclear significance in the acute clinical setting.

Differential Diagnosis

The differential diagnosis of prostatitis includes acute cystitis, benign prostatic hyperplasia, prostate cancer, urinary tract stones, bladder cancer, prostatic abscess, enterovesical fistula, foreign body within the urinary tract, voiding dysfunction, and inflammatory conditions of the bladder such as interstitial cystitis/painful bladder syndrome.

Therapy (or Treatment)

Treatment depends on the NIH Prostatitis Classification Category. For those with acute prostatitis, oral ciprofloxacin (Cipro)¹ 500 mg orally twice daily for 4 to 6 weeks or levofloxacin (Levaquin)¹ 500 mg orally once daily for 4 to 6 weeks is appropriate for nonseptic-appearing patients. Trimethoprim/sulfamethoxazole (Bactrim, Septra)¹ 160 mg/800 mg orally twice daily for 4 to 6 weeks is also appropriate, depending on local antibiotic resistance patterns. Patients appearing septic (hypotension, tachycardia, high fevers) should be admitted to the hospital and started on broad-spectrum antibiotics such as ampicillin (Principen) 2 g IV every 6 hours and an aminoglycoside such as gentamicin 1 mg/kg IV every 8 hours. Aminoglycosides should be monitored and adjusted for azotemia. Prostatic abscess should be considered if patients do not improve within 24 to 48 hours. Prostatic

¹Not FDA approved for this indication.

abscesses are urologic emergencies and can be drained with transurethral resection of the prostate, transrectal ultrasound drainage, or computed tomography (CT)-guided needle drainage. Urinary retention should be treated with suprapubic catheter drainage in cases of acute prostatitis and alpha blockers. Chronic bacterial prostatitis (CP) is treated with the same oral agents as acute bacterial prostatitis. For the treatment of chronic pelvic pain syndrome (CPPS) antibiotics play a less clear role, but fluoroquinolone antibiotics used empirically for 4 to 6 weeks have been effective in previously untreated patients. There is little value to repeated courses of antibiotics if the first course is not effective. There is conflicting evidence for alpha blockers such as tamsulosin (Flomax 0.4 mg orally once per night).¹ The interested reader is referred to a review article by Nickel and Shoskes (2010), wherein a multidisciplinary approach is advocated taking into account a more detailed six-domain phenotype with therapy directed at the relevant phenotype(s). This is known as UPOINT. These phenotype domains include Urinary (broken down into voiding and storage symptoms), Psychosocial (subdivided into depression and catastrophizing), Organ Specific (divided into bladder and prostate), Infection (noted in the urine or expressed prostatic secretions), Neurologic (divided into focal and systemic), and Tenderness (muscle). Categorizing patients according to these domains may allow clinicians to personalize treatment using a multimodal approach involving physical therapy, psychiatry, and medication. Interested readers are encouraged to review the European Association of Urology Guidelines for Chronic Pelvic Pain which encompasses all forms of pelvic pain, including prostatitis (http://uroweb.org/wp-content/uploads/26-Chronic-Pelvic-Pain_LR.pdf).

Monitoring

Monitoring is based on symptoms. In cases of acute prostatitis treated with appropriate antibiotics, persistent fevers should prompt a workup for prostatic abscess. The NIH Chronic Prostatitis Symptom Index (CPSI) patient-reported questionnaire can be used to quantify mentioned earlier can be used to quantify symptoms over

time. PSA testing plays no role in the treatment or monitoring of prostatitis, but should be considered if risk factors for prostate cancer are present such as a prostate nodule or family history. PSA testing is affected by acute inflammation and should be postponed until a few months after the symptoms of prostatitis have resolved.

Complications

Acute prostatitis can progress to urosepsis and hypotension. Chronic bacterial prostatitis might have the ability to progress to chronic pelvic pain syndrome and become a source of pain for years.

ABNORMAL UTERINE BLEEDING*Method of***Sarina Schrager, MD, MS****CURRENT DIAGNOSIS**

- Anovulation and pelvic structural abnormalities are the most common causes of abnormal vaginal bleeding in reproductive-age women.
- All women with abnormal bleeding should have a pregnancy test.
- A pelvic ultrasound will detect many structural causes of abnormal bleeding.
- Either a pelvic ultrasound or endometrial biopsy is appropriate for evaluation of postmenopausal bleeding.

**CURRENT THERAPY**

- Unstable women with acute heavy vaginal bleeding should be admitted to hospital for intravenous (IV) estrogen therapy (Premarin) or surgical intervention.
- Treatment of anovulatory bleeding includes ovulation induction if a woman desires pregnancy and hormonal cycle control if she does not.
- Anovulatory women are at risk for endometrial hyperplasia or carcinoma due to unopposed estrogen and should have regular progesterone-induced withdrawal bleeds.
- Treatment of menorrhagia can include nonsteroidal anti-inflammatory drugs (NSAIDs), tranexamic acid (Lysteda), or insertion of a levonorgestrel intrauterine device (IUD) (Mirena).

Epidemiology

Abnormal vaginal bleeding is a common complaint in primary care. The prevalence of some type of abnormal bleeding is between 10% and 30% among women of reproductive age. Anovulatory bleeding is more common in women who are perimenopausal and who are overweight. The estimated direct and indirect costs of abnormal bleeding are \$1 billion and \$12 billion annually, respectively. Abnormal bleeding is also a common reason for women to be referred to gynecologists and is an indication for up to 25% of all gynecologic surgery.

Pathophysiology

Normal menstrual bleeding is defined as regular vaginal bleeding that occurs at intervals from every 21 to 35 days. A normal menstrual cycle is ovulatory, with two distinct phases: the follicular phase and the luteal phase. The follicular phase is the first half of the cycle. The luteal phase occurs after ovulation, when the corpus luteum develops in anticipation of a possible pregnancy. [Table 1](#) defines vocabulary to describe different patterns of abnormal bleeding.

The pathologic abnormality in anovulatory cycles is a lack of ovulation, which produces an unopposed estrogen state. The luteal phase of the menstrual cycle is dominated by progesterone, which is only produced after ovulation. This lack of progesterone contributes to irregular endometrial growth and nonuniform bleeding. In a normal cycle, the entire endometrium sloughs off during menstruation. In an anovulatory cycle, different sections of endometrium outgrow their blood supply at different times and bleed erratically. Anovulatory bleeding (also referred to as dysfunctional uterine bleeding) is unpredictable in timing and amount of bleeding.

The most common structural abnormalities that cause abnormal bleeding are endometrial polyps, leiomyomas, adenomyosis, and hyperplasia or malignancy.

Abnormal bleeding is also common in women who use hormonal contraception, usually due to endometrial abnormalities from exogenous hormones. Women who take combination estrogen/progestin contraception often have intermenstrual bleeding for the first 3 months of treatment. Missed pills are a very frequent cause of abnormal bleeding. In women using progestin-only methods, the abnormal bleeding usually is caused by progestin-induced endometrial atrophy.

Diagnosis

All women with abnormal bleeding should have a thorough history and physical examination and a pregnancy test. If the pregnancy test is negative, the next step is to determine whether her cycles are ovulatory or anovulatory. [Table 2](#) describes characteristics of ovulatory cycles. Laboratory evaluation includes looking for causes of anovulation ([Table 3](#)), assessing for anemia with a hemoglobin and hematocrit level, and consideration of getting a pelvic ultrasound to look for structural abnormalities.

In menorrhagia, evaluation for a coagulation disorder (most commonly von Willebrand disease), liver failure, or chronic renal failure is also indicated. Evaluation in an acute bleeding episode (usually due to anovulatory bleeding) should include a hemoglobin and hematocrit if the bleeding is heavy assessment of volume status, and an endometrial biopsy. Postmenopausal bleeding is related to an increased risk of endometrial hyperplasia and cancer and should be evaluated with a transvaginal ultrasound to look at the endometrial thickness (under 4 mm is reassuring) or an office endometrial biopsy. [Table 4](#) describes the steps in evaluation of a woman with abnormal bleeding.

Treatment

If a woman presents with heavy bleeding and exhibits any signs or symptoms of hypovolemia, she should be admitted to the hospital and either treated with IV conjugated estrogen (Premarin) to stop the bleeding or have a surgical procedure (such as dilation and curettage). If the bleeding is heavy but the woman is stable and her hemoglobin and hematocrit are close to normal, outpatient treatment with high-dose oral contraceptive pills (OCPs), estrogen, cyclic progesterone, NSAIDs, or tranexamic acid (Lysteda) is indicated. Women with structural abnormalities causing menorrhagia should be referred for possible surgical treatment.

Treatment of women with ovulatory bleeding is indicated if the woman is anemic or is bothered by her bleeding pattern. However,

treatment of anovulation with some type of progesterone is necessary to reduce the risk of endometrial hyperplasia or carcinoma. All women with chronic anovulation should have regular progesterone-induced withdrawal bleed. OCPs, monthly cycling

TABLE 5 Treatment Options for Abnormal Vaginal Bleeding

Anovulation: cycle control with estrogen/progestin contraception, DMPA, levonorgestrel IUD (Mirena), or scheduled progestin-induced withdrawal bleeds, ovulation induction with clomiphene citrate (Clomid), and referral to gynecologist if pregnancy desired

Acute bleeding episode—outpatient: administration of high-dose OCPs (up to 4 per day) for 5–7 days with subsequent continuous cycling with OCPs for at least 1 month, administration of oral estrogen to acutely stop bleeding, or administration of oral progesterone to acutely stop bleeding

Acute bleeding episode—inpatient: IVF, supportive care, IV estrogen therapy, consultation for surgical intervention

Menorrhagia—treatment with NSAIDs, tranexamic acid (Lysteda), insertion of levonorgestrel IUD, referral for endometrial ablation or surgical treatment of structural abnormality

On combination estrogen/progestin contraception: supportive care for first 3 months, assessment of adherence to pill regimen, add supplemental estrogen, change to a method with a higher dose of estrogen or a different class of progestin

On progestin-only contraception: add supplemental estrogen or combination oral contraceptive pill and NSAID to decrease bleeding

Abbreviations: DMPA=depot medroxyprogesterone acetate (Depo-Provera); IUD=intrauterine device; IV=intravenous; IVF=in vitro fertilization; NSAID=nonsteroidal antiinflammatory drug; OCP=oral contraceptive pill.

of progesterone, and continuous administration of progestin contraception (e.g., depot medroxyprogesterone acetate [Depo-Provera] or levonorgestrel IUD [Mirena]) are all effective treatments (Table 5).

Treatment of women with abnormal bleeding on OCPs involves education and support to try to get them through the first 3 months on the pills. After that, consideration of supplemental estrogen, changing to a higher dose of an estrogen pill, changing to a pill with a different class of progestin, use of a supplemental NSAID to decrease the amount of bleeding, decreasing the hormone free interval, or changing to a nonhormonal type of contraception are all potential treatments.

CURRENT DIAGNOSIS

- Always consider the possibility of pregnancy in any woman presenting with secondary amenorrhea.

- Secondary amenorrhea is most commonly the result of some significant lifestyle change (weight gain or loss, stress, excessive exercise) or illness (with marked weight loss) in the preceding 6 months.
- Obesity and features of androgen excess are most often related to polycystic ovary syndrome (PCOS).
- Because constitutional delay of puberty is found in only one third of girls presenting with delayed menarche, an investigation should be initiated at the time of presentation rather than waiting until the girl is 16 years old (meeting the definitional criteria).
- Primary amenorrhea, particularly with the absence of other features of pubertal development (breasts and pubic and axillary hair), suggests ovarian failure.
- When amenorrhea due to ovarian failure (high FSH) occurs before age 35 years, a karyotype is indicated. If Y chromosome material is identified on karyotype, gonadectomy is required to reduce the risk of malignancy in the gonadal tissues.

Amenorrhea, simply put, is the absence of menses. It can be classified as either primary (when a woman of reproductive age has never had menstruation) or secondary (when amenorrhea occurs after menstruation has been established). There are normal situations in which amenorrhea is expected (physiologic amenorrhea): during pregnancy, during lactation, and at the onset of menopause. Approximately 5% of reproductive-age women experience amenorrhea at times other than these, which warrants investigation. Women with amenorrhea often present with significant apprehension and anxiety. Thus, an appropriate but timely workup and diagnosis are required. The clinician must have a systematic approach for evaluating such women to ensure that important causes of amenorrhea are identified. As always, a detailed history, a targeted physical examination, and selective use of simple diagnostic tests are required.

Definition

Amenorrhea may be defined as the absence of menstruation for 3 or more months in women with past menses (secondary amenorrhea) or the absence of menarche by the age of 16 years in girls who have never menstruated (primary amenorrhea). Infrequent menstruation, termed *oligomenorrhea*, may have similar causes and also warrants investigation.

Menstrual Cycle

A clear working knowledge of the menstrual cycle and its physiology is mandatory for the clinician in these circumstances. Menstruation normally results when a cascade of hormonal signals from the hypothalamus (gonadotropin-releasing hormone [GnRH]) cause pituitary release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These in turn stimulate the development of an egg-containing ovarian follicle. Estrogen from this follicle results in steady growth of the endometrial lining over a 2-week period (follicular phase). When ovulation occurs, the follicle (now called the corpus luteum) develops the ability to produce a second hormone, progesterone.

The secretion of estrogen and progesterone for the next 2-week period causes the endometrial lining to become lush (decidualized) in preparation for implantation of a pregnancy. If pregnancy fails to occur, the corpus luteum undergoes a spontaneous demise, the endometrium no longer has adequate hormonal support to survive, and the tissue is sloughed synchronously over the next 5 to 7 days as menstrual flow. The final steps of this process require a means of egress for blood, implying a normal uterus with a patent cervix and vagina (the outflow tract).

Etiology

Different classification systems have been employed. One system defines the type of amenorrhea based on the level of FSH in

Figure 1 The four compartments to consider when evaluating amenorrhea.

circulation. For example, high FSH levels indicate that the hypothalamus and pituitary are fully functioning but that the ovary is not responding (similar to menopause). The gonadotropin (FSH) levels are high and the ovary (gonad) is not functioning, which is termed *hypergonadotropic hypogonadism*. *Hypogonadotropic hypogonadism* refers to the situation where FSH levels are very low due to some central disturbance of hypothalamic or pituitary function. The problem with this classification is that normal FSH levels are often low and the distinction between hypogonadotropic and eugonadotropic causes of amenorrhea can be difficult.

A simple way to consider causes of amenorrhea is to divide the processes that regulate menstruation (the hypothalamic-pituitary-ovarian axis [HPO axis]) into compartments (Figure 1) and then consider possible contributory factors for disruption of normal processes at each of these levels. Always consider the possibility that amenorrhea may be due to unexpected pregnancy before moving on to a full investigation.

Hypothalamic Compartment

The hypothalamus integrates a wide variety of signals from the brain and is ultimately responsible for turning on or off the hormonal cascade necessary for triggering ovulatory and menstrual function. In adolescents, the development of breasts (thelarche) between ages 8 and 10 years is usually the first sign that the HPO axis has turned on and first menstruation (menarche) typically follows within 3 to 5 years. All girls with primary amenorrhea by age 14 years, particularly if 5 or more years have passed since the first evidence of pubertal development, warrant careful investigation, because girls with primary amenorrhea on the basis of constitutional delay cannot readily be differentiated on clinical history from the two thirds of patients with primary amenorrhea who have irreversible causes of reproductive failure.

Constitutional Delay

One third of young women presenting with primary amenorrhea have constitutional delay of puberty, meaning that they are undergoing a normal sequence of pubertal development at a rate that falls 2.5 standard deviations behind the mean. Girls with constitutional delay often present between ages 13 and 16 with primary amenorrhea and only early signs of breast development. Investigation reveals low to low-normal levels of gonadotropins and an otherwise negative workup.

Congenital Causes

A variety of unusual congenital conditions result in hypogonadotropic hypogonadism and primary amenorrhea. These conditions may be caused by deficiency of GnRH production or by abnormalities of the GnRH receptor. A Kallman's-like syndrome has been identified in some affected women who present with anosmia and a complete lack of pubertal development.

Acquired Causes

Acquired diseases can lead the hypothalamus to shut down the reproductive hormonal cascade, resulting in amenorrhea, which may be primary or secondary, depending on when they develop. Nutritional deprivation (including eating disorders), excessive caloric demand due to participation in demanding sports, and extreme psychological stress are common reasons for delayed activation of reproductive processes by the hypothalamus. Less commonly, systemic illnesses, including malabsorption states, active autoimmune diseases, and rare hypoxemic states related to congenital heart malformations or severe anemias (sickle cell disease), can lead to amenorrhea.

Pituitary Compartment

Lesions of the pituitary stalk that interrupt normal delivery of GnRH to the pituitary include those resulting from head trauma, rare stalk tumors such as craniopharyngiomas, or from the surgery to remove these.

Pituitary causes of amenorrhea are almost always due to over secretion of prolactin. Hyperprolactinemia resulting in amenorrhea, if associated with central retro-orbital headache and bitemporal hemianopia, can result from a prolactin-producing tumor.

Other causes of hyperprolactinemia originate outside the pituitary. For example, primary hypothyroidism, breast or chest wall lesions (or piercings) in the T4-6 dermatome, renal failure, and a variety of medications have all been linked to hyperprolactinemia. Medications that can cause hyperprolactinemia include dopamine receptor antagonists (phenothiazines, butyrophenones, thioxanthenes, risperidone, metoclopramide, sulpiride,² pimozide), dopamine-depleting agents (e.g., methyl dopa, reserpine), H₂-blockers (cimetidine), opiates, and cocaine.

Rarely, other pituitary conditions result in amenorrhea. In empty sella syndrome, radiologic examination reveals an apparently empty sella due to pituitary regression from some vascular or other insult. Other conditions include Sheehan syndrome (postpartum pituitary necrosis), pituitary apoplexy (massive pituitary infarction), and radiation-induced hypopituitarism. In each of these situations, amenorrhea is usually part of a larger picture of endocrine disruption.

Ovarian Compartment

Depletion of eggs from the ovary before or after puberty results in primary or secondary amenorrhea, respectively. FSH levels are markedly elevated in these cases, as the hypothalamus and pituitary try to elicit follicular development from the unresponsive ovary. Destruction of oocytes by any of several environmental insults, including ionizing radiation, various chemotherapeutic (especially alkylating) agents, and certain viral infections can accelerate follicular atresia.

Primary amenorrhea in a woman with evidence of gonadal failure should elicit a search for a chromosomal abnormality. It is known that two intact X chromosomes are needed for maintenance of ovarian function. A variety of X chromosome structural abnormalities have been identified in women with premature ovarian failure, including complete absence of one X chromosome (Turner's syndrome).

Elevated FSH occurs in association with a normal karyotype. These women have normal 46,XY or 46,XX karyotypes without the phenotypic abnormalities of Turner's syndrome. Those with

a Y chromosome should have their gonads removed because of the potential for malignant transformation.

Several rare inherited enzymatic defects also may be associated with premature ovarian failure. These include partial deficiencies in four enzymes in the steroidogenic pathway—17 α -hydroxylase, 17,20-desmolase, 20,22-desmolase, and aromatase—and galactosemia.

Premature ovarian failure may be associated with a number of autoimmune disorders. Most commonly associated with thyroiditis, ovarian failure also occurs in women with polyglandular failure, including hypoparathyroidism, hypoadrenalism, and mucocutaneous candidiasis.

Though it is not exclusively an ovarian disorder, it is useful to consider polycystic ovary syndrome (PCOS) in the ovarian compartment for the purpose of completeness in considering possible diagnoses. PCOS is one of the most common causes of secondary amenorrhea. Typically, women suffering from this condition are overweight (although one third have normal body weight) and have clinical features of hyperandrogenism (acne and hirsutism), hyperinsulinism (acanthosis nigricans), and hyperestrogenism (watery cervical mucus). Months of amenorrhea may be punctuated by episodes of heavy and prolonged menstrual bleeding as an estrogen-thickened endometrium sheds irregularly over several weeks.

Outflow Tract Compartment

Congenital abnormalities of development of the reproductive outflow tract can cause amenorrhea. Complete absence of a uterus can be due to isolated müllerian agenesis or it can manifest in phenotypic females with a 46,XY karyotype who have complete androgen insensitivity. Developmental abnormalities can include cervical atresia, transverse vaginal septum, and imperforate hymen. These latter abnormalities may be associated with cyclic menstrual pain in the absence of bleeding (cryptomenorrhea). Similarly, monthly cramps can occur with cervical stenosis following trachelectomy or conization. Uterine synechiae due to a vigorous curettage in the face of a postpartum or postabortion endometritis can result in obliteration of the uterine cavity and secondary amenorrhea with or without monthly menstrual-like cramps.

Other Causes

Pregnancy must always be considered in a sexually active female patient presenting with secondary amenorrhea. Hormonal suppression of the endometrium can be accomplished with a variety of medications. The progestin component of the cyclic oral contraceptive gradually results in a thinner and thinner endometrium, which can ultimately result in pill-withdrawal amenorrhea. Other medications, including danazol, medroxyprogesterone, and long-acting GnRH agonists can result in amenorrhea.

Diagnosis

History

A search for clues as to the etiology should start with a personal developmental history in the amenorrheic teen and with a menstrual and reproductive history in the older amenorrheic woman. Events in the 3 to 6 months preceding the onset of amenorrhea are often critical. Rapid weight gain or loss or a marked change in energy expenditure through exercise may be important. Systems review should examine possible disruption to any of the compartments (Box 1). Inquiry about general health, risk of pregnancy, and use of medication (including illicit drugs) is important.

Physical Examination

Height, weight, and body mass index (BMI) should be determined. Body habitus often provides an important clue to which patients are amenorrheic due to excessive physical or nutritional stress (eating disorder or malnutrition). In primary amenorrhea, examination for the stage of breast and pubic hair development (Tanner staging) can indicate whether there has been delay or disruption to the entire process of pubertal development. Restriction of later visual fields to examination by confrontation, the presence of galactorrhea, or evidence of recent scars or lesions in the region

²Not available in the United States.

Hypothalamic Compartment

- Changes in temperature regulation, sleep, appetite, thirst
- Headache or visual field defects

Pituitary Compartment

- Central retro-orbital headache, bitemporal hemianopia
- Galactorrhea
- Features of hypothyroidism
- Medications affecting prolactin

Ovary Compartment

- Hot flushes
- Insomnia
- Night sweats
- Vaginal dryness

Outflow Compartment

- Cyclic cramps
- Possibility of pregnancy
- Recent gynecologic procedures (dilation and curettage, cervical laser or conization)

of the breast (such as zoster) can implicate hyperprolactinemia. The thyroid gland should be palpated and features of hypothyroidism sought. A lower abdominal mass may be due to pregnancy, hematomas, or hematometra.

The gynecologic examination should be tailored to the patient. The external genitalia should be evaluated for pubic hair, acanthosis nigricans, and clitoral size. The hymen should be visualized; an imperforate hymen usually shows a bluish central bulge. Estrogenization of the tissues (presence of leukorrhea, thickened mucosa, or watery cervical mucus) can be assessed with speculum examination (choosing a speculum size appropriate to the sexual maturity of the patient). Visualization of the cervix in most circumstances is sufficient to rule out an outflow compartment problem.

Investigations
Initial Investigations

Initial investigation for any patient with amenorrhea or oligomenorrhea includes follicle-stimulating hormone (FSH), prolactin (PRL), thyroid stimulating hormone (TSH), and a sensitive pregnancy test if pregnancy is a possibility.

Ultrasonography can be helpful when an internal examination cannot be performed. When a congenital anomaly is considered, magnetic resonance imaging (MRI) can provide more definitive information.

Follow-up Investigations

A low normal FSH in the presence of a normal outflow tract should elicit a more detailed search for hypothalamic disruptors (such as nutritional, physical, or psychological stress). In a patient who has low FSH in conjunction with an elevated PRL and who is not taking medications known to increase PRL and whose TSH is normal, lesions of the hypothalamus or pituitary should be excluded with CT or MRI.

An elevated FSH indicates ovarian failure and should elicit a search for possible explanations such as past surgery, exposure to radiation or chemotherapy, or genetic causes. With an elevated FSH, a karyotype is usually indicated unless there is some obvious cause for loss of ovarian function. If the karyotype reveals any Y chromosome material, then, at the appropriate age, referral to a gynecologist is necessary for counseling and gonadectomy to reduce the risk of gonadoblastoma and dysgerminoma.

Evidence of outflow tract obstruction on pelvic examination or the possibility of cervical stenosis (cyclic dysmenorrhea without bleeding after a cervical surgical procedure such as a loop excision, cone biopsy, or trachelectomy) or Asherman's syndrome (obliteration of the endometrial cavity following a postpregnancy or

postabortion dilation and curettage) merits referral to a gynecologist for further assessment and management.

Secondary amenorrhea related to weight gain or obesity, particularly when associated with features of acne and hirsutism, suggests the polycystic ovary syndrome. Management depends on whether the patient is seeking menstrual cycle regulation and relief from hirsutism (cyclic progestational therapy or an oral contraceptive plus an anti-androgen) or pregnancy (weight loss and fertility medication such as clomiphene citrate [Clomid]).

BACTERIAL INFECTIONS OF THE URINARY TRACT IN WOMEN

Method of

Kinder Fayssoux, MD

CURRENT DIAGNOSIS

- Acute cystitis is the most common urologic disorder in women.
- *Escherichia coli* and *Staphylococcus saprophyticus* are the causative agents for 80% of community acquired urinary tract infections (UTIs).
- *E. coli* is also the most common uropathogen in the nosocomial setting.
- Anatomic risk factors include short urethra, the proximity of the urethra to the anus, and the colonization of the periurethral mucosa with bowel flora.
- Other risk factors include previous UTI, sexual intercourse, and, separately, the use of spermicide, pregnancy, diabetes, incontinence, cystocele, and incomplete emptying of the bladder and dysfunctional voiding (defined as abnormal bladder emptying in the absence of neurologic disease).
- Postmenopausal women are also at increased risk if they are estrogen deficient.
- Acute cystitis typically presents with abrupt onset of dysuria, increased frequency, and/or urgency. Less frequently a patient will present with hematuria, suprapubic discomfort, or back/costovertebral angle pain. If a fever is present, it is usually less than 38.9°C (102°F).
- Acute pyelonephritis can evolve from either asymptomatic bacteriuria or from an ascending bladder infection.
- Symptoms usually include fever usually greater than 38.9°C (102°F) with chills, nausea/vomiting, dysuria, increased frequency, urgency, and costovertebral angle (CVA) tenderness (usually unilateral).
- *E. coli* is the major pathogen in acute pyelonephritis and treatment depends on severity and pregnancy status.

CURRENT THERAPY

- Empiric therapy for uncomplicated UTIs should be dependent on the most recent antibiotic guidelines and the uropathogen resistance patterns in a community.
- In a community with >20% incidence of resistant *E. coli*, nitrofurantoin (Macrobid) 100 mg bid for 7 days is the treatment of choice with quinolones as second-line therapy.

Hypothalamic Compartment

- Changes in temperature regulation, sleep, appetite, thirst
- Headache or visual field defects

Pituitary Compartment

- Central retro-orbital headache, bitemporal hemianopia
- Galactorrhea
- Features of hypothyroidism
- Medications affecting prolactin

Ovary Compartment

- Hot flushes
- Insomnia
- Night sweats
- Vaginal dryness

Outflow Compartment

- Cyclic cramps
- Possibility of pregnancy
- Recent gynecologic procedures (dilation and curettage, cervical laser or conization)

of the breast (such as zoster) can implicate hyperprolactinemia. The thyroid gland should be palpated and features of hypothyroidism sought. A lower abdominal mass may be due to pregnancy, hematomas, or hematometra.

- Symptoms usually include fever usually greater than 38.9°C (102°F) with chills, nausea/vomiting, dysuria, increased frequency, urgency, and costovertebral angle (CVA) tenderness (usually unilateral).
- *E. coli* is the major pathogen in acute pyelonephritis and treatment depends on severity and pregnancy status.

CURRENT THERAPY

- Empiric therapy for uncomplicated UTIs should be dependent on the most recent antibiotic guidelines and the uropathogen resistance patterns in a community.
- In a community with >20% incidence of resistant *E. coli*, nitrofurantoin (Macrobid) 100 mg bid for 7 days is the treatment of choice with quinolones as second-line therapy.

- In a community with <20% *E. coli* resistance, trimethoprim/sulfamethoxazole 160/800 (Bactrim DS) PO twice daily for 3 days is also acceptable as first-line therapy with quinolones still considered as second-line therapy.
- Phenazopyridine (Pyridium), a smooth muscle relaxant, can be prescribed for spasm relief.
- Fungal UTIs or candiduria should be treated with fluconazole (Diflucan) 200 mg daily for 2 weeks.
- Outpatient treatment guidelines for acute pyelonephritis are the same as for uncomplicated UTI except the duration of antimicrobial therapy is longer (10–14 days).
- Inpatient treatment for acute pyelonephritis is typically IV levofloxacin (Levaquin) (750 mg daily) or ampicillin (1 g every 6 h).
- Acute pyelonephritis should resolve in 48 to 72 hours, if patients are not getting better, imaging should be undertaken with ultrasound or CT scan to assess for renal abscess or urethral obstruction.

Acute Cystitis (Urinary Tract Infection)

Acute cystitis is the most common urologic disorder among women. It represents 4% of all outpatient visits. Of these visits, 52% present to a primary care clinic and 23% to the emergency department. The annual health care costs associated with urinary tract infections (UTIs) are roughly 1.6 billion and climbing. Antimicrobial prescriptions for UTIs account for 15% of all outpatient prescriptions. One-third of all women will have at least one symptomatic UTI by age 24, with more than half of all women having at least one during their lifetime.

Acute cystitis can be defined as uncomplicated or complicated. Uncomplicated cystitis is defined as a UTI in patients with normal urinary tract anatomy without a contributing medical condition such as diabetes mellitus, neurogenic bladder, pregnancy, renal insufficiency, immune deficiency, recent antibiotic use, recent genitourinary instrumentation, spinal cord injury, ureteral obstruction, or nephrolithiasis. Complicated cystitis is defined as a UTI in patients with abnormal urinary tract anatomy or with one of the aforementioned medical conditions. These patients generally require urine culture as part of the initial work-up to guide antimicrobial therapy and often additional condition specific evaluation and treatment.

Acute cystitis is caused by ascending bacteria of perineal/urethral/fecal origin through the urethra into the bladder and renal systems. *Escherichia coli* and *Staphylococcus saprophyticus* are the causative agents for 80% of community acquired UTIs (complicated and uncomplicated). *E. coli* is also the most common uropathogen in the nosocomial setting. Other known uropathogens include *Pseudomonas spp*, *Klebsiella spp*, *Proteus*, *Corynebacterium urealyticum*, and *Providencia*. Fungal UTIs caused by *Candida spp*, *Aspergillus spp*, and *Cryptococcus neoformans* are also increasingly encountered. These are usually caused by indwelling urinary devices and seen more frequently in diabetics. Other populations prone to fungal UTIs include patients who are immunocompromised, hospitalized, or elderly.

There are numerous risk factors for acute cystitis, several specific to women. Risk factors unique to women include several related to their anatomy. These anatomic differences are the primary reason for the increased incidence of UTI in women when compared to men and include the female's relatively short urethra (when compared to the male counterpart), the proximity of the urethra to the anus, and the colonization of the periurethral mucosa with bowel flora.

Other risk factors include previous UTI, sexual intercourse, and, separately, the use of spermicide, pregnancy, diabetes, incontinence, cystocele, and incomplete emptying of the bladder and dysfunctional voiding (defined as abnormal bladder emptying in the absence of neurologic disease). Postmenopausal women are also at increased risk if they are estrogen deficient.

Dysfunctional voiding has an unknown etiology and results in increased external sphincter activity during voluntary voiding which results in reflux, increasing chances of UTI.

Commonly advised behavioral modifications thought to decrease the risk of UTI (e.g., postcoital voiding, increased fluid intake, avoidance of urinary holding, douching, front-to-back wiping, proper tampon/sanitary napkin use, and loose/cotton underwear) have been supported by the literature.

Acute cystitis typically appears as an abrupt onset of dysuria, increased frequency, and/or urgency. Less frequently a patient will present with hematuria, suprapubic discomfort, or back/costovertebral angle pain. If a fever is present, it is usually less than 38.9°C (102°F).

Obtaining a good history that assesses for risk factors and symptoms is important in diagnosing acute cystitis. In a woman who presents with one or more symptoms of UTI (dysuria, frequency, urgency, hematuria), the probability of infection is already 50%. A urine dipstick is a useful diagnostic test, with a positive (+) nitrite or leukocyte esterase result increasing the chances of infection. The combination of positive nitrite and leukocyte esterase results has the highest diagnostic correlation with UTI. Physical examination findings may include suprapubic tenderness or costovertebral angle tenderness, although these are unlikely in an uncomplicated UTI scenario.

The gold standard for diagnosis of acute cystitis is a culture that has 10² to 10³ colony-forming units of a single uropathogen from a clean catch or catheterized urine specimen. However, research has shown that, for uncomplicated cystitis, ordering cultures and sensitivities makes little difference in treatment while increasing cost of care. Thus, it is reasonable to start empiric treatment without a culture and sensitivities in a patient presenting with uncomplicated UTI.

The differential diagnosis for an uncomplicated UTI includes:

- Vaginitis/vaginal infections: can cause dysuria
 - *Gardnerella*, *Candida albicans*, and *Trichomonas*
- Urethritis: can cause dysuria/frequency
 - STDs (*Chlamydia trachomatis*, gonorrhea, herpes simplex)
 - Pelvic floor spasm (leads to urethral spasm/irritability)
- Interstitial cystitis
- Malignancy
- Renal tuberculosis

Differentiating between sexually transmitted infections (STI), vaginal infections, and UTIs can be difficult because symptoms and signs commonly overlap. History elements that should prompt a pelvic examination and laboratory evaluation for pathogens are complaints of a vaginal discharge or vaginal irritation/pruritus. Persistent hematuria should raise the concern for underlying malignancy or renal tuberculosis, and further evaluation should be done.

Empiric therapy for uncomplicated UTIs should be dependent on the most recent antibiotic guidelines and the uropathogen resistance patterns in a community. In a community with >20% incidence of resistant *E. coli*, nitrofurantoin (Macrobid) 100 mg bid for 7 days is the treatment of choice with quinolones as second-line therapy. In a community with <20% *E. coli* resistance, trimethoprim/sulfamethoxazole 160/800 (Bactrim DS) PO twice daily for 3 days is also acceptable as first-line therapy with quinolones still considered as second-line therapy. Phenazopyridine (Pyridium), a smooth muscle relaxant, can be prescribed for spasm relief and is usually only necessary for the first 24 hours after treatment is initiated. Fungal UTIs or candiduria should be treated with fluconazole (Diflucan) 200 mg daily for 2 weeks.

For a complicated UTI, a culture must always be obtained and the patient should be evaluated in the context of his or her specific comorbid condition before treatment.

Acute Pyelonephritis

Acute pyelonephritis can evolve from either asymptomatic bacteriuria or from an ascending bladder infection. Although it can progress from an uncomplicated cystitis, it more commonly presents from a complicated cystitis in the setting of other medical conditions such as cholelithiasis, urinary obstruction, malformations, or pregnancy.

Symptoms usually include fever usually greater than 38.9°C (102°F) with chills, nausea/vomiting, dysuria, increased

frequency, urgency, and CVA tenderness (usually unilateral). These symptoms can present on a spectrum from mild to severe. *E. coli* is the major pathogen, and treatment depends on severity and pregnancy status. Pregnant patients or patients with moderate to severe nausea/vomiting that would interfere with oral antibiotic treatment should be hospitalized and have blood cultures done in addition to urine culture. Patients with mild symptoms and the ability to tolerate oral antibiotics can be treated as an outpatient basis with a urine culture obtained before initializing treatment. Outpatient treatment guidelines are the same as for uncomplicated UTI, except the duration of antimicrobial therapy is longer (10–14 days). Inpatient treatment is typically IV levofloxacin (Levaquin 750 mg daily) or ampicillin (1 g every 6 h). Once the inpatient is able to tolerate oral antibiotics and the infection is felt to be controlled, he or she can be switched to oral antibiotics and discharged to complete a 14-day course of treatment as an outpatient.

Symptoms should resolve in 48 to 72 hours; if patients are not getting better, imaging should be undertaken with ultrasound or CT scan to assess for renal abscess or urethral obstruction.

Urethritis

Urethritis usually has a gradual onset and is accompanied with milder symptoms of dysuria, frequency, urgency, or hematuria. It can also occur with a vaginal discharge and complaints of dyspareunia and vaginal pruritus depending on cause. Chlamydial, gonorrheal, candidal and trichomonal urethritis is usually accompanied by a vaginal discharge. Candidal urethritis can also be associated with pruritus and dyspareunia. If urethritis is suspected, a pelvic examination and further laboratory work-up is necessary.

Asymptomatic Bacteruria

Asymptomatic bacteruria is defined as the presence of 100,000 microorganisms/milliliter of urine without any symptoms of cystitis.

No screening should be performed in healthy nonpregnant women, elderly living in the community, diabetic women, institutionalized elderly, or persons with spinal cord injury. Pregnant women are the exception. They should be screened; positive cultures need to be treated, as there is an increased likelihood of asymptomatic bacteruria turning into UTI or pyelonephritis because of vesicoureteral reflux and urinary stasis resulting from increased progesterone levels.

Recurrent Cystitis

Recurrent cystitis is defined as at least three episodes of uncomplicated UTI with one or more documented positive (+) cultures in 12 months. It can be due to relapse or reinfection. Relapse is defined as infection occurring with the same organism as a previous UTI. Reinfection is when symptoms return after treatment and a completely symptom-free interval along with a negative urine culture or when the second infection is caused by a different organism. Most recurrent cystitis tends to be caused by reinfection.

In patients presenting with recurrent cystitis, an age-based evaluation is a good place to start. Adolescents who are not sexually active should be evaluated for congenital abnormalities. Premenopausal females should be questioned about the temporal relationship of the onset of UTI to increased frequency/recent sexual intercourse, spermicide use (with or without condom or diaphragm), or renal stones. Postmenopausal females should be evaluated for decreased estrogen/vaginal atrophy, incontinence, incomplete bladder emptying, cystocele, and prolapse.

If a complete and thorough evaluation is done, complicating factors are ruled out, modifiable factors are treated, and recurrent cystitis still remains a problem, then treatment should be considered. Treatment options include continuous antibiotics, postcoital therapy, or self-initiated treatment at the first sign or symptom of an infection.

Gross hematuria or persistent microscopic hematuria should increase suspicion for an underlying malignancy. Also, recurrent cystitis symptoms in a setting of negative cultures may suggest mycobacterial infection or interstitial cystitis.

Catheter Associated Urinary Tract Infection

Catheter-associated UTI is defined as a UTI in a patient who had an indwelling urethral catheter within 48 hours of onset of infection. Indwelling urinary catheters and clean intermittent catheterization are associated with the highest rates of bacteruria; after 1 month of either there is almost 100% risk of bacteruria. Formation of a bacterial biofilm on the catheter is thought to be the mechanism of infection in this setting.

No treatment is recommended for asymptomatic patients, and neither prophylactic antibiotics nor routine UA and culture are recommended for this population. For symptomatic patients, the first step is to determine whether the catheter can be removed. If it cannot, then it should be replaced. In addition, a blood and urine culture (taken from a new catheter) should be obtained. Initial treatment is the same as for an uncomplicated UTI as discussed earlier. Confirmation of susceptibility should be confirmed with culture results.

BENIGN BREAST DISEASE

Method of

Lauren Nye, MD

CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Benign breast disease may present with an abnormality on screening breast imaging or with a breast symptom such as breast mass or nipple discharge.
- Nonproliferative breast lesions are not associated with an increased risk of breast cancer.
- Proliferative breast lesions without atypia are associated with a slightly increased risk for breast cancer, while proliferative lesions with atypia are associated with a significantly increased risk for breast cancer.
- Factors contributing to a woman's breast cancer risk include family history, personal health history, and modifiable lifestyle factors.

frequency, urgency, and CVA tenderness (usually unilateral). These symptoms can present on a spectrum from mild to severe. *E. coli* is the major pathogen, and treatment depends on severity and pregnancy status. Pregnant patients or patients with moderate to severe nausea/vomiting that would interfere with oral antibiotic treatment should be hospitalized and have blood cultures done in addition to urine culture. Patients with mild symptoms and the ability to tolerate oral antibiotics can be treated as an outpatient basis with a urine culture obtained before initializing treatment. Outpatient treatment guidelines are the same as for uncomplicated UTI, except the duration of antimicrobial therapy is longer (10–14 days). Inpatient treatment is typically IV levofloxacin (Levaquin 750 mg daily) or ampicillin (1 g every 6 h). Once the inpatient is able to tolerate oral antibiotics and the infection is felt to be controlled, he or she can be switched to oral antibiotics and discharged to complete a 14-day course of treatment as an outpatient.

Symptoms should resolve in 48 to 72 hours; if patients are not getting better, imaging should be undertaken with ultrasound or CT scan to assess for renal abscess or urethral obstruction.

Urethritis

Urethritis usually has a gradual onset and is accompanied with milder symptoms of dysuria, frequency, urgency, or hematuria. It can also occur with a vaginal discharge and complaints of dyspareunia and vaginal pruritus depending on cause. Chlamydial, gonorrheal, candidal and trichomonal urethritis is usually accompanied by a vaginal discharge. Candidal urethritis can also be associated with pruritus and dyspareunia. If urethritis is suspected, a pelvic examination and further laboratory work-up is necessary.

Asymptomatic Bacteruria

Asymptomatic bacteruria is defined as the presence of 100,000 microorganisms/milliliter of urine without any symptoms of cystitis.

No screening should be performed in healthy nonpregnant women, elderly living in the community, diabetic women, institutionalized elderly, or persons with spinal cord injury. Pregnant women are the exception. They should be screened; positive cultures need to be treated, as there is an increased likelihood of asymptomatic bacteruria turning into UTI or pyelonephritis because of vesicoureteral reflux and urinary stasis resulting from increased progesterone levels.

Recurrent Cystitis

Recurrent cystitis is defined as at least three episodes of uncomplicated UTI with one or more documented positive (+) cultures in 12 months. It can be due to relapse or reinfection. Relapse is defined as infection occurring with the same organism as a previous UTI. Reinfection is when symptoms return after treatment and a completely symptom-free interval along with a negative urine culture or when the second infection is caused by a different organism. Most recurrent cystitis tends to be caused by reinfection.

In patients presenting with recurrent cystitis, an age-based evaluation is a good place to start. Adolescents who are not sexually active should be evaluated for congenital abnormalities. Premenopausal females should be questioned about the temporal relationship of the onset of UTI to increased frequency/recent sexual intercourse, spermicide use (with or without condom or diaphragm), or renal stones. Postmenopausal females should be evaluated for decreased estrogen/vaginal atrophy, incontinence, incomplete bladder emptying, cystocele, and prolapse.

If a complete and thorough evaluation is done, complicating factors are ruled out, modifiable factors are treated, and recurrent cystitis still remains a problem, then treatment should be considered. Treatment options include continuous antibiotics, postcoital therapy, or self-initiated treatment at the first sign or symptom of an infection.

Gross hematuria or persistent microscopic hematuria should increase suspicion for an underlying malignancy. Also, recurrent cystitis symptoms in a setting of negative cultures may suggest mycobacterial infection or interstitial cystitis.

Catheter Associated Urinary Tract Infection

Catheter-associated UTI is defined as a UTI in a patient who had an indwelling urethral catheter within 48 hours of onset of infection. Indwelling urinary catheters and clean intermittent catheterization are associated with the highest rates of bacteruria; after 1 month of either there is almost 100% risk of bacteruria. Formation of a bacterial biofilm on the catheter is thought to be the mechanism of infection in this setting.

No treatment is recommended for asymptomatic patients, and neither prophylactic antibiotics nor routine UA and culture are recommended for this population. For symptomatic patients, the first step is to determine whether the catheter can be removed. If it cannot, then it should be replaced. In addition, a blood and urine culture (taken from a new catheter) should be obtained. Initial treatment is the same as for an uncomplicated UTI as discussed earlier. Confirmation of susceptibility should be confirmed with culture results.

BENIGN BREAST DISEASE

Method of

Lauren Nye, MD

CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Benign breast disease may present with an abnormality on screening breast imaging or with a breast symptom such as breast mass or nipple discharge.
- Nonproliferative breast lesions are not associated with an increased risk of breast cancer.
- Proliferative breast lesions without atypia are associated with a slightly increased risk for breast cancer, while proliferative lesions with atypia are associated with a significantly increased risk for breast cancer.
- Factors contributing to a woman's breast cancer risk include family history, personal health history, and modifiable lifestyle factors.

CURRENT THERAPY

- Some benign breast lesions do not need any further intervention after diagnosis, while others may require surgical excision to rule out malignancy.
- Women at high risk for breast cancer may warrant additional breast screening or begin screening at an earlier age.
- Women at high risk for breast cancer should be counseled on risk reduction strategies including lifestyle modification.
- Chemoprevention agents include tamoxifen, raloxifene (Evista), and aromatase inhibitors.

Breast health is an important aspect of women's health care and includes breast cancer screening and evaluation of breast concerns. Benign breast disease can be identified on a biopsy done for an abnormal screening test, a palpable breast mass, nipple discharge, or other breast concerns. Benign breast disease may be associated with an increased risk for breast cancer. Women at high risk for breast cancer should be considered for additional breast cancer screening recommendations and risk reduction strategies.

Presentation and Workup

Patients can present with benign breast disease after an abnormality detected on screening imaging or after workup for breast symptoms such as a palpable mass, breast pain, or spontaneous nipple discharge. In women who are considered at average risk for breast cancer based on medical and family history, screening includes history and physical examination by their health care provider, clinical breast examination, and breast imaging. Breast awareness should be encouraged, but formal breast self-examinations in average-risk women have not been shown to have a breast cancer mortality benefit, although in women who performed self-breast examinations, a greater number of benign breast lesions were detected.

Breast Cancer Screening

Women at average risk for breast cancer should begin screening mammography between age 40 and 50. The 2016 updated recommendations of the U.S. Preventive Services Task Force (USPSTF) recommend biennial screening mammography for women ages 50 to 74; the decision to start screening mammography prior to age 50 should be individualized. The 2015 American Cancer Society (ACS) breast cancer screening guidelines for women at average risk include a strong recommendation to begin screening mammography at age 45 and a qualified recommendation to begin at age 40, and continuing as long as the woman is in good overall health and life expectancy is 10 years or greater. The most updated recommendation from the National Comprehensive Cancer Network (NCCN) and the American College of Radiology (ACR) is for annual screening mammography beginning at age 40. The standard for breast cancer screening is the digital mammogram; however, in recent years digital breast tomosynthesis has become more prevalent and available to women at breast imaging centers. Digital breast tomosynthesis has both a higher breast cancer detection rate and a lower recall rate compared to the digital mammogram for breast cancer screening. In women with heterogeneously dense breast or dense breast tissue on screening mammogram, the risks and benefits of supplemental screening should be discussed as high breast density limits mammogram sensitivity.

Normal and abnormal findings on breast imaging are reported using the universal classification system by the ACR's classification: the Breast Imaging Reporting and Data System (BI-RADS). Table 1 includes the BI-RADS categories, the risk of malignancy, and the recommended follow-up. BI-RADS 0 indicates an incomplete assessment and that further workup is needed, typically with additional imaging recommendations. BI-RADS 3 lesions are considered probably benign based on appearance and a mammogram

TABLE 1 Breast Imaging Reporting and Data System (BI-RADS) Mammography Classification

BI-RADS CATEGORY	DEFINITION	RISK FOR MALIGNANCY	RECOMMENDED FOLLOW-UP
0	Incomplete assessment	N/A	Further imaging
1	Negative study	N/A	Routine mammogram screening
2	Benign	N/A	Routine mammogram screening
3	Probably benign	≤ 2%	Repeat imaging in 6 months
4	Suspicious	> 2%–95% depending on degree of suspicion	Biopsy recommended
5	Highly suggestive of malignancy	≥ 95%	Biopsy recommended
6	Known biopsy-proven malignancy	N/A	Appropriate action should be taken

and/or ultrasound in 6 months is recommended for follow-up. BI-RADS 4 and BI-RADS 5 lesions are suspicious or highly suggestive of malignancy, respectively, and a biopsy of the lesion is recommended.

Palpable Breast Mass

In patients who present with a palpable breast mass, workup is determined by patient age, menopausal status, and degree of suspicion of breast mass. Figure 1 outlines the algorithm for evaluation of a woman with a breast mass. In women younger than age 30 with a mass of low clinical suspicion, it would be appropriate to consider observation over one to two menstrual cycles prior to moving on to ultrasound imaging if the mass persists. If no mass is detected on ultrasound, short-term clinical follow-up is recommended. Diagnostic mammography with ultrasound may be considered in women younger than age 30 who have a mass of high clinical suspicion or increased breast cancer risk. In postmenopausal women and women ages 30 and older, a clinically palpable breast mass should be evaluated with a diagnostic mammogram and ultrasound. A patient identified to have a simple cyst on imaging can return to age-appropriate breast screening. A solitary complicated cyst should be aspirated or be followed in short-term follow-up for stability. Multiple complicated cysts are considered a benign finding and do not require aspiration or short-term follow-up. Routine cytology of aspirated fluid is not recommended. If the mass persists after aspiration of a complicated cyst or if initial imaging shows a mass of high clinical suspicion or a complex cystic and solid mass, ultrasound-guided biopsy of the mass is recommended.

The sonographic description of a simple cyst is a round or oval circumscribed mass with acoustic enhancement and lacking any solid components or Doppler signals. A nonsimple cyst may be complicated or a complex cystic and solid mass. A complicated cyst is round or oval and circumscribed but may show low-level internal echoes without demonstrating vascular flow, while a complex cystic and solid mass may have thick septations, thick and irregular walls, and an internal solid component and display internal echoes, internal blood flow, and lack of posterior wall enhancement.

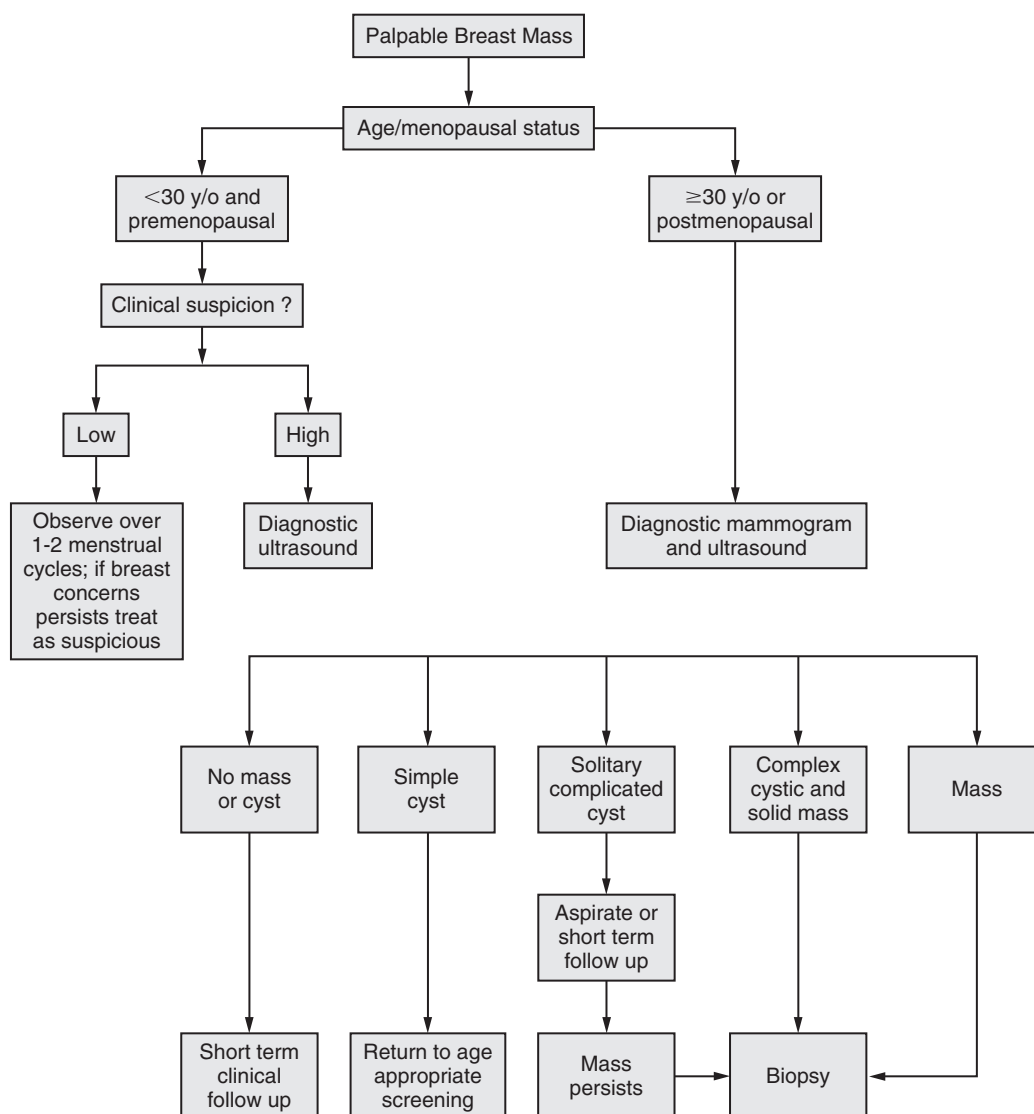

Figure 1 Algorithm for evaluation of a woman with a breast mass.

Nipple Discharge

Some women may present with nipple discharge without a palpable mass. Concerning features for pathologic nipple discharge include spontaneous, unilateral, single-duct discharge that is reproducible on examination and discharge that is clear, serous, sanguineous, or serosanguineous. Nonspontaneous nipple discharge or multiduct discharge in women is likely physiologic and the most common cause is duct ectasia. Women should be educated on avoiding further breast compression to illicit the discharge, ensure they are up to date on age-appropriate breast cancer screening, and review potential medications that could cause nipple discharge. In women with spontaneous pathologic single-duct nipple discharge, the most common etiology is an intraductal papilloma. The most common malignant explanation would be ductal carcinoma in situ (DCIS). The workup should include diagnostic mammography and ultrasound for women ages 30 or older and at least a diagnostic ultrasound women younger than 30 years old. Suspicious or highly suspicious imaging findings warrant biopsy. If initial imaging does not explain the nipple discharge, consider ductogram or magnetic resonance imaging (MRI) for further evaluation. In some cases duct excision may be recommended; otherwise, the patient should have short-term follow-up with clinical breast examination and imaging.

Benign Lesions

Benign breast diseases can be categorized as nonproliferative, proliferative without atypia, proliferative with atypia, and

TABLE 2 Benign Breast Lesions

NONPROLIFERATIVE LESIONS	PROLIFERATIVE LESIONS WITHOUT ATYPIA	PROLIFERATIVE LESIONS WITH ATYPIA
Apocrine metaplasia	Fibroadenomas	Atypical ductal hyperplasia
Breast cysts	Microglandular adenosis	Atypical lobular hyperplasia
Columnar cell change	Moderate or florid usual ductal hyperplasia	
Duct ectasia	Papilloma	
Fibrosis	Radial scar	
	Sclerosing adenosis	

miscellaneous other conditions such as fat necrosis, various types of mastitis, pseudoangiomatous stromal hyperplasia, fibrous mastopathy, amyloid deposits, and dermatologic conditions. Table 2 outlines the benign breast lesions. A study by Dupont and Page in the 1980s and a review by Hartmann et al. in 2005 found that nonproliferative breast disease was not associated with an

increased risk for breast cancer. Proliferative breast disease without atypia is associated with a slightly increased risk for breast cancer but less than two times the average population risk. Proliferative breast disease with atypia is associated with a significantly increased breast cancer risk that can be four to five times higher than the average population risk.

Nonproliferative Lesions

Nonproliferative breast lesions are also known as fibrocystic disease or change and include duct ectasia, fibrosis, and apocrine metaplasia. In women without a significant family history of breast cancer, nonproliferative breast lesions are not associated with an increased breast cancer risk. In the study by Dupont and Page including 3303 patients with benign breast disease, only 2.2% of the patients with nonproliferative lesions had breast cancer at a mean follow-up of 17 years. The Hartmann study of 9087 women followed for a median of 15 years found that the strength of family history was an independent risk factor, and in women with nonproliferative lesions the relative risk of breast cancer was 1.27. No increased risk was found in women with no family history.

Ductal ectasia and breast cysts are common findings. Occasionally the ectatic ducts are surrounded with periductal inflammation, which can occur in nonlactating women when the duct becomes congested with debris. This can lead to periductal mastitis that requires treatment with antibiotics. Breast cysts are most common in perimenopausal women but can occur in premenopausal women and postmenopausal women on hormone replacement therapy. Breast cysts may present in women with fibrocystic breast disease, which women may report as nodular breast tissue and is caused by microcystic formation and stromal proliferation of the breast. Apocrine metaplasia, in which acini and cysts are lined with large columnar cells that resemble the apocrine sweat glands, is not an uncommon finding. The individual cells are large with abundant granular eosinophilic cytoplasm. The apical aspects of these cells have a rounded protrusion into the cyst spaces. Columnar cell change is characterized by enlargement of the terminal duct lobular units and dilated acini without atypia.

Proliferative Lesions Without Atypia

Proliferative breast lesions without atypia include fibroepithelial lesions such as fibroadenomas, moderate or florid usual ductal hyperplasia, microglandular and sclerosing adenosis, papillomas, and radial scars. Proliferative breast lesions without atypia are associated with a slightly increased risk of breast cancer compared to the average risk of the population, with a relative risk estimated between 1.8 and 1.9. These lesions are not currently considered to put a woman at high risk for breast cancer unless other risk factors are present such as family history.

Fibroadenomas are benign processes containing glandular and fibrous tissue. Fibroadenomas were originally classified as nonproliferative lesions (including in the Hartmann study) but are now typically considered proliferative breast lesions. Simple fibroadenomas without associated proliferative disease are not associated with an increased risk for breast cancer, while complex fibroadenomas and those with coinciding proliferative disease are associated with a slight increase in breast cancer risk. Fibroadenomas are most common in young premenopausal women and can fluctuate in size with changes in hormones. They do not routinely need to be excised unless they are enlarging or have associated symptoms such as tenderness.

The normal number of the epithelial linings within the breast is two. Epithelial hyperplasia has a spectrum of changes from mild to severe presenting with an escalating scale of complexity. Usual ductal hyperplasia (UDH) is an increased number of cells within the duct that will vary in size and shape but will appear benign and without atypia. Microglandular adenosis and sclerosing adenosis are lesions with an increased number of glandular elements within fibrous stroma. Microglandular and sclerosing adenosis may be associated with microcalcifications and/or a mass on mammography.

Classic papillomas are masslike lesions that occur within large ducts close to the subareolar area. Histologically, they are composed of arborizing fronds of fibrovascular stroma lined by epithelial cells with a stalk attaching the mass to the wall of the cyst within which they arise. They can appear as a mass on mammography or present with unilateral nipple discharge. Papillomas can be associated with hyperplasia with and without atypia or DCIS, and in those cases, surgical excision is recommended to rule out malignancy.

Radial scars or complex sclerosing lesions are a pathologic diagnosis but can cause abnormalities on breast imaging including mass, nonmass enhancement, or architectural distortion. Histologically, they have a central fibroelastic core with radiating and branching ducts and lobules at the periphery. The etiology of these lesions is unknown. Depending on the size and presentation, surgical excision may be recommended to rule out underlying malignancy.

Proliferative Lesions With Atypia

Proliferative lesions with atypia include atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). These atypical hyperplasia lesions are characterized by an abundance of monotonous-appearing epithelial cells partially filling a duct and/or lobule. The presence of atypical hyperplasia is a risk factor for future breast cancer and is associated with a relative risk of breast cancer between four and five times the general population risk. The risk of breast cancer over the 25 years following the biopsy demonstrating atypical hyperplasia is estimated at 30%. The number of foci of atypia present in the specimen can stratify the risk, with one focus being a lower risk compared to three or more foci of atypia. These patients should be managed in a multidisciplinary fashion to include assessment of concordance between radiology and pathology. The standard management for atypical hyperplasia including ADH and ALH is surgical excision to rule out underlying malignancy; however, select patients who have concordance with imaging may be appropriate for screening in lieu of surgical excision.

Miscellaneous Benign Breast Conditions

Pseudoangiomatous stromal hyperplasia (PASH) is a lesion of a stromal proliferation with anastomosing spaces, with the dense hyalinized stroma intermixed with glandular components. These spaces could appear as vascular structures to the untrained pathologist. PASH may appear similar to an angiosarcoma but can be differentiated by the lack of atypia and mitosis. PASH can present with a palpable mass, with a mammogram abnormality, or as an incidental finding. Historically this lesion commonly underwent excision; however, depending on the size of the lesion, concordance with imaging, and other risk factors, PASH may be appropriately monitored with follow-up imaging.

Fat necrosis is secondary to trauma or injury to the breast. Fat necrosis typically presents with a painless breast mass and appears as an ill-defined dense mass on breast imaging. A biopsy is recommended to rule out malignancy; however, no further treatment is necessary.

High-Risk Evaluation and Management

The lifetime risk of breast cancer for women in the United States is approximately one in eight. There are elements of a woman's personal or family history that may increase her risk for breast cancer and potentially warrant additional screening and management. Risk factors that contribute to a woman's lifetime risk of breast cancer include family history of breast and/or ovarian cancer, genetic mutations associated with hereditary breast cancer, reproductive history, personal history of multiple breast biopsies or a breast biopsy showing atypical hyperplasia or lobular carcinoma in situ (LCIS), and dense breast tissue on mammography. Women who received thoracic radiation prior to age 30 are also at an increased risk for breast cancer. Modifiable risk factors for breast cancer include increased body mass index, sedentary lifestyle, alcohol intake, and hormone replacement therapy with estrogen and progesterone. Breast cancer risk assessment tools are available to

estimate a woman's risk and include the modified Gail Model and family history–based models such as Claus, BRCAPRO, BOADICEA, and Tyrer-Cuzick. In women with a strong family history of breast or ovarian cancer, genetic counseling should be offered.

Women considered at high risk for breast cancer include those with a Gail Model 5-year breast cancer risk of greater than or equal to 1.7%, a lifetime risk of breast cancer of greater than 20% based on a family history–based model, or a history of thoracic radiation prior to age 30, as well as women harboring a deleterious genetic mutation associated with breast cancer or a personal history of atypical hyperplasia or lobular carcinoma in situ. Women at high risk for breast cancer may be eligible for additional screening including earlier age at initiation of screening imaging and consideration of annual breast MRI.

Women at high risk for breast cancer should be counseled on screening recommendations and risk reduction strategies. Lifestyle modifications associated with decreased breast cancer risk include breastfeeding, achieving a healthy body mass index, limiting alcohol consumption, and exercising regularly. Some women may be considered for risk-reducing surgery. Chemoprevention may also be an option for women at high risk for breast cancer.

Chemoprevention

Risk-reducing agents, also known as chemoprevention, are appropriate to consider in women with atypical hyperplasia, LCIS, or a 5-year breast cancer risk of greater than or equal to 1.7%. Risk-reducing agents include tamoxifen, raloxifene (Evista), and aromatase inhibitors (exemestane [Aromasin]¹ and anastrozole [Arimidex]¹). Chemoprevention is taken daily for 5 years and associated with a potential risk reduction of 40% to 65%. No survival benefit has been demonstrated in women who take chemoprevention, and the risks and benefits of each therapy should be discussed. Tamoxifen is a selective estrogen receptor modulator (SERM) and is the only agent available for premenopausal women. Tamoxifen should not be recommended to women who are currently pregnant or considering future pregnancy owing to potential teratogenic effects. The National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (NSABP P-1) of tamoxifen 20 mg daily for 5 years versus placebo included both pre- and postmenopausal women at high risk for breast cancer and demonstrated a reduced risk of invasive breast cancer of 49%. In this study tamoxifen was associated with an increased rate of endometrial cancer, deep vein thrombosis, pulmonary embolism, and stroke, and these events were more frequent in women over the age of 50. Raloxifene is a second-generation SERM. The STAR trial (NSABP P-2) randomized postmenopausal women at high risk for breast cancer to 5 years of tamoxifen 20 mg daily versus raloxifene 60 mg daily. Raloxifene was demonstrated to be as effective as tamoxifen at reducing the risk of invasive breast cancer but not noninvasive breast cancer. Raloxifene was associated with a lower rate of venous thromboembolic events and endometrial cancer. Aromatase inhibitors were studied in postmenopausal women for breast cancer prevention in the MAP.3 (exemestane) and IBIS-II (anastrozole) trials. Exemestane 25 mg daily for 5 years was associated with a 65% relative reduction in annual incidence of breast cancer compared to placebo. Anastrozole 1 mg daily for 5 years reduced the incidence of estrogen receptor–positive breast cancers by over 50% compared to placebo with a hazard ratio (HR) of 0.47. In both trials, musculoskeletal complaints and vasomotor symptoms were more common in the aromatase inhibitor groups. Vaginal dryness and decreased libido are also common side effects of aromatase inhibitors. There is potential for a decrease in bone mineral density while taking an aromatase inhibitor; however, no increased fracture rate was seen in either trial. In postmenopausal women, age and comorbidities along with bone health should be considered when selecting a risk-reducing agent.

¹Not U.S. Food and Drug Administration (FDA) approved for this indication.

BREAST CANCER

Method of

Lauren Nye, MD; and Takae Brewer, MD

CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Women with an elevated risk for breast cancer may be considered for additional high-risk screening that can include breast magnetic resonance imaging (MRI) or other supplemental screening in addition to annual mammography.
- Individuals with a palpable breast mass or breast symptom concerning for malignancy and those with an abnormal screening mammogram need diagnostic breast imaging.
- Diagnostic breast imaging that is suspicious or highly suggestive of malignancy should undergo core needle biopsy.

CURRENT THERAPY

- Breast cancer is a heterogeneous disease and requires a multidisciplinary approach and multimodality therapy.
- The treatment of early-stage breast cancer may include local therapy such as surgery and radiation, as well as systemic therapy including chemotherapy, endocrine therapy, and biologic therapy.
- Metastatic breast cancer is treated with systemic therapy, and the goal of treatment is disease control and preserving quality of life.

estimate a woman's risk and include the modified Gail Model and family history–based models such as Claus, BRCAPRO, BOADICEA, and Tyrer-Cuzick. In women with a strong family history of breast or ovarian cancer, genetic counseling should be offered.

Women considered at high risk for breast cancer include those with a Gail Model 5-year breast cancer risk of greater than or equal to 1.7%, a lifetime risk of breast cancer of greater than 20% based on a family history–based model, or a history of thoracic radiation prior to age 30, as well as women harboring a deleterious genetic mutation associated with breast cancer or a personal history of atypical hyperplasia or lobular carcinoma in situ. Women at high risk for breast cancer may be eligible for additional screening including earlier age at initiation of screening imaging and consideration of annual breast MRI.

Women at high risk for breast cancer should be counseled on screening recommendations and risk reduction strategies. Lifestyle modifications associated with decreased breast cancer risk include breastfeeding, achieving a healthy body mass index, limiting alcohol consumption, and exercising regularly. Some women may be considered for risk-reducing surgery. Chemoprevention may also be an option for women at high risk for breast cancer.

Chemoprevention

Risk-reducing agents, also known as chemoprevention, are appropriate to consider in women with atypical hyperplasia, LCIS, or a 5-year breast cancer risk of greater than or equal to 1.7%. Risk-reducing agents include tamoxifen, raloxifene (Evista), and aromatase inhibitors (exemestane [Aromasin]¹ and anastrozole [Arimidex]¹). Chemoprevention is taken daily for 5 years and associated with a potential risk reduction of 40% to 65%. No survival benefit has been demonstrated in women who take chemoprevention, and the risks and benefits of each therapy should be discussed. Tamoxifen is a selective estrogen receptor modulator (SERM) and is the only agent available for premenopausal women. Tamoxifen should not be recommended to women who are currently pregnant or considering future pregnancy owing to potential teratogenic effects. The National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (NSABP P-1) of tamoxifen 20 mg daily for 5 years versus placebo included both pre- and postmenopausal women at high risk for breast cancer and demonstrated a reduced risk of invasive breast cancer of 49%. In this study tamoxifen was associated with an increased rate of endometrial cancer, deep vein thrombosis, pulmonary embolism, and stroke, and these events were more frequent in women over the age of 50. Raloxifene is a second-generation SERM. The STAR trial (NSABP P-2) randomized postmenopausal women at high risk for breast cancer to 5 years of tamoxifen 20 mg daily versus raloxifene 60 mg daily. Raloxifene was demonstrated to be as effective as tamoxifen at reducing the risk of invasive breast cancer but not noninvasive breast cancer. Raloxifene was associated with a lower rate of venous thromboembolic events and endometrial cancer. Aromatase inhibitors were studied in postmenopausal women for breast cancer prevention in the MAP.3 (exemestane) and IBIS-II (anastrozole) trials. Exemestane 25 mg daily for 5 years was associated with a 65% relative reduction in annual incidence of breast cancer compared to placebo. Anastrozole 1 mg daily for 5 years reduced the incidence of estrogen receptor–positive breast cancers by over 50% compared to placebo with a hazard ratio (HR) of 0.47. In both trials, musculoskeletal complaints and vasomotor symptoms were more common in the aromatase inhibitor groups. Vaginal dryness and decreased libido are also common side effects of aromatase inhibitors. There is potential for a decrease in bone mineral density while taking an aromatase inhibitor; however, no increased fracture rate was seen in either trial. In postmenopausal women, age and comorbidities along with bone health should be considered when selecting a risk-reducing agent.

¹Not U.S. Food and Drug Administration (FDA) approved for this indication.

BREAST CANCER

Method of

Lauren Nye, MD; and Takae Brewer, MD

CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Women with an elevated risk for breast cancer may be considered for additional high-risk screening that can include breast magnetic resonance imaging (MRI) or other supplemental screening in addition to annual mammography.
- Individuals with a palpable breast mass or breast symptom concerning for malignancy and those with an abnormal screening mammogram need diagnostic breast imaging.
- Diagnostic breast imaging that is suspicious or highly suggestive of malignancy should undergo core needle biopsy.

CURRENT THERAPY

- Breast cancer is a heterogeneous disease and requires a multidisciplinary approach and multimodality therapy.
- The treatment of early-stage breast cancer may include local therapy such as surgery and radiation, as well as systemic therapy including chemotherapy, endocrine therapy, and biologic therapy.
- Metastatic breast cancer is treated with systemic therapy, and the goal of treatment is disease control and preserving quality of life.

- Breast cancer survivors may have multiple long-term complications of therapy that need to be addressed, including vasomotor symptoms, osteoporosis, lymphedema, and increased cardiac risk factors.

Overview

Breast cancer is the most common cancer and the third leading cause of death among women in the United States. Breast cancer is a heterogeneous disease for which a personalized approach is important in the evaluation and treatment of each individual. Furthermore, the multidisciplinary team is vital in the management of breast cancer and can include a medical oncologist, surgical oncologist, plastic surgeon, radiation oncologist, pathologist, supportive services, and the patient's personal physician. At the conclusion of treatment and active surveillance, the patient typically returns to their primary care physician for continued survivorship care.

Epidemiology

It is estimated that there were 252,710 new cases of breast cancer in 2017, comprising 15% of all new cancer cases. The estimated deaths from breast cancer in the same year were 40,610, accounting for 6.8% of all cancer deaths. Female breast cancer is most commonly diagnosed among women from 55 to 64 years of age with the median age at diagnosis of 62. Although rare, male breast cancer comprises of 1% of all breast cancer cases in the United States. The incidence of breast cancer has risen slowly by 0.3% annually, whereas the mortality rate has been falling by 1.8% each year. The 5-year relative survival improved rate by 16% over 30 years, from 74% in 1980 to 90.9% in 2010.

Risk Factors

Well-recognized risk factors for breast cancer include older age, female sex, white race, obesity, high exposure to hormones (either exogenous or endogenous), personal and family history of breast cancer, inherited genetic mutations, certain benign breast disease (e.g., atypical hyperplasia and LCIS), previous history of radiation therapy to the chest, as well as lifestyle factors such as alcohol consumption and smoking.

Individuals who carry a BRCA1 or BRCA2 mutation are at a significantly higher risk for developing breast cancer. In a case-control study by Couch et al. in 2017 of more than 65,000 women with breast cancer, genetic mutations associated with an increased risk of breast cancer were identified in 10.2% of cases. The most common gene mutations identified included BRCA1, BRCA2, ATM, CHEK2, PALB2, BARD1, and RAD51D. Individuals with a strong family history of cancer should be considered for genetic counseling and testing for appropriate risk stratification.

Prevention

For women at an average risk for breast cancer, lifestyle modifications including regular aerobic exercise, maintaining a healthy weight, and limiting alcohol are most important for breast cancer prevention. In addition, complying with breast cancer screening recommendations provides opportunity for early detection and decreased mortality. Women at average risk for breast cancer should begin screening mammography between age 40 and 50. The United States Preventive Task Force (USPSTF) updated recommendations in 2016 recommend biennial screening mammography for women aged 50 to 74 years, and the decision to start screening mammography prior to age 50 should be individualized. The 2015 American Cancer Society (ACS) breast cancer screening guidelines for women at average risk include a strong recommendation to begin screening mammography at age 45 and a qualified recommendation to begin at age 40, and continuing as long as in good overall health and life expectancy is 10 years or greater. The most updated recommendations from the National Comprehensive Cancer Network (NCCN) and the American College of Radiology

(ACR) are for annual screening mammography beginning at age 40. The standard for screening breast imaging is the digital mammogram; however, in recent years digital breast tomosynthesis has become more prevalent and available to women at breast imaging centers. Digital breast tomosynthesis has both a higher breast cancer detection rate and lower recall rate compared with the digital mammography for breast cancer screening.

Women who are at an increased risk for breast cancer may be considered for additional screening and prevention measures. Risk factors that increase a women's risk include having a known genetic mutation associated with hereditary breast cancer, having a family history of breast cancer in a first- or second-degree relative, especially premenopausal breast cancer or male breast cancer, having a personal history of a breast biopsy with atypical hyperplasia or lobular carcinoma in situ, having a personal history of chest radiation before age 30, or having a high breast density. Several breast cancer assessment tools are available for evaluation for women who are at a higher risk of developing breast cancer than the average population (e.g., Gail, Tyrer-Cuzick, Claus, BRCA-PRO, BOADICEA models). Women with a lifetime risk of breast cancer greater than 20% on a family history-based model or women with a genetic mutation or prior chest radiations may be eligible for additional annual screening with breast MRI. Certain high-risk populations may benefit from risk-reducing therapies such as chemoprevention and prophylactic mastectomy, especially for high-penetrance mutation carriers.

Clinical Manifestations

Women with DCIS and early-stage breast cancer may be asymptomatic. The most common symptoms of breast cancer include the following:

- New palpable mass in the breast or axilla
- Skin changes such as dimpling, erythema, irritation, edema, thickening, Peau d'orange (Figure 1)
- Nipple retraction
- Abnormal nipple discharge
- New asymmetric appearance of breast

Differential Diagnosis

Differential diagnoses include benign conditions such as fibroadenoma, papilloma, breast cyst, mastitis, as well as malignant conditions such as breast lymphoma, sarcoma, neuroendocrine tumors, leukemia, and skin metastasis from breast or other primary tumors.

Diagnosis

Once breast malignancy is suspected clinically, either by palpation or mammography (Figure 2), further evaluation is warranted. Women with an abnormal mammogram should undergo further

Figure 1 Peau d'orange of the breast.

Figure 2 Breast cancer on mammogram.

diagnostic imaging, which may include diagnostic mammography, ultrasonography, or breast MRI. Normal and abnormal findings on breast imaging are reported using the universal classification system by the American College of Radiology—Breast Imaging Reporting and Data System (BI-RADS). BI-RADS 0 indicates an incomplete assessment and further workup is needed, typically with additional imaging recommendations. BI-RADS 1 and BI-RADS 2 lesions are negative or benign, respectively. BI-RADS 3 lesions are considered probably benign based on appearance and a mammogram or ultrasound scan in 6 months is recommended for follow-up. BI-RADS 4 and BI-RADS 5 lesions are suspicious or highly suggestive of malignancy, respectively, and a biopsy of the lesion is recommended. Core needle biopsy is the recommended approach for tissue sampling. The pathology report from a biopsy of a primary breast cancer will typically include the histology and tumor prognostic markers. These histologic subtypes of breast cancer include ductal, lobular, mixed, metaplastic, as well as the more favorable histologic subtypes of tubular, mucinous, and papillary.

Once a breast cancer is diagnosed, appropriate clinical staging is done, directed by a medical oncologist or surgical oncologist. This may include further breast imaging to characterize the extent of the tumor, axillary staging with ultrasound to assess for abnormal-appearing lymph nodes, and clinical examination with consideration of whole-body staging with computed tomography (CT) scan of the chest, abdomen, and pelvis depending on the size and lymph

node involvement of the primary breast cancer. Bone scanning or positron emission tomography (PET/CT) may also be considered in some circumstances. Staging of the breast cancer is done in accordance with the American Joint Committee on Cancer (AJCC) staging system. The most updated version, the AJCC Cancer Staging Manual, Eighth Edition, was published in December 2017 and includes anatomic stage groups, clinical prognostic stage groups, and pathologic prognostic stage groups. All patients should have a clinical prognostic stage documented as part of their treatment plan, and those with surgery as initial treatment may also have a pathologic prognostic stage. The updated staging guidelines also include biomarker testing results within the staging system.

Pathophysiology

Breast cancer is a heterogeneous disease. Malignant cells arise from neoplastic proliferation of epithelial cells in the ducts or lobules of the breast. If neoplastic cells are confined inside of the duct or lobule, the lesion is termed ductal or lobular in situ, respectively. Ductal carcinoma in situ (DCIS) is a precursor lesion that can potentially develop into invasive carcinoma (Figure 3). Invasive carcinoma is classified into four distinct molecular subtypes: luminal A, luminal B, basal-like, and HER2 enriched. More frequently we use the tumor receptor markers of the breast cancer to guide therapy, namely estrogen receptor (ER), progesterone receptor (PR), and HER-2 overexpression. Hormone receptor–positive breast cancer, meaning progesterone or estrogen receptor–positive, is the most common type of breast cancer, comprising more than 65% of all breast cancers and in general has less aggressive disease course with a long survival, even in the metastatic setting. In contrast, hormone receptor negative and HER-2 negative breast cancer, also known as triple negative breast cancer (TNBC), tends to be more aggressive and has a much poorer outcome, especially in the advanced setting. Although the natural course of HER-2 overexpressed disease tends to be aggressive, HER-2 positive breast cancer now has a longer survival time since the advent of effective HER-2 directed therapies.

Treatment

Breast cancer is a complex disease and requires multidisciplinary management, as well as a tailored therapy plan depending on the stage, histologic subtype, and prognostic tumor marker status. Current modalities for treating breast cancer include local therapy such as surgery and radiation therapy, as well as systemic therapy including chemotherapy, endocrine, and biologic therapy.

Early-stage breast cancer is treated with surgery (lumpectomy or mastectomy) with or without radiation therapy. Women who undergo lumpectomy and radiotherapy have equivalent outcomes to those receiving mastectomy. Axillary lymph nodes are typically evaluated by sentinel lymph node biopsy and/or axillary lymph node dissection depending on initial clinical findings and lymph node involvement with metastases on pathologic review. For

Figure 3 Breast adenocarcinoma histopathology of ductal carcinoma in situ and invasive breast cancer.

selected cases, preoperative (neoadjuvant) treatment with chemotherapy or endocrine therapy are used. Neoadjuvant chemotherapy is indicated for inoperable or locally advanced breast cancer such as inflammatory breast cancer, extensive primary tumor extending to the chest wall or skin, bulky or matted axillary lymph nodes, and extraaxillary lymph node involvement. In the setting of operable breast cancer, neoadjuvant systemic treatment may be recommended to optimize surgical outcomes in the setting of a large tumor or to allow for breast-conserving surgery.

After the definitive surgical management, adjuvant systemic therapy may be offered to reduce the risk of local and distant recurrence. Chemotherapy is considered for those at high risk for recurrence, characterized by large tumor size, positive lymph nodes, high-grade histology, or a triple negative (hormone receptor negative, HER2 negative) breast cancer. For hormone receptor-positive, HER2-negative, axillary node-negative breast cancer, the 21-gene recurrence score is widely used to evaluate for the potential benefit of adjuvant chemotherapy. HER2-positive breast cancer is treated with HER2-directed biologic agents along with chemotherapy followed by maintenance therapy with anti-HER2 agents such as trastuzumab (Herceptin). The FDA has recently approved two additional anti-HER agents to be considered in the adjuvant setting—pertuzumab (Perjeta) and neratinib (Nerlynx). When an anthracycline chemotherapy or trastuzumab is indicated, baseline cardiac function evaluation by either echocardiogram or multigated acquisition (MUGA) scan must be obtained before treatment and will be regularly monitored during the treatment with trastuzumab. Radiation therapy, if indicated, is typically offered after chemotherapy.

After local treatment of hormone receptor-positive breast cancer with or without chemotherapy, adjuvant endocrine therapy is recommended for a minimum of 5 years with either a selective estrogen-receptor modulator (SERM) such as tamoxifen (Nolvadex), an aromatase inhibitor such as anastrozole (Arimidex), letrozole (Femara) or exemestane (Aromasin), or a selective estrogen receptor degrader (SERD) such as fulvestrant (Faslodex). In general, the choice of endocrine therapy agents is based on the menopausal state and side effects profiles. Adjuvant endocrine therapy is associated with an approximate 50% reduction in breast cancer recurrence.

Locally recurrent disease without distant metastasis can be managed with a curative intent. Combination of local therapies and systemic treatment may be used depending on the clinical scenario. Metastatic (stage IV) breast cancer with distant metastasis is not curable and is managed with the intent of disease control while maintaining quality of life and requires systemic therapy. Local therapies such as surgery and radiation therapy are indicated for palliative purposes when appropriate. Hormone-positive metastatic breast cancer with bone-only involvement or small tumor burden can be treated with endocrine therapy. Recently the advent of combination therapy with cyclin-dependent kinases (CDK4/6) inhibitors has emerged as a promising agent for hormone receptor-positive, metastatic disease. In combination with endocrine therapy, CDK inhibitors demonstrated longer progression-free survival, although the data for overall survival is immature at this time. The mTOR inhibitor can be also used in this setting in combination with endocrine therapy. The mTOR inhibitor is known to overcome endocrine resistance, although toxicity (e.g., mucositis and gastrointestinal side effects) may limit its use.

Metastatic HER2-positive breast cancer is treated with HER2-directed agents and chemotherapy. Additional strategies include drug antibody conjugates or dual HER2 blockade such as trastuzumab (Herceptin) and pertuzumab (Perjeta) or lapatinib (Tykerb) with chemotherapy, which demonstrate superior progression-free survival compared with a single HER2 agent added to chemotherapy. For HER2-positive and hormone receptor-positive disease, dual HER-2 targeted therapy combined with an aromatase inhibitor may be beneficial.

Although single chemotherapy is preferred for metastatic disease, combined chemotherapy may be indicated for diseases with

high tumor burden or in visceral crisis. Management of metastatic breast cancer may also include germline genetic testing for a BRCA1 or BRCA2 mutation and/or genomic testing of the tumor to identify potential molecular targets unique to the individual or tumor. In 2018, the FDA approved olaparib (Lynparza), which is a poly-ADH ribose polymerase (PARP) inhibitor, for the treatment of metastatic HER2-negative, BRCA-associated breast cancer. Further targeted therapies may be explored in the setting of a clinical trial.

For patients with bone metastasis, bone-targeted therapy such as denosumab (Xgeva) or intravenous bisphosphonates are given to reduce skeletal-related events, such as pathologic fractures. Patients with poor dentition or oral hygiene who need future dental procedures during treatment are at increased risk for osteonecrosis of the jaw; thus dental evaluation is important before initiating bone-directed therapy.

Monitoring and Survivorship

The majority of breast cancer patients are treated with curative intent and enjoy long-term survival. The risk of recurrence, however, is a realistic concern for many years after definitive therapy, especially for women with locally advanced or node-positive disease. Once the patient has completed definitive treatment, careful history taking and physical examination are the most important aspects of surveillance. Patients are advised to have an office visit up to 4 times yearly for the first 5 years, then annually. The monitoring for recurrence by laboratory and radiologic tests should be kept minimal in the non-metastatic setting unless clinically indicated.

Women should continue to undergo annual screening mammography for their remaining breast tissue. If they were receiving high-risk screening with a breast MRI based on a genetic mutation, this may also be continued after breast cancer treatment. Annual gynecologic assessment is recommended for women on tamoxifen because of the associated increased risk of uterine cancer, which typically presents with abnormal bleeding in postmenopausal women. Patients on aromatase inhibitor should have a bone mineral density completed at baseline and then annually while receiving treatment with an aromatase inhibitor. Bone-modifying agents such as intravenous bisphosphonates or RANK ligand inhibitors may be used for management or prevention of osteoporosis while on aromatase inhibitor therapy.

In addition, women receiving adjuvant endocrine therapy may experience menopause-related symptoms such as vasomotor symptoms, vaginal dryness, and sexual dysfunction. Patients are encouraged to discuss these symptoms with their physician because they can frequently be managed with non-hormone-based approaches. Venlafaxine (Effexor)¹ and gabapentin (Neurontin)¹ have demonstrated efficacy in management of hot flashes, as well as cognitive behavioral therapy and avoiding triggers. Vaginal moisturizers and lubricants can be applied to help alleviate symptoms of vaginal dryness. Laser therapy may also be considered in some circumstances.

Long-term complications after definitive treatment may include lymphedema and self-image issues after surgery, skin changes after radiation therapy and persistent neuropathy, prolonged hair loss, fatigue, cognitive impairment, and a small risk of developing leukemia and MDS after chemotherapy.

Heart disease remains the leading cause of death in US women. Those women who have undergone treatment for breast cancer may be at a higher risk for myocardial events depending on their baseline risk factors and the treatment they received. Accumulating evidence suggests that lifestyle modifications including regular exercise, achieving a healthy body mass index, limiting alcohol intake, and abstaining from tobacco products lead to optimal outcomes for breast cancer survivors.

¹Not FDA approved for this indication.

CANCER OF THE ENDOMETRIUM

Method of

Locke Uppendahl, MD; and Boris Winterhoff, MD

CURRENT DIAGNOSIS

- The high incidence of uterine cancer in developed countries reflects increased obesity rates.
- The progression from atypical hyperplasia to adenocarcinoma is a consequence of prolonged, unopposed estrogen exposure.
- Approximately 90% of women with uterine cancer report abnormal uterine bleeding, with postmenopausal bleeding the most common.
- Over 95% of uterine cancers are diagnosed in women 40 years or older.
- In most uterine cancer cases, the tumor is confined to the uterine corpus at the time of diagnosis and portend a good prognosis.
- Uterine carcinomas are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

CURRENT THERAPY

- Comprehensive surgical staging with total hysterectomy, bilateral salpingo-oophorectomy, and bilateral pelvic and para-aortic lymphadenectomy is a critical component for the diagnosis and management of all endometrial cancers.
- The utility and extent of lymph node dissection in endometrial cancer is controversial.
- The decision for adjuvant therapy is based on the risk of relapse and persistent disease.
- Surgery alone is usually curative for women with early-stage, low-risk disease.
- Adjuvant vaginal brachytherapy is recommended for early-stage endometrial cancers that demonstrate pathologic features known to increase risk of vaginal cuff recurrence, such as high-grade, deep myometrial invasion, cervical involvement, or presence of lymphovascular space invasion.
- Women with advanced-stage (stage III or IV) or recurrent endometrial cancer are frequently treated with systemic, platinum-based chemotherapy

Epidemiology

In the United States, uterine cancer is the most common gynecologic malignancy of the female genital tract, with an estimated 63,230 new cases and 11,350 deaths expected for 2018. Approximately 1 in 35 women will develop invasive cancer over their lifetime, with an average age of diagnosis of 62 years. The high incidence observed in developed countries is attributable to increased obesity rates and other risk factors.

Uterine cancer is one of the few malignancies where survival has not improved since the mid-1970s. In fact, death rates for uterine cancer rose in 2011 through 2015 by 2% per year. The 5-year survival rate for all stages is 22% lower for black women compared to white women. This large disparity likely reflects a delay in diagnosis in this population.

Classification

Uterine cancers arising from the lining of the uterus are called endometrial carcinoma and are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

Type I tumors

Type I tumors are the predominant form of endometrial cancer, comprising approximately 80% of new diagnoses. They include tumors of endometrioid histology and often arise in the background of atypical endometrial hyperplasia. Type I tumors are more indolent, diagnosed at earlier stages, occur in younger women, and overall portend a favorable prognosis. Patients with high-grade (grade 3) endometrioid adenocarcinoma have a less favorable prognosis. The average age at diagnosis is approximately 63 years old, with nearly 70% of the tumors confined to the uterus at time of diagnosis.

Recent, comprehensive genomic characterization has identified a number of genetic alterations associated with type I tumors. The loss of function in the DNA mismatch repair (MMR) enzymes MLH1, MSH2, MSH6, and PMS2 results in the inability to properly detect and repair abnormal DNA sequences. This leads to mutations in genes that have microsatellite repeats. Microsatellite instability (MSI) is found in approximately one-third of type I tumors and can be as a result of germline or sporadic mutations. Other commonly mutated genes include *PTEN*, *CTNNB1*, *PIK3CA*, *ARID1A*, and *KRAS*.

Type II tumors

In contrast to type I tumors, other endometrial cancers are unrelated to unopposed estrogen exposure. Type II cancers include clear cell and serous histology tumors. They are diagnosed more frequently among older, non-obese, non-white women and portend an unfavorable prognosis due to the later stage in diagnosis and the aggressive nature of the tumor.

Serous carcinoma of the endometrium represents ~10% of endometrial carcinomas but accounts for 40% of all endometrial cancer-related deaths. They often invade deep into the myometrium and demonstrate the ability for early peritoneal spread. Uterine serous carcinomas are molecularly distinct and are characterized by high genomic instability (high copy number alterations), low mutational burden, and *TP53* mutations. Newer evidence demonstrates dysregulation of the *Her2/neu* oncogene in 27% of cases. Clear cell carcinomas, another rare but aggressive subtype, represent ~5% of endometrial carcinomas. The 5-year overall survival rates for serous and clear cell carcinomas are 41% and 65%, respectively. Recently, genomic characterization identified approximately 25% of grade 3 endometrioid tumors cluster with serous carcinomas, with very high somatic copy-number alterations. Nearly 90% of these tumors have *TP53* mutations. Novel mutations in *TAF1* have been implicated in a subset of clear cell carcinomas.

Risk Factors

Type I tumors are strongly linked to long-term, unopposed exposure to estrogen. Therefore risk factors include any excessive

CANCER OF THE ENDOMETRIUM

Method of

Locke Uppendahl, MD; and Boris Winterhoff, MD

CURRENT DIAGNOSIS

- The high incidence of uterine cancer in developed countries reflects increased obesity rates.
- The progression from atypical hyperplasia to adenocarcinoma is a consequence of prolonged, unopposed estrogen exposure.
- Approximately 90% of women with uterine cancer report abnormal uterine bleeding, with postmenopausal bleeding the most common.
- Over 95% of uterine cancers are diagnosed in women 40 years or older.
- In most uterine cancer cases, the tumor is confined to the uterine corpus at the time of diagnosis and portend a good prognosis.
- Uterine carcinomas are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

CURRENT THERAPY

- Comprehensive surgical staging with total hysterectomy, bilateral salpingo-oophorectomy, and bilateral pelvic and para-aortic lymphadenectomy is a critical component for the diagnosis and management of all endometrial cancers.
- The utility and extent of lymph node dissection in endometrial cancer is controversial.
- The decision for adjuvant therapy is based on the risk of relapse and persistent disease.
- Surgery alone is usually curative for women with early-stage, low-risk disease.
- Adjuvant vaginal brachytherapy is recommended for early-stage endometrial cancers that demonstrate pathologic features known to increase risk of vaginal cuff recurrence, such as high-grade, deep myometrial invasion, cervical involvement, or presence of lymphovascular space invasion.
- Women with advanced-stage (stage III or IV) or recurrent endometrial cancer are frequently treated with systemic, platinum-based chemotherapy

Epidemiology

In the United States, uterine cancer is the most common gynecologic malignancy of the female genital tract, with an estimated 63,230 new cases and 11,350 deaths expected for 2018. Approximately 1 in 35 women will develop invasive cancer over their lifetime, with an average age of diagnosis of 62 years. The high incidence observed in developed countries is attributable to increased obesity rates and other risk factors.

Uterine cancer is one of the few malignancies where survival has not improved since the mid-1970s. In fact, death rates for uterine cancer rose in 2011 through 2015 by 2% per year. The 5-year survival rate for all stages is 22% lower for black women compared to white women. This large disparity likely reflects a delay in diagnosis in this population.

Classification

Uterine cancers arising from the lining of the uterus are called endometrial carcinoma and are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

Type I tumors

Type I tumors are the predominant form of endometrial cancer, comprising approximately 80% of new diagnoses. They include tumors of endometrioid histology and often arise in the background of atypical endometrial hyperplasia. Type I tumors are more indolent, diagnosed at earlier stages, occur in younger women, and overall portend a favorable prognosis. Patients with high-grade (grade 3) endometrioid adenocarcinoma have a less favorable prognosis. The average age at diagnosis is approximately 63 years old, with nearly 70% of the tumors confined to the uterus at time of diagnosis.

Recent, comprehensive genomic characterization has identified a number of genetic alterations associated with type I tumors. The loss of function in the DNA mismatch repair (MMR) enzymes MLH1, MSH2, MSH6, and PMS2 results in the inability to properly detect and repair abnormal DNA sequences. This leads to mutations in genes that have microsatellite repeats. Microsatellite instability (MSI) is found in approximately one-third of type I tumors and can be as a result of germline or sporadic mutations. Other commonly mutated genes include *PTEN*, *CTNNB1*, *PIK3CA*, *ARID1A*, and *KRAS*.

Type II tumors

In contrast to type I tumors, other endometrial cancers are unrelated to unopposed estrogen exposure. Type II cancers include clear cell and serous histology tumors. They are diagnosed more frequently among older, non-obese, non-white women and portend an unfavorable prognosis due to the later stage in diagnosis and the aggressive nature of the tumor.

Serous carcinoma of the endometrium represents ~10% of endometrial carcinomas but accounts for 40% of all endometrial cancer-related deaths. They often invade deep into the myometrium and demonstrate the ability for early peritoneal spread. Uterine serous carcinomas are molecularly distinct and are characterized by high genomic instability (high copy number alterations), low mutational burden, and *TP53* mutations. Newer evidence demonstrates dysregulation of the *Her2/neu* oncogene in 27% of cases. Clear cell carcinomas, another rare but aggressive subtype, represent ~5% of endometrial carcinomas. The 5-year overall survival rates for serous and clear cell carcinomas are 41% and 65%, respectively. Recently, genomic characterization identified approximately 25% of grade 3 endometrioid tumors cluster with serous carcinomas, with very high somatic copy-number alterations. Nearly 90% of these tumors have *TP53* mutations. Novel mutations in *TAF1* have been implicated in a subset of clear cell carcinomas.

Risk Factors

Type I tumors are strongly linked to long-term, unopposed exposure to estrogen. Therefore risk factors include any excessive

exogenous (hormonal therapy, tamoxifen [Nolvadex]) or endogenous (obesity, chronic anovulation, estrogen-secreting tumors) estrogen exposure to the uterine lining. In the United States, the high prevalence of obesity has increased the incidence of uterine cancer over the past two decades. A BMI 25 to < 30 kg/m² confers a relative risk of 1.5 to develop endometrial cancer, compared to 7.1 for BMI > 40 kg/m². Other risk factors for type I tumors include nulliparity, diabetes mellitus, and hypertension.

Tamoxifen (Nolvadex) is a selective-estrogen receptor modulator (SERM) used in the treatment and prevention of breast cancer. The drug functions as an antagonist in the breast but has agonist effects on the endometrium. The risks of endometrial cancer associated with tamoxifen, although very low, are well documented in the literature.

Lynch / Hereditary Non-Polyposis Colorectal Cancer (HNPCC) syndrome is caused by mutations in DNA mismatch-repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*. The lifetime risk of developing colorectal and endometrial cancer is 25–50% and 15–71% (depends on mutated gene), respectively.

Pathophysiology

The World Health Organization (WHO) has recently clarified the classification of endometrial hyperplasia, differentiating between only two categories: (1) hyperplasia without atypia and (2) atypical hyperplasia / endometrioid intraepithelial neoplasia. Multiple studies have demonstrated the progression of atypical hyperplasia to adenocarcinoma is a consequence of prolonged, unopposed estrogen exposure.

Prevention

Over 95% of uterine cancers are diagnosed in women 40 years or older. Therefore abnormal uterine bleeding in these women should prompt evaluation with endometrial biopsy or dilatation and curettage (D&C). Depending on age and reproductive desire, women with endometrial hyperplasia may be treated with removal of estrogen stimulus, the periodic use of progestins, or by hysterectomy to prevent the onset of uterine cancer. For women with atypical hyperplasia, hysterectomy is the treatment of choice, because coexistent adenocarcinoma may be present in 40% of cases. In addition, this group of women carries a 30% risk of developing invasive carcinoma later in life. Finally, women with a uterus should never receive estrogen-only hormone replacement therapy (HRT). The addition of a progestin to HRT can prevent endometrial hyperplasia and subsequent endometrial cancer.

Despite no current scientific evidence, women diagnosed with Lynch syndrome should consider annual screening with endometrial sampling and transvaginal ultrasound, beginning between ages of 30 and 35 years. Hysterectomy with or without oophorectomy is an option after childbearing to deter the risk of endometrial cancer.

Clinical Manifestations

Abnormal uterine bleeding is often the only presenting symptom in women diagnosed with endometrial cancer. Upwards of 90% of women diagnosed with endometrial cancer report abnormal uterine bleeding, with postmenopausal bleeding the most common. However, postmenopausal bleeding has many etiologies, and only ~15% of these women will have endometrial cancer.

For pre- and perimenopausal women, the diagnosis is more challenging and often delayed. For this group of women, intermenstrual bleeding, prolonged, heavy bleeding, or the absence of menses for several months interrupted with episodes of bleeding warrants investigation.

Finally, Papanicolaou smears demonstrate malignant cells in only ~50% of women with underlying endometrial cancer. This highlights the ineffectual screening method of indirectly sampling the endometrium. To date, no screening method for the general population is recommended.

Diagnosis

Diagnosis of endometrial cancer is confirmed with a histological specimen. All women suspected of having uterine cancer due to

abnormal uterine bleeding should have their endometrium sampled via biopsy. Most often, this can be done in the clinic with a rigid or flexible catheter. With this technique, reported detection rates for postmenopausal and premenopausal are 99.6% and 91%, respectively. However, there is approximately a 10% false-negative rate with endometrial biopsy. Therefore a negative biopsy result in women highly suspicious for endometrial cancer should undergo exam under anesthesia and curettage. Finally, transvaginal ultrasound demonstrating an endometrial thickness of 5 mm or more in a postmenopausal woman requires endometrial sampling.

Women taking tamoxifen should be counseled about the increased risk of endometrial cancer and to report any abnormal vaginal bleeding so they can be thoroughly evaluated. However, no evidence supports the screening of asymptomatic women with ultrasound or serial endometrial sampling.

Staging

Due to the high incidence of lymph node metastases, the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) replaced a clinical staging system with a surgical staging system in 1988. The current, updated in 2009 FIGO staging system is detailed in [Table 1](#).

Treatment

Comprehensive surgical staging with exploration of the abdominal cavity, total hysterectomy with bilateral salpingo-oophorectomy, and bilateral pelvic and para-aortic lymphadenectomy are critical components for the diagnosis and management of all endometrial cancers. For type II tumors, meticulous surgical staging with the addition of collection of peritoneal washings for cytology, omentectomy ± peritoneal biopsies is required, since metastatic disease is often only identified microscopically. In cases with gross metastatic disease, cytoreductive surgery may be required. Surgical staging can be performed by laparotomy, laparoscopy, or robotically assisted procedure.

The utility and extent of lymph node dissection in endometrial cancer is controversial. Different strategies, including universal, selective, and sentinel lymph node mapping, are currently used. The universal method performs uniform comprehensive surgical staging for nearly all patients with endometrial cancer. This method allows for the most complete information postoperatively to make adjuvant decisions, but a significant percentage of women will develop lymphedema secondary to the nodal dissection. A common selective approach involves avoiding lymph node dissection in patients who have grade 1 or 2 endometrioid histology with

TABLE 1 Carcinoma of the Endometrium

Stage I: Tumor confined to uterine corpus

IA	Tumor limited to endometrium or < 50% myometrial invasion
IB	≥50% myometrial invasion

Stage II: Extension to cervical stroma

II	Cervical stromal invasion
----	---------------------------

Stage III: Local and/or regional spread

IIIA	Tumor invades serosa and/or adnexa
IIIB	Vaginal and/or parametrial extension
IIIC1	Pelvic lymph node involvement
IIIC2	Para-aortic lymph node involvement

Stage IV: Distant spread

IVA	Tumor invades bladder and/or rectal mucosa
IVB	Distant metastases, including abdominal spread and/or inguinal lymph nodes

Tumor grade, cell type, and presence/absence of malignant cytology in pelvic washings should be reported along with stage.

< 50% myometrial invasion and tumor size < 2 cm, since these patients have < 1 % risk of nodal metastases. Finally, an alternative approach utilizing sentinel lymph node mapping with indocyanine green dye is becoming more popular. Early studies have demonstrated promising results in decreasing morbidity while optimizing the pathological assessment of nodes in these women. Regardless the strategy, the presence of pelvic or para-aortic lymph node metastases remains one of the most important prognostic factors for endometrial cancer.

Following surgery, women are stratified by age and pathologic features to determine their risk for recurrence and the need for adjuvant therapy.

Adjuvant Therapy

The decision for adjuvant therapy is difficult and is based on the risk of relapse and persistent disease. In general, women with stage IA, grade 1 or 2 endometrioid adenocarcinoma have a favorable prognosis, and no adjuvant radiation is necessary following surgery. Early-stage endometrial carcinomas with risk factors for recurrence, stage II-IV cancers, and all serous and clear cell carcinomas often require adjuvant therapy in the form of radiation, chemotherapy, or a combination of both.

Early-Stage Disease

Surgery alone is usually curative for women with early-stage, low-risk disease. Women with early-stage, high-risk or high-intermediate risk factors are often recommended adjuvant radiation. The treatment can be in the form of external beam radiation therapy or vaginal brachytherapy. All serous and clear cell carcinomas of the uterus are recommended to receive adjuvant platinum-based combination chemotherapy regardless of stage. Adjuvant systemic therapy in patients with high-risk, early-stage endometrioid carcinoma remains controversial.

Metastatic Disease

Approximately 10–15% of patients will present with metastatic disease at presentation. Surgical cytoreduction is the preferred treatment approach if complete resection is achievable because it is associated with improved progression-free and overall survival. This would be followed by adjuvant platinum-based combination chemotherapy. The most common regimens are carboplatin (Paraplatin)¹ plus paclitaxel (Taxol)¹ or the triple drug combination of cisplatin (Platinol)¹, doxorubicin (Adriamycin)¹, and paclitaxel.

Patients who are not candidates for surgical cytoreduction either due to grossly metastatic disease or too poor a surgical candidate have a poor prognosis, with 5-year relative survival of < 20%. These patients should be offered systemic chemotherapy generally with palliative intent. Radiation therapy to achieve local control in the pelvis to palliate bleeding, discharge, and pain is often performed.

Recurrent Disease

Local recurrences, distance metastases, and simultaneous local and distant metastases are found in 50%, 29%, and 21%, respectively. Isolated vaginal recurrences are often salvaged with either surgery or radiation.

Distant recurrent endometrial cancer portends a poor prognosis. Systemic chemotherapy is given with a palliative intent, with the most active agents including platinum, taxanes, and anthracyclines.

Combination Chemotherapy and Radiation Therapy. Several studies have evaluated combining chemotherapy and radiation therapy in advanced-stage endometrial cancer. Most recently, a randomized phase III trial compared cisplatin and tumor volume directed irradiation followed by four cycles of chemotherapy (experimental arm) against six cycles of chemotherapy (control arm). While the overall survival is immature, the study reported no increase in

recurrence-free survival in optimally debulked, stage III or IV endometrial cancer.

Our experience involves using a “sandwich” method of irradiation between rounds of chemotherapy for advanced or recurrent endometrial cancer. The phase II trial demonstrated an overall 5-year survival of 79% with acceptable toxicity. The optimal sequencing of chemotherapy and radiation warrants further development.

Hormone Therapy

Prior to endometrial cancer, the risk of endometrial hyperplasia and the development into carcinoma can be significantly reduced with administration of a progestin. After the development of carcinoma, patients whose tumors test positive for estrogen receptor (ER) and progesterone receptor (PR) are associated with longer survival, with PR being a stronger predictor than ER. However, the role of adjuvant progestins in stage I or II endometrial cancer has not been demonstrated to be of value and may worsen cardiovascular disease. Progestins are commonly used in advanced or recurrent well-differentiated endometrial cancers. Oral megestrol acetate (Megace) and medroxyprogesterone acetate (Provera)¹ are two of the most commonly used progestins.

The SERM tamoxifen¹ has been used to treat patients with recurrent endometrial cancer, with response rates seen in ~22% of patients. The aromatase inhibitors anastrozole (Arimidex)¹ and letrozole (Femara)¹ were investigated in recurrent and metastatic endometrial cancer and demonstrated minimal activity.

Targeted Therapy

Multiple novel agents are being evaluated in clinical trials for use in treatment against endometrial cancer. Bevacizumab (Avastin)¹ is a monoclonal antibody directed against vascular endothelial growth factor (VEGF) that is active in endometrial cancer. Recent randomized trials demonstrated a benefit with the addition of bevacizumab to carboplatin and paclitaxel in first-line and second-line treatment of advanced, metastatic, and recurrent endometrial cancer. Results from phase 3 trials are needed prior to adopting as standard of care.

Pembrolizumab (Keytruda)¹ is an immune checkpoint inhibitor that has FDA approval for the use in advanced solid tumors demonstrating MMR deficiency or MSI. In patients with endometrial cancer, it is often used following progression on platinum-based chemotherapy in women with MMR or MSI tumors.

Trastuzumab (Herceptin)¹ and lapatinib (Tykerb)¹ are anti-human epidermal growth factor 2 (HER2) are investigational agents being tested as single agents and in combination with chemotherapy in some endometrial cancers, although the results thus far are not encouraging. The mechanistic Target of Ramamycin (mTOR) inhibitors everolimus (Zortress)¹ and ridaforolimus (MK-8669)⁵ have been used to treat advanced-stage and recurrent endometrial cancers, with mixed response.

Monitoring

Surveillance recommendations for endometrial cancer are stratified by risk of recurrence, and most women diagnosed and treated for endometrial cancer will fall into the low-risk category. High risk for recurrence is defined as advanced stage or grade 3 endometrioid, serous, or clear cell histology. Follow-up recommendations for low-risk women involve a history and physical examination, including a speculum and pelvic examination, scheduled every 6 months for the first 2 years, then yearly. Women with high risk of recurrence should have the same follow-up recommendations at intervals of 3 months for the first 2 years, every 6 months in years 2–5, then yearly. Pap test/cytology, CA 125, and routine radiographic imaging are not recommended. Women suspected of recurrence should have imaging performed.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

CANCER OF THE UTERINE CERVIX

Method of

Lucybeth Nieves-Arriba, MD; and Peter G. Rose, MD

CURRENT DIAGNOSIS

- New recommendations for cytology screening recommend starting screening at 21 years of age.
- Initial workup must include a biopsy.
- Imaging techniques including magnetic resonance imaging and positron emission tomography–computed tomography can assist in treatment planning.

CURRENT THERAPY

- Despite recent availability of human papilloma virus (HPV) vaccination (Gardasil, Cervarix) and advances in screening, cervical cancer remains a significant global health problem, especially in underserved populations.
- Improved understanding of the disease has allowed more conservative treatment of selected patients with early-stage disease.
- For advanced and high-risk cervical cancer, chemoradiation has had a significant impact on survival.

Epidemiology

Worldwide, cervical cancer is the second most common cancer in women. It is the greatest cancer killer of young women and the most common cause of death from cancer in women in the developing world. Worldwide in 2008, among the 530,000 new cases of cervical cancer, the highest incidence rates were in Africa, Central and South America, and Asia. In the United States, it is estimated that approximately 12,200 new cases were diagnosed and 4,210 patients died from cervical cancer in 2010. Significant disparities in incidence and stage at time of diagnosis have been identified among different ethnic groups—African Americans, Asian Americans, European Americans, and Latin Americans—in the United States. Factors that increase the risk of cervical cancer include early age at first coitus, multiple sexual partners, history of sexually transmitted diseases, low socioeconomic status, cigarette smoking, immunosuppression, and Fanconi's syndrome.

Pathophysiology

Cervical cancer occurs secondary to viral transformation of the surface (epithelial) cells by high-risk types of the human papilloma-virus (HPV), and it is the only gynecologic cancer that can be prevented by regular screening. Persistent infection with high-risk HPV has been identified as the essential factor in the pathogenesis

of the majority of cervical cancers. The virus's ability to transform human epithelium has been associated with the expression of two viral gene products, E6 and E7, which interact with p53 (a tumor-suppressor protein) and retinoblastoma protein (pRB), respectively, and affect control mechanisms of the cell cycle.

The prevalence of genital HPV infection in the world is estimated to be 400 million. Data from the National Health and Nutrition Examination Survey (NHANES) estimate the prevalence of HPV infection among girls and women in the United States aged 14 to 59 years is 26.8%. In about 90% of cases, the high-risk HPV infection is cleared by the immune system within 16 months. HPV infections in girls and younger women are more likely transient and therefore less likely to be associated with significant cervical lesions.

Prevention and Screening

Recent advances in molecular biology have allowed the development of viral-like particles using the L1 protein (major immunogenic capsid protein) of the HPV virus. Current vaccines, Gardasil (approved 2006) and Cervarix (approved 2009) contain two high-risk genotypes, HPV-16 and HPV-18, and could theoretically prevent 70% of cervical cancer cases. The Gardasil vaccine also contains two low-risk genotypes, HPV-6 and HPV-11, to prevent viral genital warts. The vaccines were FDA approved to use in girls and women between the ages of 9 and 26 years. If all children younger than 12 years were vaccinated, the most optimistic predictions expect a major effect on the cancer incidence will not be seen for 30 years. In 2009 HPV vaccination of males in the same age group was approved.

The current standard screening algorithm in the United States for preventing cervical cancer is presented in Table 1. Women with abnormal cytology are referred for a colposcopic examination. The colposcopic examination is used to guide biopsies of the exocervix, and in most cases an endocervical biopsy is also performed.

TABLE 1

Cervical Cytologic Screening Guidelines from the American College of Obstetricians and Gynecologists

RECOMMENDATION FOR CYTOLOGIC SCREENING		
AGE (Y)		COMMENTS
Younger than 21	Avoid screening	
21 to 29	Screen every 3 y	
30 to 65 or 70	May screen every 3 y*	This recommendation applies only to women with 3 consecutive cytologic tests; exceptions include women with HIV infection, compromised immunity, a history of cervical intraepithelial neoplasia grade 2 or 3, or exposure to DES in utero.
	Screen every 5 y	If HPV co-testing use
Between 65 and 70	May discontinue screening	This recommendation applies only to women with ≥3 consecutive negative cytologic tests and no abnormal tests in the preceding 10 y; exceptions include women with multiple sexual partners.

Abbreviation: DES = diethylstilbestrol.

Adapted from American College of Obstetricians and Gynecologists (ACOG). Cervical cytology screening. Washington DC: American College of Obstetricians and Gynecologists (ACOG); 2012 Nov. (ACOG practice bulletin; no.131); 2009 Dec. 12 (ACOG practice bulletin; no. 109).

In the United States, it is estimated that approximately 12,200 new cases were diagnosed and 4,210 patients died from cervical cancer in 2010. Significant disparities in incidence and stage at time of diagnosis have been identified among different ethnic groups—African Americans, Asian Americans, European Americans, and Latin Americans—in the United States. Factors that increase the risk of cervical cancer include early age at first coitus, multiple sexual partners, history of sexually transmitted diseases, low socioeconomic status, cigarette smoking, immunosuppression, and Fanconi's syndrome.

Pathophysiology

Cervical cancer occurs secondary to viral transformation of the surface (epithelial) cells by high-risk types of the human papilloma-virus (HPV), and it is the only gynecologic cancer that can be prevented by regular screening. Persistent infection with high-risk HPV has been identified as the essential factor in the pathogenesis

of the majority of cervical cancers. The virus's ability to transform human epithelium has been associated with the expression of two viral gene products, E6 and E7, which interact with p53 (a tumor-suppressor protein) and retinoblastoma protein (pRB), respectively, and affect control mechanisms of the cell cycle.

The prevalence of genital HPV infection in the world is estimated to be 400 million. Data from the National Health and Nutrition Examination Survey (NHANES) estimate the prevalence of HPV infection among girls and women in the United States aged 14 to 59 years is 26.8%. In about 90% of cases, the high-risk HPV infection is cleared by the immune system within 16 months. HPV infections in girls and younger women are more likely transient and therefore less likely to be associated with significant cervical lesions.

Prevention and Screening

Recent advances in molecular biology have allowed the development of viral-like particles using the L1 protein (major immunogenic capsid protein) of the HPV virus. Current vaccines, Gardasil (approved 2006) and Cervarix (approved 2009) contain two high-risk genotypes, HPV-16 and HPV-18, and could theoretically prevent 70% of cervical cancer cases. The Gardasil vaccine also contains two low-risk genotypes, HPV-6 and HPV-11, to prevent viral genital warts. The vaccines were FDA approved to use in girls and women between the ages of 9 and 26 years. If all children younger than 12 years were vaccinated, the most optimistic predictions expect a major effect on the cancer incidence will not be seen for 30 years. In 2009 HPV vaccination of males in the same age group was approved.

The current standard screening algorithm in the United States for preventing cervical cancer is presented in Table 1. Women with abnormal cytology are referred for a colposcopic examination. The colposcopic examination is used to guide biopsies of the exocervix, and in most cases an endocervical biopsy is also performed.

TABLE 1

Cervical Cytologic Screening Guidelines from the American College of Obstetricians and Gynecologists

RECOMMENDATION FOR CYTOLOGIC SCREENING		
AGE (Y)		COMMENTS
Younger than 21	Avoid screening	
21 to 29	Screen every 3 y	
30 to 65 or 70	May screen every 3 y*	This recommendation applies only to women with 3 consecutive cytologic tests; exceptions include women with HIV infection, compromised immunity, a history of cervical intraepithelial neoplasia grade 2 or 3, or exposure to DES in utero.
	Screen every 5 y	If HPV co-testing use
Between 65 and 70	May discontinue screening	This recommendation applies only to women with ≥3 consecutive negative cytologic tests and no abnormal tests in the preceding 10 y; exceptions include women with multiple sexual partners.

Abbreviation: DES = diethylstilbestrol.

Adapted from American College of Obstetricians and Gynecologists (ACOG). Cervical cytology screening. Washington DC: American College of Obstetricians and Gynecologists (ACOG); 2012 Nov. (ACOG practice bulletin; no.131); 2009 Dec. 12 (ACOG practice bulletin; no. 109).

TABLE 2 Revised FIGO Staging for Carcinoma of the Cervix

STAGE	CRITERIA
Stage I	
I	The carcinoma is strictly confined to the cervix
IA	Invasive carcinoma, which can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm
IA1	Measured stromal invasion of ≤ 3 mm in depth and extension of ≤ 7 mm
IA2	Measured stromal invasion of > 3 mm in depth and extension of > 7 mm
IB	Clinically visible lesions limited to the cervix or preclinical cancers greater than stage IA
IB1	Clinically visible lesion ≤ 4 cm in greatest dimension
IB2	Clinically visible lesion > 4 cm in greatest dimension
Stage II	
II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤ 4 cm in greatest dimension
IIA2	Clinically visible lesion > 4 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	
III	The tumor extends to the pelvic wall and/ or involves lower third of the vagina and/ or causes hydronephrosis or nonfunctioning kidney
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/ or hydronephrosis or nonfunctioning kidney
Stage IV	
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum; a bullous edema, as such, does not permit a case to be allotted as stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

Adapted from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynaecol Obstet* 2009;105(2):103-104. Erratum in *Int J Gynaecol Obstet* 2010;108(2):176.

The biopsy results then determine the type of follow-up and/or therapy required.

Staging

The International Federation of Gynecology and Obstetrics (FIGO) defined the most commonly accepted staging of cervical cancer. This staging is based on a careful clinical examination and the results of specific radiologic studies and procedures. FIGO's latest update (2009) is summarized in [Table 2](#).

In cervical cancer, primary lesions initially progress to lymphatics in the parametrium and pelvic nodes and then extend laterally to the pelvic side wall, bladder, and rectum. The two major spread patterns identified in cervical cancer include direct extension and lymphatic spread.

Diagnosis

The initial workup for cervical cancer depends on whether a cervical lesion is visible. Patients without a visible cervical lesion require a cone biopsy to diagnose stage IA1 or IA2 tumor. Patients with a cervical lesion are assessed by history and physical examination and possibly by examination under anesthesia for biopsy, cystoscopy, sigmoidoscopy, and conventional imaging (chest x-ray, intravenous pyelogram). Other imaging modalities including computed tomography (CT), magnetic resonance imaging (MRI), and fluorodeoxyglucose positron emission tomography (FDG-PET) are useful in

evaluating nodal or other metastatic sites but are not incorporated in the FIGO staging system owing to their limited availability worldwide. MRI performed significantly better than CT in detecting parametrial invasion, presence of bladder or rectal invasion, and identification of women suitable for fertility-preserving surgery. PET-CT is the most sensitive modality in identifying nodal metastasis or metastatic disease assisting with radiotherapy planning and evaluation of metabolic response to therapy. A 3-month post-therapy PET scan is highly predictive of long-term survival outcome.

Treatment

Multiple factors including tumor stage, size, histologic features (lymphovascular space invasion [LVSI], nonsquamous components, and depth of cervical stromal invasion), and evidence of lymph node metastasis influence the choice of treatment for cervical cancer. Patients with stage IA1 cervical cancer have undergone a cone biopsy and pathology demonstrates 3 mm of invasion or less, less than 7 mm width, no LVSI, and negative margins. Patients with this extent of disease can safely be treated with a less-radical hysterectomy, an extrafascial hysterectomy. Pelvic lymphadenectomy is not recommended owing to the low risk of pelvic node metastasis ($< 1\%$). In patients who desire to retain fertility, a cone biopsy may be considered. Wright and colleagues reported on 1409 women from the SEER database who were younger than 40 years and had stage IA1 cancer. The 5-year survival was 98% among 568 who underwent cone biopsy alone versus 99% among 841 who underwent hysterectomy.

Patients with stage IA2 to IB1 are generally treated with radical hysterectomy; in patients who are not candidates for surgery owing to comorbidities, radiation therapy is used. In patients with high-risk criteria after surgery—positive surgical margin, parametrial involvement, and positive pelvic nodes—cisplatin-based¹ chemoradiation, based on a positive randomized trial, is recommended. Those with intermediate risk factors including tumor size, cervical stromal invasion, and lymphovascular invasion had an improved progression-free survival with adjuvant radiation.

Radical trachelectomy—laparoscopic, vaginal or open—in conjunction with lymphadenectomy is a reasonable alternative treatment for select young patients with stage IA2 and IB1 who desire to maintain their childbearing capacity. The criteria used for patient selection include early-stage cervical cancer with a lesion less than 2 cm, no lymphovascular invasion, and no lymph node metastasis. Reports comparing radical trachelectomies with matched controls identified increased complications (25% vs. 3%) and overall less-radical dissection.

Treatment of stage IB2 cancer of the cervix varies depending on the bulkiness and shape of the lesion. Surgery and chemoradiation therapy have advantages and disadvantages. Finan and colleagues reported that up to 72% of patients with stage IB2 disease who were treated with surgery received adjuvant radiation owing to high-risk factors identified in pathologic evaluation of specimens. In a randomized Gynecologic Oncology Group trial, 94% of patients with IB2 cervical cancer who underwent radical hysterectomy had high or intermediate risk factors warranting adjuvant radiation.

In 1999 the National Cancer Institute (NCI) initiated a clinical alert recommending that concurrent cisplatin-based¹ chemotherapy be given with radiotherapy to women with cervical cancer based on five randomized studies, and this established a new standard of care ([Table 3](#)).

It is estimated that approximately 35% of patients with invasive cervical cancer will have recurrent or persistent disease, with most recurrences occurring in the first 2 years following primary therapy. Recurrence can be expected in 10% to 20% of patients treated with radical hysterectomy in contrast to 30% to 50% treated for more-advanced disease primarily with radiation plus concurrent chemotherapy. The site of the recurrence can direct further treatment. Patients with central pelvic recurrences after surgery are candidates for curative radiation; after primary treatment with radiation therapy patients may be candidates for curative radical

surgery (exenteration). Prognosis is more favorable for patients undergoing exenteration when there is a small (<3 cm) central recurrence, no sidewall involvement, and longer than 2 years of disease-free interval. Those with small recurrences limited to the cervix or upper vagina can occasionally be treated with radical hysterectomy and upper vaginectomy.

However, most recurrences are distant, involving the lung, bone, abdominal cavity, and supraclavicular lymph nodes. Recurrences within irradiated areas have a poor response to therapy (0% to

5%). Recurrences in the nonirradiated areas respond better to chemotherapy, with response rates of 25% to 70%. The use of chemotherapy in the treatment of recurrent cervical cancer is challenging because agents are only moderately active and patients can present with renal impairment secondary to obstructive uropathy, resulting in altered excretion with increased toxicity from chemotherapeutic agents. Table 4 compares results of randomized chemotherapy trials for the treatment of recurrent cervical cancer.

Conclusion

Adherence to current screening guidelines should allow early cervical cancer or precancerous detection. However, most patients with cervical cancer have not participated in regular screening and present with a variety of disease extents.

CONTRACEPTION

Method of

Rachel A. Bonnema, MD, MS; and Abby L. Spencer, MD, MS

CURRENT THERAPY

- Combined estrogen and progesterone methods (e.g., pills, patch, ring) are effective and commonly used. They provide excellent cycle control and decreased rates of ectopic pregnancy, pelvic inflammatory disease, and endometrial and ovarian cancer, and they can be used in extended-cycle methods for patients who desire fewer than 12 periods per year.
- The use of estrogen has been associated, albeit rarely, with the development of deep vein thrombosis, myocardial infarction, and stroke; estrogen should not be used in smokers older than 35 years, in patients with diabetes with end-organ damage, coronary artery disease, migraines with aura, or a known hypercoagulable condition.

CONTRACEPTION

Method of

Rachel A. Bonnema, MD, MS; and Abby L. Spencer, MD, MS

CURRENT THERAPY

- Combined estrogen and progesterone methods (e.g., pills, patch, ring) are effective and commonly used. They provide excellent cycle control and decreased rates of ectopic pregnancy, pelvic inflammatory disease, and endometrial and ovarian cancer, and they can be used in extended-cycle methods for patients who desire fewer than 12 periods per year.
- The use of estrogen has been associated, albeit rarely, with the development of deep vein thrombosis, myocardial infarction, and stroke; estrogen should not be used in smokers older than 35 years, in patients with diabetes with end-organ damage, coronary artery disease, migraines with aura, or a known hypercoagulable condition.

- For women with a contraindication to estrogen, progestin-only methods are safe to use.
- Long-acting reversible contraception (LARC) such as an implant or intrauterine device (IUD) is safe and extremely effective and should be considered in all women, including nulliparous women.

Nearly half of all pregnancies in the United States are unplanned, a rate higher than the rate in other developed countries. Primary care physicians need up-to-date knowledge on contraceptive counseling for women in order to provide the best match between patient and contraceptive method, in part because providers frequently need to supply contraceptives to women who have particular medical comorbidities. Newer contraceptive preparations are now available, including long-acting implants and altered oral formulations, which differ from traditional oral contraceptives in their hormonal dosages, cycle length, and hormone-free intervals.

Nonhormonal Methods

Nonhormonal methods of contraception include barrier methods and the copper IUD. These methods are safe, easily available, inexpensive, and reversible. Common barrier methods include male and female condoms, spermicides, vaginal sponges, diaphragms, and cervical caps (Table 1). Only condom use has been consistently found to protect against sexually transmitted diseases including HIV, and condom use may reduce risks of cervical cancer as well. Barrier methods have the lowest efficacy rates of all contraceptive methods, and users should also be counseled about emergency contraception. The copper IUD is an extremely effective form of LARC

and is a particularly attractive option for a woman with contraindications to hormone use desiring effective contraception.

Combined Hormonal Contraception

Combined hormonal contraception (CHC) contains estrogen (ethinyl estradiol) and a progestin and works primarily by preventing the surge of luteinizing hormone and thereby preventing ovulation. CHC can be delivered as an oral contraceptive pill (OCP), as a vaginal ring (NuvaRing), or as a transdermal patch (Ortho Evra). Risks, benefits, side effects, and contraindications of CHC are thought to be largely similar across delivery methods.

There are many noncontraceptive benefits to CHC, including first-line treatment for dysfunctional uterine bleeding, dysmenorrhea, and menorrhagia. Benefits in addition to menstrual control include reduction in the risks for, and symptoms of, endometriosis, ovulatory pain, ovarian cysts, benign breast disease, premenstrual syndrome, and premenstrual dysphoric disorder. CHC also reduces risk of ovarian and endometrial cancers; these risk reductions extend for years after stopping CHC. The most common side effects of CHC are outlined in Table 2. The risk of venous thromboembolism (VTE) may be higher in obese women, smokers, and those who use certain progestins such as desogestrel or drospirenone. This risk is lower, however, than the risk of VTE associated with pregnancy, and the absolute risk of VTE among CHC users remains small.

CHCs can be used safely by women who have a range of medical conditions, including well-controlled hypertension, uncomplicated diabetes, migraines *without* aura in women less than age 35, and a family history of breast cancer, to name a few. CHC use is contraindicated in women who have a history of migraine headache with

TABLE 1 Nonhormonal Contraception

	BARRIER METHODS			INTRAUTERINE DEVICE
	CONDOM (MALE/FEMALE)	DIAPHRAGM OR CERVICAL CAP	SPONGE	COPPER IUD
Duration	Female condom can be inserted up to 8 hours before intercourse; male condoms must be changed with each act of intercourse	Can be placed up to 6 hours before intercourse and should be removed within 6 hours after	Can be left in for 30 hours and through multiple acts of intercourse	Approved for up to 10 years
Typical-use failure rate*	15%	15%	15%	Less than 0.1%
Side effects and considerations	High failure rates: condom can break, slip Acceptability by partner may be limited	Requires expert fitting Needs to be refitted after childbirth Requires dexterity and self-placement by patient Use with spermicide increases efficacy but can lead to risk of UTIs, increased risk of toxic shock syndrome, and potential increased risk of HIV transmission	May increase risk of UTIs Use with spermicide increases efficacy but can lead to risk of UTIs, increased risk of toxic shock syndrome, and potential increased risk of HIV transmission	Bleeding and cramping with menses initially Low risk of ectopic pregnancy, premature delivery, perforation, or expulsion Avoid with active infection, undiagnosed genital bleeding, cervical cancer, or Wilson's disease
Consider in:	Patients at risk for STIs Patients without access to medical care and who are looking for nonhormonal, reversible, and convenient methods of contraception	Women who are looking for nonhormonal, reversible, and convenient methods of contraception	Women who are looking for nonhormonal, reversible, and convenient methods of contraception Patients without access to medical care	Women with contraindication to hormones or who desire hormone-free, long-acting, reversible contraception Women in need of EC followed by long-term effective contraception

*Trussel 2011.

Abbreviations: EC=emergency contraception; HIV=human immunodeficiency virus; IUD=intrauterine device; UTI=urinary tract infection.

TABLE 2 Hormonal Contraception

	COMBINATION ESTROGEN-PROGESTIN		PROGESTIN-ONLY		
	TRADITIONAL OCPs	EXTENDED-CYCLE OCPs	PILL	INJECTION	IMPLANT/IUD
Duration	Daily pill	Daily pill	Daily pill with no hormone-free interval	3 months	3–5 years
Reversibility	Immediate	Immediate	Immediate	Variable	Immediate
Typical-use failure rate†	9%	9%	9%	6%	0.05%–0.8%
Side effects‡	Spotting, nausea, headache, breast tenderness, breakthrough bleeding, VTE, stroke, MI	Spotting, increased unscheduled bleeding, nausea, VTE, stroke, MI	Spotting, unscheduled bleeding, or absence of bleeding; headaches, nausea, mood changes, breast tenderness, depression, enlarged ovarian follicles	Spotting, unscheduled bleeding, or absence of bleeding; weight gain, depression, reversible decrease in BMD	Spotting, unscheduled bleeding, or absence of bleeding
Consider in:	Women with dysmenorrhea, menorrhagia, irregular menstrual periods, acne, hirsutism, or polycystic ovary syndrome.	Women who do not desire monthly periods. Fewer withdrawal bleeds per year and shorter placebo may offer particular benefit for women with estrogen withdrawal symptoms, dysmenorrhea, or endometriosis.	Women with contraindication to estrogen, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding.	Women with contraindication to estrogen, seizure disorder, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding.	Women with contraindication to estrogen, seizure disorder, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding.

†Trussell J: Contraceptive failure in the United States. *Contraception* 2011;83:397–404.

‡Note: For all combination methods, must have no contraindication to estrogen.

Abbreviations: BMD = bone mineral density; IUD = intrauterine device; MI = myocardial infarction; OCP = oral contraceptive pill; VTE = venous thromboembolism.

aura at any age, or in women over age 35 with any migraine, due to elevated risk for stroke. Due to the increased risk of a cardiovascular event, CHC is also contraindicated in women with moderate hypertension, diabetes with end-organ damage, or known cardiovascular disease and in women who smoke after age 35 years. Other contraindications include a personal history of breast cancer, an estrogen-dependent tumor, unexplained vaginal bleeding, stroke, known thromboembolic disorder, or known VTE. Elevated risk of VTE and negative effect on lactation restrict use of CHC in the first 6 weeks after delivery.

Combined Oral Contraceptive Pills

There are dozens of formulations of OCPs, which differ by their estrogen dosage, progestin type and dosage, and hormone delivery schedule. OCPs can be monophasic, where each pill contains the same amount of hormones, or multiphasic, where pills contain different amounts of hormones throughout the monthly cycle. The different formulations offer patients options in cycle length, hormone levels, duration of withdrawal bleeding, and side-effect profile. Women should be educated to take their pill at the same time each day; this becomes even more critical in OCPs containing lower dosages of estrogen (20 mcg). If a pill is missed, it should be taken as soon as the woman remembers. If 2 days of pills are missed, she should take two pills daily for 2 days in a row and use a backup method. If 3 days of pills are missed, she should discard the pill pack and use a backup method. At that point, it should be discussed whether to start a new pack or to change contraceptive methods.

Traditional OCP regimens include 21 days of hormones, followed by 7 days of placebo pills during which women get their menses. Other women desire fewer days of menses or fewer than 12 menses per year. For these women, extended-cycle OCP regimens can be offered that shorten the placebo period to 4 days, offer a placebo week every 4 months, or eliminate the placebo week altogether. Extended-cycle regimens have other benefits, including decreased hormone withdrawal symptoms such as headaches, tiredness, bloating, excessive bleeding, or menstrual pain.

In addition to estrogen dose and scheduling, it is also important to consider the progestin component, which theoretically may affect libido, weight gain, acne, and hirsutism. But these choices must be balanced with potential increased risk for VTE; levonorgestrel-containing OCPs have a long track record and are associated with a lower risk of VTE than other progestins such as desogestrel, gestodene, and drospirenone.

Contraceptive Patch

Norelgestromin/ethinyl estradiol (Ortho Evra) is a thin transdermal patch containing 75 mcg of ethinyl estradiol and 6 mg of norelgestromin; it delivers a daily dose of about 20 mcg of estrogen and 150 mcg of progesterone daily. Patches should be changed weekly for 3 weeks on “patch change day” followed by a patch-free week during which menses occur. Only one patch should be worn at a time, and no more than 7 days should pass during the patch-free week. The patch has decreased efficacy in women who weigh more than 90 kg. Most of the noncontraceptive benefits, side effects, cardiovascular risks, and contraindications are similar to those of other forms of CHC, but there may be an increased risk of VTE in patch users as compared to users of OCPs. Studies are controversial as to the actual increase in risk associated with patch use, but did prompt the updating of the drug label to indicate a higher risk of VTE. Of note, the VTE risk associated with patch use is lower than that associated with pregnancy.

Vaginal Ring

Etonogestrel/ethinyl estradiol (NuvaRing) is a soft plastic ring that is inserted vaginally by the patient, usually for 3 weeks, and then removed for 1 week at which time menses occur. A new ring is inserted 7 days after the last was removed even if bleeding is not complete. The ring releases 15 mcg of ethinyl estradiol and 0.12 mg of etonogestrel daily for 3 to 5 weeks, so it can be kept in longer than 3 weeks for women who desire the benefits of extended-cycling use discussed above. Each ring releases about half the level of hormones as the average OCP without affecting efficacy. If the ring falls out (as occurs in 2.5% of women per year),

it can be rinsed and reinserted without a change in efficacy. Unlike the patch, the ring is not affected by excess weight. Most women find the ring easy to insert and remove and comfortable to retain during intercourse. The vaginal ring has been associated with an increase in leukorrhea. Otherwise, its noncontraceptive benefits, side effects, cardiovascular risks, and contraindications are similar to those of other forms of CHC.

Progestin-Only Contraceptives

Progestin-only contraceptives are of particular benefit for women who have a contraindication to estrogen, because progestin-only methods have decreased medical risks associated with their use including no increased risk of stroke, myocardial infarction, or VTE. All progestin-only methods have a similar method of action: ovulation is variably inhibited, cervical mucus is thickened, and the endometrial lining undergoes histologic alterations making implantation less likely. Because many of the progestin-only methods are long acting, they tend to have lower failure rates as opposed to CHCs (see Table 2). All progestin-only methods are appropriate for breast-feeding women.

Pill

Progestin-only pills (POPs) are taken without a hormone-free interval and fertility returns immediately on discontinuation. In fact, most experts believe fertility can return in as little as 3 hours after a missed dose; thus a woman should be counseled to use a backup method if she is 3 or more hours late in taking her dose. Given this small window for error, this method should be prescribed only to patients who can adhere closely to a daily pill schedule. Additionally, women should be counseled that while taking the POP, normal menstrual patterns may include anything from amenorrhea to menorrhagia. This unpatterned bleeding is likely one of the greatest obstacles to wider use of progestin-only oral contraception. Because POPs have demonstrated no significant negative effects on breast-feeding, POPs are most commonly used in the postpartum period and can be prescribed immediately postpartum. POPs may have similar effects as other progestin-only methods in decreasing the frequency of sickle cell crises; however, unlike depot medroxyprogesterone acetate (DMPA, Depo-Provera) injections, certain anti-convulsants may lower effectiveness of the POP so other methods may be more beneficial in women with seizure disorders.

Injectable

The intramuscular DMPA injection (Depo-Provera) is given every 12 weeks and has a typical-use failure rate of 6%. A lower dose of DMPA (104 mg in Depo-SubQ Provera) has been approved for subcutaneous injection. Women with seizure disorders are particularly good candidates for DMPA injections because, unlike other forms of contraception, DMPA's efficacy is not affected by enzyme-inducing antiepileptic drugs. Depo-Provera may also decrease seizure frequency, providing additional benefit for patients who have a seizure disorder. DMPA reduces serum estradiol levels, which can adversely affect bone health. In 2004, the FDA issued a black box warning that women who use Depo-Provera may lose significant bone mineral density (BMD) and recommended that use be limited to less than 2 years unless other methods are inadequate. Since that time, data have shown that although there is a clear association between DMPA use and decreased BMD, the BMD loss was reversible with discontinuation of use and there is no increased risk of fracture with use of DMPA. The World Health Organization has recommended that there be no restriction on the use of Depo-Provera in women ages 18 to 45. According to recent consensus guidelines, clinicians should advise patients about the risk for BMD loss but can reassure them about reversibility with discontinuation.

Intrauterine System

The levonorgestrel intrauterine system (LNG-IUS) is a highly effective contraceptive method long considered to be reversible sterilization due to its excellent efficacy in preventing pregnancy and quick return to fertility after its removal. There are now multiple

formulations of LNG IUS that prevent pregnancy up to 3 years (Liletta, Skyla) and 5 years (Kyleena, Mirena). Mirena is an IUS that releases approximately 20 mcg/day of LNG and is effective for 5 years. Skyla is a lower dose LNG-IUS that releases approximately 14 mcg/day of LNG and is effective for 3 years. The LNG-IUS is ideal for women who require highly effective contraception and is particularly beneficial for women requiring a progestin-only contraception. Its relatively low cost over time is another factor for patients to consider. Numerous studies have confirmed the effectiveness of the LNG-IUS for reduction of menstrual blood loss in menorrhagia, leiomyomas, and pain due to endometriosis. In fact, the LNG-IUS (Mirena) recently received FDA approval for the indication of menorrhagia and has also been shown to decrease menorrhagia even in women on anticoagulation. Insertion of the LNG-IUS requires a trained provider. At the time of placement, women may have cramping and pain; a rare complication of placement is uterine wall rupture. Though women will likely develop amenorrhea, they should be counseled about initial irregular bleeding and spotting.

Implant

There is one single-rod subdermal implant available in the United States called Nexplanon that is a highly effective long-term contraceptive containing the progestin etonogestrel (ENG). The rod is implanted in the upper arm and remains active for 3 years. ENG does not cause a hypoestrogenic state, thus this method is not considered to have any significant effect on BMD. ENG implantation can be done as a simple office procedure by a trained provider under local anesthetic with a preloaded, disposable applicator. Women experience a quick return to normal cycles after implant removal, and there have been no reports of infertility after removal. Similar to other progestin-only forms of contraception, irregular bleeding is the major side effect of the ENG implant. The most common bleeding pattern associated with the implant is infrequent, irregular bleeding. Unfortunately, there is no method to predict bleeding response for an individual patient after ENG implantation, so this is an important counseling point, particularly since the highest rate of discontinuation is during the first 8 to 9 months of use, primarily due to frequent bleeding.

Permanent

Permanent birth control methods include vasectomy and female sterilization by various procedures. These methods are highly effective (typical failure rate 0.15% to 0.5%); however, they are permanent, and can be associated with regret. Each sterilization procedure has advantages and disadvantages that should be considered by the patient before choosing which one to use.

Emergency Contraception

Familiarity with emergency contraception (EC) is critical both for women who are having unprotected sex and for those who are using methods with higher failure rates. EC use has not been shown to reduce compliance with other first-line methods. EC primarily acts by inhibiting or delaying ovulation, and works before implantation; if a fertilized egg has already implanted, EC will not work. EC includes pills (comprised of estrogen+progestin, progestin only, and anti-progestins) and copper IUD placement (inserted up to 5 days after unprotected intercourse); EC pills are most effective when taken in the first 12 hours, but have gradually decreasing effectiveness for up to 120 hours after intercourse. The most commonly used and most accessible form of EC in the United States contains levonorgestrel only (Plan B One Step) and is over the counter without age restrictions.

Counseling

When counseling patients about their contraceptive choices, it is important that providers are aware of their role in giving information and allowing patients to make informed decisions. The only effective contraceptive is one that a patient is willing to use consistently and correctly, and the choice of contraception is ultimately the patient's decision. Providers must educate patients regarding the advantages and disadvantages of each method that is medically

appropriate for them. Discussing a patient's preferences for menstrual frequency and tolerance for scheduled and unscheduled bleeding will be important in deciding which contraceptive will best fit her needs. Providers should counsel patients on expected side effects as well as expectant management strategies. Every effort should be made to remove barriers to initiation, including having no requirement for a pelvic examination or Pap smear before initiation. Using the conversation about contraceptives to also discuss safe sex is ideal.

DYSMENORRHEA

Method of

Linda Speer, MD

CURRENT DIAGNOSIS

- Primary dysmenorrhea (painful menses without underlying pathology) is common among adolescents and young women. It usually begins shortly after menarche.
- Diagnosis of primary dysmenorrhea can be made based on typical history of crampy pelvic pain during the first 1 to 3 days of the menstrual cycle. Pelvic examination is not required.
- Secondary dysmenorrhea (with underlying pathology) should be considered in cases that do not match the typical history, begin later in life, and/or are refractory to treatment.
- The most common cause of secondary dysmenorrhea is endometriosis. The clinical standard for diagnosis of endometriosis is laparoscopic confirmation. Ultrasound imaging is useful in some cases.

CURRENT THERAPY

- Nonsteroidal antiinflammatory drugs (NSAIDs) are well-established first-line therapy for treatment of primary dysmenorrhea. None has been confirmed as superior to others.
- Cyclooxygenase-2 (COX-2) inhibitors are effective and have fewer gastrointestinal side effects but may be less effective than NSAIDs.
- Oral contraceptives and the levonorgestrel intrauterine system (Mirena)¹ reduce dysmenorrhea.

- Other effective therapies include topical heat, high-frequency transcutaneous electrical nerve stimulation (TENS), and several herbal preparations.
- Treatments for endometriosis as a secondary cause of pelvic pain and dysmenorrhea include hormonal suppression of the endometrial tissue, conservative laparoscopic surgical debulking, and hysterectomy in selected cases.

¹Not FDA approved for this indication.

Dysmenorrhea is defined as painful menses. Primary dysmenorrhea occurs without underlying pathology, typically beginning soon after menarche. It is common in adolescent girls, with prevalence ranging from 20% to 90% depending on measurement methods; about 15% of adolescents describe their dysmenorrhea as severe. The median duration of each episode is 2 days beginning with the onset of menses. During adolescence, dysmenorrhea leads to high rates of school absence and activity nonparticipation. According to representative national survey data in the United States, 14% of adolescent girls aged 12 to 17 years frequently miss school because of menstrual cramps.

A prospective cohort study showed that the prevalence and severity of dysmenorrhea was lower at 24 years of age than at 19 years of age. At 24 years of age, 67% of the women still experienced dysmenorrhea, and 10% reported pain severity that limited daily activity. The prevalence and severity of dysmenorrhea were reduced in women who were parous at 24 years and nulliparous at 19 years, but they were unchanged in women who were still nulliparous or women who had had a miscarriage or abortion.

There is a significant correlation between the severity of dysmenorrhea and the amount of menstrual flow. Survey data demonstrate that depression and anxiety are associated with menstrual pain and suggest that loss of social support is a significant contributor to menstrual symptoms. The severity of dysmenorrhea is not associated with height, weight, or regularity of the menstrual cycle. A relationship to smoking has been found inconsistently. Physical activity has been studied and found not to be associated with any pain parameter.

Secondary dysmenorrhea typically starts later in life after the onset of an underlying causative condition, most often endometriosis. The association between dysmenorrhea and endometriosis is uncertain for women with minimal disease. However, based on a study of more than 1000 women with laparoscopically confirmed endometriosis, chronic pelvic pain, dyspareunia, and dysmenorrhea are in fact related to the extent of endometriosis.

Diagnosis

For adolescents who present with complaints typical for primary dysmenorrhea, treatment may be started empirically without a pelvic examination or diagnostic studies. Sexually active adolescents and young women should be screened for chlamydia and gonorrhea, which can be done with either urine or a genital sampling.

For adolescents and women who do not have a history consistent with primary dysmenorrhea or who are refractory to treatment, endometriosis may be suspected. The gold standard for diagnosis is laparoscopy and biopsy. Ultrasound may also be useful, especially to identify endometriomas.

Treatment

Nonsteroidal Antiinflammatory Drugs

A Cochrane review of randomized, controlled trials (RCTs) concluded that among women with primary dysmenorrhea, NSAIDs were significantly more effective for pain relief than placebo or acetaminophen (Tylenol). No specific NSAID was shown to be superior to others for either pain relief or safety. However, the available evidence had little power to detect such differences, because most individual comparisons were based on few small trials. In one study in which diclofenac (Voltaren) 100 mg was compared with placebo for treatment of primary dysmenorrhea, the

appropriate for them. Discussing a patient's preferences for menstrual frequency and tolerance for scheduled and unscheduled bleeding will be important in deciding which contraceptive will best fit her needs. Providers should counsel patients on expected side effects as well as expectant management strategies. Every effort should be made to remove barriers to initiation, including having no requirement for a pelvic examination or Pap smear before initiation. Using the conversation about contraceptives to also discuss safe sex is ideal.

The prevalence and severity of dysmenorrhea were reduced in women who were parous at 24 years and nulliparous at 19 years, but they were unchanged in women who were still nulliparous or women who had had a miscarriage or abortion.

There is a significant correlation between the severity of dysmenorrhea and the amount of menstrual flow. Survey data demonstrate that depression and anxiety are associated with menstrual pain and suggest that loss of social support is a significant contributor to menstrual symptoms. The severity of dysmenorrhea is not associated with height, weight, or regularity of the menstrual cycle. A relationship to smoking has been found inconsistently. Physical activity has been studied and found not to be associated with any pain parameter.

Secondary dysmenorrhea typically starts later in life after the onset of an underlying causative condition, most often endometriosis. The association between dysmenorrhea and endometriosis is uncertain for women with minimal disease. However, based on a study of more than 1000 women with laparoscopically confirmed endometriosis, chronic pelvic pain, dyspareunia, and dysmenorrhea are in fact related to the extent of endometriosis.

Diagnosis

For adolescents who present with complaints typical for primary dysmenorrhea, treatment may be started empirically without a pelvic examination or diagnostic studies. Sexually active adolescents and young women should be screened for chlamydia and gonorrhea, which can be done with either urine or a genital sampling.

For adolescents and women who do not have a history consistent with primary dysmenorrhea or who are refractory to treatment, endometriosis may be suspected. The gold standard for diagnosis is laparoscopy and biopsy. Ultrasound may also be useful, especially to identify endometriomas.

Treatment

Nonsteroidal Antiinflammatory Drugs

A Cochrane review of randomized, controlled trials (RCTs) concluded that among women with primary dysmenorrhea, NSAIDs were significantly more effective for pain relief than placebo or acetaminophen (Tylenol). No specific NSAID was shown to be superior to others for either pain relief or safety. However, the available evidence had little power to detect such differences, because most individual comparisons were based on few small trials. In one study in which diclofenac (Voltaren) 100 mg was compared with placebo for treatment of primary dysmenorrhea, the

authors found that leg strength and aerobic capacity were maintained at the level found during luteal phase when women took diclofenac for dysmenorrhea, but they were reduced during menses in the placebo group.

COX-2 Inhibitors

Several COX-2 inhibitors have been evaluated for treatment of dysmenorrhea in RCTs. Celecoxib (Celebrex) 200 mg was compared with naproxen sodium (Naprosyn) 550 mg and placebo for treatment of dysmenorrhea and found to be superior to placebo but not as effective as naproxen. Etoricoxib (Arcoxia)⁵ 120 mg daily was found to be better than placebo and equivalent to mefenamic acid (Ponstel) for treatment of primary dysmenorrhea with less nausea and epigastric pain than mefenamic acid. Lumiracoxib (Prexige)⁵ 200 mg daily was compared with naproxen 500 mg twice daily and placebo for treatment of primary dysmenorrhea and found to reduce pain more than placebo and similar to naproxen.

Oral Contraceptives

In a systematic review of NSAIDs and oral contraceptives (OCs) for treatment of dysmenorrhea that included 10 placebo-controlled RCTs of NSAIDs, two RCTs of OCs and six prospective observational studies of OCs, the authors concluded that both are effective. In a study of women with laparoscopically proven endometriosis, low-dose ethinyl estradiol and norethisterone (norethindrone) decreased dysmenorrhea associated with endometriosis as compared with placebo (with pain assessment on a verbal rating scale from 0 to 3). There was also a significant reduction in volume of endometriomas with OCs but not placebo.

Levonorgestrel Intrauterine System

The levonorgestrel intrauterine system¹ (LNG-IUS; Mirena) reduces menstrual bleeding and dysmenorrhea, which can be a desirable side effect for women desiring long-term contraception. In an uncontrolled case series of women treated with LNG-IUS for adenomyosis, dysmenorrhea diminished continuously during the 3-year study from a mean 78 mm to a mean 12 mm on a 100-mm visual analog scale. Overall satisfaction with treatment was 73%. Depot medroxyprogesterone acetate¹ (Depo-Provera) is similarly effective, but it is less likely to be well tolerated owing to unpredictable bleeding, weight gain, and mood changes.

Nifedipine

In one uncontrolled study, nifedipine¹ (Procardia) 20 to 40 mg given orally reduced myometrial activity and relieved dysmenorrhea. This drug could be considered as an adjunct in severe cases of primary dysmenorrhea after ruling out endometriosis.

Transcutaneous Electrical Nerve Stimulation

In a study comparing transcutaneous electrical nerve stimulation (TENS) with interferential current for treatment of dysmenorrhea, each group received application of the modality for 20 minutes while experiencing dysmenorrhea. Both groups improved significantly from baseline without significant difference between them. High-frequency TENS has been found to be effective for the treatment of dysmenorrhea in a number of small trials. Low-frequency TENS does not appear to be effective.

Topical Heat and Infrared Light

Continuous low-level topical heat therapy has been shown to be as effective as ibuprofen (Advil) for the treatment of dysmenorrhea in one RCT. In a trial comparing far-infrared emitting belt versus placebo belt for treatment of primary dysmenorrhea, both with concurrent application of topical heat, both groups improved, and the duration of the analgesic effect was significantly longer in the group treated with the infrared belt.

Complementary and Alternative Medicine Approaches

Herbal

Several herbal remedies have been studied in RCTs for treatment of dysmenorrhea and found to be effective as compared with placebo or NSAIDs. They include *Psidium guajava* extract⁷ 6 mg/day, French maritime pine bark extract (pycnogenol),⁷ and ginger root powder⁷ 250 mg 4 times daily.

Acupressure and Acupuncture

The evidence for the effectiveness of acupuncture is not conclusive. In unblinded studies women experience clinically relevant reduction in pain scores, a mean of more than 10 points on a 100-point scale, which could be due to placebo effect. In fact, in a well-designed RCT of electro-acupuncture at the Sanyinjiao point (the point expected to be related to uterine pain) compared to an unrelated nonacupoint or no acupuncture, the only significant differences were with the no-acupuncture group as measured with a visual analogue rating scale.

Adequate blinding is also an issue among studies of acupressure. For example, in an RCT comparing auricular seed acupressure versus adhesive tape only for treatment of primary dysmenorrhea the acupressure group (but not the tape only group) had instructions to massage the seed 15 times, three times daily for 20 days. Menstrual pain decreased significantly in the acupressure group. Several other studies suggest that acupressure at the Sanyinjiao point or Taichong point is more effective than no intervention or inadequately blinded control groups. Because acupressure is a low-cost and harmless intervention, it may be worth considering even if the pain reduction is a placebo response.

Yoga

Yoga is another alternative approach with low cost and little risk that may be worth considering despite weak evidence for effectiveness. In one unblinded RCT, three yoga poses (cat, cobra, and fish) were studied for treatment of primary dysmenorrhea. Participants randomized to the intervention group were told to do the yoga poses during luteal phase and complete a questionnaire regarding menstrual characteristics. The control group was asked to complete the questionnaire only. There was significant reduction in intensity and duration of pain in the yoga group compared with baseline and with the control group.

Spinal Manipulation

Overall there is no evidence to suggest that spinal manipulation is effective in the treatment of primary and secondary dysmenorrhea.

Surgical Treatment

Surgical treatment may be considered in severe and refractory cases of pelvic pain including dysmenorrhea. Laparoscopic uterosacral nerve ablation (LUNA, $n=35$) alone has been compared with LUNA plus presacral neurectomy ($n=32$). There were no differences between groups for relief of dysmenorrhea at 3-, 6-, and 12-month follow-up, but more surgical complications were experienced with neurectomy.

Treatment of Endometriosis

Treatment of endometriosis may start with use of NSAIDs, hormonal contraceptives, and/or LNG-IUS.¹ However, often endometriosis is diagnosed after those first-line therapies have failed. Debunking of the ectopic endometrial tissue during laparoscopy can relieve pain.

Other treatments involve hormonal suppression of endometrial tissue. Danazol is a 19-nortestosterone derivative with a long history of use for treatment of endometriosis pain at a dosage of 400 to 800 mg daily for 6 months, but it is often poorly tolerated

owing to androgenic side effects. Oral progestin regimens (medroxyprogesterone acetate¹ [DepoProvera] up to 100 mg daily³ or norethindrone [Aygestin] up to 15 mg daily) may be used to suppress menses for a 6-month course. Other accepted therapies include gonadotropin-releasing hormone (GnRH) agonist analogues such as leuprolide (Lupron). Aromatase inhibitors have been shown to be effective in a systematic review of several small RCTs. Etonogestrel subdermal implant¹ (Implanon, Nexplanon) has been evaluated in an uncontrolled case series and found to be associated with pain relief.

In severe refractory cases, hysterectomy may be considered.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

ENDOMETRIOSIS

Method of

Zachary Kuhlmann, DO

CURRENT DIAGNOSIS

- Clinical symptoms associated with endometriosis include chronic pelvic pain, dysmenorrhea, dyspareunia, and infertility.
- A pelvic sonogram may be helpful to aid in diagnosis of endometriosis. Care should be taken to exclude other gynecologic and non-gynecologic etiologies of pain.
- Diagnostic laparoscopy may reveal powder burn–like lesions, adhesions, endometriomas, or other signs of endometriosis on inspection.
- The gold standard to make a pathologic diagnosis of endometriosis requires a tissue biopsy of a suspected lesion.

CURRENT MANAGEMENT

- Initial therapy for endometriosis includes NSAIDs, progestones, combined OCPs, danazol (Danocrine), and GnRH agonists.
- Diagnostic laparoscopy with excision or ablative techniques are often used to treat endometriosis.
- It is reasonable to consider empiric medical therapy with a GnRH agonist before surgery in some situations.
- Hysterectomy with bilateral salpingo-oophorectomy is definitive surgical treatment for endometriosis.

owing to androgenic side effects. Oral progestin regimens (medroxyprogesterone acetate¹ [DepoProvera] up to 100 mg daily³ or norethindrone [Aygestin] up to 15 mg daily) may be used to suppress menses for a 6-month course. Other accepted therapies include gonadotropin-releasing hormone (GnRH) agonist analogues such as leuprolide (Lupron). Aromatase inhibitors have been shown to be effective in a systematic review of several small RCTs. Etonogestrel subdermal implant¹ (Implanon, Nexplanon) has been evaluated in an uncontrolled case series and found to be associated with pain relief.

In severe refractory cases, hysterectomy may be considered.

ENDOMETRIOSIS

Method of

Zachary Kuhlmann, DO

CURRENT DIAGNOSIS

- Clinical symptoms associated with endometriosis include chronic pelvic pain, dysmenorrhea, dyspareunia, and infertility.
- A pelvic sonogram may be helpful to aid in diagnosis of endometriosis. Care should be taken to exclude other gynecologic and non-gynecologic etiologies of pain.
- Diagnostic laparoscopy may reveal powder burn–like lesions, adhesions, endometriomas, or other signs of endometriosis on inspection.
- The gold standard to make a pathologic diagnosis of endometriosis requires a tissue biopsy of a suspected lesion.

CURRENT MANAGEMENT

- Initial therapy for endometriosis includes NSAIDs, progestones, combined OCPs, danazol (Danocrine), and GnRH agonists.
- Diagnostic laparoscopy with excision or ablative techniques are often used to treat endometriosis.
- It is reasonable to consider empiric medical therapy with a GnRH agonist before surgery in some situations.
- Hysterectomy with bilateral salpingo-oophorectomy is definitive surgical treatment for endometriosis.

Endometriosis is a common and benign gynecologic condition diagnosed when endometrial tissue is found outside the uterus. Common places for endometrial tissue to implant include the peritoneum and ovaries, although endometriosis can occur outside the pelvis as well. Other locations for endometriosis to be found include the rectovaginal septum, bowel, bladder, pleura, abdominal wall, and even the brain in rare cases. Endometriosis is an estrogen-dependent, inflammatory disorder.

Epidemiology

Endometriosis affects between 5% to 10% of women of reproductive age. Women who experience infertility may have a prevalence of endometriosis of up to 50%, and women with chronic pelvic pain may experience a prevalence of endometriosis well over 80%.

Risk Factors

There appears to be an inheritable component for endometriosis. Women who have a first-degree relative affected by endometriosis may have a 6 to 7 times higher incidence than women without an affected relative. Other risk factors for endometriosis include menarche before age 11 and extremes of cycle length (either short or long cycles). Women who breastfeed for long durations, women who have more children, and women who exercise regularly may see a reduction in their risk of endometriosis.

Pathophysiology

There are many theories regarding the origin of endometriosis. Perhaps the most popular hypothesis proposes that retrograde menstruation allows for endometrial tissue to be passed back through the fallopian tubes and implant into the pelvis. Another theory suggests that coelomic metaplasia occurs. In this theory, it is thought that the differentiation of mesothelial cells into endometrial cells results in endometriosis lesions. It is also thought that hematogenous or lymphatic spread is a plausible explanation for endometriosis. Endometrial cells may be deposited from the vascular or lymphatic vessels onto tissues outside the uterus. One final theory for the etiology of endometriosis involves bone marrow. Cells originating from the bone marrow may differentiate into endometrial tissue outside the uterus.

No matter how endometriosis originates, the immune system plays a pivotal role in the disease process. Endometriosis is associated with an overproduction of estrogen, prostaglandins, and cytokines. Estrogen is overproduced by an increase in aromatase activity. Cyclooxygenase-2 (COX-2) activity is also increased, which stimulates prostaglandin production. Endometriosis is also associated with progesterone resistance, and that magnifies the effect of estrogen in an already estrogen-rich environment. This inflammatory cascade leads to an increase in cytokines and macrophages. The cytokines increase the presence of macrophages and lymphocytes in the peritoneum.

The chronic inflammation identified in endometriosis may cause pain by stimulating the nerve endings or affect the neural innervations of the uterus. Fallopian tube function and sperm function may be adversely affected by the inflammatory cytokines. Also, the fallopian tubes may be completely blocked in some cases of endometriosis.

Clinical Manifestations

Many clinical symptoms have been associated with endometriosis. Cyclical pain is often described with endometriosis. Some of the more commonly recognized symptoms include dysmenorrhea, chronic pelvic pain, dyspareunia, and infertility. Dysmenorrhea can be described as primary or secondary. The dysmenorrhea with endometriosis is classically described as secondary dysmenorrhea because it is associated with a pathologic diagnosis. Primary dysmenorrhea is when there is painful menstruation in the absence of pelvic pathology. Examples of chronic pelvic pain with endometriosis may include other visceral symptoms such as dyschezia or dysuria. Hematuria, diarrhea, constipation, and chronic back pain may all be symptoms associated with endometriosis.

Interestingly, the extent of disease may not necessarily correlate with the severity of symptoms. Some women with a small foci of endometriosis may have excruciating symptoms, whereas others with extensive endometriosis may only experience mild symptoms.

Exam findings consistent with a diagnosis of endometriosis may include uterosacral ligament nodularity/tenderness and presence of an adenxal mass. Tenderness in the cul-de-sac with a fixed and immobile uterus may also indicate presence of endometriosis. Cyclical hemoptysis has been reported with endometriosis. Endometriotic implants have also been located in scars, so the presence of cyclical pain in an abdominal incision may lead to suspicion of endometriosis.

Diagnosis/Differential Diagnosis

The diagnosis of endometriosis is made surgically. The gold standard to make a diagnosis of endometriosis is to have a pathologic specimen from a tissue biopsy of a suspected lesion. Histology will reveal endometrial glands and stroma and inflammation. If a biopsy is not performed, surgical findings consistent with an endometriosis diagnosis include lesions that look like black powder burns and nonclassical red or white lesions. Endometriomas have also been described as a classic surgical finding of endometriosis. Endometriomas are an ovarian structure filled with endometriosis and are colloquially described as chocolate cysts because when they rupture, it appears as though chocolate syrup flows out of the cyst. Endometriomas appear on sonographic imaging as cysts with homogenous internal echoes. Although rare, endometriosis can sometimes be found in the bladder. If bladder involvement is suspected, such as the case of cyclical hematuria, a cystoscopy may be of benefit for diagnosis. Although surgery remains the mainstay of diagnosis for endometriosis, some studies suggest there is a low correlation between the severity of symptoms, the amount of endometriosis visualized on surgical inspection, and diagnostic histologic findings.

Pelvic imaging may be helpful in the evaluation of endometriosis, especially in the presence of an adenxal mass. In patients with pelvic pain or disorders of menstruation, a sonogram is usually the preferred imaging modality for the pelvis. Computed tomography (CT) may help delineate the size and characteristic of an adenxal mass and is likely most useful to rule out other pathology or surrounding organ involvement. The usefulness of magnetic resonance imaging (MRI) is limited in the evaluation of endometriosis and should be reserved for extreme cases where specific organ involvement such as the bladder or bowel is suspected. MRI may also be useful in evaluating specific musculoskeletal conditions.

There is no good serum marker to make the diagnosis of endometriosis. CA-125 levels may be elevated in endometriosis, but there are many other inflammatory conditions that cause an elevation in CA-125 levels.

When initially evaluating for endometriosis, one should consider a thorough differential diagnosis for causes of chronic pelvic pain. Table 1 lists the differential diagnosis for chronic pelvic pain. A basic approach to the patient with chronic pelvic pain should include a detailed history and physical, urinalysis, gonorrhea/chlamydia cultures, consideration of pelvic sonogram, and serum or urine beta human chorionic gonadotropin (Bhcg). If after careful evaluation, endometriosis is at the top of the differential diagnosis for the patient's pelvic pain, then discussion with the patient regarding empiric treatment or diagnostic workup should occur.

Medical Therapy

The goal of medical intervention for endometriosis is the treatment of pain. A reasonable approach to treating the patient with suspected endometriosis is to give a trial of empiric medical therapy. Although endometriosis is a surgical diagnosis, some patients with suspected endometriosis may wish to avoid surgery. Medical therapy is usually preferred for those patients who would like to preserve fertility and who are interested in delaying childbearing while managing their symptoms.

The combined oral contraceptive pill (OCP) is a usual first-line therapy for the treatment of suspected or diagnosed endometriosis.

TABLE 1 Differential Diagnosis for Chronic Pelvic Pain Based on Organ Systems

GYNECOLOGIC	GASTROINTESTINAL	URINARY	MUSCULOSKELETAL
Endometriosis	Irritable bowel syndrome	Urinary tract infection	Fibromyalgia
Adenomyosis	Diverticuli	Interstitial Cystitis	Ankylosing spondylitis
Cervicitis	Crohn's	Malignancy	Arthritis
Leiomyoma	Ulcerative Colitis	Renal lithiasis	Muscle strains
Ovarian cysts	Gastroenteritis		
Pelvic adhesive disease	Hemorrhoids		
Hydrosalpinx/tubal disease			
Pelvic congestion syndrome			

A 3- to 6-month trial with empiric treatment with OCPs is a reasonable time frame to assess effectiveness of medical treatment. OCPs should be avoided in patients that have contraindications to OCPs including pregnancy, history of thrombosis, liver disease, migraine with aura, uncontrolled hypertension, and those patients that smoke and are over the age of 35 years.

Other medications used to treat endometriosis include danazol (Danocrine), nonsteroidal antiinflammatory drugs (NSAIDs), progestins, and gonadotropin-releasing hormone (GnRH) agonists. NSAIDs may improve the pain and dysmenorrhea associated with endometriosis. Danazol is an effective treatment for endometriosis. The side effect profile for danazol limits its use. Danazol has been associated with masculinizing symptoms, which can include acne and hair growth. Danazol should be avoided in pregnancy because the masculinizing effects could be detrimental to a female infant.

Physicians commonly prescribe progestins in three different ways to treat endometriosis: injectable, oral, or intrauterine. Injectable medroxyprogesterone (Depo-SubQ Provera 104) is approved by the Food and Drug Administration (FDA) for the treatment of endometriosis. Depo-Provera's side effects may include weight gain, bleeding, amenorrhea, and slow return to fertility. Patients using Depo-Provera may initially experience irregular bleeding but often develop amenorrhea after the second dose is administered. Return to fertility after Depo-Provera is discontinued can also pose a problem. Oral agents such as norethindrone acetate (Aygestin) have also been approved by the FDA for the treatment of endometriosis. The levonorgestrel-containing intrauterine device (IUD) (Mirena)¹ is approved only for contraception and the treatment of menorrhagia, but it may still be an effective treatment for endometriosis.

The GnRH agonists are among the most effective medications available to treat endometriosis. The side effects of GnRH agonists include menopausal-like symptoms such as vaginal dryness, hot flashes, and osteopenia. The addition of add-back therapy may help ameliorate some of the GnRH agonist symptoms. Typically, add-back therapy involves the use of progestins concurrently with a GnRH agonist. Practice patterns vary; some providers may start add-back therapy immediately when a patient is started on a GnRH agonist. It is recommended that add-back therapy be initiated after 6 months of GnRH agonist use if it was not started previously. In addition to progestins, the combination of progestins and estrogen have been used for add-back therapy. The maximum duration of GnRH agonist treatment is typically 12 months.

Surgical Therapy

The goal of surgery for endometriosis is to relieve pain and/or infertility. One of the first questions the provider must answer is when to perform surgery. Surgery may be indicated if medical treatment has failed. Other times, the severity of symptoms or

presence of large endometriomas may direct a provider to consider surgery sooner.

Laparoscopy is a common surgical approach for patients with confirmed or suspected endometriosis. At the time of laparoscopy, the surgeon can assess the uterus, ovaries, and surrounding viscera for pathology. When endometriosis is encountered on laparoscopy, common approaches are to excise or ablate the lesions. Excision of endometriosis allows for a pathologic diagnosis. If the provider elects to ablate the lesions, this can be performed through electrocautery or laser. In addition to diagnosing and treating endometriosis, further evaluation of patients with infertility can be done at the time of laparoscopy. Tubal function can be assessed through a chromotubation where dye is passed through the fallopian tubes to prove the tubes are patent. Although laparotomy allows for thorough evaluation of the pelvis, it is usually reserved for cases of confirmed endometriosis where the extent of adhesions and distorted anatomy makes laparoscopy unsafe.

Endometriomas present an array of challenges when noted at the time of surgery. The decision to drain the cyst versus perform a cystectomy during surgery must be made by the surgeon. A general approach is to use a "3-centimeters (cm) rule" to help guide management decisions. Patients with an endometrioma greater than 3 cm may benefit from cystectomy, whereas endometriomas less than 3 cm may be managed by drainage and ablation. Although removing the endometrioma through cystectomy may confer a decreased risk or recurrence, the risk of damaging healthy ovarian tissue is ever present. Other confounders to consider are future fertility plans of the patient, severity of symptoms, and previous treatments for endometriosis.

In a patient who has completed childbearing or has no desire for future fertility, hysterectomy with a bilateral salpingo-oophorectomy (BSO) may be considered for treatment of endometriosis. Studies suggest that hysterectomy alone is less effective at curing pain than hysterectomy with a BSO. Although hysterectomy with BSO offers definitive treatment for endometriosis, surgery does not guarantee resolution of pain. Many routes may be considered for surgery, including laparoscopic, robotic-assisted laparoscopic, or laparotomy with a total abdominal hysterectomy/BSO. Although vaginal hysterectomy is a common and preferred route of surgery, the distorted anatomy and presence of adhesions often associated with endometriosis tends to discourage many surgeons from performing vaginal hysterectomies for endometriosis.

Monitoring

Patients diagnosed with endometriosis may require frequent monitoring of symptoms. Routine visits with a physician may help determine the effectiveness of current treatment regimens. Physicians should consider what the patient's goals of treatment are: Does the patient want resolution of pain or infertility or both? Individualized plans may help each patient achieve their goals of treatment. As with any diseases involving chronic pain, care should be taken to regularly assess patients with endometriosis for depression.

¹Not FDA approved for this indication.

FEMALE SEXUAL DYSFUNCTION

Method of

Melissa Hague, MD

CURRENT DIAGNOSIS

- Sexual pain is a common cause of distress for women and their partners, with up to 50% of women experiencing distress at some point in their lifetime.
- Women may present with a complaint of decreased libido, but on further questioning may have significant pain with sex that is causing or contributing to decreased desire.
- Always ask about relationship stress, pain, and ability to achieve climax when discussing sexual distress with female patients.
- Many medications interfere with libido, as does a patient's lifestyle and overall health status.
- Like many medical concerns, female sexual dysfunction is a complex, multifactorial problem that should be addressed with a holistic multidisciplinary approach.

CURRENT THERAPY

- You cannot treat decreased libido in a patient who is having sexual pain without addressing the source of the pain.
- Determine the cause of sexual pain and once this has been adequately addressed you may consider a treatment plan for decreased libido.
- Consider the approach to sexual pain from the outside working in. Start with skin or vulvar causes such as lichen sclerosis, atrophy, or herpes. Work in toward the pelvic floor and consider muscle or nerve pain as a cause. Once you have considered these as a source of pain and not found a problem, you can consider a bimanual exam and see if pain occurs with cervical or uterine motion, or if there is evidence of pelvic mass.
- Realize that patients that have suffered sexual trauma such as abuse or rape will need a multidisciplinary approach that may include a physician, physical therapist, and counselor or sex therapist to help them with pain and libido concerns.
- Physical therapists trained in the treatment of pelvic floor dysfunction are an essential part of the team approach to treatment of patients with neuromuscular pelvic floor pain or dyspareunia.

- Mindfulness is a tool utilized by therapists to help patients struggling with anorgasmia to improve the sexual experience.
- Engaging the partner in developing a treatment plan for sexual pain or decreased libido is important to obtain endorsement from the patient. This is especially the case if you are recommending abstaining from sex for a period of time to allow for healing.

Epidemiology

The prevalence of female sexual function concerns in the primary care clinic is difficult to quantify. Depending on which article you read, the prevalence is between 30% and 100% throughout the lifespan of a woman. The emotional toll that low libido, sexual pain, and anorgasmia take on women and their partners is significant. Patients experiencing sexual pain may be hesitant to discuss their concerns, or may have had a negative experience with a health care provider in the past when they tried to discuss concerns. On average, patients see more than six health care providers before the source of their sexual pain or libido concerns are adequately addressed. The occurrence of sexual concerns is higher in patients with depression, chronic pain, cancer diagnosis, bowel or bladder problems, and arthritis as well as in the postmenopausal years.

The general topic of female sexual function can be difficult to address in the primary care setting. When a patient presents for an annual exam, for example, and she says she is having pain with intercourse, it can cause anxiety on the part of the practitioner. This is often not a visit that can be accomplished in a 10-minute slot, so do not hesitate to tell the patient that you want to make sure you have adequate time to address her concern. If this was not the reason for her visit, consider asking her to schedule a visit when you have more time available so that you can best help her. Having a basic knowledge about a systematic approach to female sexual pain can help the practitioner have confidence in discussing this area of distress with women and their partners. We will approach this from two different areas of concern: decreased libido and sexual pain.

Pathophysiology, Diagnosis, Treatment: Decreased Libido

If a patient comes in complaining of decreased sex drive, you must consider myriad reasons that can impact her desire. At the heart of hypoactive sexual dysfunction disorder (HSDD) is an imbalance between excitatory (dopamine and norepinephrine) and inhibitory (serotonin) neurotransmitters in key regions of the brain. The difficulty in women is that libido is impacted by psychosocial factors such as relationship concerns, physical concerns such as obesity or arthritis, medical conditions, and medications.

In research that includes women complaining of decreased libido, 30% may improve with placebo alone. This tells us how important just addressing the problem can be. The first question to consider is very simple but very powerful, “Do you like your partner?” This question alone can open up lines of communication with your patient that help you to start to help her sort out the cause of her decreased desire (Table 1). If the patient indicates that her relationship is not currently rewarding or that she does not get along well with her spouse, there is no pill that will solve her desire concerns. Help her to see that intervention in the form of counseling from a qualified provider may provide the best treatment for her sexual concerns, or at least a good starting point. Make sure to follow your first question with the next great question for triage, “Does sex hurt?” If a woman has sexual pain, she may certainly avoid sexual encounters. Helping her to understand that sexual pain is not normal and is treatable may help her open up to you about the other important considerations for diagnosis including onset, duration, circumstances in which the pain occurs, and associating factors. You may also need to assess her willingness and desire to address the problem of pain. Some

women are resistant to explore this due to a history of poor medical encounters with physicians, previous trauma, or a foundational religious or cultural belief system surrounding sex.

As stated previously, treatment for this condition is best guided by careful history and discussion with the patient. If libido has been a concern for a significant period of time, encourage the patient to see a qualified counselor. Creating a list of resources available in your area is helpful to have on hand. If the patient previously had what she considers a good sex drive and this is a new problem, consider new medications, trauma, or recent events. See the list of medications impacting libido (Table 2). Although this is not exhaustive, if the patient is on more than one medication that affects sex drive you may need to work with her to adjust medications. If she is premenopausal and not on any medications, treatment for HSDD includes psychosocial intervention, lifestyle adjustment, and medications. Lifestyle adjustments may include changing her schedule so there is time for intimacy, as many patients are too busy to allow for adequate time for arousal and a positive sexual experience. Also keep in mind the positive effect exercise has on sex drive, both directly by increasing norepinephrine, and indirectly by improving stamina and self-image. Currently, flibanserin (Addyi) is the only US Food and Drug Administration (FDA)–approved treatment for HSDD, but many other medications have been used to improve libido. Another consideration in women being treated for depression is to switch them from an inhibitory medication to one that may have a positive

effect on libido. Encouraging patients to have open communication with their partners about what leads to pleasure and what does not is essential when addressing desire and arousal.

Pathophysiology, Diagnosis, Treatment: Sexual Pain

Dyspareunia can have many origins. The layered approach described by Dr. Coady is a systematic way to consider evaluation and also helps us understand the pathophysiology of this often complex problem (Table 3). Consider that the pain can be due to skin concerns or changes, neurologic problems, muscle pain, bowel conditions, bladder pain, medications (such as chemotherapy), and medical problems such as endometriosis or enlarged uterus. A careful history and exam are the most important diagnostic tools when helping discern the cause for sexual pain.

There are many different ways to evaluate a patient for pain with sex, and specifically, pain with intercourse. When you take a history in a patient complaining of sexual pain it is important to glean from her the duration, inciting factors, alleviating factors, previous treatment, and what she thinks is causing the pain. Understanding if she has primary (never had a sexual encounter without pain) or secondary (new onset, previous pain-free encounters) dyspareunia is also important. Primary sexual pain can be caused by a history of sexual trauma, tight hymenal ring, skin-level concerns such as atrophy, herpes, or lichen sclerosis, pelvic floor muscle pain, or internal pain such as endometriosis, ovarian cysts, or other pelvic organ pathology. Secondary sexual pain can include the same causes, but may be easier to treat depending on the sequence of events that led to the patient's onset of pain. When taking a history of the patient's pain, it is important to ask her if the pain is only on penetration or occurs through the entire encounter. Pain that only occurs with deeper penetration may be more likely pelvic floor muscle pain or endometriosis, whereas pain that occurs with any touch points you toward vulvar causes such as lichen sclerosis or atrophic changes.

Once you have gathered a careful history, it is important to perform a careful exam. Start with a very careful inspection of the vulva. Note the presence of labia minora—if absent or blunted, this may be consistent with atrophy. Note the clitoral hood—if it is retracted or adhesions are noted the patient may have lichenification. A bright light and magnification (such as a colposcope) are often helpful in careful visualization. If no abnormalities are noted on careful inspection, look at the introitus. Patients with localized provoked vestibulodynia (LPV) may have an area of erythema at the 6 o'clock position of the introitus, just external to the hymenal ring. Show the patient a cotton swab and tell her you are going to touch areas on the vulva and you want her to tell you if anything hurts. With light pressure (depressing about 1 mm), touch the patient's thigh, slowly working inward to the labia. Touch the clitoris, the area around the urethra, and the area just external to the hymenal ring. Lastly, touch the area around the anus, as the rectal branch of the pudendal nerve could be the cause of pain. If she has significant pain on palpation with the swab along Hart's line, note the location of the pain and consider referral to a specialist who can address LPV. If the exam is normal and her pain does not appear to be external, do a careful exam of the pelvic floor. One way to do this is to insert one finger and gently palpate the muscles of the

TABLE 3 Sexual Pain Pathophysiology**CAUSES OF SEXUAL PAIN: THE LAYERED APPROACH**

Surface layer: lichen sclerosis, herpes, atrophy

Nerve layer: localized provoked vestibulodynia, pudendal neuralgia

Myofascial layer: chronic pain or acute secondary to injury

Organ layer: ovarian cyst, endometriosis

Body-wide systems: gastrointestinal, psychological (history of trauma or abuse)

pelvic floor one at a time. A careful review of the anatomy of this area is helpful. If you are not comfortable evaluating for pelvic floor pain, referral to a sexual pain specialist or pelvic floor physical therapist is appropriate. If the patient does not seem to have pain on palpation of the pelvic floor muscles, performing a bimanual exam can be helpful; however, great care must be taken to avoid further trauma. I do not often do a bimanual exam on patients with a complaint of sexual pain as their pain is often elicited by the previously described exam. A speculum is rarely useful for these patients and should be avoided if they are complaining of pain with intercourse as you may cause her more pain and further discourage the patient from seeking medical help.

Your treatment plan for sexual pain must be guided by the differential diagnosis you develop following a careful history and exam. For skin concerns, clobetasol topical is the treatment for lichenification that includes lichen sclerosis and lichen simplex chronicus. If nerve or pelvic floor muscle pain is noted, sending the patient to a qualified physical therapist is a good first step. If this fails, or if the patient desires medication to help with the discomfort while working with a therapist, vaginal diazepam (Valium) can be utilized. The patient uses 10 mg at HS and is encouraged to use this as needed to help with more severe discomfort as many of the patients that have dyspareunia also have generalized pelvic floor pain that may interfere with sleep or activities of daily living. If physical therapy does not provide relief, a sexual medicine specialist may perform dry needling or trigger point injections to help with the pain. If the cause does not seem to be related to either skin or pelvic floor pain an ultrasound may help to identify ovarian masses or uterine enlargement and the patient may need referral to a gynecologist for surgical intervention. In cases of gastrointestinal dysfunction such as constipation or diarrhea, consider treatment of this dysfunction as it could lead to improvement in dyspareunia.

A Note About Atrophy

When considering atrophic or hypoestrogenic changes many clinicians think of a postmenopausal woman. When it comes to sexual pain, however, do not forget that atrophy can be seen in premenopausal women in the setting of cancer treatment, post-oophorectomy patients, and patients who have been on combined oral contraceptive pills for a period of time. Each of these patients may require a unique approach to treatment. For instance, if a woman is experiencing atrophy due to treatment of a nonhormonal cancer such as leukemia, treating her with systemic or local hormonal therapy is likely the most appropriate approach. If she is currently being treated for certain breast cancers, however, you should first consider nonhormonal treatments such as moisturizers and lubricants. When considering hormonal treatment options for these patients there is good evidence that vaginal and topical estrogen is quite safe when used appropriately. The lowest possible dose for the shortest duration is recommended in these patients and often providers will feel more comfortable considering hormonal therapies in consultation with the patient's oncologist. Be aware that many patients that are breastfeeding or are taking combination oral contraceptives may also experience atrophic changes that cause pain during sexual encounters. For these patients, topical vulvar hormones are often quite effective in relieving symptoms.

INFERTILITY

Method of

Jessica Kanter, MD; and Michael P. Diamond, MD

CURRENT DIAGNOSIS

- Infertility is defined as the inability to conceive with regular intercourse after 12 months in couples in which the female partner is younger than 35 or after 6 months in couples in which the female partner is older than 35.
- The incidence of infertility is increasing.

CURRENT THERAPY

- Assisted reproductive technologies are being used with increasing frequency and with increasing success rates.

Epidemiology

Infertility is defined as the failure to conceive after 12 months of regular, unprotected intercourse. In couples where the female partner's age exceeds 35 years, evaluation may begin after just 6 months of infertility owing to the time-sensitive nature of the problem. In some circumstances, diagnostic evaluation and therapeutic intervention is warranted at an earlier time. Infertility affects approximately 15% of couples. Many of these patients present to their primary care physician. Timely evaluation and potential referral to an infertility subspecialist is prudent.

Risk Factors

There are numerous risk factors that contribute to infertility. The most common is age. However, it is necessary to evaluate other potential contributing factors to infertility as these may lead to narrowing of the differential diagnosis and a more targeted subsequent treatment plan. For example, a history of sexually transmitted infections, especially chlamydia, and episodes of pelvic inflammatory disease have been associated with tubal factor infertility in women. Metabolic disorders such as obesity and polycystic ovarian syndrome, which may lead to anovulation, are an increasingly more prevalent concern and a major risk factor for infertility. Finally, certain genetic diseases such as fragile X, Turner syndrome, cystic fibrosis, and Klinefelter disease may also lead to inability or difficulty in conceiving.

Pathophysiology

The pathophysiology of infertility should be grouped first by male and female factors and then by components of their respective reproductive tracts. One must not discount the fact that multiple factors may coexist. Unexplained infertility is accountable for 8% to 28% of infertility in couples.

Prevention

Some etiologies of infertility may be preventable. Many cases of tubal factor infertility may be prevented by protecting against transmission of sexually transmitted infections (STIs). Barrier contraception is essential to prevent STIs, particularly in high-risk individuals with an early age of coitarche and/or those with multiple sexual partners. Even with highly efficacious forms of contraception such as intrauterine devices, long-acting injectable progestins, and progestin-containing subdermal implants, providers must counsel their patients that barrier contraception is still of the utmost importance in preventing STI transmission.

There are various medical therapies, particularly those related to cancer treatments, that may be detrimental to fertility. In these cases, oncofertility consultation prior to treatment is paramount

pelvic floor one at a time. A careful review of the anatomy of this area is helpful. If you are not comfortable evaluating for pelvic floor pain, referral to a sexual pain specialist or pelvic floor physical therapist is appropriate. If the patient does not seem to have pain on palpation of the pelvic floor muscles, performing a bimanual exam can be helpful; however, great care must be taken to avoid further trauma. I do not often do a bimanual exam on patients with a complaint of sexual pain as their pain is often elicited by the previously described exam. A speculum is rarely useful for these patients and should be avoided if they are complaining of pain with intercourse as you may cause her more pain and further discourage the patient from seeking medical help.

Your treatment plan for sexual pain must be guided by the differential diagnosis you develop following a careful history and exam. For skin concerns, clobetasol topical is the treatment for lichenification that includes lichen sclerosis and lichen simplex chronicus. If nerve or pelvic floor muscle pain is noted, sending the patient to a qualified physical therapist is a good first step. If this fails, or if the patient desires medication to help with the discomfort while working with a therapist, vaginal diazepam (Valium) can be utilized. The patient uses 10 mg at HS and is encouraged to use this as needed to help with more severe discomfort as many of the patients that have dyspareunia also have generalized pelvic floor pain that may interfere with sleep or activities of daily living. If physical therapy does not provide relief, a sexual medicine specialist may perform dry needling or trigger point injections to help with the pain. If the cause does not seem to be related to either skin or pelvic floor pain an ultrasound may help to identify ovarian masses or uterine enlargement and the patient may need referral to a gynecologist for surgical intervention. In cases of gastrointestinal dysfunction such as constipation or diarrhea, consider treatment of this dysfunction as it could lead to improvement in dyspareunia.

A Note About Atrophy

When considering atrophic or hypoestrogenic changes many clinicians think of a postmenopausal woman. When it comes to sexual pain, however, do not forget that atrophy can be seen in premenopausal women in the setting of cancer treatment, post-oophorectomy patients, and patients who have been on combined oral contraceptive pills for a period of time. Each of these patients may require a unique approach to treatment. For instance, if a woman is experiencing atrophy due to treatment of a nonhormonal cancer such as leukemia, treating her with systemic or local hormonal therapy is likely the most appropriate approach. If she is currently being treated for certain breast cancers, however, you should first consider nonhormonal treatments such as moisturizers and lubricants. When considering hormonal treatment options for these patients there is good evidence that vaginal and topical estrogen is quite safe when used appropriately. The lowest possible dose for the shortest duration is recommended in these patients and often providers will feel more comfortable considering hormonal therapies in consultation with the patient's oncologist. Be aware that many patients that are breastfeeding or are taking combination oral contraceptives may also experience atrophic changes that cause pain during sexual encounters. For these patients, topical vulvar hormones are often quite effective in relieving symptoms.

INFERTILITY

Method of

Jessica Kanter, MD; and Michael P. Diamond, MD

CURRENT DIAGNOSIS

- Infertility is defined as the inability to conceive with regular intercourse after 12 months in couples in which the female partner is younger than 35 or after 6 months in couples in which the female partner is older than 35.
- The incidence of infertility is increasing.

CURRENT THERAPY

- Assisted reproductive technologies are being used with increasing frequency and with increasing success rates.

Epidemiology

Infertility is defined as the failure to conceive after 12 months of regular, unprotected intercourse. In couples where the female partner's age exceeds 35 years, evaluation may begin after just 6 months of infertility owing to the time-sensitive nature of the problem. In some circumstances, diagnostic evaluation and therapeutic intervention is warranted at an earlier time. Infertility affects approximately 15% of couples. Many of these patients present to their primary care physician. Timely evaluation and potential referral to an infertility subspecialist is prudent.

Risk Factors

There are numerous risk factors that contribute to infertility. The most common is age. However, it is necessary to evaluate other potential contributing factors to infertility as these may lead to narrowing of the differential diagnosis and a more targeted subsequent treatment plan. For example, a history of sexually transmitted infections, especially chlamydia, and episodes of pelvic inflammatory disease have been associated with tubal factor infertility in women. Metabolic disorders such as obesity and polycystic ovarian syndrome, which may lead to anovulation, are an increasingly more prevalent concern and a major risk factor for infertility. Finally, certain genetic diseases such as fragile X, Turner syndrome, cystic fibrosis, and Klinefelter disease may also lead to inability or difficulty in conceiving.

Pathophysiology

The pathophysiology of infertility should be grouped first by male and female factors and then by components of their respective reproductive tracts. One must not discount the fact that multiple factors may coexist. Unexplained infertility is accountable for 8% to 28% of infertility in couples.

Prevention

Some etiologies of infertility may be preventable. Many cases of tubal factor infertility may be prevented by protecting against transmission of sexually transmitted infections (STIs). Barrier contraception is essential to prevent STIs, particularly in high-risk individuals with an early age of coitarche and/or those with multiple sexual partners. Even with highly efficacious forms of contraception such as intrauterine devices, long-acting injectable progestins, and progestin-containing subdermal implants, providers must counsel their patients that barrier contraception is still of the utmost importance in preventing STI transmission.

There are various medical therapies, particularly those related to cancer treatments, that may be detrimental to fertility. In these cases, oncofertility consultation prior to treatment is paramount

for fertility preservation. For men, sperm cryopreservation is a relatively easy, noninvasive option. For women, oocyte or embryo preservation, experimental approaches to medically induced ovarian suppression, and ovarian transposition are all tools to have in the arsenal for women undergoing gonadotoxic chemotherapy or radiation therapy.

Finally, fertility should also be considered when managing tubal ectopic pregnancy in women. Medical therapy, when not contraindicated, is an excellent option in the compliant patient with an ectopic pregnancy. When surgery is necessary, salpingostomy may be considered when possible in lieu of salpingectomy in an attempt to preserve tubal function.

Clinical Manifestations

Infertile patients generally present with failure to conceive after a variable time of home intercourse. The definition of infertility is subdivided into primary and secondary infertility. Primary infertility means the patient has not borne children in the past. Secondary infertility means the patient has successfully procreated in the past.

Diagnosis

The diagnosis of infertility begins with a thorough history and physical examination. It is important to remember that a history must be obtained from both partners during this evaluation. The male partner assessment begins with a semen analysis. Textbooks often suggest two semen analyses, preferably separated in time by at least 1 month.

Female partner assessment can include determination of ovarian reserve by hormonal evaluation of antimüllerian hormone (AMH) or cycle day 3 follicle-stimulating hormone (FSH). Frequently, prolactin and thyroid-stimulating hormone (TSH) are also obtained, as is a measure of ovulation such as a midluteal progesterone level. Other labs may be ordered if clinically indicated, such as androgens in women with hirsutism. Tubal patency is assessed by sonohysterogram or hysterosalpingogram. These imaging tests also allow assessment of the uterine cavity for uterine contour and any abnormalities including fibroids or polyps. Sonography may also be useful in identifying müllerian anomalies or anomalies of the basic structure of the uterus; the gold standard for identifying these anomalies is magnetic resonance imaging. In cases where other pelvic pathology such as endometriosis and adhesions are suspected, diagnostic laparoscopy may be considered. Chromotubation during laparoscopy may be empirically performed. Finally, for both partners, karyotype analysis may be considered.

Differential Diagnosis

When determining a differential diagnosis, both male and female factors must be considered.

Male Factors

The most common etiologies of male factor infertility are oligospermia and azoospermia. The etiologies leading to these diagnoses are broad and varied, and include genetic conditions such as cystic fibrosis (leading to congenital absence of the vas deferens).

Female Factors

Female factors for infertility are numerous and most easily subdivided by system.

Ovulatory Dysfunction

Inability to produce a viable oocyte each month can be related to several factors. First, anovulation may occur, meaning oocytes are present in the ovaries but none are released on a regular basis. This can be related to hormonal ovarian suppression (e.g., hyperprolactinemia) and metabolic disturbances (e.g., polycystic ovarian syndrome). Alternatively, an oocyte may not be produced secondary to a paucity of oocytes owing to age, genetic factors, or prior insults to the ovaries such as radiation therapy. In addition to the aforementioned AMH and day 3 FSH and serum estradiol to assess ovarian function, ultrasound may be employed to evaluate antral follicle count, another marker of ovarian reserve.

Tubal Factor

The fallopian tubes are responsible for transporting the oocyte from the ovaries to the uterine cavity. For this to occur, at least one fallopian tube must be patent. Perhaps the most common etiology of tubal factor infertility is a history of pelvic inflammatory disease, with one of the most common inciting agents being *Chlamydia trachomatis*. *C. trachomatis* is particularly problematic in women as the initial infection may be asymptomatic. Other tubal infertility may arise from prior tubal ligation, other tubal surgery, history of ectopic pregnancy with salpingectomy or salpingostomy, or scarring of the tubal lumen.

Uterine Factor

Any irregularities within the uterine cavity may also lead to infertility, generally secondary to poor implantation of the fertilized embryo. Some such etiologies may be present from birth, namely müllerian anomalies and uterine septae. The abnormally shaped uterine cavity in these anomalies reduces the opportunity for normal implantation and embryo growth.

During the course of a woman's life, she may develop benign intrauterine growths including polyps and leiomyomas that can reduce the opportunity for normal embryo implantation. Finally, prior uterine surgery may damage the endometrium and myometrium, as in Asherman syndrome, or cause uterine cavity scarring, called synechiae.

Combined

One must not forget that multiple etiologies in a wide variety of combinations may be at play in female factor infertility.

Unexplained

Perhaps the most frustrating of all diagnoses is unexplained infertility. In couples who have had a negative fertility workup, a specific etiology of infertility is never revealed. There is new, burgeoning research in the area of sperm microRNA that may identify male factor infertility in men with otherwise normal semen analyses. Although not currently in wide use, such studies may be of great utility in the future.

Prior Diagnosis

As the field of infertility is becoming understood to an increasingly greater degree, there are prior diagnoses that have fallen out of favor. One such diagnosis is cervical factor insufficiency. It was previously evaluated by the postcoital test, in which a sample of cervical mucus would be taken after intercourse and evaluated for the presence of motile sperm. This test has fallen out of favor owing to subjectivity, lack of reproducibility, and poor correlation with future fertility.

Also out of favor is the prior diagnosis of luteal phase deficiency (LPD), previously defined as inadequate endogenous progesterone production during the luteal phase of the menstrual cycle. No clinical tests have proven reliable for LPD, nor have any treatments demonstrated any significant improvement in fertility.

Treatment

The mainstay of therapy is first treating underlying disorders such as obesity, thyroid disease, hyperprolactinemia, and so forth. Lifestyle modifications should be recommended to all women, including folate supplementation (at least 400 mcg daily), caffeine reduction, and weight loss for those who are overweight or obese. Other known causes of infertility that require surgical management may include intrauterine pathology (e.g., polyps, fibroid tumors) or repair of a hydrosalpinx, a distally blocked fallopian tube filled with serous fluid.

With a normal male partner semen analysis, the first step in intervention is generally an oral agent to induce ovulation combined with intrauterine insemination. Options for induction include clomiphene citrate (Clomid) and off-label use of letrozole (Femara), an aromatase inhibitor. If this fails, therapy can proceed to treatment with injectable gonadotropins (i.e., FSH and luteinizing hormone) to stimulate development of ovarian follicles and ovulation with intrauterine insemination or in vitro fertilization. Various additional procedures may include assisted hatching of the embryo with

the hope to increase implantation rates; intracytoplasmic sperm injection to increase fertilization rates of the oocytes, particularly in the setting of male factor infertility; and preimplantation genetic screening to evaluate for embryo genetic anomalies, particularly in women of advanced maternal age.

Monitoring

To reduce risks associated with ovulation induction and ovarian stimulation, monitoring of serum estradiol and follicular development is performed. Monitoring provides the ability to minimize the occurrence of multiple gestation and complications associated with ovarian hyperstimulation syndrome.

MENOPAUSE

Method of

Andrew M. Kaunitz, MD; and JoAnn E. Manson, MD, DrPH

CURRENT DIAGNOSIS

- In women who meet clinical criteria for menopause who present for management of vasomotor symptoms (VMS), checking follicle-stimulating hormone (FSH) and estradiol levels is not necessary. However, if no recent level is available, checking a thyroid-stimulating hormone (TSH) level to rule out thyroid disease is appropriate.
- Occasionally, nonmenopausal conditions can masquerade as menopausal VMS.
- Although genitourinary syndrome of menopause (GSM) can be presumptively diagnosed based on a characteristic history, a pelvic examination can help exclude other vulvovaginal conditions that can present with similar symptoms.
- Although laboratory assessment is not necessary to establish that GSM is present, vaginal pH is typically higher than 5.0.

CURRENT THERAPY

- Estrogen represents the most effective therapy for VMS and related symptoms.
- Oral and transdermal estrogen have similar efficacy in treating menopausal VMS.
- Estrogen plus progestin therapy (EPT) is appropriate when treating menopausal symptoms in women with an intact uterus.
- For healthy symptomatic women younger than age 60 or within 10 years of menopause onset, the benefits of systemic hormone therapy (HT) outweigh risks.
- Conjugated estrogen (CE) 0.45 mg combined with the selective estrogen receptor modulator bazedoxifene 20 mg (Duavee) (without concomitant use of a progestational agent) is approved to treat VMS and prevent osteoporosis in women with an intact uterus.
- Low-dose paroxetine mesylate (Brisdelle) 7.5 mg is the only nonhormonal formulation approved to treat VMS. Off-label use

of venlafaxine (Effexor) is also effective in treating VMS. These agents are less effective, however, than standard-dose hormone therapy.

- Although controversial, extended use of systemic HT may be appropriate in well-counseled women for treatment of persistent VMS, prevention of bone loss, and prevention/treatment of atrophic genital changes. Women considering extended use of systemic HT should be aware that with a longer duration of EPT, the risk of breast cancer increases. Arbitrary discontinuation of systemic HT when women turn 65 is not evidence based.
- If genitourinary syndrome of menopause/atrophic changes represents the only indication for HT, local low-dose vaginal estrogen is appropriate, and highly effective.

Epidemiology

Menopause, the permanent cessation of menstruation caused by loss of ovarian function, occurs at a mean age of 51 to 52 years. With increases in life expectancy, it is projected that by 2020, more than 50 million U.S. women will be older than 51 years.

Risk Factors

Spontaneous menopause represents a natural event. Spontaneous menopause occurs at a younger age in women who smoke or undergo hysterectomy with ovarian conservation. Chemotherapy, radiation therapy, or bilateral oophorectomy can induce menopause.

Clinical Manifestations and Pathophysiology

Often described by women as hot flashes or night sweats, VMS represent the most bothersome symptoms of menopause and the most common reason women present for care at the time of the menopausal transition. VMS often include a sudden sensation of heat in the face, neck, and chest and persist for several minutes or less. VMS may cause flushing, chills, anxiety, and sleep disruption. VMS are caused by estrogen withdrawal and are associated with pulsatile luteinizing hormone secretion and decreased endorphin concentration in the hypothalamus, as well as increased release of norepinephrine and serotonin. VMS occur in almost three quarters of women during the late perimenopausal transition, and are more prevalent among the groups listed in Table 1. The median duration of moderate to severe VMS is approximately 10 years.

GSM, also known as vulvovaginal or genital atrophy, signifies the progressive changes in the vulva, vagina, and urethra resulting from estrogen deficiency. GSM, which characteristically causes vaginal dryness and pain with sex, represents a common condition that adversely impacts health, sexuality, and quality of life in menopausal women.

Diagnosis

Although FSH levels increase and estradiol levels decline in menopausal women, such testing is not necessary when late perimenopausal or postmenopausal women report characteristic VMS as described previously. Because thyroid disease is common in women and can cause symptoms that mimic VMS, checking a TSH level is appropriate in women seeking treatment for VMS.

Although GSM can be presumptively diagnosed based on a characteristic history, a pelvic examination can help exclude other vulvovaginal conditions that can present with similar symptoms

TABLE 2 Physical Findings Characteristic of Genitourinary Syndrome of Menopause

Loss of mons and labia majora fat pads
Loss of labia minora tissue and pigmentation
Urethral meatus: erythematous and prominent in size in relation to introitus
Introital narrowing (consider use of ultrathin speculum)
Vaginal mucosa: smooth (decreased rugation), dry, and friable

(see next section). Physical examination findings characteristic of GSM are listed in Table 2. Although laboratory assessment is not necessary to establish that GSM is present, vaginal pH is typically higher than 5.0.

Differential Diagnosis

Nonmenopausal conditions that can masquerade as menopausal VMS include anxiety disorders, thyroid disease, autoimmune conditions, carcinoid syndromes, diabetic autonomic dysfunction/hypoglycemia, insulinoma/pancreatic tumors, epilepsy, infections including tuberculosis, mast cell disorders, and new-onset hypertension, as well as use of certain selective serotonergic reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors.

Lichen sclerosis, chronic candidiasis, contact dermatitis, and lichen planus represent vulvar conditions that might be confused with GSM.

Therapy

Estrogen represents the most effective therapy for VMS and related symptoms. Higher doses are more effective; oral and transdermal formulations have comparable efficacy. Many estrogen formulations/doses are also approved for prevention of osteoporosis. Because estrogen-only therapy (ET) in women with an intact uterus increases the risk of endometrial neoplasia, estrogen plus progestin therapy (EPT) is appropriate when treating VMS in women with a uterus. In the United States, the most commonly used oral estrogens for systemic treatment of VMS are estradiol (E2, Estrace) and conjugated equine estrogens (CEE, Premarin). Standard doses of these estrogens are 1.0 mg and 0.625 mg, respectively; lower and higher doses are available. Weekly and twice-weekly skin patches and other transdermal E2 formulations are available: estradiol patches releasing 0.05 mg and 0.0375 mg daily are considered standard dose; lower- and higher-dose patches are available. A 3-month vaginal systemic E2 ring (Femring) for treatment of VMS is also available; the ring releasing 0.05 mg E2 daily is considered the standard dose.

In the United States, the progestational agents most commonly prescribed to accompany systemic ET in women with an intact uterus are medroxyprogesterone acetate (MPA [Provera], available in 2.5 mg, 5 mg, and 10 mg doses) and micronized progesterone (Prometrium) 100 mg and 200 mg capsules. Micronized progesterone is formulated with peanut oil. With standard-dose estrogen, an appropriate daily dose of MPA or micronized progesterone used continuously is 2.5 mg and 100 mg, respectively. Because micronized progesterone has a hypnotic effect, it should be taken at night. A variety of oral estrogen–progestin formulations, all of which have demonstrated endometrial safety, are available in different doses and combine CEE with MPA (Prempro); E2 or ethinyl E2 with norethindrone acetate (Activella, Femhrt); or E2 with drospirenone (Angeliq) or norgestimate (Prefest). Transdermal estrogen–progestin combination formulations combine E2 with norethindrone acetate (CombiPatch) or levonorgestrel (Climara Pro). The North American Menopause Society regularly updates and posts tables listing all formulations approved in the United States or Canada for treating menopausal symptoms (see references) (<http://www.menopause.org/docs/default-source/professional/nams-ht-tables.pdf?sfvrsn=18.pdf>). Although use of testosterone can increase sexual desire in menopausal women, efficacy is achieved

only with supraphysiologic doses, which may cause hyperandrogenic adverse effects.

CE 0.45 mg combined with the selective estrogen receptor modulator bazedoxifene 20 mg (Duavee) (without the concomitant use of a progestational agent) is approved to treat VMS and prevent osteoporosis in women with an intact uterus and does not increase the incidence of uterine bleeding or endometrial hyperplasia. This novel combination formulation may be useful for women with an intact uterus who choose not to use progestin, including those intolerant of progestin side effects.

Among U.S. women using HT, approximately one-third are using compounded HT; most users are not aware these formulations are not evaluated or approved by the FDA. FDA-approved HT is preferable to compounded HT unless a specific FDA-approved formulation is not available.

Nonhormonal therapy with paroxetine (Paxil),¹ escitalopram (Lexapro),¹ citalopram (Celexa),¹ venlafaxine (Effexor),¹ desvenlafaxine (Pristiq),¹ gabapentin (Neurontin),¹ and pregabalin (Lyrica)¹ are more effective than placebo but less effective than HT in treating VMS. Low-dose paroxetine mesylate (Brisdelle) 7.5 mg is the only nonhormonal formulation approved to treat VMS. Lowering the ambient temperature, use of fans, wearing layered clothing, and avoiding tobacco, alcohol, and caffeine represent common sense measures for women bothered by VMSs. In a clinical trial, clinical hypnosis was found more effective than placebo in addressing VMS. Although over-the-counter herbal formulations including soy⁷ and black cohosh⁷ have been widely used to treat VMS, these have not been found to be more effective than placebo.

When clinicians identify GSM, they should advise women that (unlike VMS) without proactive management, GSM progresses. If severe symptoms are not present, recommending use of over-the-counter lubricants (or substances such as coconut or olive oil) for sexual activity, as well as regular use of vaginal moisturizers, is helpful. Such women should also be advised that regular sexual activity may help improve symptoms and prevent progression. If other indications for systemic HT such as treatment of VMS or prevention of osteoporosis are present, systemic HT is effective in treating GSM. However, if GSM represents the only indication for HT, local low-dose vaginal estrogen is appropriate and highly effective treatment. Vaginal estrogen also reduces the risk of recurrent urinary tract infections and overactive bladder symptoms in menopausal women. In the United States, two low-dose creams, estradiol (Estrace) and CEE (Premarin), are available. Although package labeling provides instructions for patients regarding dose and schedule, in practice, most women use a fraction of an applicator vaginally (and often also benefit from digital application to vestibular tissues) one to three times weekly. Some women find use of vaginal estrogen creams to be messy. Vaginal tablets (Vagifem) equivalent to 10 mcg E2 are inserted vaginally nightly for 2 weeks, then twice weekly for maintenance. The 3-month low-dose E2 vaginal ring (Estring) releases 7.5 mcg E2 daily. A systemic selective estrogen receptor modulator, ospemifene (Osphena), improves symptoms of GSM; some users report VMS. In late 2016, the FDA approved vaginal dehydroepiandrosterone (DHEA, prasterone) (Intrarosa) for treatment of GSM.

Monitoring

For most women using systemic HT, monitoring serum estrogen levels is not indicated. However, when women continue to report bothersome symptoms despite escalating HT doses, monitoring can be useful. In contrast to fluctuating serum estrogen levels in women using oral estrogen, transdermal ET results in relatively steady-state levels: serum E2 levels of 40 to 100 pg/mL represent a reasonable target range.

¹Not U.S. Food and Drug Administration (FDA) approved for this indication.

⁷Available as dietary supplement.

Side Effects of Systemic Hormone Therapy

Breast tenderness, bloating, and uterine bleeding represent common side effects of ET. Although lowering the ET dose may reduce side effects, this may cause VMS to increase. Progestins cause dysphoria in some women. Prescribing a different progestin, prescribing progestins sequentially, off-label use of a progestin intrauterine device (Skyla, Kyleena, Mirena, Liletta), or use of the CEE/bazedoxifene combination formulation (Duavee) or antidepressant therapy may be useful in this setting.

Safety of Hormone Therapy

Findings from the Women's Health Initiative (WHI) study of oral CEE and MPA, CEE alone, and other recent randomized clinical trials have helped to clarify the benefits and risks of combination estrogen–progestin and estrogen-alone therapy. A 2013 WHI report detailed findings from the two HT trials with a median 13 years of cumulative follow-up. Since initial findings of the WHI were first published in 2002, use of systemic HT has dramatically decreased, owing to misinterpretation of WHI findings, which has generated anxiety and confusion among clinicians and women. Importantly, absolute risks of adverse events related to hormone therapy were much lower for younger women (ages 50–59) than for older women (Figure 1). Overall, for healthy women with bothersome VMS younger than age 60 and/or within 10 years of menopause onset, the benefits of HT for women outweigh risks.

With respect to coronary heart disease (CHD), HT's impact varies by age of users. Among women who initiate HT before age 60 and/or within 10 years of menopause, HT does not increase (and may reduce) risk. In contrast, among women older than age 60 and/or more than 10 years following menopause onset, HT appears to increase CHD risk.

With respect to stroke, the WHI found that CEE alone or with MPA increased risk; however, for women younger than age 60, the absolute increase in risk was small (see Figure 1).

With respect to venous thromboembolism (VTE), including pulmonary embolism, oral estrogen with or without progestin increases risk, particularly within 2 years of HT initiation. Absolute risks of VTE are higher for women initiating HT more than 10 years following menopause onset. Observational studies have consistently found that in contrast to oral HT, HT with transdermal (e.g., skin patch) estrogen elevates VTE risk less (if at all) compared with oral HT. Because oral estrogen and body mass index represent independent risk factors for VTE, transdermal estrogen may be preferable for women at elevated baseline VTE risk, including obese women. Personal and familial risk of cardiovascular disease, stroke, and VTE should be considered when initiating HT. Low-dose vaginal estrogen has not been found to elevate the risk of CHD, stroke, or VTE.

With respect to breast cancer risk, WHI results diverged, with increased risk in the CEE-plus-MPA group and borderline reduced risk in the CEE-alone group. With 13 years of follow-up, a modest elevation of risk (hazard ratio 1.28) persisted in the CEE-plus-MPA group in all participant age strata. To put the elevated risk of breast cancer observed among women randomized to CEE plus MPA into perspective, the attributable risk with combination hormone therapy is less than one additional case of breast cancer diagnosed per 1000 users of combination hormone therapy annually. Another way to put this elevated hazard ratio into perspective is to recognize that the hazard ratio of 1.28 is slightly higher than that seen with one daily glass of wine, and less than that noted with two daily glasses. With long-term follow-up of WHI participants randomized to CEE alone, a significantly reduced risk of breast cancer (hazard ratio = 0.79) emerged over this time period. During

Figure 1 Benefits and risks of the two hormone therapy formulations evaluated in the Women's Health Initiative. Results are shown for the two formulations, conjugated equine estrogens (CEEs) alone or in combination with medroxyprogesterone acetate (MPA), for women 50 to 59 years of age. Risks and benefits are expressed as the difference in number of events (number in the hormone therapy group minus the number in the placebo group) per 1000 women over 5 years. (Data are from Manson JE, Chlebowski RT, Stefanick ML, et al. Menopausal hormone therapy and health outcomes during the intervention and extended poststopping phases of the Women's Health Initiative randomized trials. *JAMA* 2013;310:1353.)

cumulative 18 year follow-up of participants in the WHI hormone therapy trials, all-cause mortality rates did not differ appreciably between the intervention and control groups in the overall cohort. The hazard ratio [HR] for all-cause mortality among women assigned hormone therapy compared to those assigned placebo was 0.99 (95% CI, 0.94-1.03) in the overall pooled cohort; HRs were 1.02 (95%CI, 0.96-1.08) with CEE+MPA and 0.94 (95% CI, 0.88-1.01) with CEE alone.

Although trials up to 2 years' duration found that CEE plus bazedoxifene did not increase risk of breast cancer, long-term trials are needed. In women with BRCA1 or 2 mutations, limited observational data suggest that use of HT does not increase breast cancer risk, suggesting that mutation carriers should not defer risk-reducing salpingo-oophorectomy owing to concerns that HT to treat VMS would be unsafe.

Low-dose vaginal ET may be used as long as needed, including indefinitely; routine use of concomitant progestin therapy for endometrial protection is not recommended. In the absence of reported spotting or bleeding, routine endometrial surveillance during use of vaginal ET is not recommended. However, clinicians should recognize that endometrial safety data for currently marketed formulations are based on 1-year trials, with no trials assessing the safety of longer-term administration available.

Current package labeling for low-dose vaginal estrogen, as for all systemic HT formulations, includes a boxed warning that refers to endometrial cancer, myocardial infarction, stroke, invasive breast cancer, pulmonary emboli, and dementia. This warning reflects safety concerns associated with findings from clinical trials of systemic HT, and does not reflect current evidence regarding local low-dose vaginal estrogen. At the time this chapter was being prepared, the FDA was considering a proposal to modify package labeling so that it better reflects the safety profile of vaginal estrogen.

A personal history of breast cancer is listed as a contraindication to use of all systemic and local low-dose vaginal HT (other contraindications to use of HT are listed on package labeling). However, one study found that use of the low-dose estrogen vaginal ring does not cause persistently elevated serum estradiol levels in breast cancer survivors using aromatase inhibitors; some oncologists prescribe this ring off-label to treat symptomatic atrophy in breast cancer survivors (including those using aromatase inhibitors), periodically checking serum estradiol levels. Nonetheless, many oncologists caution against use of vaginal HT in breast cancer survivors. In package labeling for vaginal DHEA (Intrarosa), a personal history of breast cancer is not listed as a contraindication.

Extended Use/Discontinuation of Systemic Hormone Therapy

Although controversial, extended use of systemic HT may be appropriate for treatment of persistent VMS, prevention of bone loss, and prevention/treatment of GSM in well-counseled women. Extended use of systemic HT should not be confused with initiation of systemic HT by women older than age 60 or more than 10 years following menopause onset, a practice that is known to be associated with elevated risk of coronary heart disease (see previous section on safety). Women considering extended use of systemic HT should be aware that with longer duration of EPT, the risk of breast cancer increases. Since older age is an independent risk factor for venous thromboembolism, use of transdermal estrogen formulations should be considered in this setting. Arbitrary discontinuation of systemic HT when women turn 65 is not evidence based.

When women discontinue systemic HT, loss of bone mass and progression of GSM/atrophic genital changes occur. The likelihood of recurrent VMS in this setting appears similar with abrupt and gradual (dose-tapering) discontinuation of HT.

One approach to decision making regarding treatment of menopausal symptoms is available in a free mobile app called MenoPro (dual mode for clinicians and patients, downloadable on iPhone, iPad, and Android devices).

OVARIAN CANCER

Method of

Michelle A. Roett, MD, MPH

CURRENT DIAGNOSIS

- The U.S. Preventive Services Task Force (USPSTF), American Academy of Family Physicians and American College of Obstetricians and Gynecologists recommend against routine screening for ovarian cancer in asymptomatic women. Screening for ovarian cancer may lead to significant harms, including invasive surgical interventions for women without cancer.
- The USPSTF recommends that women with family history associated with increased risk for deleterious mutations in *BRCA1* and *BRCA2* should be referred for genetic counseling and evaluation for *BRCA* testing.
- The Society of Gynecologic Oncology (AAGL) recommends against screening low-risk women with cancer antigen (CA) 125 or ultrasound for ovarian cancer. The American College of Physicians recommends against routine screening pelvic examinations in asymptomatic women.

CURRENT THERAPY

- Cancer antigen 125 (CA-125) and transvaginal ultrasound are indicated for known adnexal mass, but not recommended as screening tools.
- Ovarian cancer is treated with surgical debulking and adjuvant chemotherapy.

cumulative 18 year follow-up of participants in the WHI hormone therapy trials, all-cause mortality rates did not differ appreciably between the intervention and control groups in the overall cohort. The hazard ratio [HR] for all-cause mortality among women assigned hormone therapy compared to those assigned placebo was 0.99 (95% CI, 0.94-1.03) in the overall pooled cohort; HRs were 1.02 (95%CI, 0.96-1.08) with CEE+MPA and 0.94 (95% CI, 0.88-1.01) with CEE alone.

Although trials up to 2 years' duration found that CEE plus bazedoxifene did not increase risk of breast cancer, long-term trials are needed. OVARIAN CANCER

Method of

Michelle A. Roett, MD, MPH

CURRENT DIAGNOSIS

- The U.S. Preventive Services Task Force (USPSTF), American Academy of Family Physicians and American College of Obstetricians and Gynecologists recommend against routine screening for ovarian cancer in asymptomatic women. Screening for ovarian cancer may lead to significant harms, including invasive surgical interventions for women without cancer.
- The USPSTF recommends that women with family history associated with increased risk for deleterious mutations in *BRCA1* and *BRCA2* should be referred for genetic counseling and evaluation for *BRCA* testing.
- The Society of Gynecologic Oncology (AAGL) recommends against screening low-risk women with cancer antigen (CA) 125 or ultrasound for ovarian cancer. The American College of Physicians recommends against routine screening pelvic examinations in asymptomatic women.

CURRENT THERAPY

- Cancer antigen 125 (CA-125) and transvaginal ultrasound are indicated for known adnexal mass, but not recommended as screening tools.
- Ovarian cancer is treated with surgical debulking and adjuvant chemotherapy.

- Prophylactic bilateral salpingo-oophorectomy should be considered in women with a mutation in the *BRCA1* or *BRCA2* gene, or hereditary nonpolyposis colorectal cancer syndrome.
- AAGL recommends against performing routine oophorectomy in premenopausal women undergoing hysterectomy for non-malignant indications who are at low risk for ovarian cancer.

Epidemiology

Ovarian cancer accounts for only 3% of cancers in women in the United States but results in more deaths than any other gynecologic cancer. Ovarian cancer has an age-adjusted incidence of 11 per 100,000 women, slightly decreased in recent years. In 2015, an estimated 224,940 women were living with ovarian cancer. According to the National Cancer Institute, 22,240 new cases of ovarian cancer and 14,070 deaths were expected in the United States in 2018.

Caucasian women have the highest incidence rate of ovarian cancer followed by Hispanic, Asian/Pacific Islander, African American, and American Indian/Alaska Native women. Caucasian women are more likely to die of ovarian cancer than any other group. African American and AI/AN women have the second highest rates of death from ovarian cancer, followed by Hispanic and Asian/Pacific Islander women. African American women with advanced epithelial ovarian cancer are more likely to die than their Caucasian counterparts (Hazard Ratio 1.27). Hispanic women have intermediate incidence and death rates compared to non-Hispanic women. Similar to other cancers affecting women, incidence of ovarian cancer and associated mortality increase with age, with women over 50 years of age experiencing the highest incidence. However, varying types of ovarian cancer may be diagnosed at any age, from infancy onward.

Risk Factors

Women at highest risk of ovarian cancer have a family history, associated genetic syndrome, or specific genetic mutation. For women of Ashkenazi Jewish descent, increased-risk family history refers to having one first-degree relative with breast or ovarian cancer or two second-degree relatives on the same side of the family. For other women increased-risk family history refers to having two or more first- or second-degree relatives with a history of ovarian cancer, a combination of breast and ovarian cancer among first- or second-degrees relatives, breast cancer in a male relative, one first-degree relative with bilateral breast cancer, or three or more first- or second-degree relatives with breast cancer.

Women with hereditary breast and ovarian cancer syndrome have an autosomal dominant mutation in the *BRCA1* or *BRCA2* gene. This occurs in one in every 500 women. Hereditary breast and ovarian cancer syndrome increases the risk of breast, ovarian, pancreatic, and prostate cancers, and is associated with up to 54% lifetime risk of ovarian cancer. Hereditary nonpolyposis colorectal cancer syndrome (Lynch II) is also autosomal dominant, increases risk of breast, colorectal, endometrial and ovarian cancers, and is associated with up to 12% lifetime risk of ovarian cancer.

Early age of menarche and later age at menopause are both associated with increased risk of ovarian cancer. Current smoking status increases risk of mucinous epithelial ovarian cancer (RR 2.22), along with former smoking (RR 2.02). Other risk factors including 7-fold increased risk from taking 12 or more monthly cycles of clomiphene, or taking fertility drugs used in in-vitro fertilization (RR 1.59).

Pathophysiology

While earlier evidence suggested that ovarian cancer frequently developed from ovarian surface epithelium or cortical inclusion cysts, recent studies suggest that serous carcinoma originates from distal fallopian tube epithelium. The age distribution of patients with ovarian cancer corresponds with the type of ovarian tumor. Germ cell tumors commonly occur in adolescents or patients under

1 year of age. Stromal cell tumors may occur at any age but include types more common in adolescence, such as androblastomas. Epithelial cell tumors commonly affect patients 50 years of age and older.

Ovarian cancer primarily spreads based on proximity to the uterus and opposite ovary, followed by intraperitoneal metastasis. Death usually arises from complications associated with local spread. Distant metastases may spread to the lungs, liver, adrenal glands, or spleen. In 2014, the International Federation of Gynecology and Obstetrics redefined stages of ovarian cancer to include ovarian, peritoneal and fallopian tube cancers because of similarities in their origins and treatment. FIGO staging guides treatment and prognosis to complement tumor-node-metastasis (TNM) staging defined by the American Joint Committee on Cancer. Stage II includes pelvic extension of an ovarian tumor, with a 60% to 80% 5-year survival rate. The 5-year survival rate is greatly diminished for stages III and IV. Some 85% of ovarian cancer cases are diagnosed in Stage III, which is associated with 20% survival. Stage III includes metastasis to the peritoneum outside the pelvis, primary peritoneal cancer, and/or metastasis to retroperitoneal lymph nodes. Stage IV is associated with less than 10% survival and includes distant metastases.

Prevention

The U.S. Preventive Services Task Force recommends again routine screening for ovarian cancer in asymptomatic women. The USPSTF also recommends that primary care clinicians screen women who have any family members with breast, ovarian, tubal or peritoneal with a validated screening tool to identify a significant family history with increased risk for *BRCA-1* or *BRCA-2* mutations. If the screening is positive, the patient should be referred for genetic counseling, and if indicated by counseling, *BRCA* testing. Screening with serum cancer antigen 125 (CA-125) level or transvaginal ultrasound does not reduce deaths from ovarian cancer and may lead to significant harms, including possibly unnecessary major surgical interventions in women without cancer. The most protective factors decreasing risk of ovarian cancer include older age at menarche, hormonal contraceptive use, multiparity, and younger age at menopause, primarily by decreasing the frequency of ovulation. Oral contraceptives (OR 0.75) and tubal ligation (OR 0.63) both decrease risk with longer duration. IUD use for up to 4 years is also protective (OR 0.53), but risk increases with IUD in place for more than 10 years (OR 1.4). Statin use for more than 5 years also reduces risk (RR 0.48). Multiple dietary interventions may be associated with lower risk of ovarian cancer. Drinking two or more cups of tea per day is associated with lower risk of ovarian cancer compared to one cup or less per day. A low-fat, high-fiber diet and a diet with increased vegetable consumption are both associated with decreased risk of ovarian cancer. Ovarian cancer is effectively reduced in women with *BRCA* mutations (NNT = 36) and hereditary nonpolyposis colorectal cancer syndrome (NNT = 28) by prophylactic bilateral salpingo-oophorectomy (BSO). Given the risk of ovarian cancer and 60% lifetime risk of endometrial cancer, total abdominal hysterectomy with BSO may be considered for patients with hereditary nonpolyposis colorectal cancer syndrome.

Clinical Manifestations

Although presenting symptoms for ovarian cancer may be nonspecific, the most common symptom is abdominal pain. Children and teenagers may also present with irregular menses, precocious puberty, or hirsutism. Any one of six symptoms for more than 12 days per month for less than 1 year has a 56.7% sensitivity for early ovarian cancer and 79.5% sensitivity for advanced stage ovarian cancer. These symptoms include abdominal pain, pelvic pain, increased abdomen size, bloating, difficulty eating, and early satiety. For patients with a pelvic mass, an irregular or enlarged ovary more than 10 cm, a nodular or fixed pelvic mass, or bilateral lesions more significantly increase suspicion of ovarian cancer. For women more than 3 years postmenopausal, ovaries are normally significantly diminished in size and often nonpalpable.

TABLE 1 Diagnostic Findings Associated With Ovarian Cancer

History

- Abdominal fullness
- Back pain
- Bowel obstruction
- Constipation
- Diarrhea
- Early satiety
- Fatigue
- Nausea
- Pelvic pain
- Shortness of breath
- Subacute cerebellar degeneration
- Trousseau syndrome (unexplained spontaneous, recurrent, or migratory venous thrombotic events)
- Ureteral obstruction
- Urinary symptoms

Physical Examination

- Abdominal mass
- Inguinal lymphadenopathy
- Pelvic or adnexal mass
- Sister Mary Joseph nodule
- Seborrheic keratoses (Leser-Trélat sign) sudden onset
- Laboratory tests for patient with known adnexal mass:
 - CA-125 levels > 200 U/mL (200 arb U/L) in premenopausal women
 - CA 125 > 35 U/mL (35 arb U/L) in postmenopausal women
 - Increased β -human chorionic gonadotropin*
 - Increased serum alpha-fetoprotein*
 - Increased neuron-specific enolase*
 - Increased lactate dehydrogenase*

Family History

- Bilateral breast cancer
- Early-onset breast cancer (younger than 50 years)
- Male breast cancer
- Personal or family history of colon or endometrial cancer
- Two or more first- or second-degree relatives with ovarian cancer

*Primarily used to evaluate adnexal masses during adolescence.

Diagnosis

Ovarian cancer patients with primarily gastrointestinal symptoms such as nausea, vomiting, diarrhea, and constipation tend to be diagnosed at a later stage than patients presenting with primarily gynecologic symptoms such as abnormal vaginal bleeding or pain. Diagnostic evaluation involves consideration of nonspecific signs and symptoms (Table 1). Women over 40 with persistent or unexplained symptoms should undergo laboratory evaluation including complete blood count, comprehensive metabolic panel, and CA-125. Pelvic inflammatory disease, endometriosis, functional ovarian cysts, menstruation, pregnancy, ascites, and other malignancies may cause elevated CA-125 levels.

Unfortunately, early detection is limited because CA-125 is elevated in only 50% of stage I tumors, but 90% of advanced stage ovarian cancer. Highest estimates of sensitivities, specificities, and positive predictive values are most applicable to postmenopausal women with known adnexal mass. An elevated CA-125 level (more than 200 U/mL in a premenopausal women, more than 35 U/mL in postmenopausal women) with an adnexal mass warrants evaluation by a gynecologic oncologist. OVA-1 is an FDA-approved panel measuring five biomarkers: CA-125, transferrin, prealbumin, apolipoprotein A1, and beta-2 microglobulin. Scored results identify ovarian cancer with 93% sensitivity and 43% specificity. Doppler transvaginal ultrasound for patients with adnexal masses has up 86% sensitivity and up to 91% specificity for ovarian cancer. Suspicious findings include a complex mass with both solid and cystic areas, extramural fluid, echogenicity, wall thickening, septa, or papillary projections, or an increased number and tortuosity of vessels on Doppler evaluation. Gadolinium-enhanced magnetic resonance imaging is useful for further delineation of indeterminate masses seen on ultrasonography.

Differential Diagnosis

The differential diagnosis for the signs and symptoms is broad, based on the nonspecific nature of presenting complaints. The

differential for an adnexal mass may include a benign ovarian tumor, metastatic lesion, ovarian cyst or torsion, tubo-ovarian abscess, endometrioma or endometriosis, and rarely a pelvic kidney or pedunculated uterine fibroid.

Therapy or Treatment

Treatment for ovarian cancer is surgical debulking followed by chemotherapy. Chemotherapy before debulking surgery is associated with similar outcomes. Radiation may be used for palliative therapy or postchemotherapy localized disease. Surgical staging involves total abdominal hysterectomy, BSO, and the removal of pelvic and para-aortic lymph nodes and omentum.

Monitoring

Ovarian cancer of low malignant potential presents at stage I in 82% of cases typically between 30 and 50 years old, allowing for consideration of fertility-sparing measures, such as unilateral salpingo-oophorectomy. Adjuvant chemotherapy is reserved for patients with postoperative residual disease. Surgical treatment completion with total abdominal hysterectomy and unilateral salpingo-oophorectomy should be considered after the reproductive years. Positron emission tomography scans are useful for evaluation of increased CA-125 in known ovarian cancer in combination with computed tomography.

PELVIC INFLAMMATORY DISEASE

Method of

Amy E. Curry, MD

CURRENT DIAGNOSIS

- Pelvic inflammatory disease is a clinical diagnosis based on suspicious clinical findings in a woman who is at risk.
- Patients may be asymptomatic. Symptoms may range from nonspecific complaints including lower abdominal pain, vaginal discharge, dyspareunia, and irregular uterine bleeding to high fever, vomiting, and lower abdominal tenderness with rebound.
- Physical examination findings may include vaginal and endocervical discharge, as well as cervical motion, uterine and adnexal tenderness, and adnexal fullness.
- Cultures should be performed for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, the two most commonly implicated organisms, though a variety of infectious agents may be causative.

CURRENT THERAPY

Empiric treatment for pelvic inflammatory disease (PID) should be initiated in any woman at risk for sexually transmitted infections if:

- Pelvic or lower abdominal pain is present;
- Cervical motion tenderness *OR* uterine tenderness *OR* adnexal tenderness is found on pelvic examination;
- No other cause for the pain can be identified.

Inpatient therapy for PID:

- Regimen A: either cefotetan (Cefotan) 2 g IV every 12 hours *OR* cefoxitin (Mefoxin) 2 g IV every 6 hours *PLUS* doxycycline (Vibramycin) 100 mg PO/IV every 12 hours.
- Regimen B: clindamycin (Cleocin) 900 mg IV every 8 hours *PLUS* gentamicin (Garamycin) 2 mg/kg of body weight loading dose followed by 1.5 mg/kg of body weight IV/IM every 8 hours. A single daily dose of 3 to 5 mg/kg of body weight IV/IM can also be used.
- Alternate regimen: ampicillin/sulbactam (Unasyn) 3 g IV every 6 hours *PLUS* doxycycline (Vibramycin) 100 mg PO/IV every 12 hours.

Outpatient therapy for PID:

- Ceftriaxone (Rocephin) 250 mg IM single dose *PLUS* doxycycline (Vibramycin) 100 mg PO every 12 hours for 14 days *WITH/WITHOUT* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.
- *OR*
- Cefoxitin (Mefoxin) 2 g IM and probenecid (Benemid) 1 g PO both given concurrently as a single dose *PLUS* doxycycline (Vibramycin) 100 mg PO every 12 hours for 14 days *WITH/WITHOUT* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.
- *OR*
- Other parenteral third-generation cephalosporins: either ceftizoxime (Cefizox) 1 g IM single dose *OR* cefotaxime (Claforan) 1 g IM single dose *PLUS* doxycycline (Vibramycin) 100 mg PO every 12 hours for 14 days *WITH/WITHOUT* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.
- Alternative treatment options are available for those who have penicillin or cephalosporin allergy.

Pelvic inflammatory disease (PID) is a polymicrobial infection of any or all of the upper genital tract organs in women. It is initiated by a community-acquired sexually transmitted agent and can involve the uterus, fallopian tubes, and ovaries, as well as adjacent pelvic structures.

Epidemiology

In the United States, the diagnosis of PID accounted for 110,000 initial visits to physician offices and over 35,000 admissions to the hospital in 2009 among women 15 to 44 years of age.

Risk Factors

The single greatest risk factor for PID is a history of multiple sex partners. Other risk factors include 15 to 25 years of age, a male partner with symptoms of a sexually transmitted infection (STI) such as dysuria or urethral discharge, history of previous PID, inconsistent use of condoms, African American ethnicity, and use of vaginal douching. Any phenomenon that disrupts the mucus barrier of the endocervical canal can also potentially facilitate PID, such as menses, bacterial vaginosis, or intrauterine instrumentation. Accordingly, the risk of an intrauterine device causing PID usually occurs during the first 3 weeks following insertion and rarely thereafter.

Pathophysiology

PID occurs when bacteria from the vagina ascend into the normally sterile environment of the upper genital tract. This typically occurs in the setting of a *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection. Ascending bacteria can include anaerobes, especially those implicated in bacterial vaginosis, group A and B *Streptococcus*, *Escherichia coli*, *Klebsiella*, *Proteus mirabilis*, *Haemophilus influenzae*, *Peptococcus*, genital *Mycoplasma*, *Actinomyces*, and cytomegalovirus. Methicillin-resistant *Staphylococcus aureus* has been reported to cause PID, but rarely. Once present, this polymicrobial infection can remain asymptomatic or cause endometritis, salpingitis, oophoritis, peritonitis, perihepatitis, or tubo-ovarian abscesses.

Pelvic inflammatory disease (PID) is a polymicrobial infection of any or all of the upper genital tract organs in women. It is initiated by a community-acquired sexually transmitted agent and can involve the uterus, fallopian tubes, and ovaries, as well as adjacent pelvic structures.

Epidemiology

In the United States, the diagnosis of PID accounted for 110,000 initial visits to physician offices and over 35,000 admissions to the hospital in 2009 among women 15 to 44 years of age.

Risk Factors

The single greatest risk factor for PID is a history of multiple sex partners. Other risk factors include 15 to 25 years of age, a male partner with symptoms of a sexually transmitted infection (STI) such as dysuria or urethral discharge, history of previous PID, inconsistent use of condoms, African American ethnicity, and use of vaginal douching. Any phenomenon that disrupts the mucus barrier of the endocervical canal can also potentially facilitate PID, such as menses, bacterial vaginosis, or intrauterine instrumentation. Accordingly, the risk of an intrauterine device causing PID usually occurs during the first 3 weeks following insertion and rarely thereafter.

Pathophysiology

PID occurs when bacteria from the vagina ascend into the normally sterile environment of the upper genital tract. This typically occurs in the setting of a *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection. Ascending bacteria can include anaerobes, especially those implicated in bacterial vaginosis, group A and B *Streptococcus*, *Escherichia coli*, *Klebsiella*, *Proteus mirabilis*, *Haemophilus influenzae*, *Peptococcus*, genital *Mycoplasma*, *Actinomyces*, and cytomegalovirus. Methicillin-resistant *Staphylococcus aureus* has been reported to cause PID, but rarely. Once present, this polymicrobial infection can remain asymptomatic or cause endometritis, salpingitis, oophoritis, peritonitis, perihepatitis, or tubo-ovarian abscesses.

Clinical Presentation

PID may be asymptomatic. It may have an indolent presentation of low-grade fever, weight loss, and nonspecific abdominal pain. A more symptomatic presentation of PID includes bilateral lower quadrant abdominal pain, recent onset of dyspareunia, abnormal vaginal bleeding, and vaginal discharge. On physical examination, the patient may have fever, decreased bowel sounds, diffuse lower abdominal tenderness with rebound tenderness, and/or right upper quadrant tenderness. During the pelvic examination, purulent vaginal or endocervical discharge, vaginal mucosa redness, and cervical irritation or friability may be noted. Cervical motion pain or tenderness of the adnexa or uterus during the bimanual examination is strongly suggestive of PID.

There are several diagnostic findings that support the diagnosis of PID: the presence of abundant white blood cells or clue cells in vaginal or cervical mucus; the presence of an STI, especially gonorrhea or chlamydia; an elevated erythrocyte sedimentation rate or C-reactive protein; an elevated serum white blood cell count; evidence of endometritis on endometrial biopsy; findings of thickened, fluid-filled fallopian tubes, free fluid in the pelvis, or a tubo-ovarian abscess on transvaginal sonography or magnetic resonance imaging; or evidence of pelvic organ inflammation on laparoscopic exploration.

Diagnosis

Unfortunately, no single element of the history, finding on physical examination, laboratory test result, or diagnostic procedure has both the sensitivity and the specificity to help the clinician accurately diagnose PID. Consequently, PID remains a diagnosis based primarily on clinical suspicion in at-risk women.

Differential Diagnosis

The differential diagnosis of PID includes ectopic pregnancy, inflammatory bowel disorders, ovarian cysts and cyst rupture, ovarian torsion, appendicitis, endometriosis, proctitis, urinary tract infections, diverticulitis, constipation, or functional pain related to current or past abuse.

Treatment

The 2015 Centers for Disease Control and Prevention (CDC) treatment guidelines for STIs are outlined in the Current Diagnosis and Current Therapy boxes. These guidelines recommend empiric treatment for PID in all at-risk women who meet the criteria listed and encourage health care providers to “maintain a low threshold for the diagnosis” and treatment of PID due to “the potential for significant damage to the reproductive health of women.”

Treatment guidelines are based on the patient’s need for inpatient versus outpatient care. The Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) trial demonstrated no difference in the reproductive outcomes of women with mild-to-moderate PID who were randomized to inpatient treatment versus those randomized to outpatient treatment.

Indications for inpatient treatment of PID include the following: pregnancy; failed trial or intolerance to oral medications; signs of severe PID such as high fever, nausea, vomiting, or intractable abdominal pain; complicated PID (e.g., peritonitis, perihepatitis); and pelvic abscesses. The need for surgical intervention or diagnostic exploration to rule out other abdominal pathology would also mandate inpatient treatment. In those patients requiring inpatient treatment, any one of the parenteral antibiotic regimens as outlined above may be administered, depending on the patient’s history of allergies and the cost and availability of treatment options. When possible, the use of oral doxycycline (Vibramycin) is preferred over intravenous (IV) infusion due to the complications of IV infusion and the similar bioavailability of the oral form as compared to IV administration. Treatment should also include appropriate analgesia, antiemetics, antipyretics, IV fluids, and rest. Patients may be transitioned from parenteral to oral therapy after 24 hours

of sustained clinical improvement including lack of fever. Further completion of a total of 14 days of treatment with oral medications is recommended. Those patients treated with either regimen A or the alternative regimen should be transitioned to oral doxycycline (Vibramycin) 100 mg every 12 hours. Those treated with regimen B should be transitioned to oral doxycycline (Vibramycin) 100 mg every 12 hours or oral clindamycin (Cleocin) 450 mg every 6 hours. If a tubo-ovarian abscess is present, the patient should be transitioned preferably to oral clindamycin (Cleocin) 450 mg every 6 hours for a total of 14 days of treatment. Alternatively, oral doxycycline (Vibramycin) 100 mg every 12 hours with oral metronidazole (Flagyl) 500 mg every 8 hours for a total of 14 days of treatment may also be used.

In patients not meeting criteria for inpatient treatment, any of the outpatient treatment regimens as outlined above may be used, the choice being again dependent on the cost and availability of treatment options. The addition of metronidazole (Flagyl) is recommended due to cephalosporin limitations in anaerobic coverage and in the case of *Trichomonas* or bacterial vaginosis infections. The addition of metronidazole (Flagyl) is also recommended if there is a history of recent uterine instrumentation.

In patients who are at a high risk for gonorrheal infection and who have a history of anaphylaxis to penicillin (urticaria, angioedema, stridor, hypotension, or desquamation), recommended treatment options include the following: hospitalization for regimen B parenteral antibiotic treatment; azithromycin (Zithromax) 2 g PO administered as a single dose along with either levofloxacin (Levaquin) 500 mg PO every 24 hours for 14 days or moxifloxacin (Avelox) 400 mg PO every 24 hours for 14 days. If these patients are at a low risk of gonorrhea, either levofloxacin (Levaquin) 500 mg PO every 24 hours or ofloxacin (Floxin) 400 mg PO every 24 hours with or without metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days may be used.

In patients with a history of mild, nonanaphylactic reaction to penicillin, a 25 mg test dose IM of ceftriaxone (Rocephin) can be administered, followed by the remaining 225 mg dose if the patient has no signs of reaction after 2 hours of observation. The patient should be observed for another 1 hour after the second dose.

Regardless of the treatment regimen used, patients should be advised to abstain from intercourse until treatment is completed and they are free of symptoms. In patients with an intrauterine device (IUD), there are inconclusive data to recommend its removal, unless clinical improvement does not occur, but close clinical follow-up is warranted. There is no difference in the treatment regimens for PID in women with a history of HIV.

Patient Monitoring and Counseling

Patients treated with an outpatient regimen should be evaluated for clinical improvement within 48 to 72 hours. If no improvement is noted, the patient should be hospitalized for parenteral antibiotics and further diagnostic evaluation. All patients should be counseled on the need to complete the full course of antibiotic treatment to decrease the potential complications of PID. Patients should be informed of the cause of their infection, if known, and the need for any sexual partners to be tested and treated. Testing for HIV, syphilis, and hepatitis B and C should also be offered. If the patient is an appropriate candidate, immunization against hepatitis B (Engerix-B, Recombivax HB) and human papillomavirus (Cervarix, Gardasil) should also be offered. In order to decrease future PID episodes, patients should be advised on the need for safe sex practices and the recommendation for future routine screening for chlamydia and gonorrhea.

Complications

Complications of PID include recurrence of the infection, infertility secondary to fallopian tube scarring, chronic pelvic pain, and ectopic pregnancy. Extension of the infection can also occur, potentially causing pelvic abscesses, peritonitis, and perihepatitis (Fitz-Hugh-Curtis syndrome).

PREMENSTRUAL SYNDROME

Method of

Ellen W. Freeman, PhD

CURRENT DIAGNOSIS

- Confirm that symptoms occur premenstrually and abate following menses.
- Confirm that symptoms are clinically significant and impair daily activities and/or cause problems for the woman.
- Obtain a medical history and conduct a physical examination to determine that other disorders are not causing the symptoms.
- Assess depression, stress, substance abuse, and other diagnoses that could cause the symptoms.
- Ask the woman to maintain a daily symptom report for two or more menstrual cycles to confirm the reported symptoms and their relation to the menstrual cycle.
- Perform laboratory tests only as needed to confirm general good health or rule out other suspected conditions.

CURRENT THERAPY

SSRI	Range Studied (mg)	Mean Dose (mg/d)
Citalopram (Celexa ¹)	10–30	20
Escitalopram (Lexapro ¹)	10–20	15
Fluoxetine (Prozac, ¹ Sarafem*)	10–60	20
Paroxetine (Paxil ¹)	10–30	20
Paroxetine-CR* (Paxil-CR)	12.5, 25	NA [†]
Sertraline (Zoloft*)	50–150	75
SNRI		
Venlafaxine (Effexor ¹)	37.5–200	112.5

¹Not FDA approved for this indication.

*FDA approved for the indication of premenstrual dysphoric disorder (PMDD).

[†]Not applicable because of fixed-dose study.

The premenstrual syndromes (PMS) are characterized by mood, behavioral, and physical symptoms that occur from several days to 2 weeks before menses and remit with the menstrual flow. The term *PMS* as used by clinicians and the general public is generic, imprecise, and commonly applied to numerous symptoms. Included symptoms range from the mild and normal physiologic changes of the menstrual cycle to clinically significant symptoms that limit or impair normal functioning. In recent years, randomized controlled trials and other well-designed studies have defined

diagnostic criteria for PMS and identified effective treatments for this disorder.

Based on scientific evidence at this time, serotonergic antidepressants are considered the primary treatment for clinically significant PMS, and particularly its severe form termed *premenstrual dysphoric disorder* (PMDD). This review focuses on PMS and its treatment with serotonergic antidepressants. It is not a comprehensive review of all treatments or associated literature. Other recent reviews may guide the reader to further information and other treatments for PMS and PMDD.

Symptoms

Numerous symptoms were traditionally attributed to PMS. This plethora is related in part to the absence of a clear diagnosis that distinguishes PMS from other comorbid conditions. Many disorders, both physical and psychiatric, are exacerbated premenstrually or occur as a comorbid disorder with PMS. When a careful diagnosis is made to distinguish PMS from other conditions, a much smaller group of symptoms appear to be typical of the disorder (Box 1).

Mood symptoms are usually the main complaint (irritability, anxiety, tension, mood swings, feeling out of control, depression), but behavioral symptoms (e.g., decreased interest, fatigue, poor concentration, poor sleep) and physical symptoms, most commonly breast tenderness and abdominal swelling, are also present. Multiple studies suggest that irritability is the cardinal symptom of PMS. Although depressive symptoms such as low mood, fatigue, sleep difficulties, and poor concentration are frequent complaints of women with PMS, the growing evidence indicates that PMS is not a simple variant of depression but has distinct mechanisms that differ from those of depressive disorders.

Prevalence

Surveys indicate that PMS is among the most common health problems reported by reproductive-age women. Current estimates from epidemiologic data indicate that up to 30% of women experience severe and clinically significant premenstrual symptoms, although only 6% to 8% of menstruating women meet the stringent and predominantly dysphoric criteria for PMDD.

Morbidity

The morbidity of PMS is related to its severity, chronicity, and resulting distress that affect work, personal relationships, or daily activities. The level of impairment is significantly above community norms and similar to that of other health problems such as major depressive disorder. Studies consistently demonstrate that the greatest impairment or distress resulting from PMS is in relationships with the partner or children and in the effectiveness of work.

BOX 1 Symptoms of Premenstrual Syndrome

Affective

- Irritability
- Anxiety
- Angry outbursts
- Confusion
- Social withdrawal
- Depression

Somatic

- Abdominal bloating
- Breast tenderness or swelling
- Swelling of extremities
- Headache
- Joint or muscle pain

PREMENSTRUAL SYNDROME

Method of

Ellen W. Freeman, PhD

CURRENT DIAGNOSIS

- Confirm that symptoms occur premenstrually and abate following menses.
- Confirm that symptoms are clinically significant and impair daily activities and/or cause problems for the woman.
- Obtain a medical history and conduct a physical examination to determine that other disorders are not causing the symptoms.
- Assess depression, stress, substance abuse, and other diagnoses that could cause the symptoms.
- Ask the woman to maintain a daily symptom report for two or more menstrual cycles to confirm the reported symptoms and their relation to the menstrual cycle.
- Perform laboratory tests only as needed to confirm general good health or rule out other suspected conditions.

CURRENT THERAPY

SSRI	Range Studied (mg)	Mean Dose (mg/d)
Citalopram (Celexa ¹)	10–30	20
Escitalopram (Lexapro ¹)	10–20	15
Fluoxetine (Prozac, ¹ Sarafem*)	10–60	20
Paroxetine (Paxil ¹)	10–30	20
Paroxetine-CR* (Paxil-CR)	12.5, 25	NA [†]
Sertraline (Zoloft*)	50–150	75
SNRI		
Venlafaxine (Effexor ¹)	37.5–200	112.5

¹Not FDA approved for this indication.

*FDA approved for the indication of premenstrual dysphoric disorder (PMDD).

[†]Not applicable because of fixed-dose study.

The premenstrual syndromes (PMS) are characterized by mood, behavioral, and physical symptoms that occur from several days to 2 weeks before menses and remit with the menstrual flow. The term *PMS* as used by clinicians and the general public is generic, imprecise, and commonly applied to numerous symptoms. Included symptoms range from the mild and normal physiologic changes of the menstrual cycle to clinically significant symptoms that limit or impair normal functioning. In recent years, randomized controlled trials and other well-designed studies have defined

diagnostic criteria for PMS and identified effective treatments for this disorder.

Based on scientific evidence at this time, serotonergic antidepressants are considered the primary treatment for clinically significant PMS, and particularly its severe form termed *premenstrual dysphoric disorder* (PMDD). This review focuses on PMS and its treatment with serotonergic antidepressants. It is not a comprehensive review of all treatments or associated literature. Other recent reviews may guide the reader to further information and other treatments for PMS and PMDD.

Symptoms

Numerous symptoms were traditionally attributed to PMS. This plethora is related in part to the absence of a clear diagnosis that distinguishes PMS from other comorbid conditions. Many disorders, both physical and psychiatric, are exacerbated premenstrually or occur as a comorbid disorder with PMS. When a careful diagnosis is made to distinguish PMS from other conditions, a much smaller group of symptoms appear to be typical of the disorder (Box 1).

Mood symptoms are usually the main complaint (irritability, anxiety, tension, mood swings, feeling out of control, depression), but behavioral symptoms (e.g., decreased interest, fatigue, poor concentration, poor sleep) and physical symptoms, most commonly breast tenderness and abdominal swelling, are also present. Multiple studies suggest that irritability is the cardinal symptom of PMS. Although depressive symptoms such as low mood, fatigue, sleep difficulties, and poor concentration are frequent complaints of women with PMS, the growing evidence indicates that PMS is not a simple variant of depression but has distinct mechanisms that differ from those of depressive disorders.

Prevalence

Surveys indicate that PMS is among the most common health problems reported by reproductive-age women. Current estimates from epidemiologic data indicate that up to 30% of women experience severe and clinically significant premenstrual symptoms, although only 6% to 8% of menstruating women meet the stringent and predominantly dysphoric criteria for PMDD.

Morbidity

The morbidity of PMS is related to its severity, chronicity, and resulting distress that affect work, personal relationships, or daily activities. The level of impairment is significantly above community norms and similar to that of other health problems such as major depressive disorder. Studies consistently demonstrate that the greatest impairment or distress resulting from PMS is in relationships with the partner or children and in the effectiveness of work.

BOX 1 Symptoms of Premenstrual Syndrome

Affective

- Irritability
- Anxiety
- Angry outbursts
- Confusion
- Social withdrawal
- Depression

Somatic

- Abdominal bloating
- Breast tenderness or swelling
- Swelling of extremities
- Headache
- Joint or muscle pain

From the American College of Obstetricians and Gynecologists (ACOG), FAQ057, May 2015.

Etiology

The etiology of PMS remains undefined, although the monthly cycling of the reproductive hormones appears to have an essential role in the disorder. While circulating levels of the hormones are in normal range, the dominant theory is that some women have an underlying vulnerability to the normal fluctuations of one or more of these hormones. It is further believed that PMS involves central nervous system–mediated interactions of the reproductive steroids with neurotransmitters. The principal research evidence at this time supports the involvement of reproductive hormones, serotonergic dysregulation, and possibly dysregulation of GABAergic receptor functioning. Recent evidence suggested a pathophysiological role of beta-adrenergic mechanisms in the clinical pain of PMS.

Diagnosis

A diagnosis of PMS is determined primarily by the *timing* and the *severity* of the symptoms. These factors, together with an assessment of whether other physical or psychiatric disorders may account for the symptoms, are more important for the diagnosis than the particular symptoms, which are typically nonspecific and must be assessed for their relationship to the menstrual cycle.

Box 2 lists the diagnostic criteria for PMS presented by the American College of Obstetricians and Gynecologists. These criteria indicate that PMS symptoms must be experienced during the 5 days before menses and abate during the menstrual flow. The symptoms should cause identifiable impairment or distress, be confirmed by prospective reports recorded daily by the woman for at least two to three consecutive menstrual cycles, and not be accounted for by other disorders.

To diagnose PMS, a medical history should be obtained and a complete physical with gynecologic examination performed. PMS is understood to occur in ovulatory menstrual cycles; cycles that are irregular or outside the normal range are an indication for further gynecologic investigation. Comorbid conditions such as dysmenorrhea, endometriosis, uterine fibroids, pelvic inflammatory disease, thyroid disorders, migraine, diabetes, mood disorders, substance abuse, and numerous other possibilities should be identified. It may be difficult to determine whether the symptoms under investigation are an exacerbation of a comorbid condition or superimposed on another condition. In either case, the usual recommendation is to treat the ongoing condition first, then reassess and possibly add treatment for the symptoms that arise premenstrually.

The diagnostic criteria for PMDD are listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) and are intended to diagnose a severe, dysphoric form of PMS. Importantly, the Food and Drug Administration (FDA) has approved medications only for the indication of PMDD and not for the indication of PMS at the present time. Briefly, the PMDD criteria require 5 of 11 *listed* symptoms including at least one mood symptom. Physical symptoms, regardless of the number, are considered a single symptom in meeting the diagnostic criteria. The 11 PMDD symptoms are depressed mood, anxiety or tension, mood swings, anger or irritability, decreased interest, concentration difficulties, fatigue, appetite change or food cravings, sleep disturbance, feeling overwhelmed, and physical symptoms. At least five of these symptoms must *each* be severe premenstrually and abate with the

menstrual flow. The symptoms must markedly interfere with functioning, be confirmed by daily symptom reports for at least two menstrual cycles, and not be an exacerbation of another physical or mental disorder.

No laboratory test identifies PMS or PMDD and none should be routinely performed for diagnosis. Laboratory tests that indicate or confirm other possible disorders are useful if suggested by the individual woman's symptom presentation or medical findings.

The key diagnostic tool for evaluating premenstrual symptoms is the daily symptom report. The diagnostic criteria for both PMS and PMDD include a daily symptom report that is maintained by the woman for at least two menstrual cycles to confirm that the woman's reported symptoms are linked to the menstrual cycle in the requisite pattern. Numerous symptom reports appropriate for this diagnosis are identified in the medical literature. It is important that the ratings indicate the severity of each symptom (and not simply check the presence or absence of symptoms).

It is informative to use two visits for the diagnostic evaluation. Although counterintuitive, seeing the patient following menses when PMS symptoms have abated is instructive. If symptoms are absent, it provides strong evidence for the diagnosis. If symptoms are present in the follicular phase, the type and severity of the symptoms are important diagnostic information for identifying other physical or mental disorders that may be the primary focus of treatment.

Treatment

Selective Serotonin Reuptake Inhibitors

Serotonergic antidepressants are the primary treatment for severe PMS and PMDD at this time. Modulating serotonergic function is consistent with a leading theoretical view that the normal gonadal steroid fluctuations of the menstrual cycle are associated with an abnormal serotonergic response in vulnerable women. A meta-analysis of randomized controlled trials of selective serotonin reuptake inhibitors (SSRIs) in treatment of PMS and PMDD determined that these drugs were an effective first-line therapy, with both a statistically significant and clinically meaningful difference from placebo. The FDA has approved fluoxetine (Sarafem), sertraline (Zoloft), and controlled-release paroxetine (Paxil CR) for the indication of PMDD. Other randomized, placebo-controlled, double-blind trials show efficacy of citalopram (Celexa), escitalopram (Lexapro¹), venlafaxine (Effexor¹) (a selective serotonin-norepinephrine reuptake inhibitor [SNRI]), and clomipramine (Anafranil¹) (a tricyclic antidepressant) for treatment of PMS and PMDD, but they are not FDA approved for this indication.

Effective doses of SSRIs are consistently at the low end of the dose range for depressive disorders in all reports of PMS and PMDD treatments. Significant response is often seen in the first menstrual cycle of treatment, with smaller increments with or without dose adjustments in the second and third treatment cycles. If there is not sufficient response in the first treated menstrual cycle, the dose should be increased in the next cycle unless precluded by side effects.

Side effects are common with the initiation of an SSRI but are usually transient and abate within 1 to 2 weeks of continued treatment. The most common side effects include headache, nausea, insomnia, fatigue or lethargy, diarrhea, decreased concentration, dizziness, and decreased libido or delayed orgasm. The sexual side effects of SSRIs have received considerable attention, although it is often difficult to determine the extent to which sexual effects are related to the medication or to preexisting conditions. The incidence of decreased sexual interest or delayed orgasm in the few published reports of PMS patients is approximately 9% to 16%, which is notably lower than the rates reported with the use of SSRIs by depressed patients. Another important issue is the lack of any well-controlled clinical trials of SSRI treatment for PMS and PMDD in adolescents. Whether SSRIs are safe and effective for this indication in women younger than 18 years is not demonstrated.

BOX 2 Diagnosis of Premenstrual Syndrome

Presenting symptoms:

- Consistent with premenstrual syndrome
- Restricted to the luteal phase
- Cause impairment or distress
- Not an exacerbation of another disorder
- Confirmed by 3 consecutive cycles of daily symptom rating

From the American College of Obstetricians and Gynecologists (ACOG), FAQ057, May 2015.

¹Not FDA approved for this indication.

Luteal Phase Dosing

The use of medication only in the symptomatic luteal phase of the menstrual cycle is particularly important in PMS because of the cyclic pattern of the symptoms, which occur only in the premenstrual phase and abate following menses. Efficacy of luteal phase administration of the SSRIs is demonstrated in multiple trials: three large multicenter, randomized, placebo-controlled trials that examined fluoxetine (Sarafem), paroxetine (Paxil), and sertraline (Zoloft); a trial that directly compared continuous and luteal phase administration of sertraline; and multiple preliminary studies.

Luteal phase administration of an SSRI is typically initiated 14 days prior to the expected onset of menstrual bleeding and concluded within several days of bleeding, using a taper for increased doses. As with continuous dosing, the SSRI doses are usually at the low end of the dose range.

A preliminary study compared symptom-onset dosing (mean of 6 days before menses) to luteal-phase dosing and found no difference between the two dosing regimens in improvement overall, although there was suggestion that women with more severe symptoms may respond better to full luteal-phase dosing. A recent RCT of sertraline in symptom-onset dosing suggested greater improvement with sertraline compared to placebo, but results were inconsistent and varied with the symptom scale. Importantly, however, this study showed that cessation of symptom-onset treatment was not associated with discontinuation symptoms.

Side effects may be less frequent with an intermittent dosing regimen because they may not occur when not taking the medication. However, some women experience recurring side effects when dosing is resumed.

Insufficient Response to Selective Serotonin Reuptake Inhibitors

Approximately 60% of PMS and PMDD patients in controlled studies respond well to an SSRI. There are no clear predictors of response. An adequate trial of an SSRI for PMS and PMDD is at least two menstrual cycles at a dose level of demonstrated efficacy, with a third cycle when there is partial response. If a woman has an insufficient response or unacceptable side effects, it is reasonable to try another SSRI. Although the SSRIs are similar in their structure and have similar response rates and side-effect profiles, an individual patient may respond better to one SSRI versus another.

Other approaches to a poor treatment response include augmenting the SSRI with another medication to address the nonresponding symptoms, but there is no systematic information on this in PMS or PMDD treatment. Switching to another class of medication, such as anxiolytics, is suggested, but no data indicate whether nonresponders to SSRIs will respond to another class of medication. Non-response may also be related to other comorbid disorders. A thorough review of the diagnosis and adjustments of the premenstrual doses of medication for both the primary disorder and PMS should be considered before pursuing other treatments.

Other Treatments

Hormonal

In spite of the evidence for hormonal involvement in PMS and PMDD, traditional oral contraceptives (OCs) do not show efficacy for the disorder. However, some data indicate that shortening or omitting the placebo week in the traditional OC pill pack may effectively treat PMS and PMDD. The FDA has approved the oral contraceptive YAZ, a 24/4-day combination pill, to treat PMDD. The continuous daily use of an OC (without a hormone-free interval) suppresses ovulation-related hormone cyclicality. Continuous daily levonorgestrel 90 mcg/ethinyl estradiol 20 mcg (Amethyst) has been evaluated for continuous use up to one year and may be useful for managing the symptoms of PMDD. A Cochrane review of estrogen preparations for management of PMS found only five randomized controlled trials out of more than 500 reports. The evidence was considered low-quality, inconclusive with regard to effectiveness, and too limited to provide answers regarding the safety of these preparations for the indication of PMS.

Gonadotropin-releasing hormone (GnRH) agonists such as depot leuprolide (Lupron)¹ and buserelin² (Suprefact) are effective for PMS and PMDD but are of limited usefulness because of the risks associated with low estrogen levels that result from these treatments. Although add-back therapy using low-dose estrogen and progesterone together with the GnRH agonist did not appear to reduce efficacy in a meta-analysis, there are no definitive data on the safety and efficacy of this approach in long-term treatment. The historic use of progesterone has failed to show efficacy for the mood and behavioral symptoms of PMS in numerous controlled trials.

Anxiolytics

Alprazolam (Xanax)¹ and buspirone (Buspar)¹ showed modest efficacy for PMS in some studies but not others. Although these medications offer an alternative to antidepressants, the response rates appear much lower, and it is not known whether a PMS patient who does not respond to antidepressants will respond to an anxiolytic. The risk of dependency with alprazolam should be considered. Dosing should be strictly limited to the luteal phase, and the patient should have no history of substance abuse.

Nonpharmacologic

Calcium supplementation¹ (500 mg daily; 600 mg twice daily) reduced PMS symptoms significantly more than placebo in several clinical trials. Improved symptoms included anxiety, depression, water retention, and somatic changes. Calcium offers a dietary supplement approach that may be beneficial for some women with PMS, although there are no predictors of which women will respond well to this therapy. Other complementary and alternative therapies may be helpful for some women, but there is no consistent evidence of their efficacy for PMS.

Behavioral treatments that facilitate coping or reduce stress may reduce PMS symptoms. Cognitive-behavioral therapy is effective for PMS, and in one study it was as effective as the SSRI fluoxetine after 6 months of treatment.

Treatment Duration

The published studies of treatment efficacy for PMS and PMDD are based on acute treatment of 2 to 3 months' duration. Several investigations suggest that PMS symptoms are likely to return within several months after medication is stopped. It also appears that PMS symptoms do not resolve spontaneously but continue for many years. These observations of PMS as a chronic condition and the swift return of symptoms following the cessation of medication suggest that treatment can be expected to be long term. In a controlled study that compared 4 months to 1 year of SSRI treatment, approximately half of the patients who improved with SSRI treatment relapsed within 6 to 8 months after discontinuing medication. Longer treatment was marginally better at preventing relapse. Patients with more severe symptoms before treatment were the most likely to relapse, while patients who experienced symptom remission with treatment were least likely to relapse.

Conclusions

The SSRIs are currently the first-line treatment for severe PMS and PMDD. Continuous dosing and luteal phase dosing regimens are similarly effective for these disorders when the symptoms are clearly limited to the luteal phase of the menstrual cycle. Hormonal treatments have lacked consistent scientific evidence of their efficacy or safety or both for PMS treatment. Several new oral contraceptives that decrease or omit the placebo interval, calcium supplementation, and cognitive behavioral therapy may provide an effective alternative to antidepressant medications. Evidence indicates that long-term maintenance of the medication may be required for PMS and PMDD.

interstitial (within the myometrium), and submucous (just below the endometrium). Subserosal leiomyomas can grow in a pedunculated fashion from the uterus as they enlarge. Leiomyomas arise during the reproductive years, can enlarge during pregnancy, and regress following menopause. The incidence of leiomyomas identified via ultrasound scanning is about 5% in young adults, 15% in middle-aged women, and 30% in women older than 40 years. In postmortem examinations the incidence has been found to be even higher.

Risk Factors

Factors associated with increased risk of leiomyomas include early age of menarche, alcohol intake, nulliparity, obesity, family history, age, hypertension, and African descent. Factors associated with decreased risk for leiomyomas include depot medroxyprogesterone (Depo Provera) use, increased parity, and menopause.

Pathophysiology

Leiomyomas arise from a unicellular origin in the smooth muscle of the myometrium. Leiomyomas have a relatively poor vascular supply of one or two arteries at the base of the leiomyoma, which can result in a tumor outgrowing its blood supply. Their growth rate is influenced by estrogen, growth hormone, and progesterone. Estrogen exposure is associated with an increased incidence of leiomyomas. Growth hormones act synergistically with estradiol in affecting the growth of leiomyomas. Conversely, progesterone appears to inhibit their growth. Leiomyomas produce a dysregulation of growth factors and their receptors, causing vascular abnormalities that can contribute to the symptom of menorrhagia.

Clinical Manifestations

Leiomyomas are most commonly asymptomatic. They can also be found in association with menorrhagia, dysmenorrhea, pelvic pain and pressure, obstructive symptoms, infertility, and pregnancy loss. Many women with symptomatic myomas present with more than one symptom.

Menstrual abnormalities are the most common symptoms associated with the presence of myomas. Menorrhagia is the most common bleeding pattern and can result in an iron deficiency anemia. Pelvic pain and pressure can be the result of a large leiomyoma alone or from vascular compromise. Chronically, women can experience the sensation of pressure from an enlarged uterus. Acute pain from vascular compromise can occur when pedunculated myomas torsion, when hemorrhage occurs within a myoma (usually in association with pregnancy), or when a myoma outgrows its blood supply.

Obstructive symptoms affect the urinary system (urinary frequency or urgency) more commonly, but they can also cause rectal symptoms like constipation. These manifestations are more common during pregnancy in the setting of large leiomyomas and uterine enlargement.

The role of leiomyomas in infertility is controversial. Some experts recommend the treatment of submucosal leiomyomas that distort the uterine cavity because they may impair in vitro fertilization. There is also some evidence that spontaneous conception rates may improve after myomectomies of submucosal fibroids. There is a lack of evidence at this time that these treatments result in statistically significant differences in live birth rates.

There is uncertainty regarding the possible role leiomyomas play in early miscarriage.

Diagnosis

The bimanual examination finding of an enlarged and irregularly shaped uterus is often the first indication that a patient has leiomyomas. A number of studies can be helpful in evaluating a patient for the presence of leiomyomas, including transvaginal sonography, sonohysterography, hysteroscopy, and magnetic resonance imaging (MRI). Transvaginal sonography has the lowest sensitivity and specificity, but it is the best initial test based on its noninvasiveness and cost-efficiency. MRI is preferred when precise leiomyoma mapping is required (usually for surgical purposes), but it is the most expensive modality for evaluating leiomyomas.

UTERINE LEIOMYOMAS

Method of

Patricia Evans, MD; and Susan C. Brunzell, MD*

CURRENT DIAGNOSIS

- Most leiomyomas are asymptomatic.
- Most common clinical manifestations include menorrhagia, pelvic pain, obstructive symptoms, and infertility.
- Physical examination findings are enlarged or irregularly shaped uterus.
- Transvaginal sonography is the initial imaging modality.
- Magnetic resonance imaging (MRI) is used for precise mapping of the leiomyoma.
- Sonohysterography and hysteroscopy can diagnose submucosal leiomyomas.

CURRENT THERAPY

- Expectant management is the treatment of choice for asymptomatic leiomyomas.
- Myomectomy is used to treat symptoms and preserve fertility.
- Hysterectomy provides a definitive treatment for symptoms.
- Uterine artery embolization and myolysis are nonsurgical treatment options.
- Hormone treatments are treatment options in a limited number of clinical scenarios.

Epidemiology

Uterine leiomyomas (also referred to as *leiomyomas* or *myomas*) are benign smooth-muscle tumors. They are classified according to their position in the uterus: subserous (just beneath the serosa),

*The views expressed in this publication are those of the author and do not reflect the official policy of the Department of Defense or of the US government.

- Hormone treatments are treatment options in a limited number of clinical scenarios.

Epidemiology

Uterine leiomyomas (also referred to as *leiomyomas* or *myomas*) are benign smooth-muscle tumors. They are classified according to their position in the uterus: subserous (just beneath the serosa),

*The views expressed in this publication are those of the author and do not reflect the official policy of the Department of Defense or of the US government.

Sonohysterography and hysteroscopy can be used to evaluate the extent of submucosal leiomyomas, but these methods are invasive.

Differential Diagnosis

Patients consult physicians because of symptoms related to leiomyomas or when the lesions are diagnosed incidentally during physical or radiologic examinations. Attributing symptoms to uterine leiomyoma with certainty is complicated owing to their high prevalence and because the differential diagnosis for symptoms related to leiomyomas is wide. For example, possible causes of menorrhagia include pregnancy, infection, carcinoma, and endocrine, hematologic, physiologic, systemic, structural, and iatrogenic causes. Pelvic pain causes include endometriosis, adenomyosis, pelvic adhesions, pelvic inflammatory disease (PID), cystitis, ovarian diseases, and bowel disease.

Differentiating leiomyoma from malignant leiomyosarcoma can be challenging as rapid growth alone is not an adequate marker. MRI is widely accepted as the standard of care for preoperative evaluation for clinical suspicion of leiomyosarcoma. Contrast-enhanced MRI has higher diagnostic accuracy and specificity as compared with diffusion-weighted MRI.

Treatment

Expectant Management

Expectant management is the treatment of choice for women with asymptomatic leiomyomas regardless of size. Early intervention may be an option for asymptomatic young women desiring future fertility because leiomyoma tumors can become larger with the passage of time, thereby complicating treatment in the future.

Medical Treatments

Hormone therapy with cyclic or noncyclic estrogen–progestin combinations is ineffective in alleviating the symptoms of leiomyoma tumors or limiting tumor growth. There is no evidence that low-dose contraceptives cause the growth of uterine leiomyoma tumors; thus fibroids are not a contraindication to their use. The

use of the levonorgestrel-releasing IUD¹ (Mirena) can reduce heavy menstrual bleeding in symptomatic women with uterine leiomyomas. However, the presence of fibroids increases the risk of expulsion of the IUD.

Gonadotropin-releasing hormone (GnRH) agonists (leuprolide [Lupron]) are the most well-established therapy for medical management, causing amenorrhea and a rapid reduction in the size of the tumor. This therapy is best suited for women in the perimenopausal or preoperative periods owing to significant side effects resulting from hypoestrogenism (e.g., hot flashes, vaginal dryness, bone demineralization).

Selective progesterone receptor modulators (SPRMs) are emerging as a potential medical treatment for fibroids. Mifepristone (Mifeprex) decreases bleeding and improves quality of life, but does not affect fibroid volume. Ulipristal (Ella) is approved as an emergency contraceptive in the United States, but has been used in Europe for years as a treatment for fibroids pending surgery. It is also being studied for potential use as a sequential treatment. Treatment reduces blood loss and decreases fibroid volume. They can cause endometrial changes that appear to be reversible and benign.

The aromatase inhibitor letrozole has been shown to decrease fibroid size and reduce bleeding without vasomotor symptoms, or changing bone density. Larger clinical trials are needed to fully evaluate safety and efficacy of letrozole for this indication.

Surgical Treatments

Selected patients can benefit from surgery: those with persistent abnormal uterine bleeding or symptoms resulting from uterine bulk that do not respond to conservative measures or when the diagnosis of leiomyosarcoma is being considered (e.g., a menopausal woman with an enlarging tumor) (Table 1). Abdominal or vaginal hysterectomy is the definitive treatment for *symptomatic uterine leiomyomas*. There is no chance for recurrence and there is

¹Not FDA approved for this indication.

TABLE 1 Treatment Options

TREATMENT	DESCRIPTION	ADVANTAGES AND USES	DISADVANTAGES AND RISKS	FERTILITY PRESERVED?
Hysterectomy	Surgical removal of the uterus (transabdominal, transvaginal, or laparoscopic)	Definitive treatment for women who do not wish to preserve fertility	Surgery and anesthesia risks	No
Myomectomy	Excision of fibroids via laparotomy or endoscopy	Resolution of symptoms with preservation of fertility; perioperative morbidity similar to hysterectomy	Recurrence of fibroids (up to 50% at 5 y) Success of procedure determined by number and extent of fibroids	Yes
Uterine artery embolization	Interventional radiology procedure to occlude uterine arteries	Minimally invasive Avoids surgery Short hospital stay (24–36 h)	Symptom recurrence (20% at 5 y) Risk of rehospitalization for postprocedure pain Bleeding	No (limited experience)
Myolysis	In situ destruction of fibroids by ultrasound, laser, or cryotherapy	Ease and rapidity of procedure Low blood loss Rapid recovery time	Delay in reduction of uterine size Unknown risk for recurrence Prolonged vaginal bleeding	No (unknown)
Gonadotropin-releasing hormone agonists	Preoperative treatment to decrease size of fibroids before hysterectomy, myomectomy, or myolysis, or at perimenopause	Decreases blood loss, operative time, recovery time	Long-term treatment associated with high cost, menopausal symptoms, and bone loss Possible increased recurrence risk with myomectomy	Depends on subsequent procedure
Selective Progesterone Receptor Modulators (SPRMs)	Emerging treatment for fibroids. Ulipristal only approved as emergency contraception in the US at this time	Mifepristone decreases bleeding Ulipristal decreases bleeding and decreases fibroid volume	Reversible endometrial changes	Depends on subsequent procedure

less blood than with other procedures such as myomectomy.

Myomectomy (i.e., surgical removal of leiomyoma tumors while preserving the uterus) is performed via laparotomy, endoscopy, or hysteroscopy. The choice of surgical approach largely depends on the expertise of the physician. When myomectomies are performed to preserve fertility, care must be taken to avoid adhesions, which can compromise the goal of the operation. Currently, many clinicians recommend cesarean section for all pregnancies after myomectomy despite limited data to support this recommendation.

Uterine artery embolization uses interventional radiology to occlude the uterine arteries with polyvinyl alcohol microspheres positioned by a catheter passed through the femoral artery. Postprocedure pain is significant, generally requiring admission at least overnight for narcotic analgesia. Postprocedure complications include postembolization syndrome (pain accompanied by fever, nausea, and vomiting); injury to the ovary, ureter, or other structures (misembolization); and infection. Short-term outcomes demonstrate that uterine artery embolization has lower morbidity than hysterectomy, but readmission rates are high: 5% to 10%. Long-term outcomes have been encouraging: 73% of women had continued symptom control at 5 years in one study. The issue of fertility after uterine artery embolization is still under investigation.

Myolysis involves techniques designed to destroy rather than remove leiomyoma tumors. Magnetic resonance-guided focused ultrasound (MRgFU) is a minimally invasive therapy that uses ultrasound energy, which causes coagulative necrosis of the fibroids, directed through the abdominal wall under real-time MRI monitoring. Compared with UAE and hysterectomy, MRgFU is associated with fewer complications but more re-interventions. Radiofrequency volumetric thermal ablation (RFVTA) is performed under laparoscopic guidance, using ultrasound to identify fibroids. An electrode is inserted to deliver thermal energy, which ablates the fibroids. Compared with myomectomy, RFVTA has a lower risk of periprocedural complications, and shorter hospitalizations but more reinterventions in the future.

VULVAR NEOPLASIA

Method of

Christine Conageski, MD

CURRENT DIAGNOSIS

- Most cystic lesions are benign. Excision is reserved for symptomatic cysts and suspicious Bartholin's gland cysts, especially in women older than 40 years of age.

- All solid lesions should be biopsied for diagnostic purposes.
- Multifocal disease requires multiple biopsies to rule out invasive disease.
- Most premalignant and malignant lesions cause pruritus, discomfort, or a noticeable lesion.
- The vagina and cervix in women with dysplastic or malignant vulvar lesions should be evaluated.

CURRENT THERAPY

- Benign solid lesions should be excised.
- After ablative treatment of vulvar intraepithelial neoplasia (VIN), excise any residual lesions to rule out occult invasive disease.
- Avoid podophyllin and 5-fluorouracil in women of reproductive potential.
- Rule out synchronous neoplasms in women with Paget's disease.
- Invasion more than 1 mm requires radical excision and lymph node evaluation.

The female external genitalia includes the mons pubis, labia majora, labia minora, clitoris, perineal body, and the structures of the vaginal introitus or vestibule. Whether benign or malignant, vulvar neoplasms are uncommon, occur at all ages, and have varying characteristics. Therefore liberal use of biopsies is usually required for diagnosis and treatment decisions.

Benign Cystic Neoplasms

Benign cystic lesions of the vulva include Bartholin's duct cyst, sebaceous and epidermal inclusion cysts, mucinous cysts, Skene duct cysts, and cysts of the canal of Nuck. Bartholin's duct cyst, located in the posterior labia near the vaginal introitus, is most common. Treatment is usually not required in asymptomatic young women (<40 years). If the cyst is symptomatic or infected, however, drainage, marsupialization or use of a Word catheter, is indicated. Bartholin's gland carcinomas are rare, especially in women younger than 40 years of age. But if the mass feels firm or nodular, it should be biopsied.

Sebaceous and epidermal inclusion cysts are also common. They are prone to infection but rarely malignant. If an infection develops, they should be incised and drained. Mucinous cysts are rare and possibly arise from the minor vestibular glands. They are located anteriorly on the vulva, typically on the inner labia minora. Skene duct cysts are located next to the urethra. Excision of these cysts is necessary only if symptomatic.

Cysts of the canal of Nuck are located in the anterior portion of the labia majora at the termination of the insertion of the round ligament. These cysts represent herniation of the peritoneum through the inguinal canal and contain peritoneal fluid. If symptomatic, excision must be accompanied by closure of the fascial defect to prevent recurrence.

Benign Solid Neoplasms

The benign solid tumors of the vulva include fibromas, myomas, lipomas, hidradenomas, syringomas, myoblastomas, vestibular adenomas, and angiomas, among others. Benign pigmented lesions, such as nevi and seborrheic keratoses, may occasionally be found. Malignancy is rare, but most should be excised for diagnostic and therapeutic purposes.

Condyloma Acuminatum

Vulvar condyloma acuminatum is a sexually transmitted verrucous lesion of the vulva caused by human papilloma virus (HPV), most frequently types 6 and 11. These lesions are warty growths that frequently cover large areas of the vulva. Smoking and immunosuppression are risk factors. Representative biopsies should be obtained to document disease and rule out malignancy. Wide local excision can be used for small lesions, although these growths

less blood than with other procedures such as myomectomy.

Myomectomy (i.e., surgical removal of leiomyoma tumors while preserving the uterus) is performed via laparotomy, endoscopy, or hysteroscopy. The choice of surgical approach largely depends on the expertise of the physician. When myomectomies are performed to preserve fertility, care must be taken to avoid adhesions, which can compromise the goal of the operation. Currently, many clinicians recommend cesarean section for all pregnancies after myomectomy despite limited data to support this recommendation.

Uterine artery embolization uses interventional radiology to occlude the uterine arteries with polyvinyl alcohol microspheres positioned by a catheter passed through the femoral artery. Postprocedure pain is significant, generally requiring admission at least overnight for narcotic analgesia. Postprocedure complications include postembolization syndrome (pain accompanied by fever, nausea, and vomiting); injury to the ovary, ureter, or other structures (misembolization); and infection. Short-term outcomes demonstrate that uterine artery embolization has lower morbidity than hysterectomy, but readmission rates are high: 5% to 10%. Long-term outcomes have been encouraging: 73% of women had continued symptom control at 5 years in one study. The issue of fertility after uterine artery embolization is still under investigation.

Mucinous cysts are rare and possibly arise from the minor vestibular glands. They are located anteriorly on the vulva, typically on the inner labia minora. Skene duct cysts are located next to the urethra. Excision of these cysts is necessary only if symptomatic.

Cysts of the canal of Nuck are located in the anterior portion of the labia majora at the termination of the insertion of the round ligament. These cysts represent herniation of the peritoneum through the inguinal canal and contain peritoneal fluid. If symptomatic, excision must be accompanied by closure of the fascial defect to prevent recurrence.

Benign Solid Neoplasms

The benign solid tumors of the vulva include fibromas, myomas, lipomas, hidradenomas, syringomas, myoblastomas, vestibular adenomas, and angiomas, among others. Benign pigmented lesions, such as nevi and seborrheic keratoses, may occasionally be found. Malignancy is rare, but most should be excised for diagnostic and therapeutic purposes.

Condyloma Acuminatum

Vulvar condyloma acuminatum is a sexually transmitted verrucous lesion of the vulva caused by human papilloma virus (HPV), most frequently types 6 and 11. These lesions are warty growths that frequently cover large areas of the vulva. Smoking and immunosuppression are risk factors. Representative biopsies should be obtained to document disease and rule out malignancy. Wide local excision can be used for small lesions, although these growths

are usually best treated by ablation to avoid morbidity associated with excision.

Chemical ablative techniques include self or provider-administered medications. Self-administered medications include topical podofilox (0.5%, Condyllox) or imiquimod (5%, Aldara). Podofilox is applied twice daily for 3 days, repeated weekly for 4 weeks and imiquimod is applied three times per week for up to 16 weeks. It is primarily an immune modulator. Providers may instead choose in-office application of trichloroacetic acid (Tri-Chlor), 5-fluorouracil¹ (1%, Fluoroplex or 5%, Efudex),¹ or podophyllin. Podophyllin and 5-fluorouracil should not be used in women who could become pregnant. Surgical ablative therapies include CO₂ laser vaporization and use of the Cavitron ultrasonic aspirator (CUSA), especially for extensive disease.

Intraepithelial Neoplasms of the Vulva

Vulvar Intraepithelial Neoplasia

Vulvar intraepithelial neoplasia (VIN) is a dysplastic condition of the squamous epithelium whose incidence is increasing, especially in younger women. There are two pathologically distinct types of VIN, usual and differentiated types.

The usual type has a strong association with HPV infections and thus shares similar risk factors with cervical intraepithelial neoplasias (CIN). These risk factors include early first intercourse, multiple sexual partners, smoking, and immunosuppression. Up to 22% of women have concurrent CIN lesions and up to 71% have had a previous, concomitant or subsequent history of vaginal intraepithelial neoplasia. Differentiated VIN is not associated with HPV and is found in relation to vulvar dermatoses such as lichen sclerosus. Differentiated VIN typically occurs in older women with a mean age of 67 years compared to 47.8 years in usual type VIN. Symptoms of both types include pruritus (most common), pain, a noticeable lesion, and discoloration. Most patients with HPV-related disease have multifocal lesions. Typical findings are raised white, gray, red, or mottled lesions; application of 4% acetic acid for several minutes can help identify faint lesions and outline abnormal vascular patterns. Diagnosis of VIN is made by punch biopsies through full thickness of the epithelium to rule out invasion. Usual and differentiated VIN have very different cancer progression risks, 5.7% for HPV-mediated VIN and 32.8% for differentiated VIN. Differentiated VIN, also, has a shorter time to progression, 22.8 months compared to 41.4 months.

Treatment of VIN can be categorized into excisional and ablative therapies. Management should be individualized to each patient taking into account risk of progression, distribution of disease and histologic features on biopsy. Often a combination of medical and surgical management is appropriate. Patients at risk for micro-invasion (unifocal disease, raised lesions, older age, and prior radiation) should have the lesion excised completely if possible. Skinning vulvectomy is rarely used because of psychological and sexual consequences related to scarring and disfigurement.

The ablative therapies can be divided into mechanical and chemical. The mechanical method most commonly used is the CO₂ laser, although use of the CUSA is also described. Both can ablate large or multifocal lesions successfully with an excellent cosmetic and functional outcome. The chemical method most commonly used is topical 5-fluorouracil (5%, Efudex).¹ Because of its teratogenic potential, it should not be used in women who could become pregnant. It can be applied on two consecutive nights weekly for 10 weeks. An alternative ablative therapy is use of imiquimod¹ (Aldara), as described earlier. Because of the irritation caused by these topical therapies, many patients have problems with treatment compliance. Residual disease should be excised to rule out invasion.

Patients with VIN frequently have recurrent disease, regardless of the treatment method used (Table 1). Continued smoking increases this risk, so patients should be counseled in smoking cessation. In those patients whose cancers recur and are retreated, subsequent 5-fluorouracil prophylaxis, with a single application biweekly, is used successfully to minimize further recurrences.

TABLE 1 Recurrence of Vulvar Intraepithelial Neoplasia III

TREATMENT METHOD	% RECURRENCE
Chemical ablation	20–40
Mechanical ablation	20–40
Wide local excision	
Negative margin	15–25
Positive margin	30–45

Paget's Disease

Paget's disease of the vulva is an uncommon condition characterized by a patchy, eczematoïd lesion that frequently covers much of the vulva. Most patients are postmenopausal and present with complaints of pruritus. Although Paget's disease is an in situ disease process, 15% to 25% of patients have an underlying malignancy, usually an adenocarcinoma of the apocrine glands but occasionally an invasive Paget's. In addition, up to 30% of patients have a synchronous adenocarcinoma of the breast, colon, rectum, or upper genital tract. Screening for these cancers is therefore recommended. To assess for invasion, the lesion should be excised via wide local excision or simple vulvectomy with at least 5 mm of the adjacent subcutaneous tissue. Achieving negative margin status is frequently difficult. However, the risk of recurrence is approximately 30% whether margins are negative or positive. Thus expectant management, reserving treatment for symptomatic recurrences, is usually recommended.

Invasive Vulvar Lesions

Less than 5% of gynecologic cancers arise on the vulva. Over 90% are squamous cell carcinomas. The etiology of this type appears mixed. The differentiated type is more common, occurs in older women (age 60–69, mean age 65) and is associated with vulvar dys-trophies. The classic or usual type is predominantly associated with HPV-16. These women are slightly younger (age 45–52 years) and present with earlier stage disease. Other histologic types are melanomas (5%–10%), basal cell carcinomas (2%–3%), adenocarcinomas (1%), and sarcomas (1%–2%). Most patients present with a combination of symptoms, including pruritus, discomfort, and complaints of a mass. Examination frequently reveals a suspicious lesion, which should be biopsied for diagnosis. Vulvar cancers typically spread by local extension and lymphatic dissemination. Factors that influence dissemination include tumor size (Table 2), depth of invasion (Table 3), lymphovascular space invasion, and tumor grade. Staging is surgical and classified using the tumor, nodes, and metastasis (TNM) system as well as the International Federation of Gynecology and Obstetrics (FIGO) system (Table 4).

TABLE 2 Incidence of Regional Node Metastases by Tumor Diameter

TABLE 4 Staging Vulvar Carcinoma

TNM CATEGORIES	FIGO STAGES	
T Primary tumor		
T0		No evidence of primary tumor
Tis		Carcinoma in situ
T1	I	Confined to vulva
T1a	IA	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1 mm
T1b	IB	Lesions > 2 cm in size OR any size with stromal invasion > 1.0 mm, confined to the vulva or perineum
T2	II	Tumor of any size with extension to adjacent perineal structures (lower/distal 1/3 urethra, lower/distal 1/3 vagina, anal involvement)
T2	III	Tumor of any size with or without extension to adjacent perineal structures (lower/distal 1/3 urethra, lower/distal 1/3 vagina, anal involvement) with positive inguino-femoral lymph nodes
T3	IVA	Tumor of any size with extension to any of the following: upper/proximal 2/3 of urethra, upper/proximal 2/3 vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone
T3	IVB	Any distant metases including pelvic lymph nodes
N Regional lymph nodes		
N0		No lymph node metastases
N1		One or two regional lymph nodes with the following features:
N1b	IIIAi	One lymph node metastasis, ≥ 5 mm
N1a	IIIAii	One to two lymph node metastases, < 5 mm
N2	IIIB	Regional lymph node metastasis with the following features:
N2b	IIIBi	Two or more lymph node metastases, ≥ 5 mm
N2a	IIIBii	Three or more lymph node metastases, < 5 mm
N2c	IIIC	Lymph node metastasis with extracapsular spread
N3	IVA	Fixed or ulcerated regional lymph node metastasis
M Distant metastases		
M0		No distant metastases
M1	IVB	Distant metastasis (including pelvic lymph node metastasis)

Abbreviations: TNM = tumor, node, metastasis; FIGO = International Federation of Gynecology and Obstetrics.

Squamous Cell Carcinomas and Adenocarcinomas

Surgical management of squamous cell carcinomas and adenocarcinomas depends on the size, depth of invasion, and location of the lesion. The vulvar lesion is managed with a radical excision.

TABLE 5 Survival Rate by FIGO Stage for Patients With Invasive Squamous Cell Vulvar Cancer

FIGO STAGE	OVERALL SURVIVAL (PERCENT)		
	One year	Two years	Five years
I	96.4	90.4	78.5
II	87.6	73.2	58.8
III	74.7	53.8	43.2
IV	35.3	16.9	13.0

Abbreviation: FIGO = International Federation of Gynecology and Obstetrics.

Management of the groins is based on depth of invasion. Lesions with invasion of less than 1 mm (Stage IA) have minimal risk of lymphatic spread ($<1\%$) and do not require lymphadenectomy. All others require surgical assessment of the lymph nodes. Lesions less than 2 cm in size of the primary tumor, greater than 2 cm from the vulvar midline and are of squamous histology require only unilateral lymphadenectomy. Those without these characteristics or have palpable lymph nodes of the contralateral side require bilateral assessment. This surgical approach is associated with significant morbidity including disfigurement, wound breakdown, and problems with lymphocysts and chronic lymphedema. For patients with very large lesions or lesions in sensitive areas such as the clitoris, preoperative radiation, followed by less radical excision of residual disease, may minimize problems with the vulvar wound. Current investigations are ongoing in the use of sentinel lymph node dissections as a method of minimizing the groin morbidity without sacrificing survival. Positive vulvar margins or metastases to lymph nodes are managed with postoperative radiation. Survival depends on stage at diagnosis (Table 5).

Verrucous Carcinoma

Verrucous carcinoma is a large exophytic tumor that resembles giant condyloma acuminatum. It is a variant of squamous carcinomas but has an excellent prognosis because of the lack of metastases. Verrucous carcinomas have a high tendency to recur and should be managed with radical local excision.

Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy. Most patients have disease on the mucosal surfaces of the vulvar introitus, clitoris, and labia minora. The vulvar lesion is treated by radical excision, but management of the groins is controversial. The risk of spread is significant with a tumor thickness greater than 0.75 mm, but survival at 5 years is only approximately 10% with groin node metastases. Some argue against node dissection for this reason. However, given some long-term survivors with modern melanoma therapy, either lymphadenectomy or sentinel lymph node dissection, as is done for other cutaneous melanomas, appears indicated.

Basal Cell Carcinoma

Basal cell carcinomas typically occur in elderly white women, are commonly located on the labia majora, and have characteristics similar to basal cell carcinomas at other sites. Treatment is wide local excision only because metastases are rare. Basal cell carcinomas are prone to local recurrence, however. A malignant squamous component must be ruled out because it should be managed as a squamous cell carcinoma.

Sarcomas

Leiomyosarcoma is the most common vulvar sarcoma and usually arises in the labia majora. Malignant fibrous histiocytoma is the second most common. Management of these lesions is radical vulvar excision.

VULVOVAGINITIS

Method of

Michael A. Malone, MD; and Vasudha Jain, MD

CURRENT DIAGNOSIS

- Bacterial vaginosis: pH > 4.5; 20% clue cells, malodorous “fishy” discharge.
- Vulvovaginal candidiasis: pH 4–4.5; pseudohyphae, blastospores, thick curd-like discharge, vulvar inflammation.
- Trichomonas vaginitis: pH 5–6; motile, flagellated trichomonads, many white blood cells (WBCs), purulent discharge, vulvovaginal inflammation.

CURRENT THERAPY

- The nitroimidazoles, metronidazole and tinidazole, are the only medications approved by the FDA for the treatment of trichomoniasis.
- First-line treatment with metronidazole is recommended for women with symptomatic bacterial vaginosis.
- Current data do not support universal screening and treatment of asymptomatic patients for bacterial vaginosis during pregnancy.
- Asymptomatic women with vulvovaginal candidiasis do not require treatment.
- Treatment of vulvovaginal candidiasis with oral or topical azoles results in symptom relief in 80% to 90% of patients who complete therapy and is more effective than nystatin.
- Vulvovaginitis due to *Candida albicans* is common in pregnancy and only topical azoles for 7 days are recommended.

Vulvovaginitis is the general term for disorders of the vulva and vagina caused by infection, inflammation, or changes in the normal vaginal flora. Common symptoms include vulvovaginal erythema, discomfort, odor, and vaginal discharge. From a medical perspective, vaginitis is considered a relatively benign problem. However, it can cause physical discomfort, potential pregnancy risks, and, with chronic vaginitis, body image problems and sexual dysfunction. Despite a large percentage of patients who self-treat with over-the-counter treatments, vaginal symptoms are one of the most common

reasons for gynecological consultation. A health care provider is consulted in the majority of women with symptoms of vaginitis, accounting for 10 million office visits a year in the United States.

This article addresses the most common causes of vaginitis, which account for over 90% of cases.

Differential Diagnosis

The common causes of vaginitis include bacterial vaginosis (40%–50% of cases), candidiasis (20%–25%), and trichomoniasis (15%–20%). Less common causes of these symptoms include vaginal atrophy, cervicitis, foreign body, irritants and allergens, and desquamative inflammatory vaginitis.

Clinical Manifestations

Common symptoms of vulvovaginitis include vulvovaginal erythema, discomfort, odor, and vaginal discharge. History can help differentiate the cause of the vaginitis. For example, a patient's lack of itching makes candidiasis less likely, while lack of perceived odor makes bacterial vaginosis unlikely and candidiasis more likely. However, none of the findings from the history alone allows a definitive diagnosis, as there is considerable overlap in symptoms among the different etiologies. Inspecting the vulva on examination can be helpful in determining the diagnosis. The vulva is often inflamed by candidiasis and trichomoniasis, but not by bacterial vaginosis. The characteristics of the vaginal discharge, if present, may help distinguish the type of infection (Table 1). However, the appearance of the discharge is unreliable and should not be the sole basis for diagnosis.

Diagnosis

Identifying the etiology of vaginitis is primarily based on patient history, pelvic examination, vaginal pH measurement (Table 2), whiff test, speculum examination, and microscopic evaluation of any discharge. Microscopic examination is used to look for hyphae, motile trichomonads, epithelial cells studded with adherent coccobacilli (clue cells), and increased numbers of polymorphonuclear leukocytes (PMNs). Initial office evaluation correctly results in a diagnosis of 60% of *Candida* vulvovaginitis, 70% of trichomoniasis, and 90% of bacterial vaginosis. If microscopy is negative, culture for *Candida* species or polymerase chain reaction (PCR) testing for *Trichomonas vaginalis* (the choice is dictated by the clinical findings) is important because microscopy is not sufficiently sensitive to exclude these diagnoses in symptomatic patients. Bacterial cultures are not indicated in women with vaginal

TABLE 1 Characteristics for Different Causes of Vaginitis

	TYPICAL PH	DISCHARGE CHARACTERISTICS
Bacterial vaginosis	> 4.5	Thin, homogeneous, “fishy smelling” gray discharge.
Trichomonas	5–6	Greenish-yellow purulent malodorous discharge
Vulvovaginal candidiasis	4–4.5	Thick, white, adherent, “cottage cheese-like” discharge

TABLE 2 Common Findings With Each Cause of Vaginitis

FINDING	DISCHARGE WITH AN ODOR	INFLAMMATION	VULVAR INVOLVEMENT

Trichomonas	Yes	Yes	Yes

discharge. In fact, they are frequently misleading, since a large variety of bacterial species colonize the vagina.

Trichomoniasis

Trichomoniasis is caused by the protozoan *T. vaginalis*, and most men and women who are infected do not have any symptoms. Symptomatic disease is characterized by purulent, malodorous, greenish-yellow discharge, which may be accompanied by burning, pruritus, dysuria, and/or dyspareunia, and postcoital bleeding. Although all of the common causes of vulvovaginitis have been associated with other sexually transmitted infections, trichomoniasis is the only one that is actually sexually transmitted. *T. vaginalis* can be identified in 70% of the male sexual partners of infected women, although carriage in men is often self-limited. *T. vaginalis* infection causes genital inflammation that increases the risk of HIV acquisition. Trichomonas infection increases the risk of complications in pregnancy. In a 2014 systematic review and meta-analysis of the association between *T. vaginalis* and perinatal outcomes, the risk of preterm birth was increased by 42% among infected women. The risks of premature rupture of membranes and delivery of a small for gestational age infant also increased. Although it should be treated when identified, whether the successful treatment of trichomonas in pregnancy affects or decreases these risks is unclear.

The diagnosis of trichomonas is based on laboratory testing including motile trichomonads on wet mount, positive culture, positive nucleic acid amplification test, and positive rapid antigen test (Box 1). As with other types of vaginitis, none of the clinical features of trichomoniasis is sufficiently sensitive or specific to allow a diagnosis based upon signs and symptoms alone. The presence of motile trichomonads on wet mount is diagnostic of infection, but they are identified in only 50% to 70% of culture-confirmed cases. There should not be significant delay in viewing the wet prep slide for trichomonas as they only remain motile for 10 to 20 minutes after collection. Other findings suggestive, but not diagnostic, of trichomonas include an elevated vaginal pH (> 4.5) and an increase in PMNs on saline microscopy. Fixation and staining is not useful as trichomonads may lose morphologic characteristics during this process.

Culture (sensitivity over 80%) can be useful with a high clinical suspicion, but an absence of motile trichomonads on wet mount. However, PCR detection has become the new gold standard for diagnosis of trichomoniasis and can be used with a urine or vaginal specimen. Rapid and point-of-care tests are available for the diagnosis of *Trichomonas vaginalis* in women and men with sensitivities of 83%–86% compared with nucleic acid amplification tests (NAATs) and can be performed in approximately 15 min. (Gaydos 2017) Papanicolaou (Pap) smear should not be used as a diagnostic test or screen for trichomoniasis. However, asymptomatic women with trichomonads identified on a Pap smear can be treated empirically or further evaluated by wet mount, PCR detection, or culture.

Treatment of trichomoniasis

The nitroimidazoles, metronidazole (Flagyl) and tinidazole (Tindamax), are the only medications approved by the FDA for the treatment of trichomoniasis. In randomized clinical trials, the recommended metronidazole regimens have resulted in cure rates of approximately 90% to 95%, and the recommended tinidazole

BOX 2

Amsel Criteria for Diagnosis of Bacterial Vaginitis

At least 3 of the 4 criteria must be present:

1. Homogeneous, thin, grayish-white discharge that smoothly coats the vaginal walls
2. Vaginal pH > 4.5
3. Positive whiff-amine test, defined as the presence of a fishy odor when a drop of 10% potassium hydroxide (KOH) is added to a sample of vaginal discharge.
4. Clue cells: At least 20% of the epithelial cells clue cells (vaginal epithelial cells with adherent coccobacilli at the edge of the cell)

regimen has resulted in cure rates of approximately 86% to 100%. Topically applied antimicrobials such as metronidazole gel (MetroGel Vaginal)¹ are unlikely to achieve therapeutic levels in the urethra or perivaginal glands and are not recommended. Sex partners of patients with *T. vaginalis* should be treated. Treatment of patients and sex partners results in relief of symptoms, microbiologic cure, and reduction of transmission.

Bacterial Vaginosis (BV)

Bacterial vaginosis is caused by a shift in the normal bacterial vaginal flora with a decrease of lactobacilli and overgrowth of *Gardnerella vaginalis*, *Mycoplasma hominus*, and anaerobes. The normal acidic (pH 4–4.5) vaginal environment helps maintain the normal vaginal flora and inhibits growth of pathogenic organisms. Disruption of the normal ecosystem can lead to conditions favorable for development of bacterial vaginosis. Factors that are associated with bacterial vaginosis include multiple sex partners, a new sex partner, sexual activity, phase of the menstrual cycle, contraceptive choice, pregnancy, foreign bodies, estrogen level, sexually transmitted diseases, antibiotics, and douching.

In contrast to trichomonas and candidiasis, bacterial vaginosis is associated with only minimal inflammation and minimal irritative symptoms. Clinical indicators of bacterial vaginosis include Amsel's criteria (Box 2). If two or three of the criteria are present, the clinical diagnosis of bacterial vaginosis can be made with a 90% sensitivity and 77% specificity. The presence of more than 20% clue cells on microscopy is the most reliable single finding predictor of BV. The use of culture for the diagnosis of bacterial vaginosis is not useful or recommended because the organisms that tend to overgrow are normal vaginal flora.

Use of a Gram-stained smear of vaginal discharge is the diagnostic gold standard for diagnosis of BV, but is typically performed only in research studies. In clinical practice, the diagnosis of BV is usually based on Amsel criteria, which is easy to use at the point-of-care. Using Gram's stain as the standard for diagnosing BV, the sensitivity of Amsel criteria is over 90% and has a specificity of 77%. It may have false positives with trichomonas, as the first three Amsel criteria findings are sometimes present in patients with trichomoniasis. Commercial tests for diagnosis of BV are not commonly used, given the reliability and ease of Amsel criteria, but can be useful when microscopy is not available.

Changes suggesting bacterial vaginosis reported on a Pap smear do have good specificity but do not require treatment unless the patient is symptomatic (sensitivity 49%, specificity 93%). BV has been diagnosed using a swab of vaginal discharge obtained by the patient or clinician without speculum examination. However, omission of the speculum examination results in underdiagnosis and therefore is not ideal.

In pregnant patients, bacterial vaginosis has been associated with premature rupture of membranes (PROM), prematurity, chorioamnionitis, and low birth weight. In symptomatic patients, the treatment of bacterial vaginosis decreases those risks. In asymptomatic pregnant women, however, the effectiveness of treatments in reducing pregnancy-related risk is uncertain. There conflicting

BOX 1

Treatment of Trichomoniasis

Recommended Regimens

Metronidazole (Flagyl) 2 g orally in a single dose
OR

Tinidazole (Tindamax) 2 g orally in a single dose

Alternative Regimen

Metronidazole 500 mg orally twice a day for 7 days³

³Exceeds dosage recommended by the manufacturer.

¹Not FDA approved for this indication.

BOX 3 Treatment of Bacterial Vaginosis**Recommended Treatment Regimens**

Metronidazole 500 mg orally twice a day for 7 days¹
 Metronidazole gel (MetroGel-Vaginal) 0.75%, one full applicator (5 g) intravaginally, once a day for 5 days
 Clindamycin (Cleocin) cream 2%, one full applicator (5 g) intravaginally at bedtime for 7 days

Alternative Regimens

Tinidazole (Tindamax) 2 g orally once daily for 2 days
 Tinidazole 1 g orally once daily for 5 days
 Clindamycin 300 mg orally twice daily for 7 days¹
 Clindamycin ovules 100 mg intravaginally once at bedtime for 3 days

Recommended Regimens for Pregnant Women

Metronidazole 500 mg orally twice a day for 7 days
 Metronidazole 250 mg orally three times a day for 7 days
 Clindamycin 300 mg orally twice a day for 7 days

¹Not FDA approved for this indication.

data on treatment of bacterial vaginosis in high-risk women and no evidence of risk reduction in low-risk women. Therefore the current data does not support universal screening and treatment of asymptomatic patients during pregnancy.

Treatment of Bacterial Vaginosis

Treatment is recommended for women with symptoms (Box 3). Besides relief of symptoms, potential benefits to treatment include reduction in the risk of acquiring sexually transmitted diseases (STDs). Because of positive results for much of the Amsel criteria with both BV and trichomonas (and lack of microscopy sensitivity for trichomonas), using a metronidazole regimen that covers both of these diagnoses (500 mg twice a day \times 7 days)¹ may be reasonable when a patient meets the Amsel criteria. Treatment of male sex partners has not been beneficial in preventing the recurrence of BV. No data support the use of douching for treatment or symptomatic relief and it may increase the risk for relapse. Metronidazole appears to be safe in pregnancy, as multiple studies and meta-analyses have shown no association between its use during pregnancy and teratogenic or mutagenic effects in newborns. Several studies have evaluated the clinical and microbiologic efficacy of using intravaginal lactobacillus formulations to treat BV and restore normal flora, but further research is needed to determine possible utility.

Vulvovaginitis Candidiasis (VVC)

Candida is considered part of the normal vaginal flora, but overgrowth of the organism and penetration of superficial epithelial cells can result in vulvovaginitis. Vulvovaginal candidiasis often presents with marked inflammation, scant discharge, itching, dysuria, and dyspareunia (Box 4). Vulvar pruritus is typically the dominant symptom and erythema, excoriations, and fissures of the vulva and vagina may be present. There is often little or no discharge; when present, it is classically white, thick, adherent, and clumpy (cottage cheese-like) with no or minimal odor. The diagnosis of vulvovaginal candidiasis is based on history, examination findings, and the presence of *Candida* on wet mount or culture.

Candida albicans accounts for 80% to 92% of episodes of vulvovaginal candidiasis; *Candida glabrata* is the next most common species. For the diagnosis of a specific *Candida* species, a culture must be obtained, but culture is not necessary for diagnosis if microscopy shows yeast. A culture should be obtained in women with clinical features of vulvovaginal candidiasis, normal vaginal pH, and negative microscopy and in women with persistent or recurrent symptoms. Many of the women with recurrent symptoms have non-albicans

¹Not FDA approved for this indication.

BOX 4 Classification of Vulvovaginal Candidiasis (VVC)**Uncomplicated VVC**

Sporadic or infrequent vulvovaginal candidiasis
 Mild-to-moderate vulvovaginal candidiasis
 Likely to be *C. albicans*
 Non-immunocompromised women

Complicated VVC (if any of below apply)

Recurrent vulvovaginal candidiasis ($>$ 4 episode in 1yr)
 Severe vulvovaginal candidiasis (extensive vulvar erythema, edema, excoriation, and fissure formation)
 Non-albicans candidiasis
 Women with uncontrolled diabetes, debilitation, or immunosuppression

infection resistant to azoles. If the wet mount is negative and *Candida* cultures cannot be done, empiric treatment can be considered for symptomatic women with any sign of VVC on examination.

Treatment of Vaginal Candidiasis

Asymptomatic women and sexual partners do not require treatment. The treatment regimen is based on whether the woman has an uncomplicated infection (90% of patients) or complicated infection (Box 5). Treatment with oral or topical azoles results in symptom relief in 80% to 90% of patients who complete therapy, and are more effective than nystatin. Intravaginal antifungals are available over the counter, although unnecessary or inappropriate use of these preparations is common and can lead to a delay in appropriate treatment. In pregnant women, topical azole therapies, applied for 7 days, are recommended. Oral azole therapy should be avoided in pregnancy, as case reports have described a pattern of birth defects after first trimester exposure to high dose oral azole therapy.

Candida glabrata should be considered in those who do not respond to recommended therapy or have multiple recurrences. *Candida glabrata* does not form pseudohyphae or hyphae and is not easily recognized on microscopy, making diagnosis difficult without culture. The optimal treatment of non-albicans vulvovaginal candidiasis, such as *C. glabrata*, remains unknown but recommended regimens include an azole drug for a longer duration of therapy (7–14 days) (Box 6). If recurrence occurs, 600 mg of boric acid in a gelatin capsule^{1,6} administered vaginally once daily for 2 weeks is recommended.

Severe vulvovaginitis is characterized by extensive vulvar erythema, edema, excoriation, and fissure formation. It is associated

¹Not FDA approved for this indication.

⁶May be compounded by pharmacists.

BOX 5 Recommended Regimens for Uncomplicated VVC**Over-the-Counter Intravaginal Agents:**

Butoconazole (Femstat, Mycelex), clotrimazole (Gyne-Lotrimin), miconazole (Monistat), tioconazole (Vagistat)

Prescription Intravaginal Agents:

Butoconazole (Gynazole-1) 2% cream 5 g intravaginally for 1 day
 Nystatin 100,000-unit vaginal tablet, one tablet for 14 days
 Terconazole (Terazol-7, Zazole): 0.4% cream 5 g intravaginally for 7 days
 Terconazole (Terazol-3, Zazole): 0.8% cream 5 g intravaginally for 3 days
 Terconazole (Terazol-3, Zazole) 80 mg vaginal suppository, one suppository for 3 days

Oral Agent:

Fluconazole (Diflucan) 150 mg oral tablet, one tablet in single dose

Recurrent VVC Initial Regimen:

Any topical agent 7 to 14 days

OR

Fluconazole: 100, 150, or 200 mg orally once daily every third day for three doses³**Maintenance Regimens**Fluconazole 100- or 200-mg tab: 1 tab PO every week for 6 months³**Alternative Maintenance Regimens:**Clotrimazole 200-mg suppository (Gyne-Lotrimin 3): 1 suppository intravaginally qhs 2 ×/week³

Butoconazole 2% cream (Femstat-3, Mycelex-3): 1 applicator (5 g) intravaginally qhs for 3 days

Severe VVC:Any topical azole intravaginally once daily for 7 to 14 days
ORFluconazole 150 mg in two sequential doses (second dose 72 hours after initial dose)³³Exceeds dosage recommended by the manufacturer.

with lower clinical response rates in patients treated with short courses of topical or oral therapy. Recurrent vulvovaginal candidiasis (RVVC) is usually defined as four or more symptomatic episodes in 1 year. Routine treatment of sex partners in women with RVVC is controversial and does not appear effective. Vaginal cultures should be obtained from patients with RVVC to confirm the clinical diagnosis and to identify unusual species (including non-albicans species), particularly *Candida glabrata*. Each episode of RVVC caused by *Candida albicans* tends to respond well to short-duration oral or topical azole therapy. However, for

recurrent infections, some specialists recommend a longer duration of therapy before initiating a maintenance antifungal regimen. Suppressive maintenance antifungal therapies are effective in preventing episodes, but 30% to 50% of women will have recurrent disease when maintenance therapy is stopped.

Immunocompromised populations including pregnant women, diabetics with poorly controlled diabetes, women with HIV or other immunocompromised disease, and patients receiving immunosuppressive therapy need special considerations. This population does not respond well to short duration treatment and requires longer courses of 7–14 days. Vulvovaginitis due to *Candida albicans* is common in pregnancy and only topical azoles for 7 days are recommended.

ANTEPARTUM CARE

Method of

Matthew Cline, MD; and Nata Young, MD

CURRENT DIAGNOSIS

- Pregnancy evaluation should begin 3 to 6 months before conception with optimization of underlying medical conditions, update of immunizations, and commencement of prenatal vitamins with 400 µg of folic acid.¹
- Preconception counseling with a specialist in high-risk pregnancies should be considered in all patients with underlying medical conditions, such as diabetes and hypertension.
- Early ultrasound (< 13 weeks) assists with establishment of accurate estimated date of confinement and is an essential task in the first prenatal visit.
- The first prenatal visit should include a review of the medical and obstetric histories, current medications, allergies, herbal remedies, supplements, and tobacco, alcohol, and drug use.
- Prenatal laboratory studies should be done at the first visit after a pregnancy is confirmed with a urine pregnancy test. These studies include hemoglobin, platelet count, type and screen, rubella status, hepatitis B screening, rapid plasma reagin, and a urine culture. All women should be offered screening for HIV. High-risk patients should be screened for hepatitis C, gonorrhea, and chlamydia.
- Genetic screening should be offered based on ethnic history.
- Either first-trimester screening (nuchal translucency combined with maternal serum pregnancy-associated plasma protein A [PAPP-A]/free β-human chorionic gonadotropin [β-hCG]) or second-trimester quadruple screen should be offered to all patients. These tests aid in diagnosis of chromosome abnormalities. If a patient opts for a first-trimester screen, it is important to perform an alpha-fetoprotein (AFP) screen in the second trimester to screen for neural tube defects. Women 35 years and older should be offered amniocentesis for genetic screening.
- Appropriate weight gain in pregnancy depends on maternal body mass index (BMI) before pregnancy. In patients with a normal BMI, a 25- to 30-pound weight gain is recommended. Underweight patients are encouraged to gain 30 to 35 pounds, and overweight patients are encouraged to gain no more than 20 pounds.
- Prenatal visits should begin at 8 to 12 weeks' gestation and continue monthly until 28 weeks. Visits should then be every 2 weeks until 36 weeks and then weekly. Each visit should include assessment of maternal weight, blood pressure (BP), fundal height measurement, documentation of fetal heart tones, and review of symptoms of preterm labor and preeclampsia.
- All patients should undergo a glucose challenge test at 24 to 28 weeks. This is done nonfasting by administering a 50-g load

of glucose and obtaining a serum sample 1 hour after administration. A level greater than 140 mg/dL is considered abnormal, and a 3-hour glucose tolerance test is indicated (which is done after a 12-hour fast with a 100-g oral glucose load). If a woman demonstrates abnormalities in two of the four values, gestational diabetes is diagnosed.

¹Not FDA approved for this indication.

CURRENT THERAPY

- Administration of the inactivated influenza vaccine (Fluzone, Fluvirin, Fluvarix) is recommended in all pregnant patients, regardless of trimester, who will be pregnant (or up to 3 months postpartum) during the flu season.
- Additionally, recent recommendations support Tdap vaccine (Adacel, Boostrix) in each pregnancy given between 27 and 36 weeks or immediately postpartum in order to decrease rates of pertussis in this age group.
- An updated listing of vaccination recommendations throughout pregnancy (including international travel) can be found at www.cdc.gov/vaccines/pregnancy/hcp/guidelines.html
- Folic acid supplementation should begin before conception. The recommended dose is 400 µg daily and is usually given as a prenatal vitamin. In patients with a previous pregnancy complicated by a neural tube defect, 4 mg daily is recommended to decrease the chance of recurrence of a neural tube defect.
- Pyelonephritis requires hospitalization and intravenous (IV) antibiotics in all pregnant patients. IV antibiotics should be continued until the patient is afebrile for longer than 24 hours. Oral antibiotics should then be commenced to complete a 14-day course. All patients should continue on suppressive antibiotic therapy until delivery after a diagnosed single episode of pyelonephritis or two episodes of cystitis.
- All patients with HIV should be treated with appropriate HAART (highly active anti-retroviral therapy) for the patient and her HIV viral type throughout the pregnancy.
- Intrapartum zidovudine (Retrovir) is recommended for all patients with HIV whose HIV RNA load is ≥ 50 copies/ml or who have concerns with adherence to HAART therapy. Consideration of cesarean delivery is appropriate based on viral load evaluation.

Antepartum Care

Ideally, antepartum care commences 3 months before conception with the recommendation that women who are sexually active and not using contraception should begin taking daily multivitamin or folic acid supplements. The most convincing trials of this were performed in Europe and China when it was concluded that women of reproductive age should take multivitamin supplements containing 0.4 mg of folate daily to reduce the incidence of neural tube defects. Women with histories of children with neural tube

BOX 1 Potential Indications for High-Risk Referral

- Current disease involving renal, cardiac, or endocrine systems
- Fetal anomalies (in previous pregnancies or first-degree family relatives)
- History of preterm delivery
- Incompetent cervix
- Isoimmunization
- Known carrier of genetic disorder
- Multiple gestation
- Placenta previa after 28 weeks
- Prior intrauterine fetal demise or stillbirth
- Systemic diseases such as hypertension, diabetes, or asthma
- Third-trimester bleeding

defects or other anomalies should increase this dose to 4 mg³ of folate in the periconceptional period to reduce risks of recurrence.

Preconception counseling should also include an accurate assessment of preexisting maternal medical conditions. This is the ideal time to stress changes in factors that respond to early intervention: quitting smoking, refraining from alcohol or drug abuse, treating gum disease, and avoiding teratogens. Alcohol is a known teratogen. Immunization status should be reviewed and vaccines should be administered as appropriate. Special consideration is given to patients with thyroid disease. Concern focuses on associations with low intelligence quotients (IQs) in children conceived by hypothyroid mothers. Patients with diabetes should be counseled that the increased risk of birth defects is directly related to the level of glucose control at conception.

High-risk obstetric referrals may be offered to women with potential for obstetric complications suggested by conditions listed in **Box 1**. Identification of the high-risk patient is critical to minimizing adverse outcomes.

In most cases, a woman's pregnancy is a normal event that is complicated by potentially dangerous disease in a minority of cases. The physician who manages pregnant patients must follow the normal changes that occur during antepartum care, so that abnormalities can be recognized and treated appropriately. Additionally, routine prenatal care offers multiple opportunities for patient education, primary intervention, and appropriate monitoring of the low-risk pregnancy in the setting of the family and community. For some women, antepartum care is part of their own continuum in a long-term primary care relationship with caregivers.

Timeline of Routine Antepartum Care

First Visit and Early Care

History

After pregnancy is confirmed, it is extraordinarily important to determine the duration of pregnancy and the estimated date of confinement (EDC). Further care is heavily predicated on this estimate. The history begins with ascertaining the first day of the last normal menstrual period and calculating the EDC by assuming duration of pregnancy averages 280 days (40 weeks). Because a first-trimester dating ultrasound (US) is accurate to within 5 days at confirmation or determination of an accurate EDC, its value cannot be overestimated.

The documentation of prior obstetric history includes prior complications, route of delivery, and estimated birth weights. Maternal medical disorders are often exacerbated by pregnancy; cardiovascular, renal, and endocrine disorders require evaluation and counseling concerning possible treatments required. A history of previous gynecologic surgery, including cesarean delivery, is

important to consider. A family history of twinning, diabetes mellitus, familial disorders, or hereditary disease is relevant.

Current medications (prescription and nonprescription) are reviewed, along with any herbals or supplements. Certain prescription medications are known teratogens and should be discontinued. Examples include isotretinoin (Accutane), tetracycline (Sumycin), quinolone antibiotics (ciprofloxacin [Cipro], levofloxacin [Levaquin]), and warfarin (Coumadin). Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should not be used in pregnancy because they can be associated with renal agenesis.

Open discussion of substance abuse (alcohol, tobacco, and illicit drugs) is an integral part of the patient interview. Counseling patients about smoking cessation is vital in early pregnancy. Smoking increases the risk of fetal death or damage in utero. It is also associated with increased risk of placental abruption and placenta previa, each of which put both mother and child at risk, along with premature birth. The interest that pregnant women have in delivering a healthy infant can be a potent motivator for change at this point.

Domestic Violence Screening and Counseling

1. Pregnancy is also a time of increased incidence of domestic or intimate partner violence, and because of this, it is appropriate to screen patients about the safety of their homes and relationships starting at the first prenatal visit. The United States Preventive Services Task Force (USPSTF) gives screening for domestic or intimate partner violence a "B" rating, supporting its use in routine prenatal care. A large evidence review supports benefit to patients being screened with one of many possible screening tools. The Personal Violence Screen consists of three "Yes" or "No" questions that can be quickly administered to a patient in private, and a positive result is one or more "Yes" responses:
2. Have you been hit, kicked, punched, or otherwise hurt by someone in the past year?
3. Do you feel unsafe in your current relationship?
4. Is there a partner from a previous relationship who is making you feel unsafe now?

A positive screen should be followed by specific referral to local resources for the patient to reach a safe environment and continued support. Each office should evaluate local resources and have a prepared contact list for these patients to use as their next step to safety.

Examination

Physical examination begins with a thorough general examination to assess maternal well-being, including BMI and BP. The BMI is calculated by dividing weight in kilograms by height in meters squared. The BMI of a patient is categorized as underweight (under 19.8), normal weight (19.8 to 25), overweight (25 to 30), or obese (over 30).

Breast examination may be significant for changes in pregnancy that result from hormonal responses by the mammary ducts. These changes include engorgement and vascular prominence, occasionally resulting in mastodynia. Enlargement of areolar sebaceous glands occurs between 6 and 8 weeks' gestation.

A pelvic examination is performed with attention to the adequacy of pelvis and evaluation for adnexal masses. Numerous changes in the pelvic organs occur in pregnancy. For example, congestion of the pelvic vasculature (Chadwick's sign) causes bluish discoloration of the vagina and cervix. Softening of the cervix due to increased vascularity of the cervical tissue (Goodell's sign) can occur as early as 4 weeks.

Portable devices using Doppler will reliably detect fetal heart tones at a normal rate of 120 to 160 beats per minute as early as 11 weeks.

Laboratory Studies

Routine laboratory studies and screenings in pregnancy are listed in **Table 1**, along with their USPSTF level of recommendation.

³Exceeds dosage recommended by the manufacturer.

TABLE 1 U.S. Preventive Services Task Force Recommendations for Pregnancy

Grade A = The USPSTF recommends the service. There is high certainty that the net benefit is substantial. Screening/actions in pregnancy in this category include the following:

- Screen for asymptomatic bacteriuria at 12–16 weeks or at first prenatal visit.
- Screen for hepatitis B infection in all pregnant women.
- Screen for HIV infection in all pregnant women.
- Screen for syphilis in all pregnant women.
- Screen for cervical cancer in all women between 21 and 65 who have a uterus.
- Ask about smoking and provide augmented, pregnancy-tailored counseling for those who smoke and are pregnant.
- All women planning or capable of pregnancy should take 400–800 µg of folic acid daily.

Grade B = The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial. Screening/actions in pregnancy in this category include the following:

- Screen for chlamydia in pregnant women 24 and younger or at high risk.
- Screen for gonorrhea if at high risk of infection.
- Provide intervention during pregnancy and after birth to support breast-feeding.
- Screen for alcohol misuse and provide behavioral counseling interventions to reduce its misuse.
- For women at high risk of preeclampsia, start low-dose aspirin¹ at 81 mg/day after 12 weeks of gestation.
- Screen for gestational diabetes mellitus (GDM) in asymptomatic pregnant women after 24 weeks of gestation.
- Screen for depression in pregnant and postpartum women.
- Screen women of childbearing age for intimate partner violence (IPV), such as domestic violence, and provide or refer women who screen positive to intervention services.

Grade C = Clinicians may provide this service to selected patients depending on individual circumstances. However, for most individuals without signs or symptoms there is likely to be only a small benefit from this service.

Grade D = The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.

- Screen for bacterial vaginosis in asymptomatic pregnant women at low risk for preterm birth.
- Screen for herpes simplex with serology in asymptomatic pregnant women.

Grade I = The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service.

- Screen for iron deficiency anemia in asymptomatic pregnant women.

Listing of all topics is available at <http://www.uspreventiveservicestaskforce.org/uspsttopics.htm>.

Abbreviation: USPSTF = U.S. Preventive Services Task Force.

Other Studies

Special-purpose studies are also considered in early gestation. First-trimester screening with nuchal translucency should be offered to all women between 11 and 13 weeks' gestation. The first-trimester screen uses the nuchal translucency and maternal serum-free β -hCG and PAPP-A and detects up to 85% of Down syndrome and trisomy 18 cases with a false-positive rate of 5%.

Cell-free DNA screening has been utilized primarily after 10 weeks in high-risk women such as those with prior aneuploidy, or older than age 35. However, there is now evidence using cell-free DNA screening in the general population, and results appear to be comparable. It has the highest detection rate (DR) for Down syndrome in high-risk women (98% DR with positive screening rates of less than 0.5%, positive predictive value of 93%). Positive predictive values are lower for trisomy 18 (64%), trisomy 13 (44%), and sex chromosome aneuploidies (39%). However, it must be emphasized that for younger or low-risk women, false positive rates will be higher because of a lower pretest probability in these populations. In addition, the test cannot distinguish between fetal

and maternal DNA, and causes of false positive screening tests can include placental mosaicism, a resorbing twin, or even maternal malignancy or aneuploidy. For this reason, ACOG recommends diagnostic testing with CVS or amniocentesis after a positive cell-free DNA screen prior to decisions about termination of the pregnancy. Cell-free DNA screening testing after a positive first trimester screen can also add additional information prior to diagnostic invasive tests. Appropriate pre and posttest counseling is important due to these evolving issues.

Chorionic villus sampling (CVS) (done at 10–12 weeks' gestation) or amniocentesis (performed at 14–16 weeks' gestation) should be offered to women older than 35 years, to those with abnormal first-trimester screens or second trimester “quad” screens, and to those with significant family history of genetic disease. From either test, fetal cells grown in culture may be subjected to chromosomal, metabolic, or DNA study for trisomy 13, 18, or 21 or abnormal numbers of sex chromosomes. CVS cannot be used for diagnosis of neural tube defects, but amniocentesis can accurately diagnose open neural tube defects or open abdominal defects by measuring amniotic fluid AFP.

Patients with tuberculosis exposure may be assessed for active tuberculosis with skin testing (if not vaccinated with Bacillus Calmette-Guérin [BCG]) and chest x-ray with abdominal shielding. Serologic assessment for toxoplasmosis, cytomegalovirus, and varicella immunity are not routinely indicated.

Currently it is recommended that all pregnant couples of Caucasian background be screened for being carriers of cystic fibrosis genes. Additionally, screening for genetic disorders should be undertaken if concern exists based on racial or ethnic background (hemoglobinopathies, β -thalassemia, α -thalassemia, Tay-Sachs disease) or familial background (cystic fibrosis, fragile X, Duchenne's muscular dystrophy).

Education

Several areas are appropriate for routine education during the first prenatal visit, and may be provided by handouts, nursing instruction, or directly by the physician. These will vary based on the patient's individual knowledge and prior experience, but at a minimum should include discussions of the following:

- Common discomforts of pregnancy and safe methods to relieve them
- Foods to avoid during pregnancy and safe food preparation
- Avoidance of tobacco, ethanol, and nonprescribed drugs throughout pregnancy
- Limitations on travel and importance of proper seatbelt use
- Danger signs of pregnancy and reasons to call or be seen after hours
- Availability of birth education classes, tours, and other educational resources

Follow-up

Follow-up visits are scheduled once monthly until 28 weeks' gestation, and then patients are followed twice monthly until 36 weeks. Visits are then scheduled at weekly intervals until delivery. At each visit, weight, BP, fetal heart tones, and fundal height are noted. In the last 6 weeks of pregnancy, assessing fetal position is also appropriate.

Interval history includes questions about diet, sleeping patterns, and fetal movement. Warning signs such as bleeding, contractions, leaking of fluid, headache, or visual disturbances are reviewed.

15 to 20 Weeks' Gestation

Interval History

At each visit, it is appropriate to ask about specific symptoms: headache, dysuria, swelling, vaginal discharge, any bleeding, pelvic pain, and nausea or vomiting. The nausea and vomiting of the first trimester usually begins to decrease after 12 to 14 weeks. By this point in the pregnancy, the patient is usually feeling well. The other items above, if present, may indicate reasons for a targeted examination to evaluate for the cause, such as a speculum examination

with wet prep for an increased symptomatic discharge (though the physiologic discharge of pregnancy has often become evident by this point, it should be asymptomatic).

Alpha-Fetoprotein and Aneuploidy Testing

For patients who received first-trimester aneuploidy screening, maternal serum AFP testing should be offered for all pregnancies at 16 to 20 weeks as a means of screening for open neural tube defects. High levels of AFP are associated with various fetal anomalies, including neural tube defects, multiple gestations, and ventral wall defects. Unexplained elevation of AFP has been associated with poor fetal growth, fetal loss, and preeclampsia. In cases with unexplained elevation of AFP, maternal and fetal surveillance should be increased. Low levels of AFP are associated with increased risk of Down syndrome.

For those who did not have the first trimester screen, a “quad screen” with multiple analytes can be done at this time to screen for aneuploidy such as trisomy 21, 18, and 13 as well. The interpretation of this test depends on the gestational age; even if timed correctly, it is known to have a moderate level of false-positive results. Therefore the first step after an abnormal AFP or quad screen is to refer for a detailed ultrasound to confirm gestational age. If the results of the screening remain abnormal, definitive testing via amniocentesis is recommended.

Physical Findings

Interval changes in the physical examination now include the start of colostrum secretion, which can begin as early as 16 weeks' gestation. The mother might detect fetal movements (quickening) at around 18 to 20 weeks. The uterus is palpable at 20 weeks at the umbilicus.

Chloasma is darkening of the skin over the forehead, bridge of the nose, or cheekbones and is more obvious in those with dark complexions. It can begin to manifest at this time, and is intensified by exposure to sunlight. Darkening of the skin in the areolae and nipples becomes more accentuated. A darkened line appears in the lower midline of the abdomen from the umbilicus to the pubis (linea nigra). The basis of these changes is stimulation of melanophores by increased melanocyte-stimulating hormone.

At 15 to 20 weeks, abdominal enlargement can appear more rapid as the uterus rises out of the pelvis and into the abdomen.

Ultrasonography

Sonography has long established itself as the single most useful technology in monitoring pregnancy and diagnosing complications. It is for this reason that an anatomic US is offered at 18 to 20 weeks to evaluate growth, placentation, amniotic fluid volume, and fetal anatomy. If earlier dating of the pregnancy is uncertain, this is an opportunity to confirm or refute prior estimates. If anomalous conditions are discovered or the patient has a history of diabetes, advanced maternal age, or has prior children with anomalies, more comprehensive US becomes necessary.

20 to 35 Weeks' Gestation

Interval History

This period in the middle trimester of the pregnancy is often the time when patients feel their best: the challenges of nausea and vomiting from the first trimester are usually past. Patients should be asked about diet and activity, fetal activity (which should continue to increase throughout this period), and any symptoms that might suggest preeclampsia, such as hand or face swelling, visual changes, or severe headaches. Vaginal secretions do increase during this period but any bleeding or leakage of a large amount of fluid, along with any uterine rhythmic contractions, should also prompt a call or evaluation of the patient.

Physical Findings

The uterus should be palpable at the umbilicus at 20 weeks, and from this period until 34 weeks the measurement in centimeters from the fundus to the symphysis pubis should correspond to

the gestational age in weeks. Measurements that are more than 2 cm below the expected size should raise suspicion for oligohydramnios, intrauterine growth restriction, fetal anomalies, or an abnormal fetal position. Conversely, measurements more than 2 cm larger than expected may indicate multiple gestation, polyhydramnios, or fetal macrosomia. These rules apply for the gestational ages of 20 to 32 weeks. Either situation can be evaluated with maternal US examination and consultation with a maternal-fetal-medicine specialist.

New physical examination findings at this time include the onset of stretch marks (striae) of the breasts and abdomen. These are caused by separation of underlying collagen tissue, a response to increased adrenocorticosteroid. The ligamentous structures of the pelvis also undergo slight but definite relaxation of the joints, a progesterone effect. As the uterus enlarges, it often rotates to the right. Braxton-Hicks contractions, characterized as painless uterine tightening, increase in regularity. The fetal outline can be easily palpated through the maternal abdominal wall.

Laboratory Studies

Increased surveillance for preeclampsia should occur in any patient with a previous history of preeclampsia or chronic hypertension predating the pregnancy. Newer guidelines require only two blood pressures 4+ hours apart that are 140/90 or greater for the diagnosis of preeclampsia along with 1+ urinary protein, a urinary protein to creatinine ratio of 0.3 or greater, or > 300 mg of protein in a 24-hour urine collection. Further evaluation for patients with elevated BP (>140/90) should include evaluation for symptoms or findings that are consistent with severe features: headaches, visual changes, pulmonary edema, RUQ pain or epigastric pain, BP of 160 or higher systolic or 110 or higher diastolic on two occasions 4 hours apart, or laboratory evidence of thrombocytopenia (platelets below 100,000), liver transaminases elevated to at least twice the normal level, a serum creatinine that has doubled or is greater than 1.1. If any severe feature is present, the diagnosis of preeclampsia does not require proteinuria. Once the diagnosis of preeclampsia is made, management will be based on gestational age as well as presence of severe features. For additional details, please see chapter “Hypertension in Pregnancy.”

A complete blood count (to screen for anemia) and a nonfasting 1-hour glucose tolerance test (after ingestion of 50 g of glucose) are scheduled to detect patients at risk for developing gestational diabetes at 24 to 28 weeks. If the screening test is abnormal, a 3-hour test is performed with 100 g of glucose to confirm the diagnosis. Two or more abnormal values on this test are considered diagnostic of gestational diabetes mellitus.

A repeat Rh antibody is checked at 28 weeks' gestation in Rh-negative mothers. Those who remain unsensitized at 28 weeks' gestation receive a first dose of Rho(D) immune globulin (RhoGAM) of 300 µg to prevent maternal isoimmunization to fetal red blood cells. (This should also be given at any point after the first 12 weeks of pregnancy in the setting of significant maternal trauma in an Rh-negative mother. If there is suspicion of a significant fetal-maternal hemorrhage, a Kleihauer-Betke test can be used to quantitate the amount of fetal blood in the maternal circulation in order to increase the dose of RhoGAM appropriately.)

Follow-up

Return visits at 2-week intervals are initiated beginning at 28 weeks, and the patient is oriented to the labor and delivery ward. Precautions are given regarding the onset of conditions listed in Box 2. The onset of any of these should prompt immediate medical attention.

36 to 41 Weeks' Gestation

Physical Findings

Patients often note increased vaginal discharge at this time in their pregnancy, a physiologic consequence of hormone stimulation. The discharge consists mainly of epithelial cells and cervical mucus and is treated with reassurance. Discharge accompanied by itching,

- Burning with urination
- Chills or fever
- Prolonged vomiting or inability to keep liquids down
- Pronounced decrease in fetal movements
- Rhythmic cramping pains (> 4/hr)
- Rupture of membranes
- Severe abdominal, pelvic, or back pain
- Signs of preeclampsia (headache, edema, right upper quadrant pain, visual changes)
- Vaginal bleeding (though spotting may occur after any pelvic examination)

burning, or malodor should be evaluated with a wet prep and any abnormalities treated.

Laboratory Studies

Vaginal and rectal rapid molecular tests are collected to evaluate for the presence of group B streptococci (GBS) at 35 to 37 weeks. GBS organisms are implicated in preterm labor, amnionitis, endometritis, and wound infection. If cultures are positive, the patient will be given antibiotic prophylaxis during active labor to protect the newborn against vertical transmission and the resulting infection that could occur. If a patient has a positive urine culture during the pregnancy of over 100,000 colony-forming units of GBS, she is treated at the time of that culture but also assumed to be heavily colonized and given intrapartum antibiotics without performing the vaginal/rectal cultures at 35 to 37 weeks.

Follow-up

Follow-up visits are planned on a weekly basis with emphasis on weight gain, BP, and signs of preeclampsia. Review of precautions regarding infection, pregnancy loss, and symptoms of preeclampsia completes the visit.

Postterm Gestation

About 3% to 12% of pregnancies continue beyond 42 weeks' gestation and are considered postterm. Although some of these may be due to inaccurate dating, some patients clearly progress to excessively long gestations that are a significant risk to the fetus. Increased antepartum surveillance by cervical examination, fetal heart rate testing (such as nonstress testing [NST]), and biophysical profile should be initiated between 41 and 42 weeks. Even if fetal testing is reassuring, patients with reliable dating greater than 41 weeks are candidates for induction of labor.

Common Concerns of the Antenatal Period

Bleeding

About one-half of pregnant women experience some form of bleeding during the pregnancy; often this is benign. Patients also have a heightened awareness of symptoms that previously may have gone unnoticed in the nonpregnant state. Efficient and competent evaluation, followed by compassion and reassurance when prudent, allays many fears and provides clear direction. Spotting due to bleeding at the implantation site occurs from the time of implantation (about 6 days after fertilization) until 29 to 35 days after the last menstrual period in many women. Usually, cardiac activity on US and appropriate β -hCG levels confirm a viable early pregnancy. First-trimester bleeding may be a sign of spontaneous miscarriage or ectopic pregnancy and deserves further evaluation, often with a pelvic examination and US. Vaginal bleeding in late pregnancy is covered in other chapters.

Nausea

Nausea is a common symptom that occurs in most pregnancies. It is heightened before 14 weeks' gestation and is largely benign. The

etiology is not well understood but likely is related to elevating levels of β -hCG. Nausea of pregnancy can occur at any time during the day. Aggravating factors vary with the individual patient; success varies with interventions designed to reduce symptoms.

Uncomplicated nausea may be responsive to small nonfatty portions at mealtime. Pyridoxine (vitamin B₆)¹ tablets 12.5 mg three times daily with 12.5 mg of doxylamine (Unisom)¹ twice a day are safe in pregnancy and may be helpful. A combination product of doxylamine 10 mg and pyridoxine 10 mg (Diclegis) is approved by the FDA for the treatment of nausea and vomiting of pregnancy in women who do not respond to conservative management. Antiemetic drugs in the outpatient setting are the next step; ondansetron (Zofran, FDA category B)¹ 4 to 8 mg up to three times a day and metizline (Antivert, FDA category B)¹ 12.5 to 25 mg three times a day are agents with the best safety profile.

Inability to control protracted vomiting in conjunction with clinical dehydration can require hospitalization for IV fluids and treatment of hyperemesis gravidarum. Extreme nausea and vomiting that persists beyond 18 to 20 weeks' gestation may be a sign of multiple gestation, thyroid disease, molar pregnancy, or liver or pancreatic disease.

Nutrition and Weight Gain

The mother's nutrition is a vital factor in the development of the fetus from preconception through the postpartum period. Therefore, the pregnant woman should be advised to eat a balanced diet and should be informed of the additional 300 kcal/day needed during pregnancy. The American College of Obstetricians and Gynecologists (ACOG) recommends a target weight gain of 22 to 27 pounds (10–12 kg) during pregnancy. It also advises that underweight women might need to gain more and obese women should gain less. Nutritional requirements for protein are 80 g/day, for calcium are 1500 mg/day, for iron are 30 mg/day, and for folate are 0.4 mg/day (4 mg/day in some cases, such as those patients with previous baby with neural tube defects). Patients with seizure disorders managed with valproic acid (Depakene) or carbamazepine (Tegretol) are also at risk for birth defects and might benefit from the higher dose of folate.

Heartburn

Heartburn in the form of reflux esophagitis is caused by the enlarging uterus displacing the stomach and by progesterone's relaxation of the lower esophageal sphincter. Treatment consists of taking antacids, decreasing exacerbating factors such as spicy foods, eating more frequently but in smaller quantities, limiting eating before bedtime, and taking H₂-receptor inhibitors.

Urinary Symptoms

Urinary frequency, nocturia, and bladder irritability are common complaints due to progesterone-mediated relaxation of smooth muscle and subsequent altered bladder function. Later in pregnancy, urinary frequency becomes even more prominent from pressure on the bladder by the enlarging uterus and the fetal presenting parts, such as when the fetal head descends into the pelvis.

Dysuria, however, is often a sign of infection that requires antibiotic treatment. Bacteriuria combined with urinary stasis from altered bladder function predisposes the patient to pyelonephritis. Although simple urinary tract infections are treated on an outpatient basis, pyelonephritis remains the most common nonobstetric cause for hospitalization during antenatal care.

Patients with a diagnosis of pyelonephritis require hospitalization, aggressive fluid replacement, and IV antibiotics until they remain afebrile for longer than 24 hours. Close monitoring of maternal respiratory status is important because these women are at risk for acute respiratory distress syndrome (ARDS) and renal failure as well as a significant increase in preterm labor

¹Not FDA approved for this indication.

and delivery. All patients should complete a 14-day course of antibiotic treatment. After treatment has been completed, suppressive therapy should be continued until delivery.

Infection

Two infections of special note are HIV and bacterial vaginosis (BV). HIV transmission to the newborn can be reduced significantly with appropriate infectious disease and maternal-fetal medicine specialty management. Although all symptomatic pregnant women with BV should be treated, evidence is inconclusive for screening and treating asymptomatic women, even those with a high risk history of prior preterm delivery or PPRM. Because of well-documented safety and efficacy of oral¹ and vaginal metronidazole, and vaginal clindamycin cream, any of these three are considered first-line for treatment in pregnancy.

Chlamydia trachomatis is an obligate intracellular bacterium and is the most common sexually transmitted bacterial infection in women of reproductive age. It may be associated with urethritis, mucopurulent cervicitis, and acute salpingitis, or it may be clinically silent. Perinatal transmission is clearly associated with neonatal conjunctivitis (leading to blindness) and pneumonia and is likely associated with preterm delivery, premature rupture of membranes, and perinatal mortality. Diagnosis is confirmed by polymerase chain reaction (PCR) during routine screening. Doxycycline should be avoided in pregnancy, and erythromycin is associated with gastrointestinal upset, so treatment with azithromycin (Zithromax 1000 mg as single dose) is often the best choice in pregnancy.

Gonococcal infection is associated with concomitant chlamydia infection in about 40% of infected pregnant women. It is usually limited to the lower genital tract, including the cervix, urethra, and periurethral or vestibular glands. Because of an association between gonococcal cervicitis and septic spontaneous abortion, and because preterm delivery, premature rupture of membranes, and postpartum infection are more common with gonococcal infection, routine cultures are appropriate at the first antenatal visit. Because some strains have rendered some β -lactam drugs ineffective for therapy, the recommendation for uncomplicated gonococcal infection is intramuscular ceftriaxone (Rocephin) 250 mg plus azithromycin (Zithromax) 1g orally as a single dose.

Vaginosis due to *Candida albicans* can become symptomatic with caseous white discharge and vaginal itching or burning, and it may be associated with red satellite lesions on the vulva. Marked inflammation of the vagina and introitus may be noted. Topical application of over-the-counter antifungal creams such as miconazole nitrate (Monistat) or nystatin (Mycostatin) is generally helpful in controlling the imbalance of vaginal flora, but this requires a 7-day regimen to achieve adequate cure rates. A single dose of fluconazole (Diflucan), 150 mg by mouth, is another appropriate choice, but only after the first trimester.

Trichomonas vaginalis can be found in 20% to 30% of pregnant patients, but only a small number complain of discharge or irritation. This flagellated, oval, motile organism can be seen on normal saline wet prep and is evident clinically by presence of a foamy or greenish discharge accompanied by multiple cervical petechiae. The CDC now recommends highly sensitive and specific nucleic acid amplification test (NAAT) in testing for trichomonads (95.3–100% sensitive, 93.2–100% specific for the APTIMA T. vaginalis test), as wet prep microscopy is rather insensitive (51–65%). There are also several new point-of-care tests that are now FDA-approved using antigen detection or DNA hybridization probe technology that have results available in as little as 10 minutes (OSOM *Trichomonas* rapid test) to 45 minutes (Affirm VP III). Treatment is oral metronidazole (Flagyl) as a single 2-g dose for the patient and her partner (though most states support

expedited partner treatment, each practitioner will need to individualize this approach).

Rubella, also known as German measles, is directly responsible for spontaneous miscarriage and severe congenital malformations. Although large epidemics of rubella are nonexistent in the United States because of immunization, the disease can still affect up to 25% of susceptible women. Absence of rubella antibody indicates susceptibility. Vaccination involves an attenuated live virus (MMR) and therefore is avoided in pregnancy. Vaccination of non-pregnant susceptible women (including those during the postpartum period) and hospital personnel continues to be the mainstay of therapy. Detection by immunoglobulin M (IgM)-specific antibody confirms recent infection.

Varicella-zoster virus, the etiologic agent of childhood chickenpox, is a DNA herpes virus that remains latent in the dorsal root ganglia and may be reactivated years later to cause herpes zoster or shingles. Infection early in pregnancy can lead to severe congenital malformations, including chorioretinitis, cerebral cortical atrophy, hydronephrosis, and cutaneous and bony leg defects. Varicella-zoster immunoglobulin (VariZIG) (30–40 kg: 500 U; ≥ 40.1 kg: 625 U) can attenuate varicella infection if given to an exposed, nonimmune pregnant woman within 96 hours of her exposure to a patient with active varicella.

Genital herpes simplex virus (HSV) can present at any gestational age and is characterized by multiple, painful genital ulcers or vesicles; the diagnosis can be confirmed (if not in labor) through use of PCR laboratory testing. If active genital lesions are noted in labor, cesarean delivery is indicated because the fetus is at risk for acquiring the virus during passage through the birth canal. For HSV outbreaks remote from term, acyclovir (Zovirax) and its derivatives can shorten the course of an outbreak. For those with a history of active herpes during or preceding pregnancy, prophylaxis with acyclovir from 36 weeks onward can decrease the chance of an outbreak at term and the need for a cesarean delivery.

Influenza can occur during pregnancy, and because the risk of secondary complication such as pneumonia is increased during the antepartum period, influenza vaccination is recommended for all patients in any trimester who are pregnant or up to 3 months postpartum during the local influenza season. Rapid testing of nasal or throat swabs can ascertain the diagnosis of influenza. Though oseltamivir (Tamiflu) and zanamivir (Relenza) are both FDA category C in pregnancy, no toxic effects have been observed in animal trials, so these are the preferred agents. These agents need to be started within 72 hours of the onset of symptoms to provide benefit, and they provide the greatest improvement in symptom duration and severity if started in the first 24 hours.

Varicose Veins

Pressure by the enlarged uterus on venous return from the legs and progesterone-mediated vasodilation can lead to prominent varicosities and edema of the legs or vulva. Any concern for deep vein thrombosis should be ruled out with duplex ultrasound imaging. Benign varicosities almost invariably return to normal after delivery, thus limiting the need for intervention in the antepartum period, though their symptoms may be decreased through the wearing of support hose. Edema of the lower extremities is common, responds to elevation, and must be differentiated from facial or hand edema accompanying preeclampsia. Hemorrhoids are manifestations of the varicosities of the rectal veins. Treatment focuses on stool softeners, sitz baths, and over-the-counter topical preparations. If a hemorrhoid becomes firm and tender, evaluation for possible treatment by opening and removing the thrombus can provide immediate relief.

Constipation

Bowel transit time and relaxation of intestinal smooth muscle are both increased due to progesterone effects, resulting in overall slowing of bowel function. If pronounced, this can lead to constipation. Dietary management of this condition is centered on recommendations for increased fluids and high-fiber foods; stool

¹Not FDA approved for this indication.

softeners, such as docusate (Colace), can also be used in pregnancy. Enemas and laxatives are not recommended.

Upper Extremity Discomfort

Periodic numbness and tingling of the fingers is due to exacerbations of carpal tunnel compression exacerbated by tissue edema. Splinting of the affected hand at night may help, along with stretching exercises of the wrist and neck that can be done throughout the day. Most of these symptoms resolve after delivery.

Backache and Pelvic Discomfort

Endocrine relaxation of ligamentous structures coupled with an offset center of gravity create exaggerated lordotic spinal curve, joint instability, and back pain. Most women experience some form of this discomfort as pregnancy progresses. Advice given for improvements in posture, local heat, acetaminophen (Tylenol), and massage may be helpful. Minimizing the time spent standing can have a positive effect. Round ligament pain usually occurs during the second trimester and is described as sharp bilateral or unilateral groin pain. It may be exacerbated by change in position or rapid movement and might respond to similar measures. These routine aches and pains of pregnancy must be differentiated from rhythmic cramping pains originating in the back or uterus. The latter may be a sign of preterm labor requiring appropriate evaluation.

Leg Cramps

Leg cramps in the form of recurrent muscle spasms in pregnancy are believed to be due to lower levels of serum calcium or higher levels of serum phosphorus. The calves are most commonly involved and attacks are more frequent at night and in the third trimester. There are no data from controlled trials to show benefit over placebo for treatment targeted toward reduced phosphate and increased calcium or magnesium intake. Local heat, putting the affected muscle on stretch, acetaminophen, and massage can be helpful in acute events.

Intercourse

In general, intercourse is considered safe in pregnancy. The exception to this rule is found in patients who have a known placenta previa, are experiencing uterine bleeding, or have postcoital cramps and spotting. It may be wise to avoid intercourse in couples who are at risk for special circumstances. Firmer recommendations can be made in instances of placenta previa or known rupture of membranes; in these instances intercourse should not occur.

Dental Care

Ideally, women should have dental care completed before conception. However, dental procedures under local anesthesia may be carried out at any time during the pregnancy. Use of nitrous oxide inhalants is to be avoided, however. Long procedures should be postponed until the second trimester. Antibiotics are appropriate as needed for dental infections and in cases of rheumatic heart disease or mitral valve prolapse with regurgitation.

X-rays, Ionizing Radiation, and Imaging

The adverse effects of ionizing radiation are dose dependent, but there is no single diagnostic procedure that results in a dose of radiation high enough to threaten the fetus or embryo. Diagnostic radiation of less than 5000 mrad is considered by ACOG to have minimal teratogenic risk, and if medically indicated, x-ray imaging may be performed safely (with appropriate abdominal shielding). Patients receiving dental x-rays are additionally protected by a lead apron. Still, the need for x-ray films should be evaluated for risks and potential benefits in the individual pregnant patient to conservatively protect the mother and fetus from theoretical genetic or oncogenic risk. Magnetic resonance imaging (MRI) is considered safe due to its mechanism of action, which is a nonionizing form of radiation. Radioactive iodine (^{131}I) is contraindicated in pregnancy.

Immunization

Live virus vaccines must be avoided during pregnancy because of possible effects on the fetus. These include measles, mumps, rubella (MMR), yellow fever (YF-Vax), and varicella (Varivax) vaccinations. The risks to the fetus from the administration of rabies vaccine (RabAvert, IMOVAX) are unknown.

Diphtheria and tetanus toxoid with pertussis (Tdap) is recommended between 27 and 36 weeks by the CDC and ACIP to decrease the risk of whooping cough in the newborn infant. The hepatitis B vaccine (Engerix B, Recombivax HB) series is safe and may be given in pregnancy to women at risk. The inactivated influenza vaccine (Fluzone, Fluvirin, Fluvarix) is also recommended in all women during any trimester they will be pregnant during the flu season (or up to 3 months postpartum during flu season).

Tests of Fetal Well-Being

A primary goal in antepartum care is the competent management of patient care extended to both mother and baby in order to reduce the risk of fetal demise after 24 weeks, ensure optimal conditions for term delivery after 37 weeks, and intervene for evolving conditions threatening the well-being of either patient. Any pregnancy that may be at increased risk for antepartum fetal compromise is a candidate for tests of fetal well-being performed weekly, beginning at 28 to 32 weeks. Some conditions requiring antepartum testing are listed in [Box 3](#).

Nonstress Test

The nonstress test (NST) consists of fetal heart rate monitoring in the absence of uterine contractions. A reactive tracing is one in which heart rate accelerations of 15 beats/min above the baseline of 120 to 160 beats/min are of at least 15 seconds' duration. Two of these accelerations must be observed in a 20-minute period. False-positive nonreactive tracings are more common before 28 weeks' gestation.

Biophysical Profile

The biophysical profile (BPP) consists of an NST with ultrasound observations. A total of 10 points is given for the following elements (2 points each):

- Reactive NST
- Presence of fetal breathing movements of 30 seconds or more in 30 minutes
- Fetal movement defined as three or more discrete body or limb movements within 30 minutes
- Fetal tone defined as one or more episodes of fetal extremity extension and return to flexion
- Quantification of amniotic fluid volume, defined as a pocket of fluid that measures at least 2 cm by 2 cm

The results of a BPP are usually reported out of 8 points if done without the NST, and out of 10 points if done with an NST. Scores of 8 or 10 points (out of 10) are considered reassuring, with retesting indicated in 4 to 7 days depending on the original indication for the testing. A score of 6 points is borderline; testing should be repeated in 24 hours. Scores of 4 or 2 points are nonreassuring

BOX 3

Conditions That Prompt Enhanced Fetal Surveillance

- Decreased fetal movements
- Fetal growth restriction
- Hypertensive disorders
- Insulin-dependent diabetes mellitus
- Multiple gestation with discordant fetal growth
- Oligohydramnios or polyhydramnios
- Postterm pregnancy
- Prior loss or stillbirth

and should prompt additional testing, treatment, or planning for delivery depending on the setting.

ECTOPIC PREGNANCY

Method of

Christina Kelly, MD

CURRENT DIAGNOSIS

- Vaginal bleeding and abdominal pain in the first trimester of pregnancy suggest the possibility of ectopic pregnancy, but they may also be present in a normal intrauterine pregnancy (IUP) or early miscarriage.
- High-resolution transvaginal ultrasound (TVUS) and measurement of serum β -human chorionic gonadotropin (hCG) are the best initial steps in determining if a pregnancy is ectopic.
- A single hCG value is not diagnostic of pregnancy location, viability, or gestational age. It can determine whether the level is in the discriminatory zone.
- If the hCG is above the discriminatory zone (3000–3500 mIU/mL), absence of a gestational sac with a yolk sac or embryo visualized in the uterus is highly suggestive of a nonviable gestation—either an early pregnancy loss or an ectopic pregnancy.
- If the initial hCG is below the discriminatory zone and there is no ultrasound evidence of ectopic pregnancy, patients should be followed up with repeat hCG levels every 48 hours. There is not a universal method to predict an expected minimal rise for serial hCG levels for a viable IUP. Rather, it is dependent on the initial hCG level. Updated guidelines about the appropriate hCG patterns help guide decision making and determine whether additional diagnostic interventions are needed.
- If definitive findings of an intrauterine or ectopic pregnancy are not present on TVUS in a pregnant woman by hCG, a transient state known as “pregnancy of unknown location” exists. Serial monitoring is needed to either establish a definitive diagnosis or reasonably exclude an IUP before an ectopic pregnancy is diagnosed and treated. Uterine aspiration can be considered to confirm the diagnosis of early pregnancy loss or ectopic pregnancy based on the presence or absence of chorionic villi.

CURRENT THERAPY

- Surgical management of ectopic pregnancy is indicated when a patient is hemodynamically unstable, exhibits signs of intra-peritoneal bleeding, reports symptoms concerning for a ruptured ectopic mass, or has a contraindication to methotrexate.
- For a patient who is clinically stable and has a nonruptured ectopic pregnancy, both surgical and medical approaches to treating ectopic pregnancy are safe and effective. For the patient to make an informed choice, a shared decision-making model can be used that reviews the risks and benefits of both approaches and considers the clinical features of the ectopic pregnancy, stability of the patient, future fertility plans, and additional patient characteristics that would preclude one approach or the other.
- Medical management with systemic methotrexate (not approved by the Food and Drug Administration) requires regular patient follow-up for laboratory and office visits until hCG levels are undetectable.
- Medical management with methotrexate is most effective when ectopic pregnancies are less than 4 cm on TVUS, pre-treatment hCG levels are less than 5000 mIU/mL, and fetal cardiac activity is not detected on TVUS.
- Expectant management of ectopic pregnancy may be considered in special circumstances, such as an asymptomatic, informed, and reliable patient in the setting of decreasing hCG levels that indicate pregnancy resolution.

The development of an ectopic pregnancy is a potentially serious threat to the general and reproductive health of a woman. Despite vast improvements in the clinical care of women with ectopic pregnancy over recent years, diagnostic challenges and therapeutic controversies regarding this condition still exist. The objective of this chapter is to provide an overview of the epidemiology, diagnosis, and contemporary management of ectopic pregnancy. The focus is on ectopic pregnancies that implant in the fallopian tube, which represent greater than 95% of all ectopic pregnancies.

Epidemiology

Of all pregnancies in the United States, approximately 2% are diagnosed as ectopic. The current incidence of ectopic pregnancy is difficult to calculate accurately because of the lack of tracking in both the hospital and outpatient settings, but recent studies estimate that over the last 25 years, it has increased sixfold. This rise may be due to enhanced diagnostic capabilities, increased incidence of sexually transmitted infections and other risk factors, expanded use of infertility treatments, and heightened awareness of health professionals.

Ectopic pregnancy is the leading cause of maternal mortality in the first trimester of pregnancy in the United States, and there should be continued high suspicion for at risk patients. However, the ectopic-related mortality rate is declining despite the increase in incidence. Between 1980 and 2007, 876 deaths were attributed to ectopic pregnancy, which represented a 56.6% decline in mortality rate between 1980–1984 and 2003–2007. However, age and racial disparities still persist. The ectopic pregnancy mortality ratio was 6.8 times higher for African Americans compared with whites and 3.5 times higher for women over 35 years old compared with those younger than 25 years old.

Pathophysiology

Damage to the fallopian tube and fallopian tube dysfunction are the primary factors associated with development of ectopic pregnancy. Normal embryo transport can be disrupted by damage to the structural integrity of the mucosal portion of the fallopian tube. Intratubal scarring secondary to infection or trauma could lead to trapping of a conceptus within intratubal adhesions or diverticula.

and should prompt additional testing, treatment, or planning for delivery depending on the setting.

The development of an ectopic pregnancy is a potentially serious threat to the general and reproductive health of a woman. Despite vast improvements in the clinical care of women with ectopic pregnancy over recent years, diagnostic challenges and therapeutic controversies regarding this condition still exist. The objective of this chapter is to provide an overview of the epidemiology, diagnosis, and contemporary management of ectopic pregnancy. The focus is on ectopic pregnancies that implant in the fallopian tube, which represent greater than 95% of all ectopic pregnancies.

Epidemiology

Of all pregnancies in the United States, approximately 2% are diagnosed as ectopic. The current incidence of ectopic pregnancy is difficult to calculate accurately because of the lack of tracking in both the hospital and outpatient settings, but recent studies estimate that over the last 25 years, it has increased sixfold. This rise may be due to enhanced diagnostic capabilities, increased incidence of sexually transmitted infections and other risk factors, expanded use of infertility treatments, and heightened awareness of health professionals.

Ectopic pregnancy is the leading cause of maternal mortality in the first trimester of pregnancy in the United States, and there should be continued high suspicion for at risk patients. However, the ectopic-related mortality rate is declining despite the increase in incidence. Between 1980 and 2007, 876 deaths were attributed to ectopic pregnancy, which represented a 56.6% decline in mortality rate between 1980–1984 and 2003–2007. However, age and racial disparities still persist. The ectopic pregnancy mortality ratio was 6.8 times higher for African Americans compared with whites and 3.5 times higher for women over 35 years old compared with those younger than 25 years old.

Pathophysiology

Damage to the fallopian tube and fallopian tube dysfunction are the primary factors associated with development of ectopic pregnancy. Normal embryo transport can be disrupted by damage to the structural integrity of the mucosal portion of the fallopian tube. Intratubal scarring secondary to infection or trauma could lead to trapping of a conceptus within intratubal adhesions or diverticula.

Alteration of the hormonally mediated events leading to implantation—as sometimes occurs in treatments for infertility—offers another mechanism for consideration. A change in the estrogen-to-progesterone ratio could theoretically affect smooth muscle activity in the fallopian tube, immobilizing ciliary activity.

Risk Factors

Half of all women with ectopic pregnancy will not report any known risk factors; therefore the absence of risk factors should not decrease clinical suspicion. However, identification of clinical and historical risk factors for ectopic pregnancy could aid in early diagnosis. The most significant clinical risk factors include history of prior ectopic pregnancy, prior fallopian tube surgery, infertility treatment, hospitalization for pelvic inflammatory disease (PID). History of prior ectopic pregnancy is the strongest of these. Major historical risk factors include pain or moderate-to-severe vaginal bleeding at presentation. Less significant factors are tobacco use and age >35 years old. Prior nontubal pelvic surgery, past intrauterine device use, and cervical infection at presentation with chlamydia or gonorrhea do not contribute increased risk.

Diagnosis and Clinical Manifestations

Although some patients present acutely with a ruptured ectopic pregnancy and hemoperitoneum, the vast majority (up to 80%) of ectopic pregnancies are diagnosed in stable women who can be managed in the outpatient setting. Therefore reproductive-age women who present with symptoms of vaginal bleeding or abdominal discomfort need to be tested for pregnancy. If a woman is found to be pregnant, then her pregnancy needs to be differentiated as an ectopic pregnancy, a non-ectopic gestation at risk for miscarriage, or a normally developing IUP. The use of TVUS and hCG assays represent the current standard for this differentiation and for accurate and timely diagnosis of ectopic pregnancy.

Transvaginal Ultrasonography

To evaluate a patient with suspected ectopic pregnancy properly with TVUS, it requires an understanding of the findings typical of normal and abnormal pregnancies. The earliest ultrasonographic finding of a normal IUP is the gestational sac surrounded by a thick echogenic ring, located eccentrically within the endometrial cavity. On average, the gestational sac is seen on TVUS 5 weeks after the first day of the last menstrual period. The gestational sac grows and follows an approximate developmental timeline, which is represented by the following findings on TVUS: a yolk sac seen within the gestational sac at 5.5 weeks of gestation, an embryonic (fetal) pole at 6 weeks gestation, and cardiac activity at 6.5 weeks gestation.

A definitive IUP can be diagnosed by TVUS when a gestational sac with a yolk sac or embryo with or without cardiac activity is seen. A normal-appearing gestational sac should not solely be used to diagnose an IUP because it can be simulated by a pseudogestational sac and intrauterine fluid collection, which occurs in 8% to 29% of patients with ectopic pregnancy. The pseudogestational sac likely represents bleeding into the endometrial cavity by the decidual cast. The demonstration of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific signs of ectopic pregnancy and are visualized in ectopic pregnancies 33% to 50% of the time.

A critical concept in the evaluation of early pregnancy by TVUS is that of the hCG discriminatory zone, or the level at or above which an examiner should see a normal intrauterine gestation, if present. In the setting of an hCG level above the discriminatory zone and no intrauterine pregnancy on ultrasound, an ectopic pregnancy or an abnormal intrauterine pregnancy is highly likely. The exact hCG discriminatory value varies somewhat from institution

to institution, depending on the experience of the ultrasonographer and the hCG assay used. The value used should be conservatively high—at least 3000 mIU/mL and up to 3500 mIU/mL—to minimize the risk of misdiagnosing a desired IUP as an ectopic pregnancy and treating it as such.

Hormonal Assays

Many patients with suspected ectopic pregnancy will present with a hCG below the discriminatory zone and have an ultrasound that does not provide a definitive diagnosis of an intrauterine or extrauterine gestation (7%–20%). This is a transient state known as “pregnancy of unknown location,” and serial monitoring is needed to establish a definitive diagnosis. These patients require repeat hCG measures at least every 48 hours to evaluate the appropriateness of hormonal trends, as well as serial studies with TVUS. Comparing serial measurements of hCG from an individual patient to accepted patterns of hCG trends in early pregnancy helps distinguish an ectopic pregnancy from a viable IUP or a spontaneous miscarriage.

When evaluating serial hCG levels and predicting an expected minimal rise between values for a viable IUP, current evidence demonstrates that there is not a universal trend that applies to all pregnancies at all gestations. Rather, it depends on the initial hCG level. Previous data showed that approximately 99% of viable intrauterine pregnancies are associated with a $\geq 53\%$ increase in β -hCG values every 2 days. For pregnancies with an initial hCG value below 1500 mIU/mL, this calculation could apply. However, for pregnancies with higher initial hCG values, a more lax calculation should be used. One study suggests the following for an expected minimal rise for different initial hCG levels: 49% for levels <1500 mIU/mL, 40% for levels 1500–3000 mIU/mL, and 33% for levels >3000 mIU/mL. This represents a more conservative approach to incorporating invasive diagnostic procedures when following hCG values to prevent the interruption of normal pregnancies.

Patients with symptomatic first-trimester pregnancies, nondiagnostic ultrasound, and a hCG level that is declining (when the initial value is below the discriminatory zone) should also be followed with serial hCG levels until resolution to distinguish a resolving miscarriage from an ectopic pregnancy. Fifty percent of women with ectopic pregnancies will present with declining hCG levels. Rules describing the expected elimination of hCG in spontaneous miscarriage indicate that the minimum rate of decline ranges from 12% to 35% at 2 days to 34% to 84% at 7 days. Faster rates of decline occur with higher initial hCG levels. When the serial decline in hCG is in the range associated with spontaneous miscarriage, continued follow-up surveillance is indicated. If the hCG decline is slower than expected for a miscarriage, an ectopic pregnancy must be highly suspected.

Uterine Aspiration

The patient presenting with either (1) initial hCG below the discriminatory zone followed by an abnormal rise or decline or (2) initial hCG value at or above the discriminatory zone with no detectable intrauterine pregnancy has an abnormal pregnancy. The only exception to the rule for scenario 2 would be if a multiple gestation had been conceived. The challenge for the clinician is to then determine whether the pregnancy is an abnormal intrauterine pregnancy or an ectopic pregnancy. Office uterine vacuum aspiration or dilation and curettage in the operating room can help confirm the diagnosis of early pregnancy loss or ectopic pregnancy based on the presence or absence of chorionic villi. However, before this is considered, a progressing IUP must be reasonably excluded through serial monitoring with TVUS and hCG levels.

Uterine aspiration may spare some women from receiving methotrexate. If chorionic villi are present in the uterine aspiration specimen, then a failed IUP is confirmed. No further treatment is indicated. If chorionic villi are absent, hCG levels need to be monitored starting at 12 to 24 hours after the procedure to determine whether they increase, plateau, or decrease appropriately. The

hCG trend after uterine aspiration determines if medical management of ectopic pregnancy with methotrexate should be implemented. The patient's preference, development of symptoms, and level of clinical suspicion for ectopic pregnancy also play an important role in whether methotrexate is given.

There is debate in the literature on whether uterine aspiration is needed before methotrexate is given to treat ectopic pregnancy. Empiric treatment of suspected ectopic pregnancy without the performance of uterine vacuum aspiration or dilation and curettage could result in inappropriate treatment of up to 40% of women. Performing uterine aspiration could delay treatment of an ectopic pregnancy; however, the risk of tubal rupture for these women is low (1.7%).

Treatment and Therapeutic Monitoring

Surgery has long been the mainstay of treatment for ectopic pregnancy, but medical management is a widely used alternative. Both are safe and effective treatment options for women who are clinically stable. The choice of any treatment depends on factors such as clinical presentation, the risks of either surgery or medical management to the patient, and future fertility plans.

Surgical Management

Patients with hemodynamic instability caused by a ruptured ectopic pregnancy require laparotomy and salpingectomy of the involved fallopian tube owing to extensive tubal damage. Most women with ectopic pregnancy who are stable can be safely treated with laparoscopy. For a woman with an unruptured ectopic pregnancy, surgical options include tube-sparing salpingostomy or removal of the fallopian tube (salpingectomy). Ideal candidates for linear salpingostomy include patients who have an ectopic pregnancy in the ampulla or infundibulum of the fallopian tube. Persistent ectopic pregnancy after linear salpingostomy ranges in frequency from 3% to nearly 30% of procedures, so patients must be followed with serial hCG to resolution. Prophylactic methotrexate has been proposed as a means of reducing the odds of a persistent ectopic pregnancy following conservative surgery. A suggested approach to reducing the risk of persistent ectopic after salpingostomy would be to incorporate a postoperative day 1 hCG into the monitoring strategy using a drop of less than 50% to help predict a persistent ectopic pregnancy and need for prophylactic methotrexate.

Salpingectomy is reserved for patients with isthmic ectopic pregnancies, tubal rupture, or an ipsilateral recurrent ectopic pregnancy. Salpingectomy is more appropriate for isthmic ectopic pregnancies because the narrowness of the isthmic lumen of the fallopian tube can predispose to tubal obstruction and scarring after salpingostomy. Women who have completed childbearing might be better candidates for salpingectomy than salpingostomy.

With respect to future fertility, much of the published data supports higher odds of intrauterine conception after salpingostomy compared with salpingectomy; some studies, however, suggest no difference in the odds of intrauterine pregnancy on the basis of the method of ectopic surgery. The most important determinant of normal conception after surgical treatment is the presence of a healthy contralateral fallopian tube. The odds of recurrent ectopic pregnancy appear to be higher in women after conservative rather than radical surgical treatment.

Medical Management

Methotrexate (MTX) therapy for ectopic pregnancy is a widely used medical alternative to surgery. Methotrexate is a folic acid antagonist that impairs DNA synthesis and cellular replication targeting rapidly proliferating cells such as trophoblasts. Although medical treatment of ectopic pregnancy is an appealing option for many patients, certain absolute contraindications exist to the use of the drug and are listed in Table 1. Among the most important of the contraindications to MTX therapy is the inability of the patient to comply with follow-up after initiation of therapy. Without the ability to monitor response to medication and provide additional doses if deemed appropriate, opportunities to prevent ectopic rupture could be missed. To ascertain whether a patient is eligible for MTX therapy, a comprehensive laboratory and medical evaluation should first be performed, including tests of renal and liver function, as well as a complete blood count. Treatment failure occurs when decline in hCG levels is deemed inadequate and surgery is required. In some cases, medication failure presents as tubal rupture requiring emergent surgery.

Relative contraindications to MTX treatment pertain to patient characteristics that reduce the odds of successful treatment. These include hCG levels of 5000 mIU/mL or greater, ultrasonographic evidence of an ectopic pregnancy with fetal heart activity, and an ectopic gestational mass measuring ≥ 3.5 cm in diameter. The strongest predictor for the efficacy of MTX treatment is the hCG concentration.

Three methotrexate treatment regimens exist: single-dose, two-dose, and multidose regimens (Table 2). These designations refer more to the number of intended doses in the protocol rather than the actual number or doses received by all patients. For any of the protocols, once hCG levels have declined by at least 15% between interval assessments, no additional doses of medication are required, but hCG must still be followed until complete resolution to ensure treatment efficacy. Although each regimen has demonstrated efficacy, only one small, randomized trial of comparative efficacy exists in which no significant difference between protocols was observed. A recent meta-analysis demonstrated that the risk of treatment failure was nearly 5 times higher in women receiving single-dose MTX than in those receiving multidose MTX (adjusted

TABLE 1 Contraindications to Medical Management of Ectopic Pregnancy With Methotrexate

	ACOG*	ASRM†
Absolute contraindications	Intrauterine pregnancy; breastfeeding; laboratory evidence of immunodeficiency; preexisting blood dyscrasias (bone marrow hypoplasia, leukopenia, thrombocytopenia, or clinically significant anemia); known sensitivity to methotrexate; active pulmonary disease; peptic ulcer disease; hepatic, renal, or hematologic dysfunction; alcoholism; alcoholic or other chronic liver disease; hemodynamically unstable patient; inability to participate in follow-up	Breast-feeding; evidence of immunodeficiency; moderate-to-severe anemia, leukopenia, or thrombocytopenia; sensitivity to methotrexate; active pulmonary or peptic ulcer disease; clinically important hepatic or renal dysfunction; intrauterine pregnancy
Relative contraindications	Ectopic mass > 4 cm by TVUS; embryonic cardiac activity by TVUS; high initial hCG concentration	Ectopic mass > 4 cm detected by TVUS; embryonic cardiac activity detected by TVUS; patient declines blood transfusion; patient is not able to participate in follow-up; high initial hCG level (>5000 mIU/mL)

TVUS, transvaginal ultrasound; hCG, β -human chorionic gonadotropin.

†Data are from the American Society for Reproductive Medicine (ASRM).

TABLE 2 Methotrexate¹ Protocols for Treatment of Ectopic Pregnancy

	SINGLE DOSE	TWO DOSE	MULTIDOSE
Day 1	Check hCG value. Administer first dose of MTX 50 mg/m ² IM.	Check hCG value. Administer first dose of MTX 50 mg/m ² IM.	Check hCG value. Administer first dose of MTX 1 mg/kg IM followed by leucovorin ¹ 0.1 mg/kg IM on day 2. Check hCG on day 2.
Day 4	Check hCG value.	Check hCG value. Administer second dose of MTX 50 mg/m ² IM.	Administer second dose of MTX (day 3) and leucovorin (day 4). Check hCG on day 4.
Day 7	Check hCG value looking for 15% decrease between days 4 and 7. If > 15% fall, check hCG weekly until not detectable in serum. If < 15% fall, administer second dose of MTX 50 mg/m ² IM.	Check hCG value for 15% decrease between days 4 and 7. If > 15% fall, check β -hCG weekly until not detectable in serum. If < 15% fall, administer third dose of MTX 50 mg/m ² IM.	Continue administering doses of MTX and leucovorin (i.e., course 3 days 5 and 6 and course 4 days 7 and 8) until hCG values have declined by 15%. Do not exceed 4 courses. If > 15% decline, check hCG weekly until not detectable in serum.
Day 11		Check hCG value for 15% decrease between days 7 and 11. If > 15% decline, check hCG weekly until not detectable in serum. If < 15%, administer fourth dose of MTX 50 mg/m ² IM.	
Weekly surveillance	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.

hCG, β -human chorionic gonadotropin; IM, intramuscular; MTX, methotrexate.

¹Not FDA approved for this indication.

for confounders). Of note, the meta-analysis demonstrated that patients designated to receive single-dose therapy often received more than one dose and that patients getting multidose therapy often required fewer than four doses to be cured. The two-dose protocol aims to address these considerations, improving on the efficacy of single-dose MTX while not requiring more visits than are typically required for the single-dose protocol.

Side effects of MTX therapy occur in up to 30% of women; however, most of these resolve rapidly and are generally of minor consequence. Abdominal pain is common early in treatment and is of concern as a possible indicator of tubal rupture. A potential cause of this pain in nonacute patients can be tubal miscarriage. Additional potential side effects include nausea, vomiting, diarrhea, gastritis, stomatitis, and liver transaminitis. Serious side effects such as alopecia and neutropenia can occur but are extremely rare.

Reproductive success after successful MTX therapy appears similar to that after conservative surgery. The most critical predictors of fertility after ectopic pregnancy treated by any conservative means are the condition of the contralateral fallopian tube and the presence of additional ectopic risk factors.

Expectant Management

Based on the fact that numerous ectopic pregnancies resolve spontaneously, there has been great interest in considering expectant management in selected patients. Expectant management includes close monitoring of symptoms, determination of hCG levels, and transvaginal ultrasound scanning. The likelihood of successful ectopic resolution is highest in the presence of a nondiagnostic ultrasound and hCG values less than 1000 mIU/mL.

HYPERTENSION IN PREGNANCY

Method of

Leah Peterson, MD

CURRENT DIAGNOSIS

- Hypertensive disorders of pregnancy are a major cause of morbidity and mortality for women and infants
- Hypertensive disorders of pregnancy are divided into four categories:
 - Gestational hypertension
 - Chronic hypertension
 - Chronic hypertension with superimposed preeclampsia
 - Preeclampsia–eclampsia
- Preeclampsia can be diagnosed by the presence of hypertension and end-organ damage, even in the absence of proteinuria.

CURRENT THERAPY

- Blood pressure readings $\geq 160/105$ require pharmacologic treatment.
- Nifedipine (Procardia), labetalol (Trandate), and methyldopa are approved for treatment of hypertensive disorders in pregnancy.
- Patients with gestational hypertension and preeclampsia should be monitored with regular labs, sonograms, and antenatal testing.
- Delivery is the definitive treatment for preeclampsia.
- Hypertensive disorders in pregnancy are an indication for early delivery. Delivery time is based on severity of maternal symptoms and estimated gestational age of the fetus.
- Magnesium sulfate injection is indicated in severe preeclampsia, for the prevention of eclampsia. It is also the preferred agent for treatment of eclampsia.
- Hypertensive disorders of pregnancy can present in the postpartum period.
- Preeclampsia is associated with increased risk for cardiovascular disease later in life.
- Initiation of daily low-dose aspirin¹ late in the first trimester is indicated for prevention of preeclampsia in certain high-risk women.

¹Not FDA approved for this indication.

Epidemiology

Hypertensive disorders complicate nearly 10% of pregnancies (Box 1) and their incidence is increasing. Preeclampsia causes 50,000–60,000 deaths per year worldwide, in addition to causing significant maternal and fetal morbidity in hundreds of thousands of others. Some of these outcomes can be prevented or improved on through implementation of the updated recommendations in clinical practice.

Pathophysiology

The precise mechanism for the development of preeclampsia is unknown. A major component in the development of preeclampsia is the excessive placental production of antagonists to both vascular epithelial growth factor (VEGF) and transforming growth factor β (TGF- β). These antagonists to VEGF and TGF- β disrupt endothelial and renal glomerular function resulting in edema, hypertension, and proteinuria. In addition, there appears to be a heritable component, and oxidative stress and abnormal placental implantation can further increase the risk of developing the disease.

Prevention

In women with history of a delivery at less than 34 0/7 weeks' gestation, or with history of preeclampsia in multiple pregnancies, daily low-dose aspirin therapy is suggested. Low-dose aspirin is

BOX 1 Risk Factors

- Primiparity
- Previous preeclamptic pregnancy
- Family history of preeclampsia
- History of chronic hypertension or chronic renal disease
- Thrombophilia
- Obesity
- Systemic lupus erythematosus
- Advanced maternal age (>40)
- Multifetal pregnancy
- In vitro fertilization
- Type 1 or type 2 diabetes mellitus

Data from American College of Obstetricians and Gynecologists. Hypertension in pregnancy. 2013. Available at <http://www.Acog.org/Resources-And-Publications/Task-Force-and-Work-Group-Reports/Hypertension-in-Pregnancy>.

TABLE 1 Diagnostic Criteria for Preeclampsia

Blood pressure

- Greater than or equal to 140 mm Hg systolic or greater than or equal to 90 mm Hg diastolic on two occasions at least 4 h apart after 20 weeks of gestation in a woman with a previously normal blood pressure

- Greater than or equal to 160 mm Hg systolic or greater than or equal to 110 mm Hg diastolic, hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy

and

Proteinuria

- Greater than or equal to 300 mg per 24-h urine collection (for this amount extrapolated from a timed collection) or
- Protein/creatinine ratio greater than or equal to 0.3^a
- Dipstick reading of 1+ (used only if other quantitative methods not available)

Or in the absence of proteinuria, new-onset hypertension with the new onset of any of the following:

Thrombocytopenia

- Platelet count less than 100,000/mL

Renal insufficiency

- Serum creatinine concentrations greater than 1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease

Impaired liver function

- Elevated blood concentrations of liver transaminases to twice normal concentration

Pulmonary edema

Cerebral or visual symptoms

^aEach measured as mg/dL.
American College of Obstetricians and Gynecologists. Hypertension in pregnancy. 2013. Available at <http://www.Acog.org/Resources-And-Publications/Task-Force-and-Work-Group-Reports/Hypertension-in-Pregnancy>.

not associated with increased bleeding or placental abruption. Supplementation with vitamin C¹ or E¹ is not recommended in the prevention of preeclampsia. Supplementation of calcium¹ in women with preeclampsia is only indicated in those who are calcium-deficient. Bed rest and salt restriction are not recommended for prevention of preeclampsia.

Diagnosis

Isolated hypertensive disease diagnosed prior to 20 weeks of gestation is classified as chronic hypertension. Gestational hypertension is defined as the onset of hypertension ($\geq 140/90$ on two occasions at least 4 h apart), after 20 weeks' gestation, in the absence of proteinuria or other criteria for preeclampsia.

Preeclampsia is a hypertensive disorder that is multisystemic in nature and is specific to pregnancy. It presents after the 20th week of gestation, and typically near term. Traditionally, diagnosis of preeclampsia has been based on new onset hypertension and the presence of proteinuria. Clinically significant proteinuria is defined as ≥ 300 mg on a 24-h urine, or a spot microalbumin/creatinine ratio ≥ 0.3 . The use of dipstick quantification of proteinuria is discouraged unless no other method is available. Urinary protein levels are not correlated with outcome severity and are not themselves considered a severe feature.

There are some women who present with hypertension and signs of systemic disease in the absence of proteinuria. The presence of end-organ damage, as noted in Table 1, combined with onset of hypertension after 20 weeks' gestation is sufficient for a diagnosis of severe preeclampsia, even in the absence of proteinuria.

¹Not FDA approved for this indication.

The presence of any one of these features may signal impending eclamptic seizure. In addition to seizure and maternal end-organ damage, complications from preeclampsia include intrauterine growth restriction, placental abruption, and fetal demise.

Management

Chronic hypertension is associated with intrauterine growth restriction, placental abruption, and progression to preeclampsia. Treatment of chronic hypertension is indicated if blood pressure (BP) is consistently greater than 160/105, and approved treatment agents include methyldopa, nifedipine (Procardia), and labetalol (Trandate). It is essential to avoid overtreatment, to prevent adverse fetal outcomes from decreased perfusion. Therefore the goal is to keep BP below 120/80 with treatment. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and atenolol (Tenormin) should not be used in pregnancy due to fetal risk. Women with chronic hypertension should also be monitored with serial ultrasound after fetal viability.

Gestational hypertension is managed with expectant monitoring and delivery at 37 weeks. BP should be measured twice weekly, and patient should have weekly assessment of LFTs and platelet count to assess for development of preeclampsia. Antihypertensive therapy should be initiated for BP \geq 160/105. Additionally, the patient should have once-weekly nonstress testing.

Preeclampsia should be managed similarly to gestational hypertension, with the addition of regular sonograms for fetal growth, and twice-weekly fetal nonstress testing. Delivery should occur at 37 weeks, and should occur at 34 weeks if patient develops severe features.

In the event that the patient develops preeclampsia with severe features prior to 34 weeks, steroids (12 mg betamethasone [Celestone]¹ IM q12h \times 2 doses, or 6 mg dexamethasone [Decadron]¹ q12h \times 4 doses) can be given and delivery can be postponed for 48 h, unless maternal or fetal instability develops. Contraindications to expectant management in this scenario are noted in Table 2. If severe features are noted prior to fetal viability, delivery should occur immediately. Expectant management is not recommended due to maternal risk.

In addition, magnesium sulfate (MgSO_4) is indicated in preeclampsia with severe features. Administration of MgSO_4 has been shown to prevent eclamptic seizures and placental abruption in these patients. Patients with preeclampsia without severe features should be monitored closely, and MgSO_4 should be started if severe features develop. MgSO_4 is given as a 4–6-g intravenous loading dose, followed by a maintenance infusion of 1–2 g/h. Women with normal renal function do not require serum magnesium testing, but all women receiving MgSO_4 should be monitored closely for signs of magnesium toxicity by serial evaluations of reflexes, respiratory rate, and urinary output. Signs and symptoms of magnesium toxicity are noted in Table 3.

Inpatient management for 72 h postpartum is recommended for women with gestational hypertension or preeclampsia. Blood pressure levels decrease in most women, but if blood pressure remains $>150/100$ on two occasions 4 h apart, an antihypertensive regimen should be started. If level is $<160/100$, BP should be rechecked 15 min later, and antihypertensive treatment should be started within 60 min. Oral nifedipine or labetalol, and intravenous labetalol or hydralazine (Apresoline) are commonly used agents. Non-steroidal antiinflammatory drugs (NSAIDs) should be avoided in the patient with hypertension that persists past 24 h postpartum, as they may worsen BP.

Preeclampsia may begin in the postpartum period, so all patients should be counseled about signs and symptoms prior to discharge. In addition, preeclampsia is a risk factor for future cardiovascular disease. In women who delivered prior to 37 weeks or have history of recurrent preeclampsia, yearly assessment of BP, lipids, fasting glucose, and body mass index (BMI) is suggested.

TABLE 2 Contraindications to Expectant Management

Deliver immediately if:

Uncontrollable severe hypertension
Eclampsia
Pulmonary edema
Disseminated intravascular coagulation (DIC)
Abruptio
Non-reassuring fetal heart tones
Intrapartum fetal demise

TABLE 3 Signs and Symptoms of Magnesium Toxicity

MANIFESTATIONS	LEVEL (mg/dL)
Loss of patellar reflex	8–12
Double vision	8–12
Feeling of warmth, flushing	9–12
Somnolence	10–12
Slurred speech	10–12
Muscular paralysis	15–17
Respiratory arrest	15–17
Cardiac arrest	30–36

Complications

HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count occurring in association with preeclampsia) occurs in 20% of pregnancies complicated by preeclampsia with severe features. HELLP syndrome is diagnosed by the presence of LFTs $>2 \times$ normal, hemolysis (lactate dehydrogenase $>600\text{U/L}$, damaged erythrocytes noted on peripheral smear, or bilirubin $>1.2\text{ mg/dL}$, and platelets $<100,000$). Diagnosis of HELLP can be difficult, as 12–18% of patients with the disorder are normotensive, and 13% do not have proteinuria. Evaluation for HELLP syndrome includes a complete blood count and LFT testing. A DIC panel should also be considered if platelet count is $<50,000$.

Patients with HELLP should receive MgSO_4 from admission until 24–48 h postpartum. Platelet transfusion is indicated if counts are $<20,000$ prior to vaginal delivery or $<50,000$ prior to cesarean delivery, or in women with abnormal bleeding. Corticosteroids have been shown to increase platelet counts in women with HELLP syndrome but have not been shown to improve maternal or fetal outcomes, except for the benefit of improving fetal lung function prior to 34 weeks' gestational age. Because the condition is often progressive and associated with sudden deterioration of both maternal and fetal condition, prompt delivery is indicated if the HELLP presents later than 34 weeks.

Eclampsia is a life-threatening complication of preeclampsia, defined as new-onset grand mal seizures in a woman with preeclampsia. Seizures typically last 60–90 seconds, and may be followed by a postictal state. During an eclamptic seizure, the fetus often becomes hypoxic and bradycardic. Eclampsia can occur antepartum, intrapartum, or postpartum. It can be preceded by a wide range of symptoms, and can occur even in the absence of proteinuria or hypertension. Eclampsia is often preceded by persistent headache, visual changes, altered mental status, and upper abdominal pain.

MgSO_4 is the drug of choice in treating eclampsia, both for the initial convulsion and for prevention of subsequent ones. The dosing regimen is a 6-g loading dose given over 15–20 min, followed by a maintenance infusion of 2 g/h for at least 24 h after the

¹Not FDA approved for this indication.

convulsion. No other anticonvulsants should be given in attempt to shorten or abolish the initial convulsion. Care should be taken to protect the airway, reduce risk of aspiration, and prevent maternal injury. Ten percent of eclamptic women will have a second convulsion after receiving magnesium. If this occurs, an additional 2-g dose should be given intravenously over 3–5 min.

POSTPARTUM CARE

Method of

Tara J. Neil, MD

CURRENT DIAGNOSIS

- The postpartum period consists of the period from delivery of the infant until 6 to 8 weeks postpartum.
- Postpartum hemorrhage is a medical emergency and is usually caused by uterine atony.
- Fever during the postpartum period is typically caused by endometritis or mastitis.
- Postpartum depression can significantly impact bonding with the infant.

CURRENT THERAPY

- Continue to monitor and check for resolution of any complications or medical conditions that arise during pregnancy.
- Postpartum depression can be treated with psychotherapy and medications.
- Uterine atony responds to massage and medications. Providers should be familiar with the medications and their dosages.

- Postpartum contraception counseling should be started immediately and all forms can be used by 6 weeks postpartum.
- Breast-feeding is the preferred nutrition for newborns and success is dependent on provider counseling and encouragement.

Postpartum care encompasses the period after delivery of infant and placenta until 6 to 8 weeks after delivery. The hormonal and physiologic systems that underwent changes during pregnancy return to normal during this time. During the initial 24 to 48 hours, most patients are monitored in the hospital for possible complications after delivery. Patients should have an appointment 6 weeks after discharge focusing on this period. This chapter addresses postpartum care and complications that can arise.

Postpartum Hemorrhage

Postpartum hemorrhage is defined as blood loss greater than 500 mL after vaginal delivery or greater than 1000 mL after cesarean section. It is the major cause of maternal morbidity and mortality worldwide. Practitioners should be prepared to diagnose and treat the cause.

Some common causes of hemorrhage are identified in [Box 1](#), including the most common cause: uterine atony. Once abnormal bleeding is identified, resuscitation measures should be started, including IV access, nursing assistance, starting fluid resuscitation with crystalloids or blood products, and anesthesia if needed. The uterus should be examined using a bimanual examination and vigorous massage. If the uterus is boggy, the medications listed in [Table 1](#) can be used to improve uterine tone and decrease bleeding. If the bladder is full, a catheter should be placed. Careful inspection of the cervix, vaginal walls, and perineum should be performed to identify other sources of hemorrhage. If bleeding is not slowed or the cause of hemorrhage not identified, manual exploration of the uterus can be performed with proper anesthesia to check for retained products. Surgical treatment with dilation and curettage and hysterectomy can also be used if manual exploration and medical management do not control bleeding. If the patient is hemodynamically stable and the resources are available, embolization of the uterine arteries can also control bleeding.

BOX 1 Causes of Postpartum Hemorrhage

- Uterine atony
- Vaginal or cervical laceration
- Coagulation disorder
- Uterine inversion
- Retained placenta/products

TABLE 1 Medications Used to Treat Uterine Atony

MEDICATION	ADMINISTRATION	FREQUENCY	SPECIAL CONSIDERATIONS
Oxytocin (Pitocin)	10 units IM 10–40 units in 1000 mL of IV solution	Once Continuous to maintain uterine tone	Should not be given directly in IV
Methylergonovine maleate (Methergine)	0.2 mg IM/IV 0.2 mg PO	Repeat every 2–4 hours as needed 3–4 times daily for maximum of 7 days	Contraindicated in hypertension
Carboprost tromethamine (Hemabate)	0.25 mg IM	Repeat every 15–90 minutes. Maximum dose 2 mg	Contraindicated in active cardiac, renal, pulmonary, and liver disease. Use cautiously in asthmatics.
Misoprostol (Cytotec) ¹	800–1000 µg rectally ³	One time dose	

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

convulsion. No other anticonvulsants should be given in attempt to shorten or abolish the initial convulsion. Care should be taken to protect the airway, reduce risk of aspiration, and prevent maternal injury. Ten percent of eclamptic women will have a second convulsion after receiving magnesium. If this occurs, an additional 2-g dose should be given intravenously over 3–5 min.

POSTPARTUM CARE

Method of

Tara J. Neil, MD

CURRENT DIAGNOSIS

- The postpartum period consists of the period from delivery of the infant until 6 to 8 weeks postpartum.
- Postpartum hemorrhage is a medical emergency and is usually caused by uterine atony.
- Fever during the postpartum period is typically caused by endometritis or mastitis.
- Postpartum depression can significantly impact bonding with the infant.

CURRENT THERAPY

- Continue to monitor and check for resolution of any complications or medical conditions that arise during pregnancy.
- Postpartum depression can be treated with psychotherapy and medications.
- Uterine atony responds to massage and medications. Providers should be familiar with the medications and their dosages.

- Postpartum contraception counseling should be started immediately and all forms can be used by 6 weeks postpartum.
- Breast-feeding is the preferred nutrition for newborns and success is dependent on provider counseling and encouragement.

Postpartum care encompasses the period after delivery of infant and placenta until 6 to 8 weeks after delivery. The hormonal and physiologic systems that underwent changes during pregnancy return to normal during this time. During the initial 24 to 48 hours, most patients are monitored in the hospital for possible complications after delivery. Patients should have an appointment 6 weeks after discharge focusing on this period. This chapter addresses postpartum care and complications that can arise.

Postpartum Hemorrhage

- Mastitis
- Urinary tract infection
- Wound infection (perineal or abdominal)
- Septic thrombophlebitis
- Deep vein thrombosis

Fever and Infection

Fever above 38°C (100.4°F) should be evaluated and a source identified. Box 2 lists the most common causes of postpartum fever. Evaluation should include a physical examination to include the uterus and breasts, with attention to any lacerations or incisions. Laboratory testing should include urinalysis, CBC, and blood cultures if appropriate.

Endometritis, a polymicrobial infection of the endometrium of the uterus, typically causes fever in the first 1 to 2 weeks postpartum. Diagnostic criteria include fever and uterine pain with palpation. Endometritis is treated with intravenous broad-spectrum antibiotics until fever and uterine pain resolves. No oral antibiotics are needed. If there is no clinical improvement after several days of treatment, imaging with computed tomography (CT) or ultrasound of the pelvis can be used to look for complications, including pelvic abscess and septic pelvic thrombophlebitis.

Mastitis causes fever in breast-feeding mothers. It is caused by the introduction of skin flora through cracks in the nipple and skin and infects milk ducts and surrounding soft tissues in areas of stasis. Treatment includes frequent feeding or pumping to alleviate the stasis. There is inadequate evidence to support antibiotic use, but if symptoms persist after effectively emptying breasts, most practitioners treat with a 10- to 14-day course of oral narrow-spectrum antibiotics. Complications can include breast abscesses, which are usually diagnosed by ultrasound.

Immunization

Immunizations should be updated during the postpartum period. Rubella status is routinely checked during the prenatal period and immunization should be given if indicated. Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine [Adacel, Boostrix]) should be given to the patient and offered to other members of the family if they have not received a pertussis booster to help protect the infant from contracting pertussis. Influenza vaccine (Fluzone) should be given if it was not given during pregnancy. Rh(D) negative mothers should receive anti-D immune globulin if their infants are Rh(D) positive.

Breast-feeding

Breast milk is universally recognized as the best nutrition for newborns. Infants who are breast-fed have fewer ear, lower respiratory, and gastrointestinal infections. They are also less likely to develop asthma, diabetes, and obesity. Contraindications to breast-feeding include HIV, active herpetic lesions on breasts, maternal drug abuse, and certain medications. Any medications prescribed during breast-feeding should be checked for safety. It is currently recommended, when possible, for infants to be exclusively breast-fed until 6 months and supplemented with foods between the ages of 6 months and one year. Clinicians play a crucial role in educating mothers about the importance of breast-feeding and supporting them during breast-feeding.

Postpartum Depression

Postpartum depression has an incidence as high as 15 percent in the 3 months postpartum. Risk factors include history of depression or postpartum depression, poor social support, family history of postpartum depression, depressed symptoms during pregnancy, and major life events during pregnancy. Baby blues symptoms are less severe and start 2 to 3 days after delivery and resolve within 10 days of delivery. Postpartum depression is seen during the 3 months

after delivery, and diagnostic criteria are the same as for depression. Treatment includes psychotherapy and antidepressants. The best choices for breast-feeding mothers include paroxetine (Paxil), fluoxetine (Prozac), and citalopram (Celexa). If not lactating, the choice of medications is similar to those for treating depression. The best screening tool is the Edinburgh Postnatal Depression Scale. Postpartum psychosis is rare but requires inpatient treatment.

Contraception

Discussing contraception after delivery is important for spacing healthy pregnancies. Many women resume intercourse before their scheduled 6 week postpartum appointment so this discussion should begin at the time of discharge. Breast-feeding mothers can use lactational amenorrhea during this period if they are exclusively breast-feeding. They can also use progesterone-only contraception (Micronor) starting 6 weeks postpartum. Combined estrogen-progesterone formulations can be started as early as 3 weeks postpartum in non-breast-feeding mothers. Starting estrogen-containing formulations before this can increase the risk for thromboembolism. Tubal ligation can be done immediately postpartum. Intrauterine devices and diaphragms are typically placed at 6 weeks after the uterus has returned to its normal size. Medroxyprogesterone (Depo-Provera) and etonogestrel (Implanon) may be given in the first 5 days postpartum if a patient is not breast-feeding, and at 6 weeks if breast-feeding.

Other Considerations

Close evaluation and continued management of medical conditions that develop during pregnancy, including thyroid disease, gestational diabetes, and preeclampsia, should be continued.

The postpartum period is an important time for new mothers. Open communication with their providers during this time helps support them and helps them to recognize conditions that are important for their health and the health of their newborn.

VAGINAL BLEEDING LATE IN PREGNANCY

Method of

Jennifer Frank, MD

CURRENT DIAGNOSIS

- Avoid a digital vaginal examination in a patient with late-pregnancy bleeding until placenta previa is excluded by ultrasound.
- A patient can have more than one serious cause of late-pregnancy bleeding.
- Vaginal bleeding with rupture of membranes should prompt consideration of vasa previa.

- Mastitis
- Urinary tract infection
- Wound infection (perineal or abdominal)
- Septic thrombophlebitis
- Deep vein thrombosis

Fever and Infection

Fever above 38°C (100.4°F) should be evaluated and a source identified. Box 2 lists the most common causes of postpartum fever. Evaluation should include a physical examination to include the uterus and breasts, with attention to any lacerations or incisions. Laboratory testing should include urinalysis, CBC, and blood cultures if appropriate.

Endometritis, a polymicrobial infection of the endometrium of the uterus, typically causes fever in the first 1 to 2 weeks postpartum. Diagnostic criteria include fever and uterine pain with palpation. Endometritis is treated with intravenous broad-spectrum antibiotics until fever and uterine pain resolves. No oral antibiotics are needed. If there is no clinical improvement after several days of treatment, imaging with computed tomography (CT) or ultrasound of the pelvis can be used to look for complications, including pelvic abscess and septic pelvic thrombophlebitis.

Mastitis causes fever in breast-feeding mothers. It is caused by the introduction of skin flora through cracks in the nipple and skin and infects milk ducts and surrounding soft tissues in areas of stasis. Treatment includes frequent feeding or pumping to alleviate the stasis. VAGINAL BLEEDING LATE IN PREGNANCY

Method of

Jennifer Frank, MD

CURRENT DIAGNOSIS

- Avoid a digital vaginal examination in a patient with late-pregnancy bleeding until placenta previa is excluded by ultrasound.
- A patient can have more than one serious cause of late-pregnancy bleeding.
- Vaginal bleeding with rupture of membranes should prompt consideration of vasa previa.

CURRENT THERAPY

- Complete placenta previa requires cesarean section; however, with a placental edge more than 2 cm from the cervical os, vaginal delivery may be attempted in a stable patient.
- Antenatal diagnosis of vasa previa allowing delivery between 34 and 36 weeks of gestation is associated with significantly reduced perinatal mortality.
- Definitive management of a patient with late-pregnancy bleeding who is hemodynamically unstable or with a concerning fetal heart tracing should not be delayed in order to obtain ultrasound or other diagnostic testing.

Bleeding in the second half of pregnancy complicates 2% to 5% of pregnancies. Placenta previa, placental insertion into the lower uterine segment covering all or part of the internal cervical os, is the most common serious diagnosis, causing 30% of late-pregnancy bleeds and occurring in 0.5% of all pregnancies. Other serious causes include placental abruption (causing 20% of antepartum hemorrhages and occurring in 1% of all pregnancies), uterine rupture (occurring in approximately 0.7% of women with a history of previous low-transverse cesarean section), and vasa previa (0.5% of late-pregnancy bleeding and approximately 0.0002–0.0008% of all pregnancies). About 2% to 3% of cases go undiagnosed.

Risk Factors

Higher parity and maternal age, smoking or cocaine use, history of the same condition, and multifetal gestation are risk factors for both placenta previa and abruption. Risk factors for placenta previa also include uterine abnormalities, assisted reproductive technology (ART), and history of uterine surgery, including cesarean section. Additional risk factors for abruption include blunt abdominal trauma, polyhydramnios, and external cephalic version. The greatest risk factor for uterine rupture is a trial of labor following previous cesarean section. A uterine scar increases risk; spontaneous uterine rupture rarely occurs in an unscarred uterus. Other risk factors include uterine abnormalities, maternal connective tissue disease, abnormal placental implantation, and uterine hyperstimulation during labor. Shortened interpregnancy interval (less than 18 to 24 months between pregnancies) can also increase risk. Risk factors for vasa previa include artificial reproductive techniques, bilobed or succenturiate lobed placenta (odds ratio [OR] = 22.11), placenta previa (OR = 22.86), certain fetal anomalies, and velamentous cord insertion.

Pathophysiology

The cause of placenta previa is unknown but may be related to impaired placental attachment in a uterus with a previous scar. Placental abruption, defined as premature separation of the placenta from the uterus, is caused by hemorrhage where the placenta and decidua meet. Abruption is often preceded by vasospasm (such as that induced by cocaine), thrombosis, or shearing forces. Some cases are acute, but many cases could represent a chronic process in which abruption is the end result. Uterine rupture most often occurs in a uterus with a previous scar and is a dehiscence of the scar. Vasa previa occurs when fetal blood vessels are present in the membranes, traversing the cervix beneath the fetal presenting part. The pathophysiology of vasa previa is unknown, although it is theorized to be caused by abnormal development or growth of the umbilical cord secondary to velamentous insertion or reduced intrauterine space.

Prevention

Because previous cesarean section is a risk factor for both placenta previa and uterine rupture, reducing unnecessary cesarean section can prevent these conditions. Patients who have had a cesarean

section might decrease the risk of uterine rupture by spacing out the next pregnancy by at least 24 months. Uterine rupture may also be prevented by limiting or avoiding certain agents to induce or augment labor in women undergoing a trial of labor after cesarean section. Although vasa previa cannot be prevented, fetal morbidity and mortality are significantly reduced by early diagnosis and delivery. Placental abruption is associated with smoking and cocaine use; counseling directed to cessation theoretically reduces risk. Seat belts are recommended for all pregnant women; trauma sustained during a motor vehicle accident is a potential cause of abruption. Control of hypertension and treatment of thrombophilia have not been proved to prevent abruption, although both interventions are recommended. Magnesium sulfate given intrapartum to women with pre-eclampsia can reduce the risk of placental abruption.

Clinical Manifestations

Placenta previa classically manifests with painless vaginal bleeding, whereas placental abruption and uterine rupture are typically associated with pain and bleeding. Because these conditions are not mutually exclusive, it is important to consider the possibility of more than one serious cause of antepartum hemorrhage. Bleeding secondary to placenta previa may be heavy or light, can recur, and is not associated with the degree of previa or prognosis. Thirty percent of women with placental abruption may have a retroplacental clot concealing an abruption. Approximately one-half of women with placental abruption present in labor, and 30% of cases are complicated by fetal death. Monitoring can reveal uterine irritability or hypertonicity. Uterine rupture can manifest with loss of fetal station or palpable uterine defect. Pain and bleeding might not occur until after uterine rupture, when both maternal and fetal status are compromised. Vasa previa is detectable on ultrasound and color Doppler imaging but it still most commonly occurs as vaginal bleeding with rupture of membranes. Placental abruption, uterine rupture, and vasa previa can manifest with concerning fetal heart tracings.

Diagnosis

Ultrasound can detect placenta previa and vasa previa. In contrast, ultrasound is not reliable in establishing the diagnosis of placental abruption or uterine rupture. Transvaginal ultrasonography (TVU) is recommended to establish placental location because transabdominal ultrasonography has a false-positive rate for placenta previa up to 25%. TVU has a sensitivity of 87.5% and a specificity of 98.8% for placenta previa and is safe in the presence of vaginal bleeding.

Placental abruption has variable appearance on ultrasound, including absence of any abnormality. Diagnosis is made clinically in a patient with bleeding and a hard or tender uterus, uterine irritability, and often a nonreassuring fetal heart tracing, although bleeding may be absent. Vasa previa can be diagnosed using TVU and color Doppler.

High-risk women may be screened in order to plan for cesarean delivery at 34 to 36 weeks of gestation. Vasa previa may also be detected on magnetic resonance imaging (MRI; rarely used), amnioscopy, palpation of vessels during vaginal examination, or identifying fetal blood cells in vaginal blood, although tests to detect fetal hemoglobin cannot be performed quickly enough to be clinically useful.

Differential Diagnosis

In addition to placenta previa, placental abruption, uterine rupture, and vasa previa, diagnostic considerations include bloody show, cervical trauma, cervical polyp, cervical cancer, or infection.

Therapy

Women with placenta previa and active bleeding are managed expectantly in the hospital, although outpatient management may be a reasonable approach in women who are not bleeding, have adequate support at home, and are able to get to the hospital

quickly. Cervical cerclage in women with placenta previa and bleeding before term is not currently recommended.

Treatment of women with placental abruption depends on multiple factors including severity of clinical presentation, gestational age, fetal status, and maternal status. In the most severe case in which there has been fetal death, vaginal delivery is acceptable if the maternal status is reassuring. Because of risk for disseminated intravascular coagulopathy (DIC) and blood loss, women should be carefully monitored, proceeding to cesarean section for worsening maternal status or failed vaginal delivery. In mild cases of placental abruption before term, steroids should be administered between 24 and 34 weeks of gestation; preterm birth is the leading reason for perinatal death. Corticosteroid administration between 34 and 36 6/7 weeks gestation should be considered if not previously given. With a stable abruption in a preterm patient with reassuring fetal and maternal status, outpatient management may be reasonable after a period of inpatient observation. When placental abruption is known or suspected in a term patient, delivery should proceed. Labor may progress toward a goal of vaginal delivery if both maternal and fetal status are reassuring, although cesarean section should be performed expeditiously for any fetal or maternal compromise. Longer decision-to-incision intervals are associated with worse perinatal outcomes.

Uterine rupture is associated with high perinatal morbidity and mortality as well as potential maternal morbidity and mortality. When rupture is recognized or suspected, delivery should proceed rapidly.

Vasa previa is managed with immediate cesarean section if diagnosed during labor and with planned cesarean section if diagnosed antenatally. Administration of steroids is recommended at 28 to 32 weeks of gestation, and hospitalization should be considered at around 30 to 32 weeks of gestation because approximately 10% of women have premature rupture of membranes and could need urgent cesarean section. Certain patients are appropriate candidates for outpatient management. Optimal time for planned cesarean section is not definitively established and has been recommended between 34 and 36 weeks gestation. Neonatal resuscitation, including fluid resuscitation or transfusion, may be required and should be anticipated.

Monitoring

In placenta previa, the distance between the placental edge and cervical os is monitored during pregnancy because the placental location can change with advancing pregnancy. After 35 weeks' gestation, women with a placental edge more than 20 mm from the internal cervical os may be offered a trial of labor because they are likely to achieve vaginal delivery. Women with any degree of placental overlap should be delivered by cesarean section. When the placental edge is

greater than 0 mm but less than 20 mm from the internal cervical os, vaginal delivery might still be possible, although the likelihood of cesarean section is much higher. Women at increased risk of vasa previa should be screened with TVU and color Doppler. When vasa previa is identified, serial ultrasound is indicated because abnormal vessels regress in up to 20% of women.

Complications

Maternal risks associated with placenta previa include need for cesarean section, postpartum hemorrhage, and blood transfusion. Women who have a history of cesarean section and who have placenta previa are at increased risk for placenta accreta. Fetal risks are primarily associated with prematurity. Placental abruption can cause hypovolemic shock, postpartum hemorrhage, and DIC. Perinatal complications include prematurity, intrauterine growth restriction, anemia, coagulopathy, and death. Uterine rupture can be catastrophic for both mother and baby. Maternal risks include surgical risk associated with cesarean section, hypovolemic shock and hemorrhage, and hysterectomy. Perinatal morbidity can include hypoxic-ischemic encephalopathy. Stillbirth and neonatal death are possible as well. When undiagnosed prior to labor, vasa previa carries a fetal mortality rate of greater than 60%. Antenatal diagnosis with planned cesarean section decreases fetal mortality to 2 to 3% and reduces the need for transfusion from 60% to 3%. Because the hemorrhage is fetal blood, maternal risk from vasa previa is primarily associated with complications related to cesarean section.

ACUTE LEUKEMIA IN CHILDREN

Method of

Patrick Brown, MD; and Stephen P. Hunger, MD

The word “leukemia” is derived from the Greek roots *leukos* (white) and *haima* (blood). Leukemia, cancer of the blood-forming cells, is characterized by a marked proliferation of abnormal leukocytes in the bone marrow and blood that may be associated with widespread infiltration in extramedullary sites including the central nervous system (CNS), testes, thymus, liver, spleen, and lymph nodes.

Classification

The first level of classification of leukemia is *acute* versus *chronic*. Acute leukemia is characterized by the predominance of very immature white blood cell precursors, or blasts, and is an aggressive, rapidly fatal disease if left untreated. Chronic leukemia is characterized by proliferation of relatively mature white blood cells and is typically an indolent disease.

The second level of classification is *lymphoid* versus *myeloid*, depending on whether the leukemic cells display characteristics of lymphocyte precursors or myelocyte (granulocyte, erythrocyte, monocyte, or megakaryocyte) precursors. Acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) account for the overwhelming majority of pediatric leukemias. Chronic leukemias are uncommon in pediatrics.

ALL and AML are further subclassified by morphology and expression of cell surface antigens using flow cytometry. For ALL, classification is largely based on cell surface and cytoplasmic marker expression (Table 1). AML cases are classified by characteristic chromosomal abnormalities (if present) or by light microscopic morphology in cases where these specific chromosomal changes are absent (Box 1).

Epidemiology

The incidence of childhood cancer is 14 cases per 100,000 children younger than 16 years of age per year, which translates into approximately 11,000 new cases per year in the United States. Leukemia accounts for approximately 30% of childhood cancers, making it the most common form of childhood cancer. The distribution of the major forms of leukemia is vastly different in children than in adults (Figure 1). In general, children are far more likely to have acute leukemia, and ALL is much more common than AML. In adults, most cases of leukemia are chronic, and AML is much more common than ALL.

The incidence of the various forms of leukemia varies by age in both children and adults (Figure 2). This is especially true for childhood ALL, for which there is a marked incidence peak in the 2- to 4-year-old age group. This ALL age peak is primarily found in children living in industrialized nations, leading to speculation that a common environmental exposure, coupled with age-related immunologic susceptibility, is at least partially responsible for many cases of ALL. Except for a small peak in infants, the incidence of AML is fairly constant in childhood but rises quickly in later adulthood.

Prognosis

One of the most dramatic success stories in modern medicine is the improvement in survival of children with ALL over the past four decades. Leukemia was once a uniformly fatal diagnosis, with less than a 5% to 10% cure rate until the mid to late 1960s. Today, approximately 85% of children with ALL are cured. The improved prognosis has been built on pioneering observations on the efficacy of multiagent systemic therapy and the importance of presymptomatic CNS treatment in the late 1960s and early 1970s. Further successive, incremental improvements in outcome have been achieved due to clinical trials conducted by large single centers and national and international cooperative groups that have successfully enrolled a high percentage of eligible children.

Similar approaches have unfortunately not been quite so successful in improving the prognosis of children with AML. Although approximately one half of children with AML are cured today, this has been accomplished by intensifying therapy to the point that the toxic death rate in the early phases of therapy is about 10%. Current research in AML is therefore focusing on developing novel molecularly targeted agents that hold the promise of improving efficacy and limiting toxicity.

Etiology

The question “What is the cause of leukemia?” can be considered on a few different levels. First, what is wrong with *this child* that caused the child to develop leukemia? Second, what is wrong with *the leukemia cell* that causes it to behave so badly? Third, what is wrong with *the leukemia cell's genes* that cause the cell to behave that way?

Predispositions

The answer to the first question is unknown in the vast majority of cases. Attempts to correlate various genetic features or environmental or infectious exposures with risk of childhood leukemia have been largely uninformative. It is presumed that children are particularly susceptible to ALL because of the marked expansion and genetic rearrangement of lymphocytes that occurs during early childhood as the result of exposure to a multitude of immunogenic antigens for the first time. The proliferation required to meet the constant demand for granulocytes, erythrocytes, and platelets is likely a setup for the development of AML in children.

Although a number of constitutional and single-gene disorders are known to confer an increased risk of childhood leukemia (Table 2), in total, these are involved in only a very small minority of cases. The most common of these is Down syndrome. Children with Down syndrome have a 10- to 20-fold increased risk of leukemia, with an approximately equal incidence of ALL and AML. The peak age at onset of leukemia for children with Down syndrome is earlier than for other children. Approximately 30% of Down syndrome children with AML have the megakaryoblastic form (M7AML), a subtype that is extremely rare in children without Down syndrome. In the newborn period, Down syndrome patients can present with transient myeloproliferative disease, a disorder distinguishable from congenital AML primarily by its spontaneous resolution within 3 months. Children with Down

TABLE 1 Classification of Childhood Acute Lymphoblastic Leukemia

ALL SUBTYPE	PHENOTYPIC MARKER				%	COMMENT
	CD19	CD10	clg	slg		
Pre-pre B	+	—	—	—	5	Mostly infants, poor prognosis, frequent <i>KMT2A</i> 11q23 rearrangements
Early pre-B	+	+	—	—	63	Common ALL, young children, good prognosis

BOX 1 Classification of Childhood Acute Myeloid Leukemia (World Health Organization Criteria)

Acute Myeloid Leukemia with Recurrent Genetic Abnormalities

Acute myeloid leukemia with t(8;21)(q22;q22), (*RUNX1/RUNX1T1*)
 Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(p13;q22), (*CBFβ/IMYH11*)
 Acute promyelocytic leukemia with t(15;17)(q22;q12), (*PML/RARA*), and variants
 Acute myeloid leukemia with 11q23 (*KMT2A*) abnormalities

Acute Myeloid Leukemia, Not Otherwise Categorized

Acute myeloid leukemia, minimally differentiated (FAB M0)
 Acute myeloid leukemia without maturation (FAB M1)
 Acute myeloid leukemia with maturation (FAB M2)
 Acute myelomonocytic leukemia (FAB M4)
 Acute monoblastic/acute monocytic leukemia (FAB M5)
 Acute erythroid leukemia (FAB M6)
 Acute megakaryoblastic leukemia (FAB M7)

Abbreviation: FAB = French–American–British classification.

(cyclophosphamide [Cytosan], etoposide [Vepesid]). There is good evidence that in utero exposure to maternal diagnostic radiation also increases the risk of childhood cancer (including leukemia), particularly if the exposure is in the first trimester. Other environmental or infectious exposures remain unproved as risk factors for childhood leukemia, including electromagnetic fields from power lines.

Cellular Pathogenesis

Three major characteristics of leukemia cells distinguish them from normal hematopoietic cells. They proliferate rapidly, they do not differentiate, and they have defects in apoptosis. This results in a growth advantage for leukemia cells, leading to progressive replacement of the normal bone marrow with a massive clonal population of poorly differentiated leukemic blasts. Another characteristic of leukemia cells is their tendency to spread throughout the body and infiltrate organs other than the bone marrow. This is discussed in more detail in the section on clinical presentation.

Molecular Pathogenesis

As is true of most human cancers, development of leukemia is a multistep process. The initiating or permissive mutation (first hit) in childhood ALL often occurs in utero or early infancy, which is the peak of lymphocyte expansion and recombination activity.

The initiating events are typically chromosomal rearrangements that activate expression of cellular proto-oncogenes by fusing them to transcriptionally active immunoglobulin or T-cell receptor genes or by joining two genes from different chromosomes to create a new fusion gene that encodes a chimeric protein with unique functional properties. The most common of these sentinel chromosomal rearrangements are translocations (exchanges of genetic material between chromosomes), which can serve as a unique marker of the malignant clone. Retrospective studies of

syndrome tend to present with biologically favorable subtypes of leukemia, but they also suffer increased toxicity from therapy. On balance, the prognosis of leukemia in Down syndrome patients is similar to that in other children.

The only environmental exposures that are known to predispose to leukemia are ionizing radiation (such as was seen with atomic bomb survivors) and prior exposure to certain chemotherapy drugs

Figure 1 Relative incidence of four major leukemia subtypes in children and adults. Abbreviations: ALL = acute lymphoblastic leukemia; AML = acute myeloid leukemia; CLL = chronic lymphoblastic leukemia; CML = chronic myeloid leukemia.

Figure 2 Age-specific incidence of acute lymphoblastic leukemia (*ALL*) and acute myeloid leukemia (*AML*) in children and in adults (*inset*).

TABLE 2 The CRAFFT Questionnaire (version 2.1)

To be completed by patient

Please answer all questions **honestly**; your answers will be kept **confidential**.

During the PAST 12 MONTHS, on how many days did you:

1. Drink more than a few sips of beer, wine, or any drink containing alcohol?
Put "0" if none.

of days

2. Use any **marijuana** (weed, oil, or hash by smoking, vaping, or in food) or "**synthetic marijuana**" (like "K2," "Spice")? Put "0" if none.

of days

3. Use **anything else to get high** (like other illegal drugs, prescription or over-the-counter medications, and things that you sniff, huff, or vape)? Put "0" if none.

of days

READ THESE INSTRUCTIONS BEFORE CONTINUING:

- If you put "0" in ALL of the boxes above, ANSWER QUESTION 4, THEN STOP.
- If you put "1" or higher in ANY of the boxes above, ANSWER QUESTIONS 4-9.

	NO	Yes
4. Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs?	<input type="checkbox"/>	<input type="checkbox"/>
5. Do you ever use alcohol or drugs to RELAX , feel better about yourself, or fit in?	<input type="checkbox"/>	<input type="checkbox"/>
6. Do you ever use alcohol or drugs while you are by yourself, or ALONE ?	<input type="checkbox"/>	<input type="checkbox"/>
7. Do you ever FORGET things you did while using alcohol or drugs?	<input type="checkbox"/>	<input type="checkbox"/>
8. Do your FAMILY or FRIENDS ever tell you that you should cut down on your drinking or drug use?	<input type="checkbox"/>	<input type="checkbox"/>
9. Have you ever gotten into TROUBLE while you were using alcohol or drugs?	<input type="checkbox"/>	<input type="checkbox"/>

blood obtained at birth and preserved on filter paper used for diagnosis of genetic disorders (Guthrie cards) of children who developed leukemia in early childhood have shown that leukemia-associated fusion genes were present at birth in a large percentage of children, including some who did not develop leukemia for one or more years.

In ALL, the promotional mutation (second hit) likely occurs during the proliferative stress generated by immune responses to exogenous antigens. Because these are maximal in the 2- to 4-year-old age group, this is thought to explain the age peak of childhood ALL during these years. The lack of such a peak in AML suggests that the promotional mutations can occur at any time or are not triggered by immune stimulation. Examples of specific genetic hits known to be associated with the development of childhood leukemia are summarized in [Table 3](#).

Clinical Presentation

Most symptoms and signs of childhood leukemia are the result of the propensity of leukemia cells to replace the bone marrow and infiltrate multiple other organs throughout the body. It is estimated that approximately 10^9 (1 trillion) leukemia cells are present in the child’s body at diagnosis.

The replacement of normal bone marrow is responsible for the characteristic abnormal blood counts, which in most cases include the triad of neutropenia, anemia, and thrombocytopenia. Depending on the number of circulating leukemic blasts in the peripheral blood, the total white blood cell count may be low, normal, or high. The neutropenia is often profound (absolute neutrophil count $<500/\mu\text{L}$), and is associated with an increased risk of serious infection. Blood cultures and broad-spectrum intravenous antibiotic coverage are indicated in any patient with newly diagnosed leukemia and fever. Anemia is often manifested by fatigue, lethargy, headache, pallor, and, in extreme cases, congestive heart failure that may be precipitated by vigorous transfusion or intravenous hydration. Thrombocytopenia often

leads to bruising and petechiae; however, clinically significant hemorrhage is uncommon in industrialized countries. Platelet transfusion is indicated for bleeding or for very low platelet counts ($<10,000\text{--}20,000/\mu\text{L}$).

Infiltration of organs other than the bone marrow with leukemia cells is responsible for additional presenting clinical features. [Box 2](#) summarizes the organ systems most often involved in leukemia and the typical clinical manifestations.

Medical Emergencies in Childhood Leukemia

Newly diagnosed leukemia in a child is a medical emergency. There are several potentially life-threatening complications that may be present at diagnosis or can develop within a short time after diagnosis. The need to diagnose and treat potential infection in patients who are febrile and neutropenic was discussed earlier.

Tumor lysis syndrome (TLS) is a complication resulting from the rapid lysis of large numbers of tumor cells, releasing intracellular contents. Although TLS is seen most often after initial treatment with chemotherapy, it can also be present before therapy is initiated due to spontaneous lysis. Risk factors include high white blood cell (WBC) count, lymphadenopathy, hepatosplenomegaly, high mitotic index, and a diagnosis of ALL (especially Burkitt’s leukemia or lymphoma and T-cell ALL). TLS is characterized by the triad of hyperuricemia (from breakdown of purines by xanthine oxidase), hyperkalemia, and hyperphosphatemia (with secondary hypocalcemia). Renal insufficiency can develop due to the nephrotoxic effects of precipitated urate crystals in the renal tubules; in severe cases, dialysis may be necessary.

Management consists of aggressive hydration to reduce tubular uric acid concentration. The xanthine oxidase inhibitor allopurinol (Zyloprim) is routinely used during the first 3 to 7 days of leukemia treatment to decrease uric acid production. Rasburicase (Elitek) (recombinant urate oxidase) is a new agent

Abbreviation: ALL = acute lymphoblastic leukemia; AML = acute myeloid leukemia; TBSA = total body surface area.

lead to increased blood viscosity that can produce sludging of blood in the brain, lungs, kidneys, and other organs, causing clinical features such as depressed level of consciousness, stroke, intracranial hemorrhage, respiratory distress, hypoxia, diffuse pulmonary infiltrates, and renal insufficiency. The risk of hyperviscosity is higher with AML than ALL, because myeloblasts are generally larger and stickier than lymphoblasts (likely due to increased expression of integrins and other mediators of cell-cell adherence on the surface of myeloblasts). Management consists of treating the leukemia as soon as possible and performing exchange transfusion or leukopheresis in cases where symptoms are prominent.

Life-threatening bleeding is another potential complication of leukemia. Although all patients with thrombocytopenia are at risk, patients with concomitant coagulopathy due to disseminated intravascular coagulation (DIC) are at particularly high risk. The leukemia subtype most commonly complicated by DIC and serious bleeding is acute promyelocytic leukemia (APL). This association results from the release of thromboplastin from the cytoplasmic granules in promyelocytic blasts. Aggressive blood product support and early treatment with the differentiation-inducing agent *all-trans* retinoic acid (ATRA) has been shown to decrease the risk of bleeding in APL. Despite these measures, up to 10% of patients die of bleeding complications during the initial weeks of therapy, and additional patients suffer lasting morbidity from retinal hemorrhages and nonfatal central nervous system hemorrhages.

Tracheal compression and superior vena cava syndrome can result from large anterior mediastinal masses, which are commonly present in T-cell ALL but are rare in other forms of leukemia. Patients can present with respiratory distress, cough, orthopnea, headaches, syncope, dizziness, facial swelling, or plethora. A chest x-ray should be performed to assess the mediastinum in any patient suspected to have ALL. If the mediastinum is enlarged, a CT is indicated to assess airway patency. This evaluation must precede any attempts at sedation for diagnostic procedures, because even light sedation can precipitate acute airway collapse. Diagnostic material should be obtained by the least invasive method possible before treatment. If necessary, emergent airway compromise can be treated with radiation or steroids, or both.

Differential Diagnosis

Although leukemia should be considered in cases of isolated neutropenia, anemia, or thrombocytopenia, the vast majority of leukemia patients present with depressions in more than one cell line. In suspected cases of immune thrombocytopenic purpura (ITP), for example, a careful review of the peripheral blood smear should be performed to rule out the presence of circulating leukemic blasts. Routine bone marrow aspiration is not necessary for children with ITP, but it should be performed in patients with atypical features, such as concomitant anemia or neutropenia, hepatosplenomegaly, bone pain, or significant weight loss. Treatment of ITP with corticosteroids should only be instituted after evaluation by an experienced hematologist.

Pancytopenia can be caused by diseases other than leukemia. Some viral infections have a propensity to suppress bone marrow function and cause low peripheral blood cell counts, including Epstein-Barr virus (EBV), herpes simplex virus (HSV), influenza, hepatitis viruses, and HIV. Infectious mononucleosis from EBV infection can be particularly difficult to differentiate from leukemia, because patients often have hepatosplenomegaly and circulating atypical lymphocytes (which can appear very similar to leukemic blasts). Pancytopenia on the basis of bone marrow failure (from acquired aplastic anemia or rare inherited bone marrow failure syndromes) can be distinguished from leukemia by bone marrow biopsy for assessment of overall marrow cellularity. Certain solid tumors have a tendency to metastasize to the bone marrow and cause cytopenias, including neuroblastoma, rhabdomyosarcoma, and retinoblastoma, but it

used in severe cases of TLS to almost instantaneously convert uric acid to the more soluble allantoin. Frequent electrolyte monitoring with standard management of abnormal levels is essential.

Hyperleukocytosis becomes a potential clinical problem when the WBC count rises above 100,000/ μ L. Markedly elevated WBCs

is rare for pancytopenia to be the primary presenting feature in these cases.

Joint pain, fever, hepatosplenomegaly, and pallor are common presenting features in both systemic-onset juvenile idiopathic arthritis (JIA) and leukemia. A bone marrow aspirate should be performed to rule out leukemia before treatment with steroids in suspected cases of systemic-onset JIA.

Risk Stratification

In the last several years, treatment decisions for children with newly diagnosed acute leukemia have been based on the concept of risk stratification. Using factors identified during clinical trials to predict a high or low risk of relapse, patients are separated into risk groups before the start of treatment or at the end of the first month of induction therapy. The treatment plan is then tailored to the degree of risk. The desired result is that patients with relatively low-risk disease can be treated with less toxic therapy without compromising cure rates, and patients with high-risk disease receive more-intensive, potentially toxic therapy. The risk groups are currently defined based on several criteria and differ for ALL and AML. Different centers and cooperative groups typically employ different risk-stratification strategies.

In ALL, the initial risk assessment is based on two simple clinical parameters that are available immediately at the time of diagnosis (the National Cancer Institute [NCI] or Rome criteria): WBC count ($>50,000/\mu\text{L}$ is high risk), and age (<1 year or >9 years is high risk). Further refinement of risk assignment is often based on a combination of leukemia phenotype (B- vs T-lineage), the presence of certain sentinel cytogenetic lesions, and how quickly the patient's leukemia responds to the first few weeks of therapy (rapid clearance of leukemia cells from the blood or marrow is associated with a lower risk of relapse).

Low-risk cytogenetic features include hyperdiploidy (≥ 50 chromosomes in the leukemia cells) or trisomies of specific

chromosomes and the presence of a $t(12;21)$ that results in *TEL/AML1* fusion. High-risk cytogenetic features include hypodiploidy (<44 chromosomes in the leukemia cells) and the presence of either an $11q23$ (*MLL* gene) rearrangement or a $t(9;22)$, or Philadelphia chromosome, that creates a *BCR/ABL* fusion gene.

Early response has historically been measured by the response to a prednisone prophase that includes a single dose of intrathecal methotrexate and 7 days of prednisone, or by the percentage of blast cells remaining in the bone marrow after 7 to 14 days of multiagent therapy. Over the past 10 to 15 years, measures of tumor burden remaining in the marrow at the end of induction therapy (minimal residual disease) have been shown to be highly predictive of outcome and have been integrated into risk-stratification schemata of all of the major leukemia cooperative groups.

In AML, risk stratification is based largely on cytogenetics. Low-risk features include a $t(8;21)$, which results in the *AML1/ETO* fusion, and either $inv(16)$ or a $t(16;16)$, both of which create the *CBF β /MYH11* fusion. High-risk features include monosomy 7 and abnormalities in the long arm of chromosome 5. In addition to these cytogenetic abnormalities, failure to achieve remission with induction chemotherapy is another high-risk feature in AML. All other cytogenetic abnormalities, as well as normal cytogenetics (which are seen in approximately 60% of cases), are considered intermediate risk. More recently, a specific type of genetic mutation in the tyrosine kinase gene *FLT3* has been identified as another high-risk feature. This type of *FLT3* mutation (called an internal tandem duplication [ITD]) occurs in 10% to 15% of childhood AML.

Treatment

There are significant differences in the specific treatments for ALL and AML, so they will be discussed separately. Table 4 summarizes the most salient features of the treatment for each.

TABLE 4 Summary of Treatment for Childhood Leukemia

CHARACTERISTICS	ACUTE LYMPHOBLASTIC LEUKEMIA	ACUTE MYELOID LEUKEMIA
Remission Induction		
Chemotherapy	4 wk with prednisone or dexamethasone, vincristine, PEG asparaginase, daunorubicin (not all cases)	Two courses (6–8 wk) with cytarabine (Ara-C), doxorubicin ¹ , others (e.g., etoposide ¹ , thioguanine)
Toxic death rate	Low ($<3\%$)	High ($>10\%$)
Remission rate	$>98\%$	75%–85%
CNS Preventive Therapy		
Intrathecal chemotherapy	Methotrexate	Cytarabine
Cranial irradiation	For high risk (blasts in CSF at diagnosis and/or high WBC count)	None
Consolidation		
Chemotherapy	Combinations of various drugs (not cross-resistant) Intensity/duration based on risk stratification	Based on cytogenetic/molecular risk group and minimal residual disease (MRD) Low risk: 2–3 additional courses Intermediate risk: If MRD-negative, treat as low risk; if MRD positive, treat as high risk High risk: BMT for patients with best available donor
Maintenance		
Chemotherapy	Low-dose oral (6-mercaptopurine and methotrexate) Total duration of therapy 2–3 y	No maintenance therapy (does not improve survival)

Abbreviations: BMT = bone marrow transplant; CNS = central nervous system; CSF = cerebrospinal fluid; HLA = human leukocyte antigen; WBC = white blood cell.

¹Not FDA approved for this indication.

Acute Lymphoblastic Leukemia

Treatment for ALL generally occurs in four phases: remission induction, CNS preventive therapy, consolidation, and maintenance. Remission induction in ALL typically lasts 4 to 6 weeks and includes three to five systemic agents. Common to almost all regimens are a corticosteroid (either prednisone [Deltasone] or dexamethasone [Decadron]), vincristine (Vincasar), and PEG asparaginase (Oncaspar), which compose the three-drug induction. An anthracycline, typically daunorubicin (Cerubidine), is also included in many regimens (four-drug induction), with other agents such as cyclophosphamide (Cytosan) or etoposide (VePesid)¹ used in a small minority of centers. More than 98% of children enter remission by the end of 4 weeks of induction therapy, and the mortality rate from toxicity during induction therapy is generally less than 2% to 3% in industrialized countries.

The concept that the CNS could be a sanctuary site for leukemia emerged in the mid 1960s when the introduction of multiagent systemic chemotherapy led to high remission rates, but a majority of patients relapsed within 6 to 12 months, with many of these recurrences being limited to the CNS. Routine introduction of presymptomatic CNS radiation in the late 1960s and early 1970s led to substantial increases in cure rates to approximately 50%. Modern CNS preventive therapy includes periodic administration of intrathecal chemotherapy (usually methotrexate) starting at the time of the first diagnostic lumbar puncture. Systemic agents with improved CNS penetration (dexamethasone rather than prednisone, higher doses of intravenous methotrexate) might also play an important role in CNS control. Cranial irradiation is currently reserved for patients at the highest risk for CNS relapse (e.g., those with high diagnostic WBC count or leukemic blasts in CSF at diagnosis). Over time, CNS radiation has been given to fewer and fewer ALL patients; some groups believe that it can be eliminated for all patients. With these modern strategies, the risk of isolated CNS relapse is less than 5%.

Following the induction of remission, patients receive additional chemotherapy designed to consolidate the remission. The intensity and duration of the consolidation phase are risk based, and alternating cycles of non-cross-resistant chemotherapy drugs are typically used. These consolidation or intensification phases typically last about 6 months and often include a reinduction phase similar to the first month of treatment.

It has been clearly demonstrated that the risk of relapse in ALL can be reduced with an extended phase of continuous low-dose chemotherapy (maintenance) that lasts until 2 to 3 years from the time of diagnosis. Oral 6-mercaptopurine (Purinethol) and methotrexate are used universally, with variable administration of intrathecal chemotherapy. Some centers or groups also employ periodic doses of vincristine and 5- to 7-day pulses of prednisone or dexamethasone. The optimal frequency of intrathecal chemotherapy treatments and vincristine and steroid pulses is uncertain and might depend on the intensity of therapy delivered during the induction and consolidation phases.

Acute Myeloid Leukemia

Remission induction in AML typically consists of two courses of very intensive chemotherapy with cytarabine (Tarabine) and doxorubicin (Adriamycin)¹, often combined with thioguanine (Tabloid) or etoposide. Remission rates are 75% to 85%, with about one half of the failures due to resistant leukemia and the others to mortality from toxicity (usually infection).

Similar to ALL, CNS preventive therapy in AML begins at diagnosis with intrathecal chemotherapy (usually cytarabine) and continues with additional periodic intrathecal treatments during consolidation. High-dose cytarabine, which is a key component of most AML treatment regimens, also contributes to CNS treatment. Cranial radiation is not typically administered by most groups to children with AML, except for treatment of chloromas

(solid masses of leukemia cells) that do not resolve with chemotherapy.

Consolidation in AML is risk dependent. High-risk patients can be identified who have less than a 20% to 25% chance of cure with intensive chemotherapy. Most groups consider these patients to be candidates for BMT. If a matched sibling is unavailable, then alternative donor sources (e.g., matched unrelated bone marrow or umbilical cord blood) are usually offered. For low-risk patients, for whom the cure rate with chemotherapy alone approaches 70%, BMT is usually not offered in first remission, even for patients with a matched sibling donor. In addition, relapses in low-risk patients, unlike relapses in intermediate-risk or high-risk patients, can often be successfully treated with BMT in second remission, justifying reservation of BMT for use as a salvage therapy for low-risk patients. Consolidation in these cases consists of two to three additional chemotherapy courses that are slightly less intense and usually consist of cytarabine combined with drugs not used in induction, such as mitoxantrone (Novantrone) and L-asparaginase. For intermediate-risk patients, minimal residual disease (MRD) testing at the end of induction is increasingly being used to determine whether to consolidate with chemotherapy or BMT. Unlike ALL, most groups have found no benefit to extended maintenance therapy in children with AML.

Relapse

The most common site of relapsed leukemia is the bone marrow (with or without concomitant CNS involvement). Less common are isolated extramedullary relapses (CNS or testicular relapse in ALL, chloromas in AML). For both ALL and AML, a critical determinant of outcome following relapse is the time from diagnosis to relapse.

ALL patients who relapse within 18 months of initial diagnosis have a dismal outcome, with only about one half able to attain a second remission and less than 10% overall cure rate; the outcome is marginally better for those who relapse between 18 and 36 months after diagnosis. ALL patients with such early relapses are typically treated with 3 to 4 months of intensive therapy in an attempt to achieve a second remission and attain further cytoreduction, followed by BMT using a matched sibling or unrelated donor. In contrast, children with ALL who relapse more than 3 years after initial diagnosis have an approximately 95% chance of entering a second remission, and 40% to 45% can be cured with intensive chemotherapy; these patients are generally considered to be candidates for matched sibling, but not unrelated donor, BMT in second remission.

Overall, relapsed AML has a dismal outcome (long-term survival approximately 20%), and the approach is to attempt to reinduce remission and then proceed to BMT or investigational treatments. Even in this setting, there is clearly an improved outcome for patients who relapse after a prolonged initial remission (>12 months from the end of remission-induction therapy) compared with patients who have refractory disease or who relapse after a shorter period of remission.

New treatment strategies are urgently needed for patients with relapsed ALL and AML, because the current regimens produce poor results and are associated with a great deal of toxicity. The major clinical trial groups are testing novel and targeted therapies in these patient populations.

Late Effects

Approximately 70% of children with leukemia are cured of their disease. As the numbers of long-term survivors of childhood leukemia has grown, there has been increasing interest in assessing the late effects of leukemic therapy. In childhood ALL, with cure rates of 85%, a major effort is being made in ongoing clinical trials to reduce the intensity of therapy for lower-risk patients, with the hope of reducing late effects of therapy without compromising high cure rates. The most common late effects of leukemia therapy, with the known treatment-related risk factors and recommended diagnostic approach for each, are summarized in Table 5. Many pediatric oncology centers have developed late-effects programs to

¹Not FDA approved for this indication.

TABLE 5 Summary of Late Effects of Leukemia Treatment

LATE EFFECT	TREATMENT-RELATED RISK FACTORS	DIAGNOSTIC APPROACH
Bone	Avascular necrosis, osteonecrosis	X-ray and/or MRI of major joints for persistent pain
Cardiac dysfunction	Anthracyclines: cardiomyopathy (risk related to cumulative dose, higher risk in AML)	ECG or echocardiogram every 3 y (cardiomyopathy can occur decades after treatment)
Cataracts	CNS RT	Yearly eye examination
CNS and psychosocial	CNS RT, IT chemotherapy: learning problems, neurocognitive dysfunction	Yearly educational assessment, neurocognitive testing
Dental abnormalities	CNS RT	Dental examination at age 5
Endocrine and reproductive	CNS RT: pituitary dysfunction Alkylators: primary gonadal failure	Yearly growth curves, TSH, LH, FSH LH, FSH, estradiol or testosterone, semen analysis
Hepatic dysfunction	Methotrexate, 6-mercaptopurine, 6-thioguanine: late hepatic fibrosis	Yearly LFTs
Secondary neoplasms	CNS RT: brain tumors Alkylators or epipodophyllotoxins: secondary AML	MRI for symptoms Yearly CBC

Abbreviations: ALL = acute lymphoblastic leukemia; AML = acute myeloid leukemia; CNS = central nervous system; ECG = electrocardiogram; FSH = follicle stimulating hormone; IT = intrathecal; LFT = liver function test; LH = luteinizing hormone; MRI = magnetic resonance imaging; RT = radiation therapy; TSH = thyroid-stimulating hormone.

conduct surveillance for the development of these problems and provide follow-up care to patients who develop late complications of therapy.

ADOLESCENT HEALTH

Method of

Kari R. Harris, MD

CURRENT DIAGNOSIS

- In addition to general medical care, it is important to identify psychosocial health concerns at all adolescent visits.
- The key components of a psychosocial history are addressed in the HEADS private and confidential interview.
- Conducting a Home/Education/Employment/Activities/Accident Prevention/Diet/Disordered Eating/Drugs/Depression/Suicide/Self-harm/Sex/Sleep/Social Media (HEADS) interview is standard practice for adolescent care: it should be part of all adolescent well-checks and used, as time permits, in acute visits for teens who have high-risk behaviors or have no regular health care.
- High-acuity areas identified from the HEADS interview include substance use, disordered eating, sexual activity, and mental health.
- Depression screening should be part of well visits for all patients between 12 and 21 years of age.
- Substance use screening should be included in all adolescent well visits.
- HIV universal screening should be completed initially between 15 and 18 years of age and the need for re-screening reassessed annually.

CURRENT THERAPY

- Long-acting reversible contraception (LARC) provides safe and effective contraception for teenagers.
- Emergency contraception should be offered within 5 days of unprotected sexual activity.
- Treatment for teens is often multidisciplinary involving subspecialists, mental health providers, medical or psychiatric inpatient units, and county welfare or health departments.

CURRENT THERAPY

- Long-acting reversible contraception (LARC) provides safe and effective contraception for teenagers.
- Emergency contraception should be offered within 5 days of unprotected sexual activity.
- Treatment for teens is often multidisciplinary involving subspecialists, mental health providers, medical or psychiatric inpatient units, and county welfare or health departments.

Setting the Stage for the Adolescent Visit

Comprehensive care for adolescents includes screening for high-risk behaviors in addition to routine medical care. To facilitate open communication, providers should be clear about consent and confidentiality policies in their practices. This can be achieved by discussing policies with patients and parents/caretakers during young adolescent visits (11–14 years) and by providing materials documenting the policies and practices such as a standard letter to parents. Policies can also be displayed in the office, provided in practice newsletters and materials, and made available through patient access portals.

Adolescent visits differ from early childhood visits in several important respects. At the beginning of the visit, time should be spent with both the teen and his/her parent or caregiver clarifying medical history and current concerns. The adolescent should then be offered time without the parent or caregiver present to discuss sensitive issues, including reproductive and mental health. At the end of the visit, the parent/caregiver should be provided with a summary of the visit, limited to the non-confidential portion, and including recommendations and arrangements for follow-up appointments.

Consent and Confidentiality Laws—Consent Does Not Equal Confidential

Consent and confidentiality laws vary by state. Most states allow minors to consent for reproductive health care, including testing and treatment for sexually transmitted infections. Most states also allow providers to prescribe contraceptives to minors. Many states have a “mature minor” statute that allows physicians to provide care if they deem the adolescent patient mature and capable of understanding the medical care. These laws give teens autonomy to consent to their own health care and they also enable care to be provided when a parent is unable to attend the appointment.

While consent and confidentiality laws are related, they are separate entities. Many states allow minors to consent for specific health services but do not prohibit a provider from informing the teen’s parent/caretaker about that service. Even if allowed by law, expert consensus holds that such disclosures should only be made when in the best interest of the minor patient. The disclosure should not compromise future health care. Many teens will not seek reproductive health care if they have to involve a parent, making confidentiality necessary for comprehensive adolescent health care.

Confidentiality is limited when a minor patient is in direct harm such as intimate partner violence, sexual coercion or rape, certain pregnancy, suicidality, or self-harm. In such instances, a parent/caretaker should become involved, unless he/she is the perpetrator or some other extraordinary circumstances exist. Local authorities or social welfare agencies may also need to be contacted. These necessary breeches in confidentiality to protect safety must be explained beforehand to the patient and be included in written policies. Any breach of confidentiality must be carried out in a professional manner, explained sensitively to the patient and others, and well documented. Every attempt must be made not to compromise future care.

Information on consent and confidentiality laws for each state is available at the Guttmacher Institute website (guttmacher.org).

The HEADS Interview

The HEADS acronym provides a structured psychosocial history-taking tool that also screens for high-risk behaviors (Table 1). Although several variations of HEADS have been described, they all cover the most common risk categories for adolescents. Progressing from the least invasive topics to the most sensitive issues, HEADS covers all essential categories (see Table 1).

When using the HEADS interview tool, it is important to build rapport with the patient. The teen deserves explanation of why they

TABLE 1 HEADS Acronym With Sample Questions

H	Home	Who lives with you at home? Tell me about your relationships at home. Are you safe at home? Do you have a trusted adult to confide in at home? Do you have your own space at home? Have there been any changes at home?
E	Education	What grade are you in and what school? Is your school safe? Tell me about your friends. Does anyone bother you at school? How are your grades? Do you have any problems with school? Have you ever gotten in trouble for missing school? Do you plan to graduate? What do you want to do after graduation?
	Employment	Are you working? Do you like your job? Do you help your family with finances? Do you feel stressed because of work? Is your family stressed by your work? How many hours a week do you work?
A	Activities	What do you do for fun? Who do you hang out with? Tell me what you do after school. Are you in any organized after-school or summer activities? Tell me about your hobbies.
	Accident prevention	Tell me about your activities. Do you wear a seatbelt? Do you wear a helmet while biking or using an all-terrain vehicle? Have you ever ridden with someone while they were under the influence of drugs or alcohol, or have you ever driven under the influence?
D	Diet/Disordered eating	Tell me about your diet. Do you eat breakfast daily? How many fruits and vegetables do you eat? How do you feel about your weight? Do you like the way you look? Have you ever not eaten to try to lose weight? Do you ever feel guilty about what you have eaten? Have you ever skipped meals or thrown up on purpose after you have eaten?
	Drugs	Have you seen drugs at your school? Do any of your friends smoke, drink alcohol, or use other drugs? Have you ever tried drugs? Have you ever been in trouble because of drug use?
	Depression	Do you ever feel sad, down, or depressed? Have you ever felt like you had nothing to look forward to? Do you still like to do the things you used to do?
S	Suicide/self-harm	Have you ever been so upset you have wanted to hurt yourself? Have you ever cut yourself? Have you ever thought about killing yourself or someone else?
	Sex	Are you in a relationship? When is the last time you had sex? Did you use a condom? Are you using anything to prevent pregnancy? Have you ever been tested for STIs? How many partners have you had? Tell me about your partner (age, gender, etc). Do you feel safe with your partner? Have you ever been forced to have sex or do something you were not comfortable with?
	Sleep	What time do you go to bed? Where is your cell-phone when you go to sleep? When do you wake up in the morning?
	Social Media	What social media sites do you have profiles on? Are you friends with people you do not know in real life? How much time do you spend on social media? Does this affect your grades? Tell me about your privacy settings. Do you have any trusted adults that can access your social media sites?

Adapted from: Klein, DA, Goldenring, JM. HEADSS 3.0: The psychosocial interview for adolescents updated for a new century fueled by media. Contemporary Pediatrics. 2014. Available at <http://contemporarypediatrics.modernmedicine.com/contemporary-pediatrics/news/probing-scars-how-ask-essential-questions?page=full> [accessed Oct 13, 2014].

are being asked personal questions and every attempt should be made to increase patient comfort and trust. The interview begins with questions regarding hobbies, school, and home life. Once rapport is established, questions proceed to more sensitive issues. Questioning should be open-ended, nonassuming and nonjudgmental. This allows for honest answers and does not discriminate among patients.

Home/Education/Employment/Activities/Accident Prevention

These topics begin the confidential interview with the least risky activities for adolescents. Although grouped together in this text, each category deserves its own time and questions (see [Table 1](#)). All adolescents should have a trusted adult with whom they can discuss concerns. Safety at home and school safety, including any bullying or coercion regardless of site or circumstances, should be discussed and addressed. Current school performance, concerns, grades and post-graduation goals should be discussed. After-school employment has benefits but can also negatively impact academic performance, mood, or family dynamics. These should be screened for and addressed if present. Healthy after-school activities should be encouraged. Predictably, adolescent illegal activity, drug use, and sexual activity peak during after-school hours. Participation in organized, supervised, extra-curricular activities has been shown to decrease these risky behaviors and confer positive health and emotional benefits. Accidents remain the leading cause of death for this age group and prevention should be emphasized. Safety should be assessed at this time as well as throughout the course of the interview as it applies to each topic.

Diet/Disordered Eating

Nutritional health problems are of concern with adolescents. Many lifestyle habits, especially regarding nutrition, are formed during this period. Asking the teen to describe his/her typical diet provides insight on potential areas for improvement. Limiting portion sizes, avoiding excessive or late night snacking, and replacing sugary drinks with water is common advice for teens. This portion of the interview provides opportunity to screen for body image distortion or disordered eating. The growth chart should be reviewed and any significant weight changes discussed.

Drugs (Substance Use)

When asking about riskier behaviors, it is important to have rapport and trust. The subject of substance use can be broached by asking if peers use substances. Because alcohol, marijuana, electronic vaping, and tobacco use is so prevalent among high school students (reported by 65%, 40%, 45% and 40%, respectively), this initial question can make a teen more comfortable moving on to talk about personal use. The CRAFFT acronym is a brief and effective screening tool designed specifically for use with adolescents and helps the provider determine if further conversation or evaluation regarding substance use is warranted. The questions are broken into part A and B. If a patient answers “yes” to any questions in A, then part B questions are asked. If the patient answers “yes” to two or more questions of part B, the screen is positive and further evaluation is recommended ([Table 2](#)). If necessary, referral should be made to a qualified mental health provider for treatment. Substance use is a leading cause of morbidity and mortality for teens in the United States, and teens who use substances at an early age are more likely to become addicted. Substance use should not be ignored or minimized by providers. Counseling on prevention should contain a clear message of nonuse.

Depression/Suicide/Self-Harm

Depression screening is recommended at all well visits beginning at age 12. Several screening tools are available. Questions covering loss of interest in normal activities and feeling depressed, down, or hopeless open the door to more specific questions regarding signs and symptoms of depression. In addition to depressive

TABLE 2 CRAFFT Substance Use Disorder Screening Tool for Adolescents

PART A

- During the past 12 months did you:
1. Drink any alcohol (more than a few sips)?
 2. Smoked any marijuana or hashish?
 3. Use anything else to get “high”?

If all answers in part A are negative then ask only question 1 of Part B.
If any answer to part A is positive then ask all 6 questions of Part B.

PART B

- C Have you ever ridden in a CAR driven by someone (including yourself) who was “high” or had been using alcohol or other drugs?
- R Do you ever use alcohol or other drugs to RELAX, feel better about yourself, or fit in?
- A Do you ever use alcohol or other drugs while you are ALONE?
- F Do you ever FORGET things you did while using alcohol or other drugs?
- F Do your FAMILY or FRIENDS ever tell you that you should cut down on your drinking or drug use?
- T Have you ever gotten into TROUBLE while you were using alcohol or other drugs?

The CRAFFT Screening Tool, The Center for Adolescent Substance Abuse Research (CeASAR), Children’s Hospital Boston, 2009. Available at <http://www.ceasar.org/CRAFFT/index.php> [accessed August 17, 2017].

feelings, teens should be explicitly screened for suicidal intention, past attempts, plans, self-harm, and safety. If a teen discloses an unsafe environment, law enforcement should be included in an immediate plan of care. If a teen is actively suicidal, then immediate inpatient treatment is warranted. Outpatient treatment for mental health disorders in teens includes cognitive-behavioral therapy with or without medication. For most teens, parental involvement is necessary when treating mental health disorders. If the provider feels the teen is unsafe due to their own actions or those of others, then the confidential interview is no longer appropriate and the caretaker must be included in the next stage of management.

Sex

Nearly half of high school students have had sex. Of those, only about a quarter used reliable contraception at their last intercourse. Adolescents and young adults account for the majority of gonorrhea and chlamydia cases each year. Risk factors for morbidity related to sexual activity include early sexual initiation, increasing number of partners, substance use prior to sex, and unprotected sexual acts. Teenagers and men who have sex with men are the highest population groups at risk for sexually transmitted infections (STIs). STI screening should be discussed for those at risk. Recommendations are outlined in [Table 3](#).

When discussing the sensitive issue of sex with teens, it is important to use neutral terms and remain nonjudgmental. Sexual history should include age of first sexual encounter, age of partner(s), gender of partner, number of partners, type of sexual activities, date of last sexual activity, and contraceptive and barrier use. Quality of relationships should also be assessed, as 10% of high school students report that they have experienced sexual dating violence including sexual coercion and rape. As with substance use, providers should relay a clear message of abstinence as the safest method to prevent morbidity. Even for patients who are already sexually active, delaying future sex should be recommended.

Teens should be counseled on contraceptive options, emphasizing that LARC (intrauterine contraception and implants) is safe and the most reliable contraception available for teens. Quick-start contraception (prescribing or providing contraception at the current appointment) should be strongly considered to improve adherence in sexually active teens. The possibility of pregnancy should be reasonably ruled out prior to providing contraception by taking a careful sexual history including last menstrual period, date of last

TABLE 3 Laboratory Screening Recommendations

SCREENING	AGE	TEST	COMMENTS
Dyslipidemia	9–11 17–21	Nonfasting lipid profile	Once between 9 and 11 years and again between 17 and 21 years with annual risk assessment (NHLBI, AAP) Insufficient evidence for screening (USPSTF)
Hemoglobin/ hematocrit	11–21	Verbally screen for risk	No routine testing recommended
Human immunodeficiency virus (HIV)	15–18	HIV 1–2 immunoassay	At least once if ≥ 15 years with more frequent screening if high-risk. (CDC, USPSTF, AAP) Screen MSM at least annually (CDC)
Chlamydia	Females < 25	NAAT at site of potential infection	Screen all sexually active women < 25 years at risk (USPSTF) or annually and MSM at least annually. (CDC)
Gonorrhea	Females < 25	NAAT at site of potential infection	Screen all sexually active women < 25 years at risk (USPSTF) and MSM at least annually (CDC)
Syphilis*	Adolescents at increased risk	Serology with confirmatory testing if positive	Screen persons at increased risk (USPSTF). Screen MSM at least annually (CDC)
Cervical dysplasia screening	21 years	Pap smear	Other indications for pelvic exam still apply but routine Pap testing < 21 years is not recommended (USPSTF, AAP)

Abbreviations: AAP = American Academy of Pediatrics; CDC = Center for Disease Control and Prevention; MSM = Men who have sex with men; NAAT = nucleic acid amplification testing; NHLBI = National Heart, Lung, and Blood Institute; Pap smear = Papanicolaou smear; USPSTF = U.S. Preventive Services Task Force.

*also consider screening high risk adolescents for Hepatitis B infection with HbsAg (USPSTF).

sex, and method of contraception; lab work may also be considered (see the U.S. Selected Practice Recommendations for Contraceptive Use for guidance on how to reasonably rule out pregnancy https://www.cdc.gov/reproductivehealth/contraception/contraception_guidance.htm). If a patient has been recently sexually active, most non-intrauterine contraceptives have not been shown to harm an existing pregnancy. Nevertheless, counseling regarding this risk is important prior to initiating contraception, and pregnancy testing should be performed 2–4 weeks following contraception initiation. For patients who have had unprotected sex in the past 5 days, emergency contraception should be discussed and offered at the time of quick start contraception. Concurrent barrier contraception should be stressed. Aside from abstinence, male condoms are the most effective way of preventing STIs.

Sleep/Social Media

The conclusion of this format of the HEADS interview concerns less sensitive topics and allows for a comfortable close to the interview. Sleep is problematic for many teens and can usually be improved with better sleep hygiene. Encourage all teens to have a consistent sleep and wake time and 8 to 10 hours of sleep daily. Caffeinated beverages should be limited. Daily exercise should be recommended. The teen's bedroom should be free from distractions including radios, TVs, computers, phones, and tablets.

Social media and cell phones are now integral to popular culture. While these offer benefits to teens, use should be limited. Both social media and cell phones contribute to unintentional injuries, especially with distracted driving. In addition, personal information being shared on the internet through electronic media opens the teen up to vulnerability. Lastly, both can act as significant distractions from academic work, family time, and sleep. Discuss safe and appropriate use of electronic devices with patients and summarize to parents.

Summary

In addition to providing routine health care to teens, providers should focus on the psychosocial history. The HEADS acronym provides a tool for providers to approach these sensitive topics systematically. This interview should take place privately, respecting the teen's ability to consent for certain care, and when able, keeping care confidential. Providers should be familiar with the laws

regarding consent and confidentiality of minors in their state. Although teens should be allowed access to confidential health care, providers must be aware that often the best care includes a trusted adult. Parents should be involved in their teen's care when appropriate. Once teens have been assessed for high-risk behaviors, problematic behaviors should be addressed and low-risk behaviors should be commended and encouraged.

ASTHMA IN CHILDREN

Method of

Susan M. Pollart, MD, MS; Katharine C. DeGeorge, MD, MS; and
Amanda Kolb, MD

CURRENT DIAGNOSIS

- Recurrent wheeze, cough, and shortness of breath are typical asthma symptoms.
- A personal or family history of atopy is associated with an increased risk of developing asthma.
- Atopy, allergic rhinitis, eczema, or nasal polyps are common comorbidities in patients with asthma.
- Specifically ask about symptom triggers such as allergens, irritants, exercise, stress, cold, or infection.
- At initial diagnosis, outline symptom frequency, intensity, and timing to classify severity.
- Physical examination of asthmatic children is often normal, but mucosal edema of nasal turbinates, eczematous skin rashes, tachypnea, tachycardia, expiratory wheezes, and lung hyperexpansion may be observed.
- In children older than 5 years spirometry revealing an obstructive pattern at least partially reversible with bronchodilators confirms the diagnosis. In children younger than 5 years, diagnosis is based on history, physical examination, and a trial of antiasthma medications.
- Chest x-ray, complete blood count (CBC), and IgE levels are not routinely recommended but may be useful in certain situations.

CURRENT THERAPY

- The goal of asthma management is to reduce impairment of activities and decrease risk of exacerbations.
- Initial assessment of asthmatics should focus on symptom frequency, timing, and effect on activities to classify the degree of severity as intermittent, mild persistent, moderate persistent, or severe persistent.
- The four central components of management are frequent assessment and monitoring, patient education, controlling environmental triggers, and appropriate use of medication.
- Short-acting inhaled β_2 -adrenergic receptor agonists such as albuterol (Proventil HFA) are the mainstay of acute therapy in an episode of bronchoconstriction. Additionally, anticholinergics such as ipratropium bromide (Atrovent HFA)¹ and systemic steroids are important components of managing an acute exacerbation. Magnesium sulfate¹, epinephrine (Adrenalin)¹, and terbutaline (Brethine)¹ are reserved for refractory cases, and terbutaline is only approved for children 12 years and older.
- Inhaled corticosteroids are the most effective daily controller medications for children. Long-acting β_2 -agonists, leukotriene-receptor antagonists, and mast cell stabilizers are commonly used adjunctive therapies.
- Visits should be scheduled frequently in the outpatient setting to reassess symptom severity, adjust medications accordingly, and emphasize patient education.
- Consider increasing medication therapy only after assessing the patient's adherence and technique with medications. Consider a step-down in therapy only after 3 months of adequate control of symptoms.
- Involve both children and their caregivers in designing a written asthma action plan to empower patients in recognizing and managing escalating symptoms.
- Refer to a pulmonologist or allergist if there is any question regarding diagnosis or if symptoms are not adequately controlled with standard treatment. Consultation by a

pulmonologist is recommended for children aged 5 years or older at \geq step 4 of therapy (or \geq step 3 in children younger than 5 years).

¹Not FDA approved for this indication.

Epidemiology

Asthma prevalence in the United States has been on the rise since the 1990s. It is currently estimated that 9.6% of children younger than 18 years (7.1 million children) carry the diagnosis of asthma. Male sex, African American or Puerto Rican ethnicity, and lower socioeconomic status are associated with an increased risk of developing asthma. Prevalence estimates for these groups are as high as 11% to 16%.

Asthma has a significant impact on both school attendance and health care expenditures. According to the National Health Statistic Report in 2007, children made 640,000 emergency department visits and were hospitalized 157,000 times as a result of asthma. In 2008 it was estimated that there were 10.5 million missed school days, and about 5% of children reported long-term limitations on their usual activities due to asthma symptoms.

Although no significant difference in asthma prevalence between urban areas and suburban or rural areas has been found, there do seem to be broader geographic trends with higher prevalence in the Northeast and Midwest. Mortality rates remain low, but preventable deaths attributable to asthma exacerbations persist.

Risk Factors

No clear precipitating factors have been associated with the onset of asthma in children, but multiple risk factors for the development of this disease have been identified. Perhaps the strongest link is that between a family history of atopy, atopic dermatitis in infancy, or elevated serum immunoglobulin (Ig)E levels and subsequent sensitization to aeroallergens at 5 years of age. Other identified associations include sensitization to dust mites, preterm birth, exposure to tobacco smoke, and certain respiratory infections such as respiratory syncytial virus (RSV).

Pathophysiology

Asthma is a chronic disease with recurrent episodes of reversible airway obstruction. It is thought to consist of three major pathophysiologic components: bronchoconstriction, airway inflammation, and bronchial hyperresponsiveness. Bronchoconstriction results from bronchial smooth muscle contraction in response to exposure to allergens, irritants, stress, infection, exercise, or certain medications such as aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Inflammation occurs via the T helper 2- (T_H2) and IgE-mediated pathways. Examination of the airways of asthmatics reveals inflammatory infiltrates consisting of neutrophils, eosinophils, lymphocytes, and activated mast cells. These mast cells release histamine along with other inflammatory mediators, causing airway edema, mucous hypersecretion, and airway hyperresponsiveness to environmental stimuli. Over time, remodeling can occur with airway thickening and smooth muscle hyperplasia, with a resulting decline in lung function and reduced response to therapeutic interventions.

Long-term observational studies have suggested that declining lung function is most commonly seen in children with symptom onset before 3 years of age. It still remains unclear whether older children or adults experience the same reductions in lung function.

Prevention

Primary prevention of asthma is a much-studied topic, yet few studies have successfully identified effective strategies for preventing asthma. The effect of breast-feeding on asthma prevalence has been a focus of extensive research. Much of the literature regarding breast-feeding as primary prevention for asthma suggests a protective effect of breast-feeding, but this has not been borne out consistently: a Cochrane review of 5 trials (952 pregnant or lactating

mothers) found no evidence that avoidance of antigens (milk, eggs, nuts) by breast-feeding mothers during pregnancy or lactation decreased asthma or eczema in children through the study period of 18 months.

There is conflicting evidence regarding allergen avoidance to prevent the onset of asthma, although reducing exposure to inhalant allergens such as mites and pet dander can improve symptoms in patients with diagnosed asthma.

Based on the best evidence at present, breast-feeding should be encouraged for its many known health benefits and potential protective effect on developing asthma. Avoidance of household dust mite aeroallergen or specific single food allergen exposure during pregnancy, breast-feeding, or first years of life is not routinely recommended for primary prevention of asthma. The topic of primary prevention of asthma warrants further study to clearly establish feasible preventive measures.

Clinical Manifestations

Asthma is characterized by recurrent episodes of wheezing, chest tightness, and shortness of breath. Asthma can also manifest as a chronic dry cough, especially if occurring at night. Young children commonly present with chronic cough alone, a form of asthma called cough-variant asthma. Wheezing that recurs in the setting of specific, predictable triggers is also a manifestation of asthma.

Diagnosis

A focused history revealing recurrent episodes of wheezing, shortness of breath, or cough suggests asthma and merits further investigation. In infants, the symptoms of asthma can involve difficulty feeding. Parents might also report intermittent grunting or loud breathing.

When taking the history, it is important to ask about symptom triggers, time course, and frequency of symptoms to assess severity. It is also important to discuss any family history of atopy, asthma, eczema, or nasal polyps. Triggers such as exposure to inhalant allergens (mold, dust, pollen, pet dander), irritants (chemicals, cigarette smoke), weather changes, intense emotion, physical activity, and viral illnesses should be elicited specifically (Box 1).

Begin the physical examination with measurements of height and weight and inspection of the growth chart. Most children do not have a significant growth or height reduction as a result of asthma.

If a child's growth chart demonstrates a marked decrease in growth velocity, it is prudent to seriously consider alternative diagnoses.

Owing to the intermittent nature of asthma symptoms, children with asthma often have an entirely normal examination. Upper airway findings can include nasal polyps or mucosal edema of nasal turbinates. The skin examination might reveal signs of atopic dermatoses such as eczema or urticaria. Lung examination may be remarkable for wheezing, hyperexpanded barrel chest, increased respiratory rate, or tachycardia, depending on severity of symptoms. The American Academy of Allergy, Asthma, and Immunology recommends spirometry as a useful means of obtaining objective data on lung function and presence of obstructive disease for the diagnosis of asthma prior to trial of medications in patients over the age of 5 years, a recommendation that is part of the Choosing Wisely campaign.

Spirometry before and after short-acting β -agonist inhalation should show reversibility of obstruction in a patient with asthma. A rise in forced expiratory volume in 1 second (FEV₁) of 200 mL and 12% above baseline after bronchodilator is consistent with reversible obstruction. In children younger than 5 years, such studies might not be feasible. In these cases, diagnosis is based on history and physical. A trial of bronchodilator is helpful in establishing the diagnosis as well as ruling out other possible etiologies of symptoms.

A common presenting symptom of asthma in children is chronic cough. In cough-variant asthma, spirometry may be entirely normal. A trial of antiasthma medication that results in resolution of cough confirms the diagnosis.

Peak flow meters are useful in monitoring symptom severity but should not be used to make a diagnosis owing to wide variations in individual results and normal values.

Chest x-ray should be considered when ruling out alternative diagnoses but is not recommended in routine diagnostic testing for asthma. Allergy skin testing can identify potentially avoidable inhalant indoor allergens and, when appropriate, guide immunotherapy. Finally, checking a complete blood count with differential and serum IgE levels is not clearly indicated in making a diagnosis but may be useful in guiding treatment. Eosinophilia (greater than 4%) can indicate the need for controller medications, and patients with high levels of IgE have been shown to have a particularly good response to inhaled corticosteroids.

Finally, fractional exhalation of nitrous oxide (FeNO) may have an emerging role in diagnosing asthma and monitoring response to treatment. A 2016 Cochrane review of nine randomized controlled trials suggested that using FeNO levels to tailor treatment may decrease exacerbations overall, including severe exacerbations requiring oral corticosteroids.

Differential Diagnosis

The differential diagnosis of recurrent respiratory symptoms is broad and must be considered when initiating diagnostic work-up. When creating a list of other diagnoses, it can be useful to consider the airway from the top down, as is shown in Box 2. Also keep in mind that the age of the patient and the chronicity of symptoms can point to certain diagnoses in your differential.

Treatment

To treat asthma in children appropriately, the severity of symptoms must first be assessed. This initial evaluation should be followed by an ongoing assessment that monitors response to therapy. The general tenets of asthma treatment are to reduce the functional limitations caused by asthma symptoms and decrease the risk of exacerbations, decline in lung function, and side effects of medications. The Expert Panel Report 3 on the National Asthma Education and Prevention Program released in 2007 describes a patient-oriented and clinically relevant approach to asthma management. Emphasis is placed on organized primary care visits and patient education. It is important to plan routine visits with a child's pediatrician or family doctor until symptoms are adequately controlled.

Once the diagnosis of asthma is made in a child, symptom severity should be assessed. Symptoms are classified as intermittent,

BOX 1 Asthma Triggers

Allergens

- Animal dander
- Pollen
- Dust mites
- Mold

Chemical irritants

- Tobacco smoke
- Wood stove smoke
- Air pollution
- Cleaning chemicals
- Gases

Medications

- Aspirin
- Nonsteroidal antiinflammatory drugs
- β -Blockers

Other

- Gastroesophageal reflux
- Exercise
- Respiratory infection
- Extremes of emotion
- Stress
- Changes in weather
- Cold air

BOX 2 Differential Diagnosis**Upper Airway**

Allergic rhinitis
Sinusitis

Large Airway Obstruction

Vocal cord dysfunction
Laryngotracheomalacia (infants)
Tracheal stenosis (infants)
Vascular rings
Tracheal webs
Inhaled foreign body
Tumor or enlarged lymph nodes compressing airway

Small Airway Obstruction

Viral bronchiolitis
Pneumonia
Obliterative bronchiolitis
Cystic fibrosis
Bronchopulmonary dysplasia
Heart failure

Other

Gastroesophageal reflux disease
Swallowing mechanism dysfunction leading to aspiration

Adapted from National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the diagnosis and management of asthma. Summary report 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm> (accessed March 13, 2108).

mild persistent, moderate persistent, or severe persistent. To determine severity, the frequency of daytime symptoms, nighttime symptoms, frequency of using short acting β_2 -agonists, impairment of activities, frequency of exacerbations requiring oral steroids, and lung function must be considered (Table 1). Once severity has been classified, treatment can be started based on the stepwise approach outlined in Table 2. This stepwise approach is intended to be a guideline only. Clinical judgment is necessary when applying these guidelines to the individual patient. Children 12 years and older may be assessed and treated according to the guidelines described for adults.

Assessing adequacy of symptom control is essential to the management of asthma. At each follow-up visit, discussion should focus on how often the patient is having asthma symptoms and how much those symptoms are interfering with normal activities. Tools such as the Asthma Control Test (ACT) or the Childhood Asthma Control Test are helpful in measuring symptom control in a standardized fashion. Symptom assessment determines adequacy of control and guides changes in treatment, as shown in Tables 2 and 3. Frequency of primary care visits depends on severity of symptoms and can initially occur every 2 to 6 weeks. As control improves, visits may be decreased to every 1 to 6 months. At each visit, medications can be reviewed, doses adjusted, and education reiterated on recognizing symptoms and using medication and spacers.

Only after at least 3 months of adequate control should a decrease in therapy be considered. When stepping down, do so gradually, with frequent reassessment for reemerging symptoms. In the same way, therapy should be increased only after ensuring that the patient has been adherent with medications and is using

TABLE 1 Classification of Asthma Severity

COMPONENTS OF SEVERITY	AGE (Y)	INTERMITTENT	PERSISTENT		
			MILD	MODERATE	SEVERE
Impairment					
Symptoms	All	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Throughout the day
Nighttime awakenings	0–4 ≥ 5	0 ≤ 2 ×/mo	1–2 ×/mo 3–4 ×/mo	3–4 ×/mo > 1 ×/wk but not nightly	> 1 ×/wk Often 7 ×/wk
SABA for symptom control	All	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Several ×/day
Interference with normal activity	All	None	Minor limitation	Some limitation	Extremely limited
Lung Function		Normal FEV ₁ between exacerbations			
FEV ₁ (predicted) or PEF (personal best)	≥ 5	> 80%	> 80%	60%–80%	< 60%
FEV ₁ /FVC	5–11 ≥ 12	> 85% Normal	> 80% Normal	75%–80% Reduced 5%	< 60% Reduced > 5%
Risk					
Exacerbations requiring oral corticosteroids	0–4 5–11 ≥ 12	≤ 1/y ≤ 1/y ≤ 1/y	≥ 2 × in 6 mo or ≥ 4 wheezing episodes/y lasting > 1 d <i>and</i> risk factors for persistent asthma ≥ 2 ×/y*		
Starting Treatment					
Recommended step	0–4 5–11 ≥ 12 All All	Step 1 Step 1 Step 1	Step 2 Step 2 Step 2	Step 3 Step 3 Step 3 Consider short course of oral corticosteroids	Step 3 Step 3 or 4 Step 4 or 5
		In 2–6 wk, evaluate level of asthma control and adjust therapy accordingly. For children 0–4 yr, if no clear benefit is observed in 4–6 wk, stop treatment and consider alternative diagnosis or adjusting therapy			

Abbreviations: FEV₁ = forced expiratory volume in 1 second; FVC = forced vital capacity; PEF = peak expiratory flow; SABA = short-acting β_2 -adrenergic receptor agonist. *Consider severity and interval since last exacerbation. Frequency and severity can fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV₁.

TABLE 2 Levels of Asthma Control

COMPONENTS OF CONTROL	AGE (Y)	WELL CONTROLLED	NOT WELL CONTROLLED	VERY POORLY CONTROLLED
Impairment				
Symptoms	0–4	≤ 2 d/wk but ≤ 1 ×/day	> 2 d/wk or multiple times on ≤ 2 d/wk	Throughout the day
	5–11			
	≥ 12	≤ 2 d/wk	> 2 d/wk	
Nighttime awakenings	0–4	≤ 1 ×/mo	> 1 ×/mo	> 1 ×/wk
	5–11	≤ 1 ×/mo	≥ 2 ×/mo	≥ 2 ×/wk
	≥ 12	≤ 2 ×/mo	1–3 ×/wk	≥ 4 ×/wk
Interference with normal activity	All	None	Some limitation	Extremely limited
SABA for symptoms	All	≤ 2 d/wk	> 2 d/wk	Several ×/d
Lung Function				
FEV ₁ (predicted) or PEF (personal best)	≥ 5	> 80%	60%–80%	< 60%
FEV ₁ /FVC	5–11	< 80%	75%–80%	< 75%
Validated Questionnaires				
ATAQ	≥ 12	0	1–2	3–4
ACQ	≥ 12	≤ 0.75	≥ 1.5	N/A
ACT	≥ 12	≥ 20	16–19	≤ 15
Risk				
Exacerbations requiring oral corticosteroids	0–4	≤ 1 ×/year	2–3 ×/yr	> 3 ×/yr
	5–11	≤ 1 ×/year	≤ 2 ×/yr	
	≥ 12	≤ 1 ×/year	Consider severity and interval since last exacerbation	
Reduction in lung growth	5–11	Evaluation requires long-term follow-up care		
Loss of lung function	≥ 12	Evaluation requires long-term follow-up care		
Treatment-related adverse effects	All	Medication side effects can vary in intensity from none to very troublesome and worrisome		
Recommended Treatment				
Recommended treatment actions	All	Maintain current step Regular follow-up q1–6 mo Consider stepping down if well controlled for ≥ 3 mo	Step up 1 step	Step up 1–2 steps and consider short course of oral corticosteroids
			Before stepping up, review adherence to medication, inhaler technique, environmental control, comorbid conditions If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step Reevaluate the level of asthma control in 2–6 wk and adjust therapy accordingly For side effects, consider alternative treatment options	

Abbreviations: ACQ = Asthma Control Questionnaire; ACT = Asthma Control Test; ATAQ = Asthma Therapy Assessment Questionnaire; FEV₁ = forced expiratory volume in 1 second; FVC = forced vital capacity; ICS = inhaled corticosteroid; PEF = peak expiratory flow; SABA = short-acting β₂-adrenergic receptor agonist.

Adapted from National Heart, Lung, and Blood Institute: National Asthma Education and Prevention Program Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication Number 08-5846. Washington, DC, National Heart, Lung, and Blood Institute, 2007.

the inhaler properly and that comorbid conditions have been addressed.

Referral to a pulmonologist or allergist is recommended if there is any question about the accuracy of diagnosis or if symptoms are difficult to control. The National Heart, Lung, and Blood Institute (NHLBI) recommends consultation if a child older than 5 years requires step 4 or higher level of therapy (step 3 or higher therapy in children younger than 5 years).

Allergen avoidance is currently recommended in the management of all asthmatics, but there is limited evidence that these interventions are effective. Various studies have analyzed the effects of controlling dust mite exposure with specially designed mattress and pillow covers and the use of air filtration units to reduce the

burden of airborne pet dander. None of these studies have demonstrated clear benefits in decreasing symptoms. One non-blinded randomized controlled trial, however, did suggest that removal of mold and improved ventilation in homes affected by mold can reduce symptoms of wheezing, rhinitis, and need for asthma medications.

Yearly inactivated influenza vaccination is recommended for all children with asthma to reduce the risk of complications due to influenza, although any clinically significant benefit for asthma symptoms is questionable. The live attenuated influenza vaccine (LAIV, FluMist) is typically not offered to children with asthma due to limited safety data in this population, although one trial of 2,229 children and adolescents with asthma demonstrated better

TABLE 3 Stepwise Treatment of Asthma in Children Younger than 12 Years

STEP	0–4 YEARS OLD	5–11 YEARS OLD
Step 1: Intermittent	SABA as needed	SABA as needed
Step 2: Mild persistent	Add low-dose daily ICS <i>or</i> cromolyn <i>or</i> montelukast (Singulair)	Add low-dose daily ICS <i>or</i> cromolyn, LTRA, nedocromil (Tilade) ² <i>or</i> theophylline
Step 3: Moderate persistent	Increase ICS to medium dose	Increase ICS to medium dose <i>or</i> continue low dose ICS <i>plus</i> either LTRA, LABA <i>or</i> theophylline
Step 4: Severe persistent	Medium-dose ICS <i>plus</i> either LABA <i>or</i> montelukast	Medium-dose ICS <i>plus</i> LABA, <i>or</i> medium-dose ICS <i>plus</i> either LTRA <i>or</i> theophylline
Step 5: Severe persistent	High-dose ICS <i>plus</i> either LABA <i>or</i> montelukast	High-dose ICS <i>plus</i> LABA, <i>or</i> high-dose ICS <i>plus</i> LTRA <i>or</i> theophylline
Step 6: Severe persistent	Step 5 <i>plus</i> oral glucocorticoids	Step 5 <i>plus</i> oral glucocorticoids
Step-Down Therapy	Step-Up Therapy	
If control is adequate for 3 mo, may consider gradual decrease in treatment Reassess every 1–3 mo	SABA use > 2 ×/wk can indicate inadequate control Check for triggers, medication adherence, medication technique, comorbid disease before increasing therapy	
Children ≥ 12 years: May be treated according to adult guidelines. Children 5–11 years: Consider subcutaneous allergen immunotherapy if the child has allergic asthma in steps 2 to 6. All children: Treat comorbid conditions to improve asthma control. For exacerbations that occur at all levels: SABA 2–4 puffs every 4–6 h for 24 h with physician consultation. Consider 3- to 10-day course of oral glucocorticoids for moderate to severe exacerbation.		

²Not available in the United States.

Abbreviations: ICS = inhaled corticosteroid; LABA = long-acting β_2 -agonist; LTRA = leukotriene receptor antagonist; SABA = short-acting β_2 -adrenergic receptor agonist. Adapted from National Heart, Lung, and Blood Institute: National Asthma Education and Prevention Program Expert Panel. Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication Number 08-5846. Washington, DC, National Heart, Lung, and Blood Institute, 2007.

prevention of influenza with LAIV than injectable vaccine and no differences in asthma symptoms or exacerbations. Pneumococcal vaccination is recommended for all children and, based on limited data, appears to reduce asthma exacerbations in those with asthma. Finally, management of comorbid conditions has been implicated in improving asthma control. Sinusitis, allergic rhinitis, gastroesophageal reflux disease (GERD), and obesity are thought to contribute to asthma symptoms. Research has shown, however, that treatment of GERD with lansoprazole (Prevacid) in children with poorly controlled asthma not only had no effect on asthma symptoms but also led to a significant increase in respiratory infections.

Medications

Asthma management requires both fast-acting rescue medications and long-term controller medications. The goal of therapy is to find a daily controller medicine that reduces symptoms to such a degree that rescue medications are needed only rarely. Patients and their caretakers must be educated regarding the different roles of these two classes of medication to ensure the best possible outcome and the patient's safety.

Rescue Medications

Fast-acting bronchodilators are important in both the mildest and the most-severe forms of asthma. Short-acting β_2 -adrenergic receptor agonists lead to smooth muscle relaxation and airway dilation. Racemic albuterol (Proventil) is a commonly used member of this group, but levalbuterol (Xopenex) is an alternative. Initially levalbuterol was thought to have fewer side effects, but studies have shown similar tolerability between racemic albuterol and levalbuterol. There is no significant difference in efficacy between these medications. Short-acting β_2 -adrenergic receptor agonists should be reserved for relief of acute symptoms. Frequent use is discouraged and can indicate inadequate control of symptoms. See Table 4 for usual dosing of rescue medications.

Controller Medications

Inhaled corticosteroids are the most effective long-term controller medications. Some commonly used inhaled corticosteroids are fluticasone (Flovent), budesonide (Pulmicort), beclomethasone (Qvar), mometasone (Asmanex), and flunisolide (Aerospan). No single formulation of inhaled corticosteroid is superior to another.

TABLE 4 Usual Dosing of Rescue Medications

DRUG	BRONCHOSPASM*	ACUTE EXACERBATION†
Albuterol (Proventil HFA, AccuNeb)	> 4 yr old: 2 inhalations q4–6 h prn > 2 yr old (min 15 kg): 0.083% nebulized soln (AccuNeb) inhaled over 5–15 min 3–4 × daily prn	4–8 inhalations q20 min × 3 doses, then q1–4 h prn; add mask in children < 4 yr 0.15 mg/kg (min 2.5 mg) q20min × 3 doses, then 0.15–0.3 mg/kg up to 10 mg q1–4 h prn
Levalbuterol (Xopenex)	Age 0–4 yr: 0.31–1.25 mg nebulized soln q4–6 h prn Age 5–11 yr: 0.31–0.63 mg q8h prn	0.075 mg/kg (min 1.25 mg) q20min × 3 doses, then 0.075–0.15 mg/kg up to 5 mg q1–4 h prn

*Symptoms of obstruction, cough, wheeze, breathlessness.

†Symptoms of obstruction not responsive to initial SABA use.

Abbreviations: SABA = short-acting β_2 -adrenergic receptor agonist; soln = solution. Information from Micromedex Healthcare Series. <http://www.micromedex.com>.

These medications reduce frequency of exacerbations and hospitalizations and are superior to leukotriene receptor antagonists and mast cell stabilizers. They are available as both metered-dose inhalers and dry-powder inhalers. A significant concern related to their use in children, however, is their effect on bone density and growth. High- and medium-dose inhaled corticosteroids have been linked to reduced growth velocity, but several studies have shown that at low doses they do not consistently or significantly affect growth. A systematic review and meta-analysis of effects of asthma and ICS on final adult height concluded that ICS does not significantly affect final adult height. To minimize potential side effects, continuous monitoring, reevaluation, and consideration of step-down treatment is imperative.

Long-acting β -agonists include salmeterol (Serevent) and formoterol (Foradil). They are an adjunctive therapy to inhaled corticosteroids and should be considered in step 3 of management of symptoms in children aged 5 to 11 years and in step 4 in children 0 to 4 years old. Long-acting β -agonists carry a risk of increased asthma-related deaths, intubations, and hospitalizations when used alone. This risk was most prominent in children 4 to 11 years of age. Long-acting β -agonists should never be used as monotherapy and are not recommended for use during exacerbations. In combination with inhaled corticosteroids, however, long-acting β -agonists have been shown to increase asthma control days and improve lung function, but safety data are unclear based on a systematic review in 2012. For children younger than 5 years, data are lacking.

Leukotriene-receptor antagonists, including montelukast (Singulair) and zafirlukast (Accolate), are another adjunctive therapy to inhaled corticosteroids. They reduce symptoms by blocking the inflammatory cascade initiated by mast cells. In the mildest forms of asthma they may be used as an alternative to inhaled corticosteroids if the steroids are not well tolerated or there is difficulty with administration. They are also effective in decreasing symptoms of exercise-induced asthma.

Mast cell stabilizers such as cromolyn sodium (Intal) or nedocromil (Tilade)² have a role similar to that of the leukotriene-receptor antagonists. They reduce inflammation by preventing mast cells from initiating the inflammatory cascade. They are safe and well tolerated in children, but the efficacy of inhaled sodium cromoglycate (Intal) has been brought into question after a systematic review found insufficient evidence to demonstrate sodium cromoglycate's superiority over placebo. The nedocromil inhaler has been discontinued owing to difficulties with manufacturing inhaler propellant.

Immunotherapy consists of subcutaneous injections of extracts from allergens intended to desensitize a patient to specific allergic triggers. This should occur in consultation with an allergist and may be considered at steps 2 through 6 of asthma treatment in children ages 5 to 11 years if asthma symptoms are predominantly allergic.

Immunomodulators are reserved for the most refractory cases of asthma. Omalizumab (Xolair, an anti-IgE agent) functions by blocking the binding of IgE to mast cells and basophils. It is effective in children with allergic triggers for their asthma but carries a risk of anaphylaxis, and the FDA as of 2014 has associated its use with an increase in cardiovascular and cerebrovascular events. In 2013, the National Institute for Health and Care Excellence (NICE) issued a recommendation that omalizumab be reserved for children age 6 and older who have frequent need for oral steroids (more than three courses in prior 12 months) and who have failed optimized therapy. Optimized therapy is defined as a full trial of inhaled high-dose corticosteroid, long-acting B2 agonist, leukotriene receptor antagonist, theophyllines, and oral steroids.

Early data from a randomized controlled trial suggests improved FEV₁ in children with severe symptomatic asthma with the addition of the anticholinergic drug tiotropium (Spirova Respimat Inhaler) to an established regimen of medium- or high-dose

inhaled steroids plus 1 or 2 other asthma control medications. More studies are needed to determine clinical benefit, however.

Theophylline (Theochron) was previously a mainstay of asthma management but is no longer a first-line medication. With the development of alternative treatments and because of theophylline's risk for toxicity, theophylline now has a lesser role in asthma management. Currently it is used as an alternative treatment in the chronic management of patients with symptoms refractory to or intolerant of standard therapies. Use of this medication requires frequent monitoring of drug serum levels. It can cause nausea, vomiting, or tachyarrhythmias if dosing is too high. See Table 5 for usual dosing of controller medications.

Acute Asthma Exacerbations

Exacerbations consist of worsening wheezing, cough, or shortness of breath. They can vary in severity from mild to life threatening. When deciding how to treat a patient in an exacerbation, use the history and physical examination to determine severity. As in all emergency situations, first assess airway, breathing, and circulation. In a life-threatening exacerbation, the patient can appear confused or obtunded, may be bradycardic, and can have minimal respiratory effort, indicating imminent respiratory arrest. A child in a severe exacerbation can appear short of breath even at rest, may be agitated, and might only be speaking one word at a time. The child is likely tachycardic and tachypneic, with obvious use of accessory muscles. In certain cases, lung examination might not reveal wheezing owing to severe impairment of aeration; only after treatment does the wheezing become audible as air movement improves. In mild to moderate exacerbations, the patient might only be short of breath with walking, might speak in short phrases or full sentences, and can appear anxious but not necessarily agitated. Lung examination can reveal wheezing.

The cornerstone of treatment of asthma exacerbations is rapid recognition of symptoms, correction of hypoxemia, and early initiation of short-acting β_2 -adrenergic receptor agonists and corticosteroids. Oxygen administration should be employed to maintain oxygen saturation at greater than 94%. Short-acting β -agonists are essential to relieve bronchoconstriction and may be combined with ipratropium (Atrovent)¹, especially if the patient is not responsive to initial therapy with a short-acting β_2 -adrenergic receptor agonist alone. Ipratropium should not be used as single agent, as it is less efficacious than β_2 agonists alone as well as combined β_2 agonist-ipratropium. Combined anticholinergics and short-acting beta agonists were shown to decrease the rate of hospitalization in children when used during initial treatment for an exacerbation with a NNT of 16; however, benefit did not persist with continuing use during hospitalization. In 2006, a systematic review showed that metered-dose inhalers with a spacer are as effective in administering β -agonists as nebulizers are in children older than 2 years. It was noted in the same study that length of stay in the emergency department was reduced in those using the spacers.

Corticosteroids given systemically are also considered rescue medications, although the onset of action is 1 to 2 hours and duration of action is 18 to 36 hours. They work primarily as anti-inflammatories and are an important treatment in exacerbations. Early use of systemic steroids, either oral or intravenous, reduced rates of relapse and decreased admissions to the hospital. The greatest benefit of systemic steroids was seen in patients having a severe attack and those who were not already on a course of steroids. Studies have shown that oral steroids are as effective as intravenous or intramuscular preparations. Even a short course of oral steroids can reduce relapse and decreases the need for rescue inhalers. Systemic corticosteroids should be continued for 3 to 10 days after an exacerbation. A taper is not necessary if the course is less than 1 week or less than 10 days in a patient who is also using an inhaled corticosteroid (ICS). Prolonged use of systemic corticosteroids carries significant risk for side effects such as adrenal

¹Not FDA approved for this indication.

TABLE 5 Usual Dosing of Controller Medications

DRUG	FORMAT	DOSING
Fluticasone (Flovent)	MDI: 44, 110, 220 µg/puff Dry powder: 50, 100, 250 µg/inhalation	Low: 88–176 µg Medium: 176–440 µg High: > 440 µg
Budesonide (Pulmicort)	200 µg/puff	Low: 100–200 µg Medium: 200–400 µg High: > 400 µg
Beclomethasone (Qvar)	40 or 80 µg/puff	Low: 80–160 µg Medium: 160–320 µg High: > 320 µg
Mometasone fumarate (Asmanex)	110, 220 µg/puff	110 µg daily is max per guidelines for 4–11 y
Flunisolide (Aerospan)	80 µg/puff	6–11 y: 80–160 µg bid > 12 y: 160–320 µg bid
Triamcinolone acetonide (Azmacort) ²	100 µg/puff	Low: 400–800 µg Medium: 800–1200 µg High: > 1200 µg
Salmeterol (Serevent)	Dry powder inhaler 50 µg/blister	> 5 y: 1 blister q12
Formoterol (Foradil)	Dry powder inhaler 12 µg/cap	> 5 y: 1 cap q12h
Montelukast (Singulair)		< 5 y: 4 mg hs 6–14 y: 5 mg hs
Zafirlukast (Accolate)		Ages 5–11 y: 10 mg bid
Cromolyn sodium	Nebulized soln (20 mg/2 mL), MDI ² 800 µg	> 2 y: nebulized soln: inhale 20 mg qid Age > 2: MDI: 2 puffs qid
Theophylline		Starting dose: 10 mg/kg/d < 1 y: max dose 0.2 × (age in weeks) + 5 = mg/kg/d ≥ 1 y: max dose 16 mg/kg/day

²Not available in the United States.

Abbreviations: cap = capsule; MDI = metered-dose inhaler; soln = solution.

Information from Micromedex Healthcare Series. <http://www.micromedex.com>.

suppression, osteoporosis, reduced growth, and cataracts, and thus their use should be minimized. Despite some evidence that use of ICS in acute exacerbations can reduce hospital admission rates, mounting data do not support treatment with increased doses of ICS (2 to 5 times maintenance dose) in children with acute asthma exacerbations, as rates of oral corticosteroid use do not appear to be reduced, yet the magnitude of increased cumulative ICS dose with this practice raises concern for potential height restriction.

Use of intravenous magnesium sulfate¹ (a smooth muscle relaxer) should be reserved for severe exacerbations only. Its use has not been shown to reduce admission rates in milder exacerbations but can improve lung function in those with only a partial response to short-acting β-agonists. Similarly, subcutaneous epinephrine¹ and subcutaneous terbutaline (Brethine)¹ should be reserved for emergency department settings when patients are not responding to short-acting β₂-adrenergic receptor agonists, anticholinergics, or corticosteroids or when air entry is so diminished that inhaled medications are not effective.

Finally, not enough evidence exists to make a recommendation regarding routine use of antibiotics during an acute asthma exacerbation. In some circumstances, when there are findings consistent with bacterial infections (such as consolidation on chest x-ray), their use may be warranted. See Table 6 for usual dosing of medications used in acute exacerbations.

Monitoring

Asthma is a dynamic disease whose symptoms fluctuate based on a number of variables. Routine scheduled appointments with a pediatrician or family physician are essential to monitor symptoms and adjust therapy. Initial management can require visits every 2 to 6 weeks; as control of symptoms improves, the interval may be increased to every 3 to 6 months.

¹Not FDA approved for this indication.

TABLE 6 Usual Dosing of Medications Used in Exacerbations

DRUG	DOSING
Chronic Management	
Corticosteroids (methylprednisolone, prednisolone, prednisone)	0.25–2 mg/kg daily or every other day
Acute Exacerbation	
Ipratropium bromide (Duoneb) ¹	Age 0–5 y: 250 µg nebulized × 2, then q4h prn Age 5–11: 500 µg nebulized × 2, then q4h prn
Corticosteroids (methylprednisolone, prednisolone, prednisone)	1–2 mg/kg/day (max 60 mg/day) in 2 divided doses × 3–10 d
Severe Acute Exacerbation	
Not Responding to SABAs	
Magnesium sulfate ¹	25–50 mg/kg IV up to 2 g over 10–20 min
Terbutaline ¹	0.01 mg/kg SC q20min for 3 doses, then every 2–6 hr prn
Epinephrine ¹	0.01 mg/kg up to 0.3–0.5 mg SC q20min for 3 doses
Related to Allergic Reaction	
Epinephrine	1:1000: 0.01 mL/kg SC (max 0.3 mL)

¹Not FDA approved for this indication.

Abbreviation: SABA = short-acting β₂-adrenergic receptor agonist.

Patient education is essential to successfully controlling this disease. Education should be focused on the theory behind controller and rescue medications, the importance of medication compliance, and how to administer these medications properly. Newer trial data support improved inhaler adherence with the use of electronic reminders such as mobile phone alarms. The National Asthma Education and Prevention Program Expert Panel 3 emphasizes the importance of asthma action plans to empower patients in recognizing and treating escalating symptoms of asthma. Action plans also provide recommendations on reducing exposure to irritants, allergens, and triggers. Some plans are based on peak flow levels, but studies show that symptom-based written action plans are better at decreasing acute care visits. Examples of asthma action plans can be found on the National Heart, Lung, and Blood Institute website.

Complications

The most worrisome complications of asthma include reduced lung function, pneumonia, pneumothorax, and death. More-common complications include chronic cough, fatigue due to poor sleep, missed school days and worse academic performance, and limited ability to participate in sports.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Method of

Scott E. Moser, MD

CURRENT DIAGNOSIS

- Diagnosis is clinical and based on DSM-5 criteria for inattentive symptoms, hyperactive/impulsive symptoms, or combined symptoms with onset by age 12 years.
- For the inattentive presentation, symptoms must include 6 of the following 9 (5 of 9 if age >17 years): fails to give attention to details, difficulty sustaining attention, does not seem to listen, does not follow through, difficulty organizing, avoids mental effort, loses things, easily distracted, and forgetful in daily activities.
- For hyperactive/impulsive presentation, 6 of the following must be documented (5 of 9 for age >17 years): fidgets, leaves seat, runs about or climbs excessively, difficulty playing quietly, “on the go/driven by a motor,” talks excessively, blurts answers before the end of questions, difficulty awaiting turn/waiting in line, interrupts/intrudes on others.
- Clinical diagnosis relies on use of standardized questionnaires and must account for potential comorbid psychological or learning problems.

CURRENT THERAPY

- For all patients older than age 6 years, stimulants are the primary treatment unless contraindicated.
- Important second line or adjunctive medications include atomoxetine (Strattera), guanfacine (Intuniv), clonidine (Kapvay), venlafaxine¹ (Effexor), and bupropion (Wellbutrin).¹
- Behavioral therapies are important adjuncts to medication for best outcomes.

¹Not FDA approved for this indication.

Epidemiology/Pathophysiology

Attention-deficit/hyperactivity disorder (ADHD) is one of the most commonly diagnosed conditions in childhood, affecting at least 5% of school-age children. It is more commonly diagnosed in boys than girls at a 2:1 ratio, but whether this is a true difference or a bias inherent in the standardized questionnaires used to detect ADHD remains debatable.

Patient education is essential to successfully controlling this disease. Education should be focused on the theory behind controller and rescue medications, the importance of medication compliance, and how to administer these medications properly. Newer trial data support improved inhaler adherence with the use of electronic reminders such as mobile phone alarms. The National Asthma Education and Prevention Program Expert Panel 3 emphasizes the importance of asthma action plans to empower patients in recognizing and treating escalating symptoms of asthma. Action plans also provide recommendations on reducing exposure to irritants, allergens, and triggers. Some plans are based on peak flow levels, but studies show that symptom-based written action plans are better at decreasing acute care visits. Examples of asthma action plans can be found on the National Heart, Lung, and Blood Institute website.

Complications

The most worrisome complications of asthma include reduced lung function, pneumonia, pneumothorax, and death. More-common complications include chronic cough, fatigue due to poor sleep, missed school days and worse academic performance, and limited ability to participate in sports.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Method of

Scott E. Moser, MD

CURRENT DIAGNOSIS

- Diagnosis is clinical and based on DSM-5 criteria for inattentive symptoms, hyperactive/impulsive symptoms, or combined symptoms with onset by age 12 years.
- For the inattentive presentation, symptoms must include 6 of the following 9 (5 of 9 if age >17 years): fails to give attention to details, difficulty sustaining attention, does not seem to listen, does not follow through, difficulty organizing, avoids mental effort, loses things, easily distracted, and forgetful in daily activities.
- For hyperactive/impulsive presentation, 6 of the following must be documented (5 of 9 for age >17 years): fidgets, leaves seat, runs about or climbs excessively, difficulty playing quietly, “on the go/driven by a motor,” talks excessively, blurts answers before the end of questions, difficulty awaiting turn/waiting in line, interrupts/intrudes on others.
- Clinical diagnosis relies on use of standardized questionnaires and must account for potential comorbid psychological or learning problems.

CURRENT THERAPY

- For all patients older than age 6 years, stimulants are the primary treatment unless contraindicated.
- Important second line or adjunctive medications include atomoxetine (Strattera), guanfacine (Intuniv), clonidine (Kapvay), venlafaxine¹ (Effexor), and bupropion (Wellbutrin).¹
- Behavioral therapies are important adjuncts to medication for best outcomes.

¹Not FDA approved for this indication.

Epidemiology/Pathophysiology

Attention-deficit/hyperactivity disorder (ADHD) is one of the most commonly diagnosed conditions in childhood, affecting at least 5% of school-age children. It is more commonly diagnosed in boys than girls at a 2:1 ratio, but whether this is a true difference or a bias inherent in the standardized questionnaires used to detect ADHD remains debatable.

Risk Factors

DSM-5 categorizes ADHD among the neurodevelopmental disorders based on its heritability of about 75%, chromosomal pattern evidence, and brain metabolism studies in the control centers for attention (prefrontal cortex) and motor activity (temporal lobe). In addition to genetic factors, several environmental factors have been associated: maternal smoking or alcohol use, pregnancy/delivery complications, psychosocial adversity, and exposure to environmental toxins including PCBs and pesticides. Food additives and television viewing have been studied without consistent evidence that they contribute.

Clinical Manifestations and Diagnosis

ADHD is a clinical diagnosis based on the criteria described in Diagnostic and Statistical Manual of Mental Disorders, 5th Edition: DSM-5 (DSM-5). In spite of growing evidence for characteristic findings in chromosomal and brain metabolism studies, there are no genetic, biochemical, or imaging tests validated for clinical use in making the diagnosis. Thus a clinician considering the diagnosis should review the explicit DSM-5 criteria.

DSM-5 recognizes three presentations: predominantly inattentive, predominantly hyperactive/impulsive, and a combined presentation. The use of the word “presentation” in DSM-5 is a change from the use of the word “type” in DSM-4, recognizing that the predominant symptoms can change modestly over time. ADHD begins in childhood, so to make the diagnosis after age 12, evidence must be found for significant symptoms before that age. At any age, the symptoms must be present in at least two different settings (home, school, work, etc.) and clearly interfere with social, academic, or occupational functioning. The symptoms cannot be better explained by another mental disorder (e.g., mood disorder, anxiety disorder, substance abuse).

To meet criteria for the inattentive presentation, the patient must exhibit age-inappropriate levels of at least six of the following nine symptoms: (1) fails to give attention to details or makes careless mistakes, (2) difficulty sustaining attention, (3) does not seem to listen when addressed, (4) does not follow through on instructions/fails to finish schoolwork or chores, (5) difficulty organizing tasks/activities, (6) avoids/refuses to engage in tasks that require sustained mental effort, (7) loses items necessary for tasks or activities, (8) easily distracted by extraneous stimuli, (9) forgetful in daily activities/routines.

To meet criteria for the hyperactive/impulsive presentation, the patient must exhibit age-inappropriate levels of at least six of the following nine symptoms: (1) often fidgets or squirms in seat, (2) leaves seat inappropriately, (3) runs or climbs excessively, (4) unable to play quietly, (5) “on the go” or “driven by a motor,” (6) talks excessively, (7) blurts out answers before a question is completed, (8) difficulty waiting their turn, (9) interrupts or intrudes on others.

The combined presentation requires meeting criteria for both the inattentive and hyperactive/impulsive presentations.

Patients age 17 years and older need to meet only five of the nine criteria in a presentation category. DSM-5 includes examples of adult equivalents of the criteria. For example, inattention criterion (6) reads, “Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).” Several of the symptoms must have been present before 12 years of age. For most patients, the hyperactivity improves by adolescence, but patients continue to have challenges with inattention and impulsivity as adults unless adequately treated.

The mainstay of diagnosis is the use of standardized questionnaires completed by parents, teachers, or other observers. The diagnosis of ADHD requires that the patient manifest symptoms in multiple environments, so it is important to obtain questionnaires from as many observers as is realistic. Each of the commercially available questionnaires has advantages and disadvantages such that clinicians should cooperate with local school and mental

health partners regarding which forms to use. Commonly used scales include the Conners, Vanderbilt, Achenbach, and others. In addition to making the diagnosis of ADHD, these scales can give clues to comorbid conditions and alternative diagnoses.

When gathering the history, it is important to obtain specific examples of behaviors rather than general labels. For example, “doesn’t pay attention” could mean “spends the day staring out the window” or “slumps in his chair and doesn’t respond to questions for several minutes.” Because there are no specific diagnostic tests for ADHD, ordering laboratory studies and imaging is individualized based on the clinician’s suspicion of comorbid or alternative diagnoses as described below.

Making the diagnosis of ADHD is more complicated in adults than in children for several reasons, including the challenges of recall bias by patients, difficulty obtaining information from other observers, less well-validated symptom questionnaires, and potential drug seeking for stimulants. Therefore clinicians should be wary and consider consultation with an experienced mental health colleague in these cases.

Careful evaluation that includes documentation of meeting DSM-5 criteria for ADHD prior to initiating treatment is important for both patients and clinicians. Studies have demonstrated that a lack of adequate documentation by physicians is common. Because the main treatment for ADHD includes use of Drug Enforcement Agency (DEA) Schedule II agents, the stimulants, the clinician is wise to perform a careful evaluation and document their findings well.

Differential Diagnosis

Comorbid learning disorders occur in as many as one-third of patients with ADHD, and comorbid oppositional defiant disorder and conduct disorder are also exceedingly common. Thus comorbidity is the rule rather than the exception, implying that when considering the differential diagnosis, clinicians must answer not only, “Could this be ADHD *or* something else?” They must also consider, “Could this be ADHD *and* something else?”

In addition to the potential comorbidities noted above, other common and important psychological conditions that share manifestations with ADHD or may be comorbid with ADHD include bipolar disorder, depression, anxiety, intellectual disability, and autism spectrum disorder. In adolescents and adults, substance use disorders are also common.

A large number of medical and neurologic conditions share some manifestations with ADHD, including absence seizure disorder, tics, hearing problems, sleep disorders, lead intoxication, allergies, and side effects of medications, particularly those used to treat asthma or allergies. A history of physical or sexual abuse is common. Children who live in a chaotic home environment or attend an unstructured school can exhibit ADHD-like symptoms or have their symptoms of ADHD exacerbated. Parental psychopathology or chemical dependency may complicate symptomatology. Therefore a careful social, developmental, and medical history and physical examination are important to making the diagnosis with individualized testing on the basis of the clinical suspicion of alternative or comorbid conditions. In cases where the clinician suspects complex or comorbid conditions, referral for neuropsychological assessment should be considered.

Treatment

The best treatment outcomes have been demonstrated with a combination of stimulant medication and behavioral interventions. This evidence comes primarily from studies of school-age children. Because of concerns about accurate diagnosis in children younger than 6 years old and less evidence of stimulant efficacy in younger children, guidelines encourage great caution in starting medications before age 6, relying primarily on behavioral therapy in younger children. As soon as ADHD is diagnosed, the clinician should point patients and families to reliable sources of education about the disorder, especially because so much misinformation is circulating among the public (Table 1). Regardless of the treatment plan, it is important to establish communication links between physician,

family, school, and mental health partners to address the myriad of complications and consequences that often develop. Regular follow-up that includes assessment of the effectiveness of treatment is important in the management of this chronic condition. Treatment in adolescents and adults is similar to that in children with exceptions noted in the text below and in [Table 2](#). [Table 2](#) includes all the medications with current FDA approval for treatment of ADHD. In general, clinicians should not exceed FDA maximum doses because this practice increases the risk of side effects with little evidence of improved efficacy.

Finally, because ADHD has a high rate of inheritance, parents of affected children often also have the disorder. The clinician should remain vigilant for ways this can complicate management, including treatment nonadherence, parental denial, or inconsistency with behavioral interventions.

Stimulants

The psychostimulants are first-line treatment for all presentations of ADHD at all ages, age 6 years and older. Their mechanism of action is thought to be primarily due to inhibition of reuptake of dopamine and norepinephrine in the prefrontal cortex, a key to regulating attention, behavior, and emotion. Children with ADHD

who take stimulants have longer attention spans, are less impulsive and distractible, perform better in school, and have better relationships with family and peers than those who do not.

All the stimulants are DEA Schedule II agents because of their abuse potential, which makes prescribing more challenging than nonstimulant alternatives. In spite of this, the stimulants remain the medications of first choice due to their strong record of efficacy and safety. The stimulants are grouped into two major categories: methylphenidate and the amphetamines. Both categories of stimulants are available in a variety of dosing options including short-acting, long-acting, and very long-acting preparations ([Table 2](#)). Standard methylphenidate and dextro-amphetamine maintain therapeutic levels for only 3 to 4 hours, necessitating multiple doses throughout the day. Therefore the longer-acting preparations have become much more popular. Many of the longer-acting drug choices achieve their prolonged effect because of technological modifications of their surface coating, resulting in slow intestinal release of the active medication. As a result, it is important that patients avoid breaking or chewing these pills. Exceptions are preparations utilizing micronized beads in capsules (methylphenidate ER [Metadate CD], dexamethylphenidate XR [Focalin XR], mixed amphetamine salts [Adderall XR], lisdexamfetamine [Vyvanse]), suspensions (methylphenidate ER suspension [Quilivant XR], dextroamphetamine solution [ProCentra]), or tablets designed to be chewed (methylphenidate ER Chewable Tablets [Quilichew ER]). The preparations of encapsulated beads can be emptied into apple sauce or other soft food for children unable to swallow pills.

The effectiveness of stimulants is great enough that if the initial trial of a stimulant is not effective or is poorly tolerated, evidence-based guidelines generally encourage the trial of a stimulant from the other category before resorting to a nonstimulant. When converting from one class of stimulant to another, 1 mg of amphetamine is roughly equivalent to 2 mg of methylphenidate.

Common side effects of stimulants include loss of appetite, abdominal pain, headache, irritability, and weight loss. These side effects are often transient and can be minimized by using a low starting dose and increasing the dosage gradually. Stimulants can exacerbate tics or seizure disorders. A rare but serious side effect is sudden cardiac death. The risk is so rare and unpredictable that current guidelines do not recommend routine electrocardiographic or other screening tests before initiating therapy. However, it is prudent to carefully assess cardiac risk factors prior to initiating treatment.

TABLE 2 Common ADHD Medications

CATEGORY	GENERIC NAME	SELECTED BRAND NAME EXAMPLES	ONSET	THERAPEUTIC EFFECT	PREGNANCY RISK	COMMENTS
Stimulants	Methylphenidate				No known teratogenicity based on animal data	Variety of dosing options as noted
	Short-acting	Ritalin	20 min	3–4 hrs		Requires multiple doses to last through school day
	Long-acting	Metadate CD	30 min	8 hrs		Single dose to last through school day but may require afternoon boost for homework; capsule contents may be sprinkled on food
	Very long-acting	Quilivant XR	20 min	8–10 hrs		Liquid suspension
		QuilliChew ER	30 min	8 hrs		Chewable tablet
		Concerta	1–2 hrs	12–14 hrs		Single dose to last entire day but more likely to interfere with sleep
		Daytrana patch	2–4 hrs	>20 hrs		Must be removed before bedtime

Continued

TABLE 2 Common ADHD Medications—cont'd

CATEGORY	GENERIC NAME	SELECTED BRAND NAME EXAMPLES	ONSET	THERAPEUTIC EFFECT	PREGNANCY RISK	COMMENTS
	Dexmethylphenidate	Focalin	20 min	3–4 hrs	Caution in pregnancy due to inadequate data to assess risk	Bioactive isomer may reduce side effects
		Focalin XR	20 min	8 hrs		Capsule contents may be sprinkled on food
	Amphetamine/dextroamphetamine				Avoid in pregnancy due to risk of teratogenicity and neonatal complications including premature delivery	
		Adderall	20 min	6–8 hrs		
		Adderall XR	30–60 min	12–14 hrs		Capsule contents may be sprinkled on food
	Dextroamphetamine				Avoid in pregnancy due to risk of teratogenicity and neonatal complications including premature delivery	
		Dexedrine	20 min	3–4 hrs		Requires multiple doses to last through school day
	Lisdexamfetamine	ProCentra	20 min	4–6 hrs		Oral suspension
		Vyvanse	30 min	10–12 hrs	No human data but avoid in pregnancy based on limited human data with amphetamines	Prodrug with theoretically less abuse potential; capsule contents may be sprinkled on food
Nonstimulants						
	Atomoxetine	Strattera	1 hr	Variable	Caution in pregnancy; inadequate human data to assess risk; no known harm	Usually once daily dosing; fast metabolizers may need twice daily dosing
	Clonidine, extended-release	Kapvay	30–60 min	8–16 hrs	Caution in pregnancy; risk of low birth weight; risk of fetal death from animal data	Dose at bedtime
	Guanfacine, extended-release	Intuniv	30–60 min	16–24 hrs	Caution in pregnancy; no known risk of fetal harm	Dose at bedtime
	Venlafaxine ¹	Effexor			Caution in pregnancy especially in third trimester due to potential withdrawal or serotonin syndrome	
	Bupropion ¹	Wellbutrin (immediate release, 12 hr extended release, 24 hr extended release)			Caution in pregnancy; risk of congenital heart defects inconclusive	Extended release forms not approved for children <12 years old

¹Not FDA approved for this indication.

Apart from the kinetics of short-acting versus longer-acting options and the various routes of administration (e.g., pills, suspensions, dermal patches), two stimulants have specific niches. Dexmethylphenidate is the active isomer of methylphenidate. Theoretically, this may improve the side effect profile, although clinical evidence for this is lacking. Because it is the active isomer,

the therapeutic conversion is 1 mg of dexmethylphenidate approximates 2 mg of methylphenidate. Lisdexamfetamine is a prodrug of dextroamphetamine. It was developed to reduce the risk of abuse, but the DEA has maintained its Schedule II designation.

Parents are often concerned about whether the use of a DEA-controlled substance might increase the risk of their child

developing a substance use disorder as they mature. Current evidence is reassuring in this regard in that appropriate treatment with stimulants likely decreases that risk.

Stimulants are also first-line treatment for ADHD in adults, though the evidence from controlled studies is not as strong as with children. As indicated in Table 2, for women who clearly benefit from treatment with stimulants and who are pregnant or could become pregnant, methylphenidate is considered the safest choice.

Nonstimulants

All of the nonstimulants are second-line agents or adjuncts to stimulant treatment. The most important agent in this class is atomoxetine (Strattera). It should be titrated up over days to weeks and may require 4 weeks to see the full benefit. Usually, once-daily dosing is effective, but genetically fast metabolizers may require multiple daily doses. Common side effects include loss of appetite, headache, and drowsiness. One benefit of atomoxetine is that it is not a DEA-scheduled agent so it is more convenient to prescribe than a stimulant. Also, it does not exacerbate tics. A downside to atomoxetine is it carries a black box warning of increased risk of suicidality, especially during the first months of treatment. A rare but serious potential side effect is hepatotoxicity. Atomoxetine should be considered first-line therapy in patients with a comorbid tic disorder, significant anxiety disorder, or recent substance abuse.

Clonidine (Kapvay) and guanfacine (Intuniv) are alpha-adrenergic agonists that are helpful adjuncts to treating hyperactivity or aggression that does not adequately respond to a stimulant alone. Because a side effect is drowsiness, nighttime dosing can actually improve sleep. Use of extended-release formulations allows for single daily dosing. Patients should be monitored for development of hypotension or bradycardia. Because of the risk of rebound hypertension, these agents should be tapered slowly rather than stopped abruptly.

In controlled trials, the serotonin-norepinephrine reuptake inhibitors (SNRIs) have demonstrated effectiveness for ADHD, and one agent in this category is venlafaxine (Effexor).¹ SNRIs are particularly useful adjuncts in patients with significant mood instability, common in adolescents. Prescribers should use caution due to the black box warning regarding potential increased suicide risk.

Bupropion (Wellbutrin)¹ has been shown to be somewhat effective in treating ADHD, and its value is similar to that of the SNRIs as adjuncts in special situations. Like the SNRIs, it has a black box warning regarding increased suicidality risk.

Several tricyclic antidepressants have demonstrated efficacy for ADHD in controlled trials, but their use is limited due to side effects and lack of FDA approval. Selective serotonin reuptake inhibitors (SSRIs) have not demonstrated effectiveness for ADHD and should only be considered for comorbid mood disorders. Other mood stabilizers and atypical antipsychotics should generally be reserved for use by specialists.

Behavior Therapy and Educational Interventions

For younger children the emphasis is on behavior training for parents and teachers. All parents should receive instruction in common behavioral mistakes such as overreliance on negative reinforcement instead of positive and too long a delay in dispensing rewards. Most parents benefit from specific training in parenting techniques or support groups. As children enter adolescence and beyond, cognitive behavior therapies, group therapy with peers, and individual coaching approaches show the most promise. Educational placement and classroom interventions are also important. The diagnosis of ADHD, at the very least, deserves consideration for special classroom accommodations under federal law for this chronic handicapping condition. If the child is still failing in spite of these accommodations, consideration should be given for special education placement.

¹Not FDA approved for this indication.

Monitoring

Once satisfactory response to treatment is established, children on stimulants should continue to be seen at least every 6 months for height and weight checks to be sure they are continuing to grow normally and for blood pressure and pulse checks, watching for onset of hypertension or tachycardia. Guidelines typically recommend annual consideration of a medication holiday to evaluate the need for continued treatment. Children typically require gradually increasing doses during the school years, then some tapering of the dose in late adolescence.

Management of Complications

Children with suspected comorbid psychiatric conditions and those who do not respond to initial treatment should be referred to a specialist.

BRONCHIOLITIS

Method of

Danae D. Goerl, MD

CURRENT DIAGNOSIS

- Clinical diagnosis made in children less than 2 years old with symptoms of congestion and rhinorrhea associated with lower respiratory tract findings that may include wheezing, crackles, tachypnea, or increased work of breathing.
- Viral polymerase chain reaction (PCR) assays are available, but are not routinely needed to establish diagnosis.
- Chest x-ray not indicated for evaluation of bronchiolitis. Consider in children with severe respiratory distress or lung findings concerning for alternate diagnosis.

CURRENT THERAPY

- Treatment remains supportive care: supplemental oxygen for oxygen saturation less than 90%, fluids to maintain hydration, and suction of the nasal passages.
- No indication for corticosteroids, racemic epinephrine, or albuterol therapy.

Bronchiolitis, or viral pneumonia in children less than 2 years old, is one of the most common diseases encountered in pediatric medicine. Respiratory syncytial virus (RSV) causes most cases of bronchiolitis; however, other viruses cause similar symptoms. Approximately 90% of children will be infected with RSV by the time they are 2 years old. Despite the high number of infants

developing a substance use disorder as they mature. Current evidence is reassuring in this regard in that appropriate treatment with stimulants likely decreases that risk.

Stimulants are also first-line treatment for ADHD in adults, though the evidence from controlled studies is not as strong as with children. As indicated in Table 2, for women who clearly benefit from treatment with stimulants and who are pregnant or could become pregnant, methylphenidate is considered the safest choice.

Nonstimulants

All of the nonstimulants are second-line agents or adjuncts to stimulant treatment. The most important agent in this class is atomoxetine (Strattera). It should be titrated up over days to weeks and may require 4 weeks to see the full benefit. Usually, once-daily dosing is effective, but genetically fast metabolizers may require multiple daily doses. Common side effects include loss of appetite, headache, and drowsiness. One benefit of atomoxetine is that it is not a DEA-scheduled agent so it is more convenient to prescribe than a stimulant. Also, it does not exacerbate tics. A downside to atomoxetine is it carries a black box warning of increased risk of suicidality, especially during the first months of treatment. A rare but serious potential side effect is hepatotoxicity. Atomoxetine should be considered first-line therapy in patients with a comorbid tic disorder, significant anxiety disorder, or recent substance abuse.

Clonidine (Kapvay) and guanfacine (Intuniv) are alpha-adrenergic agonists that are helpful adjuncts to treating hyperactivity or aggression that does not adequately respond to a stimulant alone. Because a side effect is drowsiness, nighttime dosing can actually improve sleep. Use of extended-release formulations allows for single daily dosing. Patients should be monitored for development of hypotension or bradycardia. Because of the risk of rebound hypertension, these agents should be tapered slowly rather than stopped abruptly.

In controlled trials, the serotonin-norepinephrine reuptake inhibitors (SNRIs) have demonstrated effectiveness for ADHD, and one agent in this category is venlafaxine (Effexor).¹ SNRIs are particularly useful adjuncts in patients with significant mood instability, common in adolescents. Prescribers should use caution due to the black box warning regarding potential increased suicide risk.

Bupropion (Wellbutrin)¹ has been shown to be somewhat effective in treating ADHD, and its value is similar to that of the SNRIs as adjuncts in special situations. Like the SNRIs, it has a black box warning regarding increased suicidality risk.

Several tricyclic antidepressants have demonstrated efficacy for ADHD in controlled trials, but their use is limited due to side effects and lack of FDA approval. Selective serotonin reuptake inhibitors (SSRIs) have not demonstrated effectiveness for ADHD and should only be considered for comorbid mood disorders. Other mood stabilizers and atypical antipsychotics should generally be reserved for use by specialists.

Behavior Therapy and Educational Interventions

For younger children the emphasis is on behavior training for parents and teachers. All parents should receive instruction in common behavioral mistakes such as overreliance on negative reinforcement instead of positive and too long a delay in dispensing rewards. Most parents benefit from specific training in parenting techniques or support groups. As children enter adolescence and beyond, cognitive behavior therapies, group therapy with peers, and individual coaching approaches show the most promise. Educational placement and classroom interventions are also important. The diagnosis of ADHD, at the very least, deserves consideration for special classroom accommodations under federal law for this chronic handicapping condition. If the child is still failing in spite of these accommodations, consideration should be given for special education placement.

¹Not FDA approved for this indication.

Monitoring

BRONCHIOLITIS

Method of

Danae D. Goerl, MD

CURRENT DIAGNOSIS

- Clinical diagnosis made in children less than 2 years old with symptoms of congestion and rhinorrhea associated with lower respiratory tract findings that may include wheezing, crackles, tachypnea, or increased work of breathing.
- Viral polymerase chain reaction (PCR) assays are available, but are not routinely needed to establish diagnosis.
- Chest x-ray not indicated for evaluation of bronchiolitis. Consider in children with severe respiratory distress or lung findings concerning for alternate diagnosis.

CURRENT THERAPY

- Treatment remains supportive care: supplemental oxygen for oxygen saturation less than 90%, fluids to maintain hydration, and suction of the nasal passages.
- No indication for corticosteroids, racemic epinephrine, or albuterol therapy.

Bronchiolitis, or viral pneumonia in children less than 2 years old, is one of the most common diseases encountered in pediatric medicine. Respiratory syncytial virus (RSV) causes most cases of bronchiolitis; however, other viruses cause similar symptoms. Approximately 90% of children will be infected with RSV by the time they are 2 years old. Despite the high number of infants

affected, there are no curative therapies and no medication has been shown to shorten the course of bronchiolitis.

Epidemiology and Virology

Most epidemiologic data has been reported about RSV. RSV is the most common virus that causes bronchiolitis; however, other viruses including human rhinovirus, influenza, human metapneumovirus, parainfluenza, and adenovirus may cause bronchiolitis. Outbreaks caused by RSV vary by season. In the United States, the incidence of RSV is typically highest between November and April, and regional variability does occur. Approximately 800,000 children in the United States require outpatient medical attention during the first year of life due to RSV, and between 2% and 3% of all children younger than 12 months of age are hospitalized with a diagnosis of bronchiolitis.

Risk Factors

Certain conditions put infants at risk for severe presentation of the illness. These are listed in [Box 1](#).

Pathophysiology

Bronchiolitis is a viral infection that affects the lower respiratory tract. These viruses may only affect epithelial cells of the nasal passages and cause strictly upper respiratory symptoms. However in approximately 30%–40% of patients, the lower respiratory tract will become affected. When the bronchioles are involved, shedding of respiratory epithelium, impaired ciliary function, and edema occur. As the viral-infected epithelium is sloughed into the lumen of the airway, obstruction of the airway occurs and leads to alveolar collapse or atelectasis distal to the obstruction.

Clinical Manifestations

The virus initially causes upper respiratory symptoms such as rhinorrhea, congestion, and cough that are present for 2 to 3 days. Fever may also occur. As the lower airways become involved, mucous plugging and atelectasis may cause tachypnea, and increased work of breathing demonstrated by nasal flaring, costal retractions, or grunting. On physical examination, clinicians may auscultate crackles and wheezes that are typically symmetric and bilateral. If ventilation and perfusion mismatch occur, the child will become hypoxemic. There is a spectrum of clinical presentations ranging from nonlabored breathing with mild crackles heard on exam to apnea and rarely respiratory failure. Infants may also appear clinically dehydrated if the increase in respiratory effort causes poor feeding.

Diagnosis

The diagnosis of bronchiolitis is made clinically by history and physical examination. Commercial viral polymerase chain reaction (PCR) assays that are obtained via nasopharyngeal swab are available; however, these are not routinely indicated. There are some clinical situations when viral testing may be useful. When the clinician suspects that the child has influenza, viral PCR may be used to determine need for oseltamivir (Tamiflu). Additionally, if a patient is receiving monthly palivizumab (Synagis) prophylaxis and is hospitalized with bronchiolitis, the clinician should obtain viral testing. If the patient has RSV, this would be an indication to discontinue monthly prophylaxis due to the low likelihood of a second RSV infection in the same year.

BOX 1

Infants at Risk for Severe Presentation of Bronchiolitis

- Age younger than 3 months
- History of prematurity
- History of congenital cardiac abnormalities or chronic lung disease
- Infants whose immune systems are compromised

Chest x-ray is not indicated in routine evaluation of bronchiolitis. Obtaining a chest x-ray is unlikely to change management of the patient, and may lead to inappropriate use of antibiotics. If the child is ill enough to be admitted to the intensive care unit or if there is a clinical concern for an alternate diagnosis such as bacterial pneumonia, radiographs may be warranted.

Differential Diagnosis

Other respiratory conditions must be considered when a child presents with clinical features of bronchiolitis. One clinical challenge when evaluating a patient with bronchiolitis is to distinguish it from asthma or recurrent viral-induced wheezing. Severe bronchiolitis early in life is associated with an increased risk of asthma. It is unclear whether bronchiolitis early in life results in injury that alters normal lung development and predisposes the child to subsequent wheezing, or whether certain infants have a preexisting abnormality of the immune response or of airway function that causes them to have both severe bronchiolitis and recurrent wheezing. Infants who have risk factors for asthma including eczema, and personal or family history of asthma associated with recurrent wheezing, may be difficult to clearly diagnose with viral bronchiolitis.

The differential diagnosis also includes other infections such as bacterial pneumonia caused by community acquired or atypical organisms, aspiration pneumonia, or pertussis. Undiagnosed congenital cardiac defects with heart failure may also present similarly to bronchiolitis, with tachypnea, increased work of breathing, and crackles heard on lung auscultation. Other diagnoses to consider include foreign body aspiration, congenital pulmonary abnormalities, or vascular rings.

Treatment

The treatment for bronchiolitis remains supportive therapy.

Supportive measures include:

- Supplemental oxygen to keep oxygen saturations greater than 90%.
- Hydration via intravenous fluids or nasogastric tube for children unable to maintain oral hydration.
- Nasal suctioning, though often provided for patients with bronchiolitis, has not been well studied. One study published in JAMA Pediatrics in 2013 concluded that in patients admitted with bronchiolitis, the use of deep suctioning in the first 24 hours after admission and lapses greater than 4 hours between suctioning events were associated with longer length of stay.

Outpatient Management

Outpatient management includes parental education about the expected clinical course of the illness, providing return precautions, and close follow up for infants at risk for severe disease. Information can be given to parents regarding supportive measures they can provide at home, including clearing the nasal passages prior to feeding, appropriate antipyretic therapy if fever is causing the infant discomfort, and discouraging over-the-counter decongestants for children less than 2 years old.

Inpatient Management

Admission to the hospital should be considered for infants who appear ill, hypoxemic with oxygen saturation <90% on room air, those with respiratory distress characterized by tachypnea with respiratory rate >70 breaths per minute, retractions, grunting, or apnea. Hospitalization is also indicated for infants who are dehydrated.

Medications including albuterol, corticosteroids, and racemic epinephrine have been studied, but have not been shown to cure the disease, prevent hospitalization, or shorten the course in patients hospitalized with bronchiolitis. Multiple studies have been conducted recently examining the role of nebulized hypertonic saline (3%) to determine if it decreases hospitalization when given in the emergency department or if it shortens hospital stays. Evidence is not considered strong enough at this point to advocate for routine use of hypertonic saline in the United States. In 2014, the American Academy of Pediatrics published clinical practice

TABLE 1 Summary of Evidence for Treatment of Bronchiolitis

MEDICATION	RECOMMENDATION	EVIDENCE QUALITY
Systemic corticosteroids	Not recommended	Cochrane systematic review shows that corticosteroids do not significantly reduce outpatient admissions when compared with placebo and do not reduce length of stay for inpatient admissions
Epinephrine	Not recommended	Cochrane meta-analysis systematically evaluated the evidence and found no evidence for utility in the inpatient setting
Albuterol	Not recommended	Meta-analyses and systematic reviews have shown that bronchodilators improve clinical symptom scores, but they do not affect disease resolution, need for hospitalization, or length of stay
Hypertonic saline	May consider	May decrease inpatient length of stay (LOS) in settings where LOS is greater than 3 days (typical US length of stay is 2.4 days)
Oxygen therapy	Provide supplemental oxygen if oxyhemoglobin saturation is <90%	
Nutrition and hydration	Administer IV or NG fluid for infants unable to maintain hydration orally	

Adapted from AAP Clinical Practice Guideline: The Diagnosis, Management and Prevention of Bronchiolitis. 2014.

guidelines that summarize the most recent evidence regarding diagnosis and treatment (Table 1). Chest physiotherapy is not recommended when managing hospitalized patients with bronchiolitis. A Cochrane Review evaluated nine randomized controlled trials in hospitalized patients and found no benefit to chest percussion or chest vibration. Antibiotic therapy is only indicated in the case of secondary bacterial infection. The data reviewed does not extend to patients admitted to the intensive care unit with bronchiolitis.

Prevention

Immunoprophylaxis

Palivizumab (Synagis) is an immunoglobulin G monoclonal antibody directed against a surface protein of RSV. It was approved by the FDA in 1998 after a randomized controlled trial demonstrated a reduction in the rate of hospitalization related to RSV in premature infants. In July 2014, the American Academy updated the recommendations for patients that may benefit from palivizumab. This replaced the Red Book Guidelines published in 2012. The current recommendation is that palivizumab prophylaxis be limited to:

- Infants born before 29 weeks' gestation.
- Infants with hemodynamically significant congenital cardiac disease.
- Infants diagnosed with chronic lung disease of prematurity. This is defined by an oxygen requirement of more than 21% FiO₂ for the first 28 days of life with continued requirement of supplemental oxygen, diuretic therapy, or chronic corticosteroid therapy.

If criteria for palivizumab therapy are met, the infant will receive one shot per month, 15 mg/kg per dose, for 5 months. The shots are administered during RSV season, which is typically from November until March, but may vary based on the region. Palivizumab prophylaxis is not indicated past 12 months of age except for infants with chronic lung disease of prematurity, who may benefit from therapy through a second RSV season.

Breastfeeding

Breastfeeding has many proven benefits in the neonatal period. This extends to respiratory infections. Studies have demonstrated decreased risk of hospitalization with respiratory infections, as well as shorter hospital stays for bronchiolitis in infants who are breastfed.

Complications

Complications from bronchiolitis include secondary bacterial infections such as acute otitis media or bacterial pneumonia. Respiratory failure requiring mechanical ventilation and intensive care

unit admission may also occur. Though bronchiolitis is a disease associated with high morbidity, the mortality is low. Death from respiratory failure in bronchiolitis is rare, accounting for 5.3 deaths per 100,000 children below 12 months in the United States.

DIABETES MELLITUS IN CHILDREN

Method of

Gregory Goodwin, MD

CURRENT DIAGNOSIS

- Random glucose >200 mg/dL and symptoms (polyuria, polydipsia)
- Fasting glucose >126 mg/dL
- 2-hour glucose >200 mg/dL after glucose tolerance test
- Hemoglobin A1c >6.5%
- Diabetic ketoacidosis: pH <7.3, serum bicarbonate <15 mmol/L

CURRENT TREATMENT

Type 1 Diabetes

- 1) Basal/bolus regimen: rapid-acting insulin before meals and long-acting insulin at bedtime
- 2) Insulin pump therapy: continuous infusion of short-acting insulin
- 3) NPH insulin at breakfast and bedtime, short-acting insulin before meals

TABLE 1 Summary of Evidence for Treatment of Bronchiolitis

DIABETES MELLITUS IN CHILDREN

Method of

Gregory Goodwin, MD

CURRENT DIAGNOSIS

- Random glucose >200 mg/dL and symptoms (polyuria, polydipsia)
- Fasting glucose >126 mg/dL
- 2-hour glucose >200 mg/dL after glucose tolerance test
- Hemoglobin A1c >6.5%
- Diabetic ketoacidosis: pH <7.3, serum bicarbonate <15 mmol/L

CURRENT TREATMENT

Type 1 Diabetes

- 1) Basal/bolus regimen: rapid-acting insulin before meals and long-acting insulin at bedtime
- 2) Insulin pump therapy: continuous infusion of short-acting insulin
- 3) NPH insulin at breakfast and bedtime, short-acting insulin before meals

- 4) Premixed insulins (75/25, 50/50) at breakfast and dinner
 - Total daily insulin dose (TDD): 0.25-1.0 units/kg/day
 - Basal/bolus: 50% long-acting, 50% short-acting
 - NPH/short acting: 2/3 TDD in A.M., 1/3 TDD P.M.
 - A.M. & P.M. dose: 2/3 NPH, 1/3 short-acting
 - Premixed insulins: 2/3 A.M., 1/3 before dinner

Diabetic Ketoacidosis

- Fluids: 10–20 mL/kg saline $\times 1$, repeat if shock/poor perfusion. Ongoing fluids: 1/2 normal saline with 20 mEq/L KCL and 20 mEq/L KPhos at 1.5–2.0 \times maintenance fluids.
- Regular insulin infusion: 0.05-0.1 units/kg/hour
- Add dextrose (5%-10%) when glucose <300 mg/dL.
- Urgent consultation with center experienced in treatment of pediatric ketoacidosis

Type 2 Diabetes

- 1) Aggressive dietary modification
- 2) Metformin (Glucophage): 500–1000 mg 2 times daily, titrate up to avoid gastrointestinal side effects
- 3) 1) & 2) plus insulin therapy: either as single long-acting insulin at bed or full basal bolus regimen until stable glucose control

Type 1 Diabetes: Introduction

Type 1 diabetes (T1DM) results from progressive autoimmune destruction of insulin-producing (β -cell) cells of the pancreatic islets that ultimately leads to insulin deficiency resulting in hyperglycemia and in some cases ketoacidosis.

The precise cause of T1DM remains elusive, but an association with human lymphocytic antigens (HLA) has been known for decades.¹⁻³ Whole genome-wide linkage studies have identified up to 60 genes associated with T1DM, and many are related to the immune response. The strongest linked genes to T1DM are HLA and insulin.³

However, identical twin studies show a concordance rate of 30% to 60%, suggesting that unidentified environmental factors make up the remaining risk.⁴ Environmental factors implicated in T1DM risk include viral infections (rubella), toxins (nitrosamines, vacor), and dietary factors such as early exposure to cow's milk and cereals in infancy. However, recent prospective studies showed no advantage of using elemental formulas in infants at increased risk for development of T1DM.⁶ Investigators are beginning to speculate that T1DM is probably a disorder with multiple causes.

Epidemiology

The prevalence of type 1 diabetes is about 1/300 (0.3%) in the United States, with significant global and racial variations. The presence of a first-degree relative with T1DM, such as a sibling or parent, increases the chances of developing T1DM to 3% to 6%.²

The highest incidence rates of T1DM in children are seen in early adolescence (10–14 years), followed by early childhood ages 5 to 9 years.^{1,2,4} The youngest age of onset of T1DM can be seen in infants <1 year of age but usually not before 6 months.

The incidence of T1DM has been increasing steadily by 2% to 5% per year over the past several decades in the United States, Europe, and Australia, further implicating environmental causes for this disorder.² Interestingly, in some but not all studies, the youngest age group (0–4 years) demonstrates the highest rates of rising incidence of T1DM.²

Presentation

The classic symptoms of diabetes are polyuria, polydipsia, and nocturia, which is the result of an osmotic diuresis induced by hyperglycemia. Symptoms can be present from days to months, but the majority of patients present after 1 to 2 weeks of symptoms. Weight loss is a common finding on presentation, because insulin plays an important role in protein and fat synthesis, and therefore insulin deficiency results in loss of muscle and fat stores. Weight loss also

occurs because calorie loss from high concentrations of glucose in the urine can be substantial.

Abdominal pain, nausea, and vomiting are classic signs of ketoacidosis that can often be misdiagnosed as gastroenteritis. Approximately 70% of patients with new-onset diabetes have hyperglycemia without ketoacidosis at presentation, whereas $\sim 25\%$ to 30% of cases present in diabetic ketoacidosis, although there can be significant variations from various centers internationally.^{1,2}

Diagnosis

A random glucose >200 mg/dL in the presence of classic symptoms of diabetes is diagnostic of diabetes. A fasting glucose >126 mg/dL is also diagnostic of diabetes; however, rarely is a fasting glucose or a glucose tolerance test necessary in the diagnosis of T1DM.^{1,2}

A venous pH <7.3 or a serum bicarbonate <15 mmol/L is diagnostic of diabetic ketoacidosis in the presence of hyperglycemia.^{1,2,4} Distinguishing type 1 from type 2 diabetes can sometimes be difficult at presentation, particularly in an overweight adolescent. In this circumstance islet cell autoantibodies are useful in distinguishing the two forms of diabetes. Islet cell autoantibodies include anti-glutamic acid decarboxylase (GAD), anti-insulin, anti-insulinoma autoantigen 2 (IA-2), and anti-zinc transporter 8 (ZnT8). These antibodies are available in most commercial laboratories, but results are usually not available until weeks after initial presentation. The safest course of action in most pediatric patients with new-onset diabetes is to treat with insulin until islet antibodies and other parameters such as endogenous insulin production as assessed by c-peptide levels are available.

Treatment of T1DM

T1DM (without ketoacidosis or after ketoacidosis has resolved)

Insulin is the mainstay of treatment for T1DM. Intensive insulin therapy has become the standard of care for patients with T1DM. Typically a long-acting basal insulin such as glargine (Lantus), detemir (Levemir), or degludec (Tresiba), along with premeal boluses of rapid-acting insulin such as lispro (Humalog) or aspart (Novolog), are instituted (Figure 1).

Required total daily insulin dosing (TDD) is dependent on age at presentation, pubertal stage, and the presence of acidosis at diagnosis. Total daily insulin requirements range from ~ 0.25 to 1.0 units/kg/day (Table 1). Long-acting or basal insulin is typically 50% of TDD, and the remaining 50% is bolus insulin. Bolus rapid-acting insulin dosing is calculated by the following formulas (Figure 2):

To cover meal carbohydrates, a *carbohydrate ratio* is derived from the following formula: 500/total daily insulin dose.

To correct hyperglycemia, a *correction factor* is derived from the following formula: 1500/total daily insulin dose. Correction doses should not be given more frequently than every 3 hours.

For new-onset patients, a *target glucose* of 150 mg/dL is assigned, whereas more established patients typically use 120 mg/dL. Correction at bedtime or during the night should be less aggressive, and a higher target may be assigned—for example, 150 to 200 mg/dL.

Carbohydrate ratios, correction factors, and targets are adjusted on the basis of fasting and postprandial glucose levels. High postprandial glucose levels would require a lower carbohydrate ratio. High blood glucose levels that do not correct after a correction dose has been given would require a lowering of the correction factor. High morning fasting glucose levels would require an increase in the long-acting insulin dose.

Implicit in recommending the above treatment regimen is (1) the patient or family's ability to count carbohydrates correctly and (2) the family's ability to calculate insulin dosing correctly using carbohydrate ratio, correction factor, and target. If the patient or family is unable or unwilling to perform these calculations, then a simplified insulin regimen should be devised using fixed doses

Treatment Options for Type 1 Diabetes

Regimen	12 am 6am noon 6 pm		comments
Basal-bolus		Rapid-acting insulin* Long-acting insulin#	Fixed basal dose Rapid-acting insulin with meals Ideal for insulin pens
Insulin pump		rapid acting Basal rate	Adjustable basal rate Ease of bolusing insulin Risk for infusion site failure
NPH and short-acting insulin		NPH — rapid acting	Fewer insulin injections No lunch injection Usually suboptimal control
Fixed mixed insulins (e.g. 75/25)		75/25 insulin injection ↑	Two injections per day—fixed doses Usually inadequate coverage Use only in most challenging cases

Figure 1 Treatment options for patients with type 1 diabetes. # Long-acting insulin: glargine (Lantus, Basaglar), degludec (Tresiba), detemir (levemir). * Rapid-acting insulin: lispro (Humalog), aspart (Novolog). Note: 75/25 insulin consists of 75% intermediate insulin (NPH) and 25% rapid-acting (lispro (Humalog)). Third-row arrows: NPH injections; fourth-row arrows 75/25 injections.

TABLE 1 Suggested Total Daily Insulin Dosage in New-Onset Type 1 Diabetes

PATIENT CATEGORY	INSULIN DOSE (units/kd/day)
Prepubertal without DKA	0.25–0.5
Prepubertal with DKA	0.5–0.75
Pubertal without DKA	0.5–0.75
Pubertal with DKA	0.75–1.0

Patient Example 1

- 6 y.o. girl with presents with 2 week history of polydipsia and polyuria.
- She is otherwise well with a normal exam.
- Serum glucose in the ER is 425 mg/dl and serum bicarbonate is 20.
- Weight in the ER : 20 kg
- Total daily insulin = $20 \text{ kg} \times 0.3 \text{ u/kg/d} = 6 \text{ units}$.
- ~50% basal = 3.0 units (glargine, degludec)
- Target = 150
- Carbohydrate ratio: $500/6 = 83 \sim 80$
- Correction factor: $1500/6 = 250$

Figure 2 New-onset type 1 diabetes in a 6-year-old girl who is not in DKA. Total daily insulin dosage is determined by multiplying body weight by recommended dosage requirements for a prepubertal girl who is not in DKA. One-half of total daily insulin dose is given as long-acting insulin, which is 3.0 units in this example. Carbohydrate ratio and correction factors are calculated using formulas provided in text. Calculated ratios can be adjusted up to 10% to simplify calculations.

of intermediate-acting insulin and a sliding scale of rapid-acting insulin (Figure 1).

Less complex insulin regimens include NPH and rapid- or short-acting insulin given at breakfast, dinner, and bedtime (Figure 3).

Patient Example 2

- 8 y.o. boy—2 week history of polydipsia, polyuria and vomiting for the past 24 hours.
- In doctors office: glucose 380 mg/dl and urine ketones are large.
- In emergency room serum HCO_3^- 9, anion gap 25.
- Admitted to ICU for insulin drip, IV fluids, and frequent monitoring.
- At 7 am the following morning: glucose 120, HCO_3^- 20.
- Weight: 25
- Family would like to avoid insulin at lunch as school nurse not available.
- Total daily dose $0.6 \times 25 \text{ kg} = 15 \text{ units}$
- 2/3 am = 10 units
 - 2/3 NPH ~ 6.5 units
 - 1/3 rapid acting 3.5 units
- 1/3 pm = 5 units
 - 1/3 rapid acting ~ 1.5 units before dinner
 - 2/3 NPH 3.5 units at bedtime
- Supplement with sliding scale: 0.5 unit rapid-acting insulin per 50 mg/dl above 200 mg/dl.

Figure 3 Patient example 2: An 8-year-old boy who presents in DKA. Treated with insulin drip overnight and acidosis resolved by the morning. Parents desire regimen that does not require insulin at lunch time. Total daily insulin dose—see Table 1.

NPH and short-acting insulin are given at breakfast (no insulin at lunch if glucose $<200 \text{ mg/dL}$), short-acting insulin at dinner, and NPH at bedtime. This regimen can be used to avoid giving insulin at lunchtime. Typically, 2/3 of the daily dose is given in the morning, with 2/3 NPH, 1/3 short-acting, and 1/3 of daily dose given in evening. The evening dose is divided, with 1/3 short-acting before dinner and 2/3 NPH at bedtime. The patient should, however, consume a relatively fixed amount of carbohydrate at each meal. Consistency in meal content and portion sizes is very important in overall glycemic control. A simplified sliding scale of rapid-acting insulin may be added to the NPH and short-acting insulin regimen.

In certain challenging cases in which there are significant compliance or cognitive deficits, fixed doses of premixed intermediate- and rapid- or short-acting insulin such as 75/25

Patient Example 3

- 14 y.o. boy with cognitive delays presents with 3-week history of polydipsia and polyuria and 10 lb weight loss.
- Glucose 625 mg/dl in ER
- Bicarbonate 19 meq/L.
- Tanner 4 on exam
- Weight 44 kg
- Parents also have cognitive impairments
- Total daily dose: $44 \text{ kg} \times 0.6 \text{ u/kg/d} = 26.4 \text{ units per day}$.
- Medical team decides fixed mixed 75/25 insulin regimen may be best.
- 2/3 TDD given before breakfast = 17 units
- 1/3 before dinner = 9 units
- Sliding scale rapid acting: 1 unit per 50 mg/dl over 200 mg/dl.

Figure 4 Patient example 3: A 14-year-old boy with intellectual impairments presents with new-onset T1DM without DKA. Because of cognitive delays in patient and parents, a simplified two-injection regimen is derived using above calculations. Regimen may be supplemented with sliding scale of rapid-acting insulin.

can be used before breakfast and before dinner (Figure 4). Fixed mixed 75/25 insulin preparations come in vials or pens and consist of 75% intermediate-acting (NPH) and 25% rapid-acting (lispro) insulins. Insulin pens are a very convenient way to give insulin, but in some cases, because of patient preference or insurer restrictions, dosing by syringe is preferred or required.

Treatment of Diabetic Ketoacidosis (DKA)

There are critical differences in the treatment of DKA between children and adults. A major complication of the treatment of DKA in children is cerebral edema, a complication rarely seen in adults. Although a relatively infrequent complication (<1% of DKA episodes), cerebral edema can be associated with serious morbidity and mortality rates.⁹

Risk factors for the development of cerebral edema include new-onset diabetes, younger age at diagnosis, longer duration of symptoms before diagnosis, and severity of acidosis—manifested as DKA with hypocapnia, high blood urea nitrogen, bicarbonate boluses, and a failure for the corrected serum sodium to rise as treatment for DKA progresses.⁹ For these reasons, aggressive fluid resuscitation and boluses of bicarbonate are avoided in the treatment of pediatric DKA.

Judicious fluid replacement with a bolus of normal saline—initially 10 mL/kg and, if necessary, a second 10-mL/kg bolus of saline solution—may be given in the first hour of treatment. Thereafter 1/2 normal saline with 20 to 40 (usually 40) mEq/L of potassium chloride or potassium phosphate at a fluid rate of no more than 1.5 to 2.0 \times maintenance is administered (Table 2). Dextrose (5%–10%) should be added to the intravenous fluids when the serum glucose is between 250 to 300 mg/dL to prevent hypoglycemia and interruption of the insulin drip. Although fluid deficit estimates in DKA are between 5% to 10% of body weight, intravascular volume is often preserved in the hyperosmolar state, and hence hypovolemic shock is uncommon in diabetic ketoacidosis. The goal is to replace the fluid deficit slowly over 24 to 48 hours. Frequent neurologic checks are highly recommended in the first 24 hours of treatment. Altered mental status or development of a severe headache during treatment for DKA are potentially serious signs of cerebral edema.

Insulin plays a critical role in the treatment of DKA, not only in lowering serum glucose levels but also in the paramount role of

shutting down ketogenesis in the liver. The standard insulin drip for pediatric DKA is 0.1 units/kg/hour; however, treatment with 0.05 units/kg/hr has been used effectively as well.⁹ Please note that human regular insulin remains the standard insulin in the intravenous treatment of DKA.

Once the acidosis has resolved as reflected by a normal anion gap and serum bicarbonate > 15 mmol/L and pH > 7.35, discontinuation of the insulin drip can be considered. Please note that hyperchloremic non-anion gap acidosis ($\text{HCO}_3^- < 15$ but normal anion gap < 12) can occur during the recovery phase of DKA. Hyperchloremic metabolic acidosis is likely due to large amount of chloride administered in intravenous fluids as both NaCl and KCl supplementation. For this reason, many centers typically give 50% of the potassium replacement as potassium phosphate.⁹ Subcutaneous insulin can be started per the “Treatment of T1DM” section of this chapter once the acidosis is resolved and the patient can tolerate oral intake. The most convenient time to do so is just before a meal.

Importantly, treatment of pediatric DKA should ideally occur in centers with experienced pediatric intensivists, endocrinologists, and nursing staff. If referral to a pediatric center is not practical, then early contact with a pediatric endocrinologist for treatment guidance is highly recommended.

Finally, the most common causes of pediatric DKA are (1) new-onset diabetes presenting in DKA and (2) known T1DM usually due to infusion site failure in either a patient on an insulin pump or missed long-acting insulin injections in a patient on insulin injections. Infections including gastroenteritis and febrile illnesses are infrequently the cause of DKA.

Diabetes Self-Management Education

Children and adolescents with type 1 diabetes should receive outpatient care through multidisciplinary teams, which include an endocrinologist, certified diabetes educator, nurse, registered dietician, and licensed clinical social worker.^{1,4} Provision of comprehensive education at the time of diagnosis is essential, because this is a time when the patient and family are most receptive and impressionable. Patients who do not receive proper early education often fall into suboptimal diabetes care habits that can be hard to undo once established.

Important educational topics that must be rapidly learned by the family and patient in addition to glucose monitoring and insulin administration include diet and carbohydrate counting, prevention and treatment of hypoglycemia, emergency glucagon, exercise and hypoglycemia, prevention of ketoacidosis, and sick day management. Learning to count carbohydrates accurately is a particularly challenging skill to master. Large amounts of protein and fats in a meal can result in significant hyperglycemia independent of carbohydrate content, so it is important to avoid excessive protein and fat intake.

Mental Health Considerations in T1DM

Diabetes “burnout” issues are common in the treatment of youth with diabetes, particularly during the adolescent years. Conflicts between parents and teens can often arise during this time, and it is important for the parents to maintain a healthy supporting role with their child or teenager in an age- and developmentally appropriate manner. Recognition of relatively common mental health comorbidities, such as depression, anxiety, and eating disorders, is essential to the overall well-being of the pediatric patient with T1DM.⁸

Goals of Therapy for Patients with T1DM

The number-one goal of the diabetes health care team is to prevent readmission to the hospital for severe hypoglycemia or ketoacidosis. Resumption of the full range of daily activities, including returning to school and work, as well as engaging in essentially all meaningful activities that preceded the diagnosis of diabetes, is to be expected.

Although the goal hemoglobin A1c in the pediatric age group is 7.5%, less than 25% of pediatric patients in the United States are

TABLE 2 Formulas for Calculation of Maintenance Fluids for Infants and Children

For infants 3.5–10 kg, daily fluid requirement = 100 mL/kg

For children 11–20 kg, daily fluid requirement = 1000 mL + 50 mL/kg for every 10 kg

For children >20 kg, daily fluid requirement = 1500 mL + 20 mL/kg >20, up to ≤ 2400 mL daily

able to achieve that goal.⁷ The average hemoglobin A1c in the pediatric population is approximately 8.2%, whereas in 19-year-olds the average hemoglobin A1c is 9.2%.⁷

The Diabetes Control and Complications Trial (DCCT) in 1993 showed convincingly that lowering the hemoglobin A1c from 9% to 7.1% resulted in significantly less diabetes-related retinopathy, nephropathy, and neuropathy.¹⁰ Most patients in the DCCT trial who were randomized to the intensive-treated group used insulin pumps to achieve tighter control, but tight control was achieved with injectable insulin regimens as well.

Sick Day Management

Patients with T1DM who have development of intercurrent infectious illnesses are prone to hyperglycemia with ketosis and also hypoglycemia, depending on the nature of the individual illness. Blood glucose levels should be monitored every 1 to 3 hours during illnesses. Rapid-acting insulin may need to be administered every 2 to 4 hours for hyperglycemia, especially in the presence of serum or urine ketones. Rapid-acting insulin can be dosed at 0.1 to 0.2 units/kg/dose in this setting. Improvement in hyperglycemia and particularly in ketosis using the above treatment regimen can be invaluable in preventing ketoacidosis or hospitalization. Patients with persistent vomiting who are unable to keep fluids down need to be referred to the emergency department for intravenous hydration and assessment for DKA.

For patients on an insulin pump, ketosis with nausea and vomiting is often a sign that the insulin infusion set is not properly functioning. Insulin therefore should be given by syringe or pen device until the ketones have cleared and a new infusion set has been placed.

Poor oral intake during a gastrointestinal illness may result in hypoglycemia. Frequent small volumes of sugar-containing fluids such as juice or sports drinks may be necessary to keep the blood glucose >70 mg/dL, and basal insulin requirements may need to be decreased by 10% to 50%. Low-dose glucagon may be used in the setting of recurrent hypoglycemia and poor oral intake. Glucagon can be dosed at 1 unit on an insulin syringe for every year of age, using a standard 1-mg/mL glucagon preparation. The dose may be repeated every 15 minutes as needed. In some cases, persistent low glucose levels (<70 mg/dL) in the setting of recurrent vomiting may be best managed in an emergency department or hospital setting where intravenous dextrose containing fluids are readily available.

Risk for Additional Autoimmune Disorders

Patients with one autoimmune disorder are at increased risk for development of one or more additional autoimmune conditions. Children and adolescents with T1DM are particularly at risk for thyroid and celiac disorders.^{1,4,8} Screening for thyroid disorders with serum TSH and free T₄ should occur in the first 6 months after T1DM diagnosis and every 1 to 2 years thereafter. Celiac disorder should also be screened in the first year after diabetes diagnosis. Most cases of celiac disorder are detected within the first 5 years after diagnosis of T1DM, and the majority of cases are asymptomatic. Recent American Diabetes Association recommendations include screening for celiac disorder at diagnosis and again at 2 and 5 years after diagnosis.⁸ Elevated serum tissue transglutaminase levels should be referred to a pediatric gastroenterologist. Because the diagnosis of celiac disorder is a lifelong condition, obtaining a small bowel biopsy is advised. Strongly positive serum tissue transglutaminase levels can be associated with a normal small bowel biopsy, and conversely, relatively weakly positive tissue transglutaminase levels can be associated with significant blunting of the small bowel mucosa (author's personal experience).

Autoimmune adrenal (Addison's) disease rarely occurs with T1DM but has the unique presentation of recurrent hypoglycemia, necessitating significant reductions in daily insulin requirements. Sending simultaneous ACTH and cortisol levels on a morning blood specimen usually will render the diagnosis of Addison disease.

Screening for Complications of T1DM

Microvascular complications of T1DM are infrequent in the pediatric age group, although background retinopathy and microalbuminuria become more prevalent in the late-adolescent and young-adult age ranges.¹⁰ Proactive early screening regimens are advocated to detect diabetes complications early so that medical interventions can prevent more serious diabetes-related complications such as proliferative retinopathy and end-stage renal disease.¹²

Annual screening for microalbuminuria with a random urine specimen should be performed at puberty or at age >10 years once the child has had diabetes for 5 years.¹² Elevated urine albumin/urine creatinine (>30 mg/gm creatinine) ratios should be repeated 2 to 3 times over a 6-month period to confirm the diagnosis, because transient microalbuminuria is a common finding.¹⁰ Variables such as exercise or recent illness can lead to microalbuminuria, and therefore repeating the study after recovery and on a first morning specimen will often be normal. In addition, individuals with the benign condition of orthostatic albuminuria can be identified by finding completely normal albumin excretion on a first morning-voided specimen, whereas a random specimen will often be frankly proteinuric. When urinary albumin/creatinine ratios are found to be consistently elevated, then treatment with an angiotensin converting enzyme inhibitor is recommended.⁸ Referral to a pediatric nephrologist should be obtained in complex cases.

Annual dilated eye examinations are recommended after age 10 or at pubertal onset (whichever comes first) once the patient has had diabetes for 3 to 5 years. Referral to an eye care professional with expertise in diabetic retinopathy is recommended (DC).

Cardiovascular risk factors including blood pressure and lipid profiles should be monitored in patients with T1DM. Blood pressure should be obtained at each visit.

High blood pressure is defined as systolic or diastolic blood pressure >90th percentile, and hypertension is defined as >95th percentile for age, sex, and height. Blood pressure measurements should be obtained using an appropriate cuff size, particularly in the overweight patient. White-coat hypertension can be problematic in the adolescent population. Such patients will often demonstrate elevated heart rate as a clue to stress-induced hypertension. Monitoring blood pressure in a nonthreatening environment, such as at home, using an accurate home blood pressure monitor may be helpful. Twenty-four-hour home blood pressure monitoring can be very useful when white-coat hypertension is suspected.

Initial management of high blood pressure includes salt restriction and weight control measures. For persistent hypertension, treatment with an antihypertensive medication (lisinopril [Prinivil]) may be necessary.

Obtain non-fasting total and high-density lipoprotein cholesterol shortly after diagnosis once glucose control has been established. If total cholesterol is high, then obtain a fasting morning lipid panel. If low-density lipoprotein (LDL) cholesterol is <100, then repeating in 5 years is reasonable. For elevated LDL cholesterol >100, dietary measures are taken, along with efforts to improve metabolic control. For patients >10 years of age with an LDL cholesterol >130 to 160 and in whom lifestyle changes resulted in inadequate lowering of LDL cholesterol, statin therapy may be considered. Referral to a pediatric preventive cardiology program would also be appropriate.⁸

Technological Changes in T1DM Care

Technological changes have revolutionized the care of patients with T1DM. Unheralded changes such as the emergence of ultrafine lancet technology coupled with glucose test strips requiring less than 10 µL of blood resulted in essentially painless fingerstick glucose monitoring. Ultrafine insulin syringes and pen needles helped usher in widespread adoption of intensive insulin regimens with rapid-acting insulin taken before all meals and snacks (personal observations).

The insulin pump further advanced diabetes care in making insulin dosing before meals and snacks even less challenging, especially

for children. The development of a tubeless insulin pump (Omni-pod) led to an even wider array of insulin pump choices.

Continuous glucose monitoring (CGM) has evolved into a very powerful and widely used technology in T1DM.¹¹ Subcutaneous fluid glucose levels are determined every 1 to 5 minutes and provide the user with meaningful feedback to influence diabetes self-management decisions in a real-time fashion. Particularly useful are alarm functions for low glucose levels that can be invaluable in the prevention of hypoglycemia. Alarms for hyperglycemia are also used regularly with this technology. The accuracy of glucose determinations by CGM technology is now approaching subcutaneous blood glucose technology, and the improved accuracy has led the Food and Drug Administration (FDA) to approve insulin-dosing decisions based on CGM data (Dexcom G5 and G6). It is important to remember, however, that subcutaneous glucose levels lag behind whole blood glucose levels by about 15 minutes. This fact is particularly important when glucose levels are changing rapidly, so the user is advised to pay attention to the glucose trend. Alarms for predictive hypoglycemia are also available in some CGM technology platforms.

A drawback to CGM technology has been the need to calibrate the device accurately with periodic fingerstick glucose checks. Calibration must be done correctly, or inaccurate CGM glucose data will result. Ideally calibrations should be done when glucose levels are not changing, which for some individuals with high glucose variability may not be practical. However, devices such as the Dexcom G6 that have been released to market in 2018 and the Abbott Libre are factory calibrated and no longer require consumer calibration.

A CGM sensor placed on the arm or abdomen will last 7 to 10 days before needing to be changed. Common problems related to CGM use include adhesion problems or skin reactions to the adhesive. Extra taping is often helpful in securing the CGM site in the active child, whereas an inhaled steroid preparation used topically¹ may be helpful in skin site reactions.

The most remarkable technological changes emerging in the care of patients with T1DM is the coupling of CGM and insulin pump technologies to provide closed-loop or hybrid closed-loop insulin pump therapy. *Hybrid closed-loop* refers to the fact that some aspects of management such as carbohydrate counting and manual bolusing for meals are still required.

The first hybrid closed-loop insulin pump was FDA approved in 2016 (Medtronic 670G).¹² This technology involves coupling the Medtronic Guardian sensor with the 670G insulin pump using algorithms that will deliver microboluses of insulin, depending on sensor glucose levels. Conversely, insulin delivery can be halted when the rate of falling glucose predicts hypoglycemia or the patient is in the hypoglycemic range. However, carbohydrate counting and entry of carbohydrate content of meals must be manually entered by the user before meals. Prevention of postprandial hyperglycemia can be achieved by pre-bolusing rapid-acting insulin 10 to 30 minutes before eating. Pre-bolusing of rapid-acting insulin is particularly difficult in view of modern lifestyles. Hybrid closed-loop technology can be particularly useful for overnight glycemic control, when many patients and families are most fearful of hypoglycemia. A number of additional hybrid closed-loop systems are currently in clinical trials, and the diabetes community can look forward to further remarkable technological advancements in the near future.

Type 2 Diabetes in Children

Since the 1990s, type 2 diabetes (T2DM) in the <18-year-old age group has risen dramatically. The increased incidence of type 2 diabetes has coincided with the obesity epidemic. Children from minority populations (non-Hispanic black, Hispanic, Native Americans) and those patients with a positive family history of T2DM are at the greatest risk.¹³ The majority of pediatric T2DM is found in adolescents and children >10 years of age.¹³

Diagnosis of T2DM can be made with a fasting glucose >126 mg/dL, random glucose >200 mg/dL, and oral glucose tolerance test 2-hour glucose >200 mg/dL. A hemoglobin A1c >6.5% is indicative of diabetes as well and is particularly convenient in the outpatient setting. An elevated fasting or random glucose and an elevated hemoglobin A1c are diagnostic of T2DM in high-risk patients.

Pediatric patients with T2DM are often symptom free at diagnosis but can present acutely with classic diabetes symptoms and even ketosis or mild ketoacidosis. Distinguishing the latter group from T1DM can be difficult initially, but the absence of beta cell antibodies and very stable glycemic control after diagnosis are often telltale signs of T2DM.

In individuals who present with marked hyperglycemia (hemoglobin A1c > 8.5%), ketosis, or both, stabilization with insulin initially is required. Basal bolus regimens using a combination of long- and short-acting insulins can be instituted. Insulin resistance may be quite significant at the time of diagnosis, and relatively high doses of insulin can be required to achieve target glucose levels.

Metformin (Glucophage) is the only oral agent approved for the treatment of T2DM in the <18-year-old age group.^{1,4,13} Maximal dosing is 1000 mg bid or 2000 mg/day of the extended-release preparation. Gastrointestinal side effects are relatively common, and metformin should be taken with meals. Initial dosing can be 500 mg bid or 1000 mg extended-release daily, and the dose can be titrated upward as needed and tolerated. Bear in mind that dietary modifications such as weight control and exercise are of fundamental importance in the treatment of T2DM.

Adherence to a healthy diet in combination with metformin alone, insulin therapy, or both often results in very stable glycemic control in T2DM in pediatrics. In many cases, bolus short-acting insulin and even long-acting insulin therapy can be withdrawn safely 6 to 12 months after diagnosis. However, resumption of lax dietary and self-care habits can result in significant decline in glycemic control and the need to restart insulin. Therefore patients with T2DM need to be as vigilant as patients with T1DM with regular monitoring of glucose levels and follow-up visits every 3 to 6 months with their health care team.

Monogenic or Maturity Onset Diabetes of Youth (MODY)

Single-gene mutations leading to diabetes are referred to as *MODY diabetes* or *monogenic diabetes*.¹⁴ Up to 14 individual forms of MODY diabetes have been described, although ~80% of cases are due to glucokinase and HNF1A and HNF1B gene mutations. Patients can be diagnosed at any age but usually are diagnosed before age 35 years. Routine laboratory testing or laboratory testing during an illness may lead to detection of MODY diabetes incidentally. Patients with MODY are often lean, and the family history usually reveals two to three affected generations. Testing for islet cell antibodies is universally negative.

Glucokinase diabetes is a very mild form of MODY diabetes that is nonprogressive and does not require treatment, whereas HNF alpha and beta forms of MODY diabetes are progressive, and these patients can have development of long-term complications of diabetes. HNF diabetes is uniquely sensitive to sulfonylureas, and hence the diagnosis can be life changing in an individual who has been treated with insulin.¹⁴

Genetic panels for MODY diabetes are available commercially, and genetic testing is increasingly covered by insurance companies in the United States. It is important to test for both mutations and deletions of the most common forms of MODY. A full list of laboratories that offer MODY testing is available at the NCBI Genetic Testing Registry (<http://www.ncbi.nlm.nih.gov/gtr/>).

Neonatal diabetes can also be due to monogenic forms of diabetes, and these infants are usually diagnosed before 6 to 9 months of age. Testing for monogenetic forms of diabetes should be considered in infants <9 to 12 months of age whose islet cell autoantibodies are negative. Single gene mutations in the K-ATP channel of the beta cell leading to neonatal diabetes can be remarkably responsive to oral sulfonylureas.¹⁴

¹Not FDA approved for this indication.

ENCOPRESIS

Method of

Sarah Houssayni, MD

CURRENT DIAGNOSIS

- Voluntary or involuntary passage of stools into inappropriate places at least once a month for 3 consecutive months once a chronologic or developmental age of 4 years has been reached.
- Encopresis can be primary when it persists from infancy onward or secondary when it appears after toilet training.
- The behavior is not due to the direct effects of a substance such as a laxative or a general medical condition except those associated with constipation.
- Distinguishing subtypes is essential because treatment differs:
 - Retentive encopresis: occurs as a result of involuntary leakage of liquid stools due to severe constipation and impaction.
 - Nonretentive encopresis: children pass bowel movements into their underwear due to their refusal to use the toilet.
 - Children occasionally fail to wipe after bowel movements and the secondary soiling should be distinguished from encopresis.

CURRENT THERAPY

Retentive Encopresis

Initial Disimpaction

- Hyperphosphate enemas (Pedia-Lax Enema) (one daily for 2 or 3 days):
 - Less than 1 year old: 60 mL.³
 - Greater than 1 year old: 6 mL/kg, up to 135 mL twice.³
- Glycerin suppositories (Glycerin Pediatric Suppositories) for infants and toddlers.

Older Children—Slow Disimpaction

- Polyethylene glycol with electrolytes (Golytely, Colyte)¹ ingested over 2–3 days: 25 mL/kg/hr up to 1 L/hr until stooling clear bowel movements. (This is not approved for bowel cleansing for children.)
- Over 5–7 days:
 - Mineral oil¹ 3 mL/kg twice a day for 1 week. (Mineral oil is not approved for use in children younger than 6 years of age.)
 - Lactulose¹ 2 mL/kg twice a day for 1 week.
 - Magnesium hydroxide (Milk of Magnesia) 2 mL/kg twice a day for 1 week.
 - Polyethylene glycol without electrolyte (MiraLax)¹ 1.5 g/kg/day for 3 days.

Maintenance Therapy

- Polyethylene glycol 3350 (MiraLax)¹ age greater than 1 month: 0.7 g/kg divided into 1–2 doses daily.
- Lactulose or sorbitol 70% solution age greater than 1 month: 1–3 mL/kg/day divided into 1–2 doses daily for 1–3 months.
- Sennosides (Senna, Senna-GRX, Senexon) are habit forming, doses vary greatly in the different available formulations, and they can only be used for short-term treatment. Give at bedtime for a morning bowel movement. Dose is 5 mL (1 tablet) for 1–1 to 5-year-olds and 2 tablets for 5- to 15-year-olds for a maximum of three tablets daily. (Sennosides are not approved for use in children younger than 2 years of age.)
- Glycerin enemas and bisacodyl suppositories (Dulcolax) can be used for short-term constipation treatment.
- Glycerin/saline enema in patients greater than 10 years of age: 20–30 mL/day (solution of 1/2 glycerin and 1/2 normal saline).
- Bisacodyl suppositories in patients greater than 10 years of age: 10 mg daily.

Nonretentive Encopresis

- **NO** medical treatment.
- Clean up soiling immediately, involve the child.
- Ensure adequate water and dietary fiber intake.
- Avoid use of stool softeners and laxatives.
- **STOP** all reminders, make child responsible for own toilet habits.
- Use rewards when child defecates in toilet.
- Refer to health care professional when refractory (refuses to sit on toilet and older than 5 years of age, refuses to take medication, is older than 8 years of age with nonretentive encopresis).

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer; manufacturer-recommended doses are: 5–11 y, 1 bottle (60 mL); 2–4 y, half bottle (30 mL); <2 y, do not use.

Encopresis is the voluntary or involuntary passage of stools at least once a month for 3 consecutive months once a chronologic or developmental age of 4 years has been reached. Encopresis is classified as primary when it persists from infancy onward or secondary when it appears after toilet training. Retentive encopresis occurs as a result of involuntary leakage of liquid stools due to severe constipation and fecal impaction. Nonretentive encopresis occurs in children who pass stool into their underwear due to their refusal to use the toilet. It is important to distinguish between the types of encopresis, because treatment differs.

Epidemiology

The prevalence of encopresis is reported to be 4% in 5- to 6-year-olds and 1.5% in 11- to 12-year-olds. Affected boys outnumber girls by a factor of anywhere from 3:1 to 5:1 depending on the source. Encopresis tends to decrease with age. A large number of children with encopresis go unreported due to the shame associated with the condition and underdiagnosis of the condition.

Diagnosis

The diagnosis of encopresis includes the following four criteria: (1) Repeated passage of feces into inappropriate places such as in

Encopresis is the voluntary or involuntary passage of stools at least once a month for 3 consecutive months once a chronologic or developmental age of 4 years has been reached. Encopresis is classified as primary when it persists from infancy onward or secondary when it appears after toilet training. Retentive encopresis occurs as a result of involuntary leakage of liquid stools due to severe constipation and fecal impaction. Nonretentive encopresis occurs in children who pass stool into their underwear due to their refusal to use the toilet. It is important to distinguish between the types of encopresis, because treatment differs.

Epidemiology

The prevalence of encopresis is reported to be 4% in 5- to 6-year-olds and 1.5% in 11- to 12-year-olds. Affected boys outnumber girls by a factor of anywhere from 3:1 to 5:1 depending on the source. Encopresis tends to decrease with age. A large number of children with encopresis go unreported due to the shame associated with the condition and underdiagnosis of the condition.

Diagnosis

The diagnosis of encopresis includes the following four criteria: (1) Repeated passage of feces into inappropriate places such as in

clothing or on the floor, whether intentional or involuntary. (2) At least one event a month for at least 3 months. (3) A chronologic age of at least 4 years or an equivalent developmental level. (4) The behavior is not due exclusively to the direct physiologic effects of a substance such as a laxative or a general medical condition other than constipation.

Differential Diagnosis

Retentive encopresis is organic in less than 5% of the affected patients. Organic causes include hypothyroidism, hypercalcemia, cerebral palsy, abnormal anatomy of the anus, Hirschsprung's disease, cystic fibrosis, and neuropathy with secondary impaired voiding sensation. Spinal cord conditions such as tethered cord, spina bifida occulta, and spinal cord dysplasia affect stooling through diminished bowel sensation and secondary fecal retention.

Pathophysiology

Patients who are severely constipated hold stools back because of the pain associated with defecation. This becomes a vicious cycle of constipation, rectal dilation, and secondary encopresis. Frequently, emotional problems emerge due to the fear and shame associated with the problem. Control issues with parents trying to take the stooling issues at hand may worsen the constipation problem.

From 10% to 20% of encopretic patients are not constipated. They are frequently preschoolers or school-age children who are postponing their bowel movements too long because they are distracted or because they associate the bathroom with an unpleasant experience (i.e., fear or disgust).

Clinical Manifestations

History

The history should assess for size and consistency of stools, as well as stooling intervals. Families often confuse soiling with stooling, leading to inaccurate reporting of the frequency of bowel movements. Characteristic symptoms of retentive and nonretentive encopresis differ (Table 1).

In retentive encopresis the physician may elicit a history of difficult or painful defecation, crying with bowel movements, and posturing that suggests the child is deliberately holding back stools due to the pain associated with passage.

Children may suddenly become still or hide during play, cross their legs, grimace, or shift their position in an attempt to retain stools. The physician should assess for a history of enuresis and urinary tract infections, anorexia, sensations of bloating, fullness, and abdominal pain leading to the patient's avoidance of food and weight loss. Obtain a dietary history including fiber, fluid, and dairy intake. The historian needs to inquire about streaks of blood

on toilet paper and underwear. With retentive encopresis, when the child does pass stool, it may be of large caliber and hard, indicative of constipation.

With nonretentive encopresis, the history often reveals bowel movements of normal size and consistency passed into the underwear once or twice a day. Symptoms of constipation are usually absent. A history of behavioral problems, child-parent struggles, and history of abuse may be elicited. Toilet avoidance is common.

Patients with encopresis eventually develop secondary emotional problems, which can be elicited from the history taking.

Physical Examination

Retentive Encopresis

In retentive soiling the physical examination should assess for abdominal distention and tenderness on palpation. A mass can be occasionally felt in the midline in the suprapubic area. This mass of hardened fecal matter most commonly involves the rectosigmoid area and can sometimes extend throughout the entire colon. If the patient is anxious or in pain and tightens the rectus abdominis, this mass can be missed. Rectal examination is a must; it can be done with minimal discomfort. Rectal examination assesses the dilation of the rectum, which may be 6 to 10 cm wide. It is usually packed with stools with clay-like consistency. Visually inspect the anal opening for tone, fissure, and hemorrhoids.

Nonretentive Encopresis

The child with nonretentive encopresis typically has a normal abdominal examination, is likely to have a rectal vault that is not dilated, and the stool will be of normal caliber and consistency. The rectal vault may be empty if the child has just passed a bowel movement. The anal opening may reveal protruding fecal material in children who are deliberate stool holders.

Treatment

Encopresis is treated through a multistep approach. First, clearing the colon of fecal material will allow the dilated rectal vault and rectosigmoid colon to return to normal. The rectal cleanout can be achieved in different ways (see Current Therapy). Enemas and stool softeners are often used in combination.

Maintenance is achieved by keeping stools soft and ensuring daily bowel movements with mineral oil and hyperosmolar agents (e.g., Miralax¹) that are very safe and can be used from a very young age and are not habit forming. The goal is painless stools once or twice a day with no associated withholding behavior.

Education is key for families so that they understand the physiology and process of stool elimination. Frustration is associated with failure, guilt, and depression and should be replaced with a positive attitude if success is to be achieved.

- Patients should sit daily on the toilet for 5 minutes after meals twice a day.
- Families need to keep a record of the events, as well as a record for success.
- Soiled underwear should be changed as soon as noticed and the child should be cleaned and changed in a timely, emotionally neutral fashion.
- As soon as compliance wanes, the problem is expected to return and is sometimes worse than the previous episode.
- The care provider's continued involvement in titrating medication with the patient's symptoms is necessary.
- Pain-related impaction can be cured in the majority of cases with medical management of the initial presentation. The success rate is reported to be about 70% with psychogenic impaction.
- With nonretentive encopresis, behavioral modification is essential. Stress reduction, effective coping techniques, relaxation training, and a combination of individual and family therapy is sometimes indicated.

TABLE 1 Characteristic Symptoms of Retentive and Nonretentive Encopresis

Retentive Encopresis

- Constipation
- Stained underwear
- Fewer than three bowel movements per week
- Large-caliber or hard stools
- Abdominal pain, reports of bloated sensation
- Odor of feces from leakage onto underwear
- Difficult or painful defecation
- Enuresis
- Overflow incontinence
- Anorexia

Nonretentive Encopresis

- Passage of stools in inappropriate places without presence of constipation
- Refusal to sit on toilet even though old enough to (older than 5 years, even older than 8 years at times)
- Refusal to take medications
- Child may be depressed

¹Not FDA approved for this indication.

EPILEPSY IN INFANTS AND CHILDREN

Method of

Adam L. Hartman, MD

CURRENT DIAGNOSIS

- At initial diagnosis, determine whether the event was a seizure or not.
- If appropriate, diagnose an epilepsy syndrome.
- Age of onset aids in the development of a differential diagnosis.

CURRENT THERAPY

- Selection of an antiseizure medicine should be made based on the type of seizure.
- General principles include the use of a single agent at the lowest effective dose with the goal of no side effects.
- Epilepsy can be associated with comorbidities, including depression and anxiety. Successful management includes referrals and/or management of these and associated psychosocial issues.

A seizure can be defined as clinical signs or symptoms resulting from abnormal neuronal firing. Epilepsy is defined as either (1) at least two unprovoked seizures occurring >24 hours apart; (2) one unprovoked seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome. There may be associated psychological, social, and cognitive consequences. Approximately 3% to 5% of the US population have had a seizure (mostly febrile seizures). Nearly 1% of the US population are being treated actively for seizures at any given time. Infants and children represent one of the two major peaks in seizure incidence, making this a very common diagnosis in pediatric practice.

Risk Factors

The primary risk factors for epilepsy in any age group include a history of meningitis, encephalitis, brain trauma, complicated perinatal course, and febrile seizures. Other risk factors for seizures include cortical or developmental malformations, certain inborn errors of metabolism or genetic syndromes, congenital infections, stroke, intracranial hemorrhage, acute metabolic abnormalities, and drug withdrawal.

Pathophysiology

Because the primary abnormality is abnormal neuron firing, many different types of pathology can lead to seizures. Abnormalities in

neuronal networks (e.g., cortical malformations), structure (e.g., abnormal dendrite structure in trisomy 21), or ion channels (e.g., *KCNQ2*) can lead to seizures. In many cases, an underlying cause of seizures cannot be identified. Some forms of epilepsy have been linked to various genetic mutations, although the exact relationship between specific genotypes and phenotypes is unclear for most.

Clinical Manifestations

Broadly speaking, the clinical manifestations of seizures vary depending on which brain structures are involved. Although most people think of seizures only as generalized tonic-clonic seizures (GTCS), a wide variety of signs and symptoms can be caused by seizures. Furthermore, a GTCS may be the initial manifestation of a seizure (i.e., as seen in primary generalized epilepsy) or it may be the end result of a seizure that started in one brain location and then spread to the rest of the brain (e.g., a focal-onset seizure with spread to other broad cortical regions of the brain). These two broad categories (generalized versus focal onset) are approached somewhat differently from a diagnostic and therapeutic perspective.

Signs of a generalized seizure (i.e., those involving abnormal neuronal firing in both sides of the brain) include loss of interaction or staring (absence seizures), myoclonus, tonic posturing, and/or tonic-clonic seizures. Signs of focal-onset seizures can involve specific regions controlling motor, sensory, or autonomic function, a loss of interaction and/or awareness, or automatisms (chewing, lip smacking, repetitive hand motions), to name a few. Patients with focal seizures might have an aura (a warning sign just prior to the seizure). The aura is an altered sensory function that can include salty or metallic taste, tingling sensations, rising sensation in the abdomen, déjà vu, jamais vu, sense of fear, or a nonspecific feeling that something is about to happen. After a seizure, patients also can have a period of postictal lethargy, confusion, or irritability.

The initial symptoms or signs of a seizure are the most important in determining whether a seizure is generalized or focal in origin because they often localize the anatomic site of pathology. Thus, it is the beginning of a seizure, rather than its end, that is most useful in making a specific diagnosis.

Diagnosis and Management

History and Physical Examination

A detailed history is usually more valuable than any expensive test in diagnosing a seizure or epilepsy. In addition to a description of the actual event, it is useful to inquire about subtle signs that might not be recognized by observers as a seizure, including staring spells, myoclonic jerks, loss of time, and unexplained nocturnal tongue biting, enuresis, or emesis. The presence of postictal weakness can help localize the hemisphere of onset after a focal seizure, even if secondarily generalized. Making the diagnosis of a specific epilepsy syndrome allows the clinician to develop a plan for further diagnosis and treatment and to counsel about prognosis. On physical examination, any signs of focal neurologic deficits can indicate an underlying lesion. A skin examination might identify a neurophakomatosis, such as tuberous sclerosis complex or Sturge Weber syndrome.

Diagnostic Studies

In selected cases, typical clinical findings in the right clinical context strongly support the diagnosis of epilepsy, but an electroencephalogram (EEG) may be required to confirm the diagnosis. Even if the patient does not have a seizure during the EEG recording, interictal findings (when the patient is not having a seizure) can provide enough evidence to make the diagnosis of epilepsy. Under ideal circumstances, a single EEG can detect epileptiform activity in a patient with untreated generalized epilepsy about 75% of the time, making it a very sensitive test. In contrast, an EEG can detect epileptiform activity in a patient with focal-onset seizures only 50% of the time (although this number increases to about 90% after three EEGs have been done). Conversely, a normal interictal EEG (particularly one that includes sleep and provocative maneuvers such as intermittent photic stimulation and hyperventilation)

EPILEPSY IN INFANTS AND CHILDREN

Method of

Adam L. Hartman, MD

CURRENT DIAGNOSIS

- At initial diagnosis, determine whether the event was a seizure or not.
- If appropriate, diagnose an epilepsy syndrome.
- Age of onset aids in the development of a differential diagnosis.

CURRENT THERAPY

- Selection of an antiseizure medicine should be made based on the type of seizure.
- General principles include the use of a single agent at the lowest effective dose with the goal of no side effects.
- Epilepsy can be associated with comorbidities, including depression and anxiety. Successful management includes referrals and/or management of these and associated psychosocial issues.

A seizure can be defined as clinical signs or symptoms resulting from abnormal neuronal firing. Epilepsy is defined as either (1) at least two unprovoked seizures occurring >24 hours apart; (2) one unprovoked seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome. There may be associated psychological, social, and cognitive consequences. Approximately 3% to 5% of the US population have had a seizure (mostly febrile seizures). Nearly 1% of the US population are being treated actively for seizures at any given time. Infants and children represent one of the two major peaks in seizure incidence, making this a very common diagnosis in pediatric practice.

Risk Factors

The primary risk factors for epilepsy in any age group include a history of meningitis, encephalitis, brain trauma, complicated perinatal course, and febrile seizures. Other risk factors for seizures include cortical or developmental malformations, certain inborn errors of metabolism or genetic syndromes, congenital infections, stroke, intracranial hemorrhage, acute metabolic abnormalities, and drug withdrawal.

Pathophysiology

Because the primary abnormality is abnormal neuron firing, many different types of pathology can lead to seizures. Abnormalities in

neuronal networks (e.g., cortical malformations), structure (e.g., abnormal dendrite structure in trisomy 21), or ion channels (e.g., *KCNQ2*) can lead to seizures. In many cases, an underlying cause of seizures cannot be identified. Some forms of epilepsy have been linked to various genetic mutations, although the exact relationship between specific genotypes and phenotypes is unclear for most.

Clinical Manifestations

Broadly speaking, the clinical manifestations of seizures vary depending on which brain structures are involved. Although most people think of seizures only as generalized tonic-clonic seizures (GTCS), a wide variety of signs and symptoms can be caused by seizures. Furthermore, a GTCS may be the initial manifestation of a seizure (i.e., as seen in primary generalized epilepsy) or it may be the end result of a seizure that started in one brain location and then spread to the rest of the brain (e.g., a focal-onset seizure with spread to other broad cortical regions of the brain). These two broad categories (generalized versus focal onset) are approached somewhat differently from a diagnostic and therapeutic perspective.

Signs of a generalized seizure (i.e., those involving abnormal neuronal firing in both sides of the brain) include loss of interaction or staring (absence seizures), myoclonus, tonic posturing, and/or tonic-clonic seizures. Signs of focal-onset seizures can involve specific regions controlling motor, sensory, or autonomic function, a loss of interaction and/or awareness, or automatisms (chewing, lip smacking, repetitive hand motions), to name a few. Patients with focal seizures might have an aura (a warning sign just prior to the seizure). The aura is an altered sensory function that can include salty or metallic taste, tingling sensations, rising sensation in the abdomen, déjà vu, jamais vu, sense of fear, or a nonspecific feeling that something is about to happen. After a seizure, patients also can have a period of postictal lethargy, confusion, or irritability.

The initial symptoms or signs of a seizure are the most important in determining whether a seizure is generalized or focal in origin because they often localize the anatomic site of pathology. Thus, it is the beginning of a seizure, rather than its end, that is most useful in making a specific diagnosis.

Diagnosis and Management

History and Physical Examination

A detailed history is usually more valuable than any expensive test in diagnosing a seizure or epilepsy. In addition to a description of the actual event, it is useful to inquire about subtle signs that might not be recognized by observers as a seizure, including staring spells, myoclonic jerks, loss of time, and unexplained nocturnal tongue biting, enuresis, or emesis. The presence of postictal weakness can help localize the hemisphere of onset after a focal seizure, even if secondarily generalized. Making the diagnosis of a specific epilepsy syndrome allows the clinician to develop a plan for further diagnosis and treatment and to counsel about prognosis. On physical examination, any signs of focal neurologic deficits can indicate an underlying lesion. A skin examination might identify a neurophakomatosis, such as tuberous sclerosis complex or Sturge Weber syndrome.

Diagnostic Studies

In selected cases, typical clinical findings in the right clinical context strongly support the diagnosis of epilepsy, but an electroencephalogram (EEG) may be required to confirm the diagnosis. Even if the patient does not have a seizure during the EEG recording, interictal findings (when the patient is not having a seizure) can provide enough evidence to make the diagnosis of epilepsy. Under ideal circumstances, a single EEG can detect epileptiform activity in a patient with untreated generalized epilepsy about 75% of the time, making it a very sensitive test. In contrast, an EEG can detect epileptiform activity in a patient with focal-onset seizures only 50% of the time (although this number increases to about 90% after three EEGs have been done). Conversely, a normal interictal EEG (particularly one that includes sleep and provocative maneuvers such as intermittent photic stimulation and hyperventilation)

in an untreated patient suggests, but is not necessarily diagnostic of, a focal rather than generalized onset.

Other ancillary studies can show underlying structural lesions that lead to epilepsy or provide physiologic information. Magnetic resonance imaging (MRI) can be useful in detecting lesions such as tumors, cortical dysgenesis, and strokes (both ischemic and hemorrhagic). Recent advances in image analysis have substantially improved the ability to find subtle regions of cortical dysgenesis that may be the source of seizures. Positron-emission tomography (PET) scans may show regions of abnormal metabolism that might not be evident on MRI. Another nuclear medicine study, single photon emission tomography (SPECT), can be used to identify the region of onset of a seizure. Functional MRI (fMRI) studies show regions involved in a specific task (e.g., motor or language).

Magnetoencephalography, when combined with MRI, can be useful in detecting areas of abnormal electrical activity that might not be evident on a scalp EEG recording. Neuropsychology evaluations can aid in localization of regions of dysfunction and also aid in determining risk for loss of function if surgery is performed. The intracarotid amobarbital (Amytal)¹ test (Wada test) or intracarotid methohexital (Brevital)¹ test is used to lateralize language function and memory; fMRI is being investigated as a replacement for aspects of this invasive test. Some institutions use intracranial electrodes to localize the onset of a seizure prior to a surgical resection and to identify regions of eloquent neurologic function (regions where critical function would be lost if they were resected).

Specific Epilepsy Syndromes

Some of the more common syndromes are described here, listed by typical age at presentation.

Neonatal Seizures

Seizures in neonates can be caused by any type of neurologic pathology, including infections (prenatal or postnatal), strokes, hemorrhages, electrolyte abnormalities, cortical dysgenesis, inborn errors of metabolism (including vitamin B₆ dependency), genetic syndromes, drug (illicit and licit) withdrawal, and medications. Some neonatal seizure syndromes (benign idiopathic neonatal seizures and benign familial neonatal seizures) are benign in terms of resolution of seizures; early infantile epileptic encephalopathy (Ohtahara syndrome) and early myoclonic encephalopathy frequently are refractory to medical treatment and have a poor prognosis for development. Neonatal seizures should be managed in conjunction with specialists.

Febrile Seizures

Febrile seizures are the most common type of seizure, occurring in 3% to 5% of people in the United States. Febrile seizures, even though they can recur, are not diagnostic of epilepsy because they are provoked (i.e., by fever). With an onset between 1 month and 5 years of age (and almost always outgrown by 6 to 7 years of age), these seizures can be generalized or focal in onset. Meningitis and encephalitis also can manifest with seizures and fever and thus are exclusion criteria for febrile seizures because the prognosis and treatment are completely different. Febrile seizures that last longer than 15 minutes, have a focal onset, or occur more than once in a febrile illness are complex febrile seizures (only one of the three criteria are needed to make the diagnosis). Patients with complex febrile seizures are at a higher risk for developing epilepsy, although the overall risk is still low (4%). In patients who lack all three of these factors (i.e., simple febrile seizures), routine imaging, blood work, lumbar puncture, and EEG are not necessary for diagnosing the cause of the seizure. Rather, the workup should be guided by other concerns, such as dehydration, concern for occult bacteremia, or, in the appropriate clinical context, meningitis.

Approximately one-third of patients have a recurrence of a febrile seizure. Factors that increase the recurrence risk include very

young age at onset, family history of febrile seizures, low-grade fever at onset of the seizure, frequent febrile illnesses, or the occurrence of the seizure in the first hour of the fever. Febrile seizures always are outgrown, so typically long-term seizure prophylaxis is not used. Oral diazepam (Valium) prophylaxis, started at the onset of fever, prevents febrile seizures but can lead to excessive sedation. Patients who have prolonged febrile seizures can benefit from rectal diazepam gel (Diasat) or other benzodiazepines given soon after the onset of a febrile seizure to prevent additional prolonged seizures or febrile status epilepticus. A similarly good prognosis is seen in infants and children who have febrile seizures in the setting of acute gastroenteritis (whether febrile or not). The risk of epilepsy is increased after a febrile seizure in the setting of a complex febrile seizure, abnormal development, frequent febrile seizures, or a family history of epilepsy.

Infantile Spasms

With an onset typically around 4 to 8 months of age, infantile spasms consist of a triad of typical seizures (head drops and brief flexor and/or extensor spasms occurring in clusters around sleep transitions), a highly disorganized multifocal EEG pattern called hypsarrhythmia, and developmental delays. Between 70% and 90% of patients have identifiable underlying neurologic pathology associated with this syndrome. This is one of the most medically intractable epilepsy syndromes, and the prognosis for seizure control and development is very poor, except in a small subset of patients with no identifiable underlying pathology. Treatment typically is with corticosteroids (prednisolone [Orapred]¹ or ACTH [Acthar HP]), or vigabatrin (Sabril), which is commonly the first-line treatment in infants with tuberous sclerosis complex (Box 1).

Dravet Syndrome

The typical presentation for Dravet syndrome is a prolonged febrile seizure involving one side of the body (hemiclonic) or recurrent GTCS in a previously normal infant. After a relatively quiescent period, seizures (including myoclonic, focal, and absence) may appear in the second year of life. Additional features include developmental abnormalities, ataxia, and extrapyramidal signs. Seizures induced by heat (either with fevers or exogenous) may be noted.

Genetic testing for mutations in the *SCN1A* gene is recommended because this eliminates the need for other extensive testing for an underlying diagnosis and allows the clinician to prognosticate. The EEG may be normal initially but later shows generalized spike-and-wave complexes and may show focal abnormalities. Treatment typically is with antiseizure medications; drugs that block sodium channels are typically avoided because they may exacerbate seizures. The ketogenic diet may be useful.

Lennox–Gastaut Syndrome

Typically occurring between the ages of 1 and 8 years, Lennox–Gastaut syndrome is characterized by mixed seizure types, a markedly abnormal EEG, and abnormal development. Virtually any type of brain pathology can be seen as an antecedent of Lennox–Gastaut syndrome. The syndrome of infantile spasms is a common antecedent. Patients with Lennox–Gastaut syndrome typically have combinations of tonic, atonic, and absence seizures, although focal-onset seizures and GTCS also occur. The EEG shows slow (less than 2.5 Hz) spike-and-wave complexes and occasionally a paroxysmal fast pattern, although background slowing also is very common. The vast majority of patients have developmental delays. Diagnosis is made in the setting of typical findings. Seizures are very difficult to control, but treatment commonly includes medicines and/or non-pharmacologic options (see Box 1). The prognosis for seizure control and development is poor. The differential diagnosis of Lennox–Gastaut syndrome also includes Doose syndrome, which is characterized by myoclonic and atstatic seizures (although other seizure types can occur). In Doose syndrome, patients often have normal development and a good prognosis once seizures are controlled.

BOX 1 Recommendations for Treatment**Infantile Spasms, West Syndrome**

Oral steroids¹
 Adrenocorticotrophic hormone
 Ketogenic diet
 Topiramate (Topamax)¹
 Valproate (Depakote)¹
 Zonisamide (Zonegran)¹
 Pyridoxine¹
 Benzodiazepines¹
 Surgery (if there is a lesion)
 Vigabatrin (Sabril) (may use first if patient has tuberous sclerosis)

Dravet Syndrome

Valproate¹
 Topiramate¹
 Ketogenic diet
 Benzodiazepines¹

Lennox–Gastaut Syndrome

Valproate¹
 Clobazam (Onfi)
 Lamotrigine (Lamictal)
 Topiramate
 Benzodiazepines
 Rufinamide (Banzel)
 Felbamate (Felbatol)
 Ketogenic diet
 Vagus nerve stimulator
 Surgery

Doose Syndrome

Valproate¹
 Ketogenic diet
 Lamotrigine¹
 Ethosuximide (Zarontin)¹
 Vagus nerve stimulator

Childhood Absence Epilepsy

Ethosuximide
 Valproate
 Lamotrigine¹

Juvenile Absence Epilepsy

Valproate
 Ethosuximide
 Lamotrigine¹

“Benign” Epilepsy with Centrottemporal Spikes

Levetiracetam (Keppra)
 Carbamazepine (Tegretol)
 Valproate¹
 Oxcarbazepine (Trileptal)

Juvenile Myoclonic Epilepsy

Valproate¹
 Levetiracetam
 Topiramate
 Zonisamide¹
 Lamotrigine

an absence seizure, characterized by staring and loss of interaction lasting 5 to 20 seconds, occurring tens to hundreds of times per day. Patients also can have GTCS (particularly if they present later in childhood) and/or myoclonic seizures. There is no aura and there are no postictal behavior changes. Absence seizures can be induced with 3 to 4 minutes of hyperventilation at the bedside. The interictal EEG shows a 3 Hz generalized spike-and-wave pattern. Treatment includes ethosuximide (Zarontin) if the patient has not had a GTCS (see [Box 1](#)). Valproate (Depakene) is the first choice if the patient has had a GTCS. Nearly two-thirds of patients grow out of their seizures by young adulthood.

“Benign” Epilepsy With Centrottemporal Spikes and “Benign” Occipital Epilepsy

One of the more common epilepsies in childhood, “benign” epilepsy with centrottemporal spikes (also known commonly as Rolandic epilepsy), first occurs between the ages of 3 and 13 years. The typical seizure involves the face and/or hand, but GTCS also are common. The most common time for a seizure is within the first few hours of sleep, but a minority of patients only have daytime seizures. The diagnosis is made based on a typical seizure history and EEG (which shows spikes over bilateral central and temporal regions). Learning disabilities, which may be very subtle, are fairly common in patients with this syndrome, so extra vigilance is warranted (and this is the reason for quotation marks around the word “benign”).

“Benign” occipital epilepsy (also known as Panayiotopoulos syndrome) can occur between the ages of 1 and 14 years (with a peak at 4 to 5 years) with autonomic symptoms such as emesis, pallor, flushing, or tachycardia, as well as focal-onset or generalized seizures. Patients also can have visual symptoms. The EEG can show sharp waves in the occipital regions, but abnormal activity has been reported in other brain regions as well.

Because most patients have fewer than six seizures in both syndromes, medicine usually is not prescribed. Seizures typically are outgrown by adolescence. Patients with frequent seizures are treated with medicine. Gastaut occipital epilepsy (not to be confused with Lennox–Gastaut syndrome) occurs in older children and can require medication treatment because of seizure recurrence.

Juvenile Myoclonic Epilepsy

The most common form of generalized seizures in adolescents, juvenile myoclonic epilepsy first occurs between the ages of 12 and 20 years. Most patients have brief myoclonic seizures that tend to cluster in the early morning hours (but may occur at any time of day). Patients often are unaware that these are seizures but on careful questioning report loss of control of a toothbrush or spoon. Many patients also have absence seizures. The interictal EEG typically shows a 4 to 5 Hz generalized spike-and-wave pattern. The prognosis for lifelong remission of seizures is poor, although most patients' seizures are controlled easily with medicines (see [Box 1](#)). There is a subgroup of patients (many of whom previously had childhood absence epilepsy) whose seizures are very challenging to control.

Other Epilepsy Syndromes With a Poor Prognosis

Landau–Kleffner syndrome and epileptic encephalopathy with continuous spike-and-wave during sleep are syndromes characterized by mild seizures, nearly continuous epileptiform activity during sleep, and neuropsychological deterioration. Progressive myoclonus epilepsy represents a family of disorders characterized by medically intractable epilepsy (commonly including myoclonic seizures) and significant neurologic deterioration. Underlying diagnoses include myoclonus epilepsy with ragged red fibers (MERRF), Unverricht–Lundborg disease, and Lafora's disease, among others. Gelastic (laughing) seizures can be caused either by hypothalamic hamartomas or temporal lobe seizures. The prognosis depends on response to medication and/or surgery but is not always bad. Rasmussen syndrome is characterized by medically intractable epilepsy, progressive unilateral neurologic

Childhood and Juvenile Absence Epilepsy

Most clinicians are familiar with childhood and juvenile absence epilepsy. The typical age of onset is 4 to 14 years, and there is a slight female predominance. The most common type of seizure is

deficits, and cortical atrophy on MRI. Because they are so rare, any suspicion of these diagnoses should prompt referral to a pediatric epilepsy center with expertise in diagnosing and managing these conditions.

Tumors

Brain tumors can manifest with seizures and are covered in a separate chapter. Certain developmental tumors are seen with an increased frequency in pediatric epilepsy clinics, including dysembryoplastic neuroepithelial tumors (DNET) and gangliogliomas. These tumors typically manifest with seizures and can be associated with malformations of cortical development. EEG can show abnormalities over the involved region but can be falsely localizing as well. MRI shows the location of the tumor but can underestimate the extent of surrounding abnormal tissue. If seizures are not controlled with medicine, or if there is progression in tumor size, resection surgery is recommended.

Cortical Dysgenesis

Abnormal brain development can lead to inappropriately wired brain circuitry, which can be the underlying substrate for seizures. Two forms of abnormal cortical development include lissencephaly (abnormally smooth, or simplified, gyral pattern) and polymicrogyria. Another form of cortical dysgenesis, the malformations of cortical development, is graded based on both dyslamination of the normal six-layer neocortex and the occurrence of abnormal cell types (including balloon cells). EEG shows epileptiform abnormalities over the involved region. MRI shows the anatomic location of the involved tissue in more severe cases but may be normal if the abnormality is mild. In patients with focal abnormalities, if seizures are not controlled with medicine, resection surgery is an option. Patients with more extensive abnormalities can try nonpharmacologic options if medicines do not work.

Mesial Temporal Lobe Epilepsy With Hippocampal Sclerosis

The mesial temporal structures (particularly the hippocampus) can become scarred, and the remaining neurons develop abnormal connections. This can lead to medically intractable seizures. EEG shows interictal epileptiform activity over the temporal head regions. Imaging studies show atrophic mesial temporal structures with increased signal on T2-weighted FLAIR (fluid-attenuated inversion recovery) images. A temporal lobectomy should be considered as an option for patients who do not respond to two appropriately chosen and tolerated medications for seizure control.

Comorbidities

The definition of epilepsy includes comorbidities, which in turn can have a significant impact on quality of life. Clinicians must actively probe for these underlying conditions in order to optimize outcomes. People with epilepsy have increased rates of depression and anxiety compared to the general population. Developmental disorders and learning disabilities are more common in children with epilepsy, as are attention-deficit/hyperactivity disorder and migraines. Once identified, these conditions should be managed by clinicians experienced with their treatment.

Differential Diagnosis

The differential diagnosis of seizures depends largely on age. In infants, opisthotonic posturing can be seen in gastroesophageal reflux disease (Sandifer's syndrome). Some infants have benign myoclonus or shuddering attacks. The EEG in all these disorders is normal, but the diagnosis can be made based on the history. Apparent life-threatening events can appear to be seizures, although apnea rarely is the only manifestation of a seizure. Hyperkplexia is an exaggerated startle response that can be due to abnormal glycine receptor subunits in the spinal cord. Because of potential involvement of the diaphragm, this disorder can be lethal. In children, stereotypies can be paroxysmal and persistent, but the behaviors during these episodes are typical enough that the diagnosis usually is made based on the history.

Breath-holding spells may be associated with an older infant or toddler who is upset, followed by unresponsiveness and either facial pallor or mild cyanosis, lasting less than 1 to 3 minutes. These episodes are typical enough that the history is all that is usually needed to make the diagnosis. Children with pallid breath-holding spells are at higher risk for vasovagal syncope in the adolescent and young adult ages.

Night terrors, one of the parasomnias, occur in toddlers and young children. Persistent screaming (lasting minutes to 1 hour) and lack of memory of the event are seen commonly; the latter raises a question of whether the child had a seizure. Most commonly, these are outgrown by the late preschool years.

Patients with syncope may have a few mild clonic twitches, but this typically does not represent epilepsy. Screening orthostatic blood pressures should be done to rule out one of the orthostatic syndromes. Consideration also should be given to an electrocardiogram or a cardiology consultation in the appropriate clinical context.

Older children and adolescents can have psychogenic nonepileptic events, also known as psychogenic nonepileptic seizures. Considered to be a form of a conversion disorder (DSM-5), the diagnosis is made by noting a normal EEG during a typical clinical episode (and thus should be referred to a neurologist for diagnosis). Cognitive behavioral therapy is helpful in some patients.

In all age groups, focal lesions such as infarctions, hemorrhages, and infections should be considered in the differential diagnosis, although the diagnostic workup should be guided by the history and physical examination.

Treatment

The goals for treatment are to maximize efficacy and minimize side effects. Medication is the first line of therapy for most patients. Nearly 70% to 80% of children are treated successfully by one of the first two medications tried. Practically speaking, neurologists try to use a single agent at the lowest tolerated dosage. Suggested medicines for the epilepsy syndromes discussed previously are listed in [Box 1](#). Details about specific medicines are listed in [Table 1](#). If one of the first two medicines tried does not work, there are three major options.

1. Trials of Additional Medication

Although the first two medicines might not work, new medicines often are introduced into the market. Clinical trials often show that a modest number of patients respond well to newer medicines, although the positive response to newer medicines is no greater overall than response to older medicines, despite lower rates of adverse effects and drug-drug interactions. Recent publications have also started to explore a potential role for marijuana derivatives (including cannabidiol) for select populations with medically intractable epilepsy.

2. Surgery

Any patient who fails to respond to two medications should be assessed for surgery. In patients with a potentially resectable lesion, surgery offers the greatest chance of seizure freedom. Ideal surgical candidates have identifiable lesions on imaging studies and a seizure onset zone that is distinct from eloquent cortex. Patients without identifiable lesions or those with multifocal or generalized seizures are poor candidates for resection surgery. Options for these patients include the vagus nerve stimulator, which has outstanding compliance and adherence because it is surgically implanted. Although this device significantly decreases seizure frequency in some patients, it only rarely leads to seizure freedom. Neurostimulation devices, some of which also include seizure detectors, are being introduced into clinical practice for adults and will be used in children in the future.

3. Diet Therapy

The concept of fasting to improve seizure control dates back to Hippocrates, but in modern times, dietary management of epilepsy is implemented using a high-fat, low-carbohydrate (adequate

TABLE 1 Summary of New Commonly Used Antiseizure Drugs

DRUG	MAINTENANCE DOSAGE*	STARTING DOSAGE*	HALF-LIFE (h)	COMMON SIDE EFFECTS	SERIOUS IDIOSYNCRATIC SIDE EFFECTS
Brivaracetam (Briviact)	> 16 y, 25–100 mg bid	50 mg bid	9	Agitation, behavioral disinhibition, dizziness	Suicidality
Clobazam (Onfi)	> 2 y, < 30 kg: 10 mg bid > 2 y, > 30 kg: 20 mg bid	> 2 y, < 30 kg: 5 mg/d > 2 y, > 30 kg: 5 mg bid	Parent drug: 36–42 Active metabolite: 71–82	Sedation irritability Needs to be tapered off slowly	Respiratory depression, benzodiazepine withdrawal, Stevens–Johnson syndrome
Eslicarbazepine (Aptiom)	4–17 y (11–21 kg), 400–600 mg once/day 4–17 y (22–31 kg), 500–800 mg once/day 4–17 y (32–38 kg), 600–900 mg once/day 4–17 y (>38 kg), 800–1200 mg once/day > 17 y, 800–1600 mg once/day	4–17 y (11–21 kg), 200 mg once/day 4–17 y (22–31 kg), 300 mg once/day 4–17 y (32–38 kg), 300 mg once/day > 4 y (>38 kg), 400 mg once/day	13–20	Somnolence, dizziness, hyponatremia, thyroid dysfunction	Stevens-Johnson, toxic epidermal necrolysis, withdrawal seizures if stopped abruptly
Lacosamide (Vimpat)	4–16 y (11–<30 kg), 3–6 mg/kg bid 4–16 y (30–50 kg), 2–4 mg/kg bid > 4 y (>50 kg), 100–200 mg bid	4–16 y (<50 kg), 1 mg/kg bid > 4 y (>50 kg), 50 mg bid	13	Somnolence, fatigue, headache	Cardiac conduction abnormalities, Stevens-Johnson syndrome, cytopenias
Levetiracetam (Keppra)	20–60 mg/kg/d	10 mg/kg/d, incr in 10-mg/kg increments	6–8	Agitation, behavioral disinhibition, rashes	Suicidal ideation
Oxcarbazepine (Trileptal)	30–60 mg/kg/d	8–10 mg/kg/d, incr by 10–15 mg/kg increments	Parent drug: 2 Metabolite: 9	Hyponatremia, somnolence, lethargy, dizziness, blurred vision	Rash
Perampanel (Fycompa)	> 12 y, 8–12 mg at bedtime	> 12 y, 2–4 mg at bedtime	105 h	Somnolence, headaches	Serious psychiatric and behavior reactions
Rufinamide (Banzel)	45 mg/kg/d	10 mg/kg/d	6–10	Nausea, vomiting, somnolence	Seizures, QT shortening
Vigabatrin (Sabril)	50–150 mg/kg/d	50 mg/kg/d	7.5 (5.7 in infants)	Headache, dizziness, fatigue, tremor, swallowing problems, T2-weighted or DWI hyperintensities	Vision loss
Zonisamide (Zonegran)	> 16 y: 100–600 mg/d	> 16 y: 100 mg once/day	63	Somnolence, irritability, cognitive slowing, weight loss, renal stones, oligohidrosis	Rash

*Dosages should not exceed maximum adult dosages.

Abbreviations: DWI = diffusion-weighted imaging; incr = increase.

protein) ketogenic diet. A modified Atkins diet and a low glycemic index treatment have been used successfully as well. These diets require varying degrees of clinical supervision at centers experienced in their implementation.

Monitoring

Seizure calendars (which can take the form of notebooks or Internet-based tools) are very useful for tracking frequency of events, especially if they are completed on a daily basis. There has been a recent explosion in wearable devices and other types of biotechnology for monitoring seizures and vital signs during seizures (for home use). Monitoring for medication-related adverse effects and comorbidities should continue during treatment. In addition, some comorbidities can occur even if seizures have

stopped; there is good evidence for this in patients with childhood absence epilepsy, which typically is considered a “benign” syndrome because seizures typically resolve by adulthood. Patients taking certain medicines are screened periodically for evidence of renal and/or hepatic abnormalities and abnormal blood cell counts. Scenarios for testing drug levels include the following:

- Assessing adherence to a prescribed drug regimen
- Testing whether symptoms result from drug toxicity
- Determining whether a patient can benefit from higher amounts of medicine when the administered doses are already high (i.e., fast metabolizers)

Reminders about seizure-related safety should be reinforced periodically. GTCS counseling typically includes instructions about safety for the patient, including protecting the head and

airway (putting the patient on his or her side to prevent aspiration) and not putting anything in the patient's mouth. Other safety topics include water safety and wearing helmets, as well as discouraging participation in certain sports (e.g., scuba diving). Periodic assessments of bone health should be considered for patients taking enzyme-inducing or enzyme-inhibiting medicines. Patients of an appropriate age should be counseled about local driving laws. Adolescent girls should be counseled about the effect of antiseizure medicines on hormonal forms of contraception (and vice versa). Consideration should be given to prescribing folate in this group, as well.

Complications

Single GTCS can lead to trauma (e.g., from a fall), tongue biting, pneumothorax, fractures of the vertebrae or limbs, and joint dislocations. A brief physical examination can rule out the more serious complications of a single GTCS. Adverse effects of medications are listed in Table 1. Surgical resections can lead to a variety of neurologic deficits, depending on which tissue is involved. Vagus nerve stimulator surgery can lead to hoarseness and coughing. Unsupervised diet therapy also can have adverse effects; such therapy should be undertaken only by centers with experience. Rarely, patients with epilepsy can die unexpectedly from no apparent cause, known as sudden unexplained death in epilepsy (SUDEP). The cause is unknown, but most (not all) patients have epilepsy that is resistant to medications. Counseling about this condition should be provided by an epilepsy expert.

HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

Method of

Michael A. Posencheg, MD; and Phyllis A. Dennery, MD

CURRENT DIAGNOSIS

- The direct antiglobulin, or Coombs, test (DAT) on neonatal blood is the cornerstone for differentiating isoimmune from nonimmune-mediated hemolysis.
- The presence of a positive antibody screen in maternal blood should raise suspicion for hemolytic disease resulting from minor antibody-antigen reactions.
- In utero monitoring for severe fetal anemia includes maternal antibody screen titers, ΔOD_{450} measurement, middle cerebral artery peak systolic velocity, and cordocentesis.
- Serial and frequent measurements of bilirubin levels and complete blood counts postnatally can aid the practitioner in determining whether therapy should be escalating.

CURRENT THERAPY

- Intrauterine transfusion may be indicated in the setting of severe fetal anemia with or without edema or hydrops fetalis.
- Phototherapy, the mainstay of postnatal management of hyperbilirubinemia, converts unconjugated bilirubin in a nonenzymatic fashion to a polar, water-soluble form that is more readily excretable.
- Intravenous immunoglobulin (Gammagard)¹ is indicated in infants who have isoimmune hemolytic disease and bilirubin levels approaching the threshold for double-volume exchange transfusion.
- Double-volume exchange transfusion is reserved for infants who fail phototherapy and intravenous immunoglobulin (if indicated). It replaces and removes approximately 86% of the infant's own blood. In the setting of isoimmune hemolytic disease, double-volume exchange transfusion has the added benefit of removing offending maternal antibodies, which contribute to the hemolysis from the infant's circulation.

¹Not FDA approved for this indication.

Epidemiology

Early-onset hyperbilirubinemia, anemia with or without edema in the fetus or newborn, was previously synonymous with hemolytic disease resulting from Rh-isoimmunization. With the onset of the use of Rh-immunoglobulin (RhIg [RhoGAM]) in pregnant Rh-negative women in 1968, the landscape of this disorder has changed dramatically. The differential diagnosis of hemolytic disease of the fetus and newborn is broad and can be subdivided into isoimmune and nonimmune categories (Box 1). In this article, we discuss various diseases that result in fetal and neonatal hemolysis, along with recent improvements in diagnosis and management.

Isoimmune hemolytic disease in the fetus and newborn manifests when maternal antibodies cross the placenta and bind to antigens present on the baby's red blood cells. These antigens include Rh factor (D antigen), leading to Rh isoimmunization, the major blood group antigens (e.g., A, B) leading to ABO incompatibility, or minor blood group antigens (e.g., Kell, Kidd, Duffy). The incidence of Rh isoimmunization has now fallen from nearly 14% of pregnancies in the pre-RhIg era to between 1 and 6 per 1000 live births. Incomplete eradication is due to inadvertent failures of RhIg administration, poor prenatal care, or earlier sensitization. Rh-isoimmunization can lead to severe complications, with up to 20% of fetuses having significant anemia and evidence of hydrops in utero.

ABO incompatibility occurs nearly exclusively in fetuses and newborns with type A or B blood born to mothers with type O blood. Although nearly one-quarter of pregnancies result in ABO incompatibility, only approximately 1% to 5% of ABO-incompatible infants demonstrate significant hemolytic disease. The incidence of hemolytic disease from minor antigens is more

Abbreviations: G6PD = glucose-6-phosphate dehydrogenase; RBC = red blood cell.

difficult to estimate due to the large number of antigen-antibody reactions that can result in disease. Of the minor antigens, Kell and Duffy antigens are associated with the most severe disease, and Lewis and Lutheran are more likely associated with mild or insignificant hemolysis.

The group of disorders that is nonimmune in nature results in red blood cell destruction in the absence of an antibody-antigen reaction. These include red blood cell membrane defects such as hereditary elliptocytosis or spherocytosis, red blood cell enzyme defects such as glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency, and hemoglobinopathies such as α -thalassemia. With rates up to 1 in 5000 live births, hereditary spherocytosis is the most common of the RBC membrane defects, occurring most commonly in infants of Northern European descent.

Of the enzyme defects, G6PD is the most common, especially in infants of African or Mediterranean descent. It is an X-linked disorder that is most commonly seen in male infants, but females can also manifest the disease. Interestingly, this disease accounts for a disproportionately large percentage of infants who develop kernicterus. α -Thalassemia is a rare hemoglobinopathy in which all α -globin chain genes are deleted. It is most common in Asian infants and is nearly uniformly fatal, with severe fetal anemia and hydrops fetalis, especially when intrauterine transfusions have not been performed.

Risk Factors

Several elements of the maternal, fetal, and neonatal histories can assist in determining a fetus's or infant's risk of developing one of these hemolytic processes. The results of the maternal blood type and antibody screen are useful to evaluate this risk. Infants born to mothers with type O blood are at risk for ABO incompatibility, whereas infants born to mothers with Rh-negative blood are at risk for Rh isoimmunization. The antibody screen that is performed on maternal blood is specifically searching for antibodies associated with the minor antigen groups that can also be found on red blood cells. Selected minor antigens are listed in Table 1. The presence of a positive direct Coombs' test should raise suspicion of an isoimmune hemolytic process. This test is not always available or warranted.

Assessing the risk of nonimmune disease is based almost entirely on a complete family history. Many of these disorders are associated with certain ethnic or geographic backgrounds. As examples, G6PD deficiency is found more commonly in persons of African or Mediterranean descent, and a family history of persistent anemia requiring splenectomy is often seen in hereditary spherocytosis.

Pathophysiology

The isoimmune forms of fetal and neonatal hemolysis have a similar pathophysiology in that all of them involve the passage of specific maternal IgG antibodies across the placenta, which then interact with their corresponding antigens on the fetal red blood cells. Red cell destruction results when the antibody-coated cells are scavenged by the mononuclear phagocytic

system. The production of maternal antibodies is usually the result of previous exposure of the maternal system to fetal red blood cells, which is common during labor or abortion. The initial response of the maternal immune system is to produce IgM antibodies, but repeat exposure elicits an IgG response. This is especially true for Rh isoimmunization, and therefore explains why firstborn Rh-positive infants born to Rh-negative mothers are not affected.

In ABO incompatibility, antibodies to A or B antigens already exist, but they are normally IgM antibodies. They do not cross the placenta and therefore do not result in disease. It is only when the antigenicity results in the production of IgG antibodies that passage across the placenta can occur and disease can result. This is exceedingly uncommon in blood type A with B incompatibility (mother is type A, baby is type B), but is more common in mothers with blood type O who have a fetus with either blood type A or B. This can occur in firstborn infants. As to hemolysis from antibodies to minor antigens, IgG antibody production may be the result of prior exposure to fetal cells, such as during a previous pregnancy or via prior blood transfusion.

The pathophysiology of the nonimmune group of hemolytic disease is unique to the specific disease process. Red blood cell membrane defects, such as hereditary spherocytosis, have specific abnormalities of red blood cell membrane proteins that result in abnormal red blood cell shapes. These cells are more prone to destruction from mechanical forces. The enzyme defects such as G6PD and pyruvate kinase deficiency result in an inability of the red blood cell to protect itself from oxidant stress (G6PD) or to produce energy (pyruvate kinase). This makes the cell more prone to hemolysis. Hemoglobinopathies result in anemia from decreased production of stable hemoglobin chains. Specifically, α -thalassemia major involves the lack of production of the α chain of hemoglobin and leads to early fetal anemia, severe hydrops, and death unless intrauterine transfusions are instituted.

Prevention

The administration of Rh-immunoglobulin (RhIg) to mothers who are Rh-negative has dramatically decreased the incidence of hemolytic disease resulting from Rh-isoimmunization. The current recommendation of the American College of Obstetrics and Gynecology (ACOG) is to administer 300 μ g of RhIg intramuscularly at 28 weeks' gestation and within 72 hours of delivery of an Rh-positive infant to an Rh-negative mother. RhIg should also be administered to Rh-negative mothers if the mother undergoes amniocentesis, chorionic villus sampling, or cordocentesis, or in the event of maternal bleeding due to placental abruption, placental previa, partial molar pregnancy, spontaneous abortion, or elective termination.

Controversy exists regarding the use of RhIg in the first trimester. As early as 7 weeks of gestation, fetal blood cells can express the D antigen, and women with threatened abortion in the first trimester have been shown to become Rh-sensitized, although this is a rare event. Some advocate for administration of RhIg 50 μ g

(MICRhoGAM) intramuscularly in the first trimester in the setting of spontaneous abortion, elective termination, ectopic pregnancy, or threatened abortion.

The proposed mechanism of action for RhIg involves binding to Rh-positive fetal cells with resultant scavenging by the maternal mononuclear phagocytic system before sensitization and production of maternal antibody against the Rh-D antigen. Sadly, the other forms of hemolytic disease do not have specific preventive strategies.

Clinical Manifestations

The clinical presentation of hemolytic disease in the fetus and newborn varies according to the timing and severity of the disease. Significant and early hemolysis in utero results in fetal anemia, and as oncotic pressure decreases in the fetal blood vessels, edema forms in the soft tissues and potential spaces. Hydrops fetalis results when there is edema or fluid accumulation in at least two of these spaces: skin, pleura, pericardium, or peritoneum. If this continues unabated, fetal death can result. Of all of the diseases discussed here, Rh-isoimmunization and α -thalassemia are those most commonly associated with fetal anemia and the most severe disease.

Most commonly, hemolytic disease results in early neonatal onset anemia and significant hyperbilirubinemia. Often, infants present with clinical jaundice in the first 24 hours of life and have a significant rate of rise of their serum bilirubin levels or a prolonged course of hyperbilirubinemia. Neonatal anemia with significant hyperbilirubinemia is a common manifestation of ABO incompatibility, hemolysis due to minor antigens, and red blood cell enzyme and membrane defects. The degree of anemia in each, however, is quite variable even within a given diagnosis.

Diagnosis

The assessment of maternal blood type and antibody screen can provide valuable insight into the risk of isoimmune hemolytic anemia. Ultrasound techniques and amniocentesis for the antenatal monitoring of fetal anemia are reviewed later.

In the neonate, concern for hemolytic anemia results from a rapidly rising bilirubin level, especially in the first 24 hours of life, a positive direct Coombs' test, hemolysis detected on a blood smear with anemia detected on a complete blood count (CBC), or prolonged hyperbilirubinemia, individually or in combination. In addition to following serial bilirubin levels, in this setting the practitioner should include a neonatal blood type, Coombs' (DAT) test, and complete blood count with reticulocyte count to determine whether hemolysis is occurring. A positive DAT in the appropriate clinical setting suggests isoimmune hemolysis, and a negative DAT nearly rules it out. However, in the setting of ABO incompatibility, a significant number of infants can have a positive Coombs' test and not have significant hemolysis. If umbilical cord blood is used to perform a Coombs' test, contamination with Wharton's jelly can produce a false positive result.

A G6PD level can be helpful in establishing a diagnosis in infants with the appropriate ethnic background or geographic location. Many states have adopted universal newborn screening for G6PD deficiency. Serum albumin, the primary protein transporter for bilirubin in the blood, can also be measured. Low serum levels of albumin increase the risk of developing neurologic sequelae from the subsequent increased amount of free, unbound bilirubin crossing the blood-brain barrier.

Differential Diagnosis

The differential diagnosis of hemolytic disease starts with determining whether or not the hemolysis is antibody-mediated (see Box 1).

Isoimmune hemolytic disease involves the production of maternal IgG antibodies against antigens on fetal red blood cells, resulting in hemolysis. The major diseases in this group include Rh isoimmunization, ABO incompatibility, and hemolysis resulting from the production of antibodies to minor red blood cell antigens.

Examples of these include the broad groups Kell, Duffy, Lutheran, Lewis, and Kidd.

The nonimmune-mediated hemolytic diseases result from inherent defects in the neonatal red blood cells or hemoglobin productions. Examples of these include the red blood cell membrane defects such as hereditary spherocytosis and hereditary elliptocytosis; red blood cell enzyme defects, including G6PD deficiency and pyruvate kinase deficiency; and hemoglobinopathies, most notably α -thalassemia. Descriptions of these have been included elsewhere in this article.

Treatment

The goals of therapy are different depending on the timing of disease. When significant hemolysis occurs in utero, the fetus becomes progressively anemic. In the fetus, bilirubin is normally processed and excreted through the placenta. Therefore, the primary concern is to treat the anemia and, in doing so, prevent or reverse any signs of edema or hydrops fetalis. In this circumstance, percutaneous umbilical blood sampling (PUBS) and intrauterine blood transfusion can diagnose and treat fetal anemia, respectively. In a recent cohort study, 291 children who received intrauterine transfusions (IUT) for alloimmune hemolytic disease were assessed at ages 2 to 17 years for neurodevelopmental impairment (NDI: cerebral palsy, severe developmental delay, or bilateral deafness). The overall incidence of NDI was 4.8%. Evaluating only prenatally known risk factors, severe hydrops (OR 11.2; 95% CI 1.7-92.7, $p = 0.011$) was significantly associated with NDI.

In the neonate, the problem is somewhat different. In the absence of placental transfer and maternal clearance of bilirubin, the neonate must now take on this task. However, in the first days of life, infants are ill equipped to do so owing to inadequate activity of the glucuronyl-transferase enzyme that conjugates bilirubin produced from the high heme load resulting from significant hemolysis. This leads to accumulation of bilirubin because it must be conjugated to be excreted (Figure 1). Therefore the more pressing problem faced by the pediatrician is the hyperbilirubinemia.

The mainstay of treatment for hyperbilirubinemia is phototherapy. Unconjugated bilirubin absorbs light maximally in the blue portion of the visible spectrum (approximately 450 nm). Phototherapy with a light source that approximates this spectrum results in the photoisomerization of unconjugated bilirubin into a polar, water-soluble, and more readily excretable form. As a result, both configurational and structural isomers are formed; the most common structural isomer is called lumirubin. The efficacy of phototherapy is related to the spectrum of light used, irradiance of light, exposed surface area of the skin, and the distance of the light source from the infant.

In the setting of isoimmune (or antibody-associated) hemolysis, the use of intravenous immune globulin (IVIg [Gammagard])¹ has

Figure 1 Enzymatic pathway leading to the production of bilirubin. Heme is degraded in a rate-limiting, oxygen (O_2) and energy-requiring (NADPH) step by heme oxygenase. This process results in the generation of carbon monoxide (CO) and iron (Fe) and biliverdin. Biliverdin is then converted to bilirubin by biliverdin reductase in another energy-requiring step.

been shown to decrease the need for exchange transfusion and is a helpful adjunctive therapy. The current recommendation from the American Academy of Pediatrics (AAP) is to administer IVIg 0.5 to 1 g/kg over 2 hours if the total serum bilirubin is rising despite phototherapy or if the total serum bilirubin is within 2 to 3 mg/dL of the exchange transfusion level. This dose may be repeated in 12 hours.

For some infants, the use of phototherapy and IVIg, if indicated, is not sufficient to control the rising bilirubin level. Alternatively, some infants have neurologic manifestations of bilirubin toxicity despite bilirubin levels lower than suggested therapeutic levels. In these instances, a double-volume exchange transfusion is indicated. This procedure involves removing double the infant's blood volume with simultaneous isovolemic replacement of reconstituted whole blood. This process achieves two separate but related goals. First, it removes bilirubin, and second, in the setting of isoimmune hemolytic disease, it removes offending maternal antibodies. Criteria for performing a double-volume exchange transfusion are clearly outlined in the guidelines from the AAP published in 2004, but some experts suggest performing a double-volume exchange transfusion at even lower levels when significant antibody-mediated hemolysis is occurring, owing to the added benefit provided by removing maternal antibodies.

Two pharmacologic therapies have been proposed in the treatment of neonatal hyperbilirubinemia. Phenobarbital,¹ when given to mothers just before birth, has been shown to decrease the need for exchange transfusion in their newborn infants. Synthetic metalloporphyrins (e.g., tin-mesoporphyrin, stannosporfin [Stanate]⁵) decrease the production of bilirubin by inhibiting heme oxygenase, the rate-limiting enzyme in the degradation of heme to biliverdin (which is then converted to bilirubin by biliverdin reductase; see Figure 1). Both of these therapies are still considered experimental because the safety profile of both remains in question.

Monitoring

Monitoring of hemolytic anemia may be performed for the fetus in utero and for the infant after birth. Significant advances have improved our ability to determine the degree of fetal anemia in both invasive and noninvasive manners. Initial concern for the presence of significant antibodies against fetal red blood cells begins with the routine antibody screen performed early in gestation. This is normally an indirect Coombs' test, and most centers consider a titer of 1:16 or 1:32 to be a threshold to suggest significant risk for hemolysis.

Liley first described the relationship between bilirubin level in the amniotic fluid and the degree of fetal anemia in infants greater than 27 weeks' gestation. Amniotic fluid is analyzed at a wavelength of 450 nm (ΔOD_{450}) to determine the bilirubin level, and the value is plotted on known graphs to assess risk. Interventions including delivery or intrauterine transfusion are suggested if the level, when plotted, falls in the upper 20th percentile of zone II or in zone III. An expanded form of the Liley curve as well as the development of the Queenan curve has provided practitioners with tools to determine the risk of Rh isoimmune fetal anemia as early as 14 weeks' gestation. However, these methods may be less useful when antibodies to the Kell antigens are involved.

The measurement of middle cerebral artery peak systolic velocity (MCA-PSV) by Doppler ultrasonography gives practitioners a noninvasive alternative to amniocentesis for monitoring fetal anemia. Theoretically, as a fetus becomes more anemic, the blood flow velocity increases due to increased cardiac output and vasodilatation, resulting in increased MCA-PSV. The measurement is specific for gestational age and can be charted to determine if it is more than 1.5 multiples of the median (MoM), suggesting moderate to severe

anemia. The effect of intrauterine transfusions on this measurement is unclear owing to the presence of adult red blood cells, and they can alter the interpretation of MCA-PSV. Large randomized, controlled trials are needed to determine if measurement of MCA-PSV or ΔOD_{450} are equivalent in assessing the risk of anemia. This would give practitioners a noninvasive way to monitor fetuses at risk for severe anemia.

Cordocentesis is the gold standard for measuring fetal anemia, but it comes with severe risks including fetal and perinatal death, cord bleeding, hematomas, further maternal sensitization from fetal-maternal hemorrhage, infection, and placental abruption.

After birth, the neonate at risk for hemolytic anemia must be monitored for degree of anemia and for the development of significant hyperbilirubinemia. In utero, bilirubin is transferred to the maternal circulation via the placenta and processed in the maternal liver, which explains why hyperbilirubinemia is a post-natal event. Early and frequent bilirubin levels and complete blood counts allow the practitioner to evaluate the need for intervention. The availability of hour-specific nomograms that plot the risk of severe hyperbilirubinemia based on the level of bilirubin can be used in term infants to guide therapy and timing of outpatient follow-up. These are published in the AAP position statement from 2004.

Complications

Complications of phototherapy, IVIg,¹ and double-volume exchange transfusions are all possible. Side effects of phototherapy include disruption of mother-baby bonding, increased insensible water loss (less common with modern bilirubin lights), retinal injury from UV light, and, in the setting of an elevated conjugated fraction, a brown discoloration of the skin called "bronze-baby syndrome." The presence of an elevated conjugated fraction or bronzing of the skin is not a contraindication for phototherapy. This is of cosmetic concern only and is usually reversible after removal of the phototherapy.

Complications involving the use of IVIg are rare but include renal dysfunction, necrotizing enterocolitis (NEC), increased incidence of thrombotic events, transfusion reactions, and transmission of infections that can occur with transfusion of any blood product, because blood products are derived from pooled plasma.

Many potential complications are associated with double-volume exchange transfusion. These include electrolyte disturbances, arrhythmias, cardiac arrest, thrombotic or embolic sequelae, metabolic acidosis, thrombocytopenia, disseminated intravascular coagulation, infection, necrotizing enterocolitis, temperature instability, and blood transfusion-related complications such as hepatitis, HIV infection, or transfusion reaction.

¹Not FDA approved for this indication.

NOCTURNAL ENURESIS

Method of

Alexander K.C. Leung, MBBS

Note: This chapter has been published in part in *Common Problems in Ambulatory Pediatrics: Specific Clinical Problems*, volume 1, with permission from Nova Science Publishers, Inc.

CURRENT DIAGNOSIS

- Nocturnal enuresis is defined as involuntary nighttime bedwetting in a child at least 5 years of age.
- Primary nocturnal enuresis is present when the child has never achieved a period of nighttime dryness greater than 6 consecutive months. Secondary nocturnal enuresis is present when the child has experienced a period of nighttime dryness of at least 6 consecutive months.
- The most common causes of primary nocturnal enuresis are a deep sleep pattern, nocturnal polyuria, and a small-capacity bladder or nocturnal detrusor overactivity.
- A urinalysis is warranted to rule out urinary tract infection, glycosuria, and a defect in the ability to concentrate urine.
- Ultrasound examination of the bladder (prevoid and postvoid) can be used to evaluate bladder dysfunction and functional bladder capacity.

CURRENT THERAPY

- Desmopressin (DDAVP, 1-deamino-8-arginine vasopressin) is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with nocturnal polyuria and normal bladder function.
- Enuretic alarm is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with a small bladder capacity or in children with severe enuretic symptoms refractory to desmopressin therapy.
- Behavioral therapy such as encouraging the child to urinate frequently during the daytime, emptying the bladder before bedtime, and restricting fluid in the evening may increase the success rate of pharmacologic therapy or enuretic alarm therapy.

Nocturnal enuresis is defined as involuntary nighttime bedwetting in a child at least 5 years of age. Primary nocturnal enuresis is present when the child has never achieved a period of nighttime dryness greater than 6 consecutive months. Secondary nocturnal enuresis is present when the child has experienced a period of nighttime dryness of at least 6 consecutive months. For the majority of children with secondary nocturnal enuresis, the pathogenesis is no different from that of primary nocturnal enuresis.

Nocturnal enuresis is a common problem that is frustrating for children, parents, and physicians alike. The condition may affect the child's self-esteem and may lead to reduced social interaction and behavioral problems.

Epidemiology

It has been estimated that 15% to 25% of 5-year-old children and 5% to 10% of 7-year-old children have nocturnal enuresis. Without specific treatment, approximately 15% of affected children become dry each year. The male-to-female ratio is approximately 3:1.

Risk Factors

Encopresis, daytime wetting (diurnal enuresis), and male gender are significant risk factors. Constipation, emotional stress, developmental delay, bladder dysfunction, sleep deprivation, adenotonsillar hypertrophy, and attention-deficit/hyperactivity disorder also play a role.

Pathogenesis

The most common causes of primary nocturnal enuresis are a high arousal threshold, nocturnal polyuria, and a small-capacity bladder or nocturnal detrusor overactivity. Although these causes may overlap, it is important to conceptualize them separately, because this differentiation will help the physician to understand the problem, to educate both the parents and child, and to plan an appropriate treatment program.

It has been shown that enuretic children have a high arousal threshold and a reduced prepulse inhibition of startle. In most children, arousability from sleep improves with maturation of the central nervous system.

In most circumstances, the rate of secretion of antidiuretic hormone from the posterior pituitary gland is increased at night. This circadian variation is usually established when the child is 3 to 4 years old. Some children with primary nocturnal enuresis have a lack of this circadian variation with an abnormally low nocturnal secretion of antidiuretic hormone with resultant nocturnal polyuria. Other causes of nocturnal polyuria include fluid and solute overload in the evening.

Children with a small-capacity bladder or nocturnal detrusor overactivity often have primary nocturnal enuresis. Conditions that may reduce the functional bladder capacity include cystitis and constipation.

There is a strong genetic component to nocturnal enuresis. The child of parents who were both enuretic has a 77% chance of developing enuresis. If one parent was enuretic, there is up to a 44% occurrence rate. If neither parent was enuretic, the occurrence rate is only 15%. Twin studies also support a genetic basis for nocturnal enuresis: the concordance rate is much higher in monozygotic twins (68%) when compared with dizygotic twins (36%). Linkage studies have suggested possible genetic markers for primary nocturnal enuresis located on chromosomes 12, 13, and 22.

A neurogenic bladder is one of the few anatomic abnormalities that can cause primary nocturnal enuresis. Congenital urethral obstruction is another infrequent anatomic cause of primary nocturnal enuresis. The enuresis in these children is due to an overflow phenomenon from a poorly compliant bladder. The most common cause of urethral obstruction in the male is posterior urethral valves. Girls and boys with significant congenital urethral stenosis may also present with this problem. An ectopic ureter or vesicovaginal fistula is an infrequent anatomic cause of primary nocturnal enuresis in girls.

A defect in the ability of the kidney to concentrate urine can cause primary nocturnal enuresis. The causes of concentrating defects include any cause of chronic renal failure and diabetes insipidus.

Diagnosis

History

Onset and Frequency

The timing of the onset and the frequency of nocturnal enuresis are important historical clues to the etiology. Secondary nocturnal enuresis and intermittent nocturnal enuresis are not usually associated with structural abnormalities in the urinary tract. Nocturnal enuresis due to a structural abnormality of the urinary tract is usually present from birth and is not associated with periods of remission.

Timing, Frequency, and Volume per Episode

A history of soaking absorbent underpants in the morning suggests nocturnal polyuria. Parents of children with nocturnal polyuria often remark that the volume of urine associated with the enuretic episode or the first morning void is very large. Frequent episodes of nocturnal enuresis with a small volume of urine suggest bladder dysfunction such as may occur with a urethral obstruction or a neurogenic bladder. Several episodes of nocturnal enuresis with a large volume suggest diabetes mellitus or diabetes insipidus. Constant wetting suggests an ectopic ureter or vesicovaginal fistula.

Associated Symptoms

Nocturnal enuresis associated with daytime urinary frequency, urgency, incontinence, and difficulties in initiating the urinary stream suggests urethral obstruction. Daytime urinary frequency, urgency, incontinence, squatting behavior, constipation, encopresis, gait disturbance, and a history of spina bifida or spinal trauma suggest a neurogenic bladder. Constant dampness in the underwear by day and night in a female suggests an ectopic ureter or vesicovaginal fistula. Secondary nocturnal enuresis associated with dysuria, urinary frequency, urgency, fever, suprapubic/loin pain, or cloudy, foul-smelling urine suggests a urinary tract infection. Polyuria, polydipsia, polyphagia, and weight loss suggest diabetes mellitus. Polyuria, polydipsia, and episodes of dehydration in a child with a history of central nervous system disease suggest diabetes insipidus. A history of constipation is important because the condition is associated with a reduced functional bladder capacity.

Volume of First Morning Void

Most children with nocturnal enuresis void only a small or average amount of urine in the morning after an enuretic episode. A large volume of urine voided following a significant episode of nocturnal enuresis may be a clue to the presence of low nocturnal secretion of antidiuretic hormone.

Soundness of Sleep

Children with nocturnal enuresis often sleep more deeply than other family members. Some children only wet when they are overtired. Conversely, children who are usually enuretic may be continent during periods of wakeful sleep such as during intercurrent illnesses.

Past Health

A child with a history of a structural abnormality of the urinary tract or neurogenic bladder may have nocturnal enuresis due to these causes. A history of spinal trauma may indicate a neurogenic bladder as a cause of enuresis. A history of central nervous system disorder may indicate neurogenic diabetes insipidus. Certain medications such as methylxanthines and caffeine may be associated with nocturnal enuresis.

Family History

A family history of nocturnal enuresis should be sought because nocturnal enuresis tends to run in the family. A family history of diabetes mellitus, diabetes insipidus, or kidney disease suggests the corresponding disorder. Any stressful events in the family such as birth of a sibling and parental disharmony should be explored, especially in children with secondary nocturnal enuresis.

Physical Examination

Height and weight should be measured and plotted onto standard growth charts. All children should have their blood pressure checked, which, if elevated, might indicate renal disease. A thorough physical examination should include examination of the abdomen and genitalia and a complete neurologic examination. In chronic constipation, fecal masses are often palpable in the left lower quadrant of the abdomen and in the suprapubic area.

In the majority of children with primary nocturnal enuresis, the physical examination is unremarkable. An abnormal physical examination is only present when primary nocturnal enuresis is due to a structural cause. A myelomeningocele is usually obvious

at birth; however, subtle spinal defects may also be associated with primary nocturnal enuresis. A midline tuft of hair, an exaggerated dimple, or a birthmark in the area of the lumbosacral spine; a gait abnormality; absence of anal wink; or abnormal motor power, tone, reflexes, or sensation in the lower extremities suggests a neurogenic bladder. A palpably enlarged bladder or kidney and a weak or dribbling urinary stream suggests urinary obstruction, such as may result from posterior urethral valves.

Laboratory and Imaging Studies

A urinalysis is warranted to rule out urinary tract infection, diabetes mellitus, and a defect in the ability to concentrate urine. Ultrasound examination of the bladder (prevoid and postvoid) can be used to evaluate bladder dysfunction and functional bladder capacity.

Treatment

One essential part of the treatment plan of every child with primary nocturnal enuresis should be compassion and support from both the family and physician. It is important to clarify to parents that the child is not at fault and to specify that punishment for bedwetting is inappropriate. The child and family can be reassured that in the absence of structural defect, primary nocturnal enuresis tends to resolve with time.

Simple behavioral strategies such as encouraging the child to urinate frequently during the daytime, emptying the bladder before bedtime, and limiting fluid and solute intake in the evening are often recommended. Caffeinated beverages should be avoided, particularly in the evening. Some authors recommend waking the child 1.5 to 2 hours after bedtime to go to the bathroom. Star charts and reward systems need to reinforce positive behavior. Behavioral therapy may increase the success rate of pharmacologic therapy or enuretic alarm therapy.

Desmopressin (DDAVP, 1-deamino-8-arginine vasopressin) is an analogue of vasopressin that has a profound antidiuretic activity without pressor activity. The medication acts on the V2 receptors of the renal tubules and increases the reabsorption of fluid from the renal tubules, thereby decreasing the amount of urine produced. The medication is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with nocturnal polyuria and normal bladder function. Desmopressin is available in a sublingual lyophilisate (melt) preparation,² as well as a tablet. The bioavailability of the lyophilisate (melt) preparation is approximately 60% greater than that of the tablet formulation. The recommended dose of desmopressin is 120 to 240 µg melt and 200 to 400 µg tablet. The former is usually given 30 minutes to 1 hour before bedtime, and the latter is usually given 1 hour before bedtime. Side effects are rare and include symptomatic hyponatremia with water intoxication. When desmopressin is prescribed, patients should be instructed to avoid high fluid intake in the evening.

Imipramine (Tofranil), a tricyclic agent with antimuscarinic property, may be helpful in children who have not responded to desmopressin alone. Presumably, the medication decreases the amount of time spent in rapid eye movement sleep, stimulates antidiuretic hormone secretion, and relaxes the detrusor muscle. The recommended starting dose is 25 mg for children 6 to 12 years of age and 50 mg for those older than 12 years, given 1 to 2 hours before bedtime. If necessary, the dose may be increased gradually to a maximum of 50 mg in children 6 to 12 years of age and 75 mg for those older than 12 years. However, potential side effects (anxiety, depression, dizziness, headache, drowsiness, lethargy, sleep disturbance, dry mouth, anorexia, vomiting, skin rashes) and serious adverse effects (hepatotoxicity, cardiotoxicity) with overdose limit their use.

Monotherapy with oxybutynin (Ditropan),¹ an anticholinergic and antispasmodic agent that decreases uninhibited bladder

¹Not FDA approved for this indication.

²Not available in the United States.

contraction, is not effective in treating monosymptomatic nocturnal enuresis. The medication can be added, however, as a second-line drug in the treatment of children with both diurnal and nocturnal enuresis. The dose is 5 mg administered 1 hour before bedtime.

Enuretic alarm is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with a small bladder capacity or nocturnal detrusor overactivity. Randomized controlled trials have demonstrated that the enuretic alarm has greater efficacy than other forms of treatment. The enuretic alarm is triggered when a sensor in the sheets or night clothes gets wet; a bell or buzzer is thereby activated. Presumably, alarm therapy startles the child and improves arousal from sleep either by classical conditioning or avoidance conditioning. A disadvantage of alarm therapy is that it takes a couple of weeks to take effect. As such, alarms should be used for at least 6 weeks in children who do not respond before discontinuing their use. Because success depends on a cooperative, motivated child, conditioning therapy with an alarm device is generally used in children over 6 years of age.

It has been shown that combination of alarm and desmopressin works better than either treatment alone. Such treatment may be considered for children with refractory nocturnal enuresis.

When an anatomic abnormality or defect in urinary concentration ability is present, the underlying problem may require specific dietary, pharmacologic, or surgical treatment. Any underlying constipation should also be treated.

NORMAL INFANT FEEDING

Method of

Amy Seery, MD

CURRENT THERAPY

- Breast milk is considered the best nutritional source for all infants including preterm infants.
- Breast-feeding is strongly encouraged, but many mothers require support from a multidisciplinary medical team to achieve success.
- There are few absolute contraindications to breast-feeding but these include maternal HIV, infant galactosemia, herpetic lesions on the breast, maternal use of illicit drugs, and mothers undergoing some types of chemotherapy.
- Maternal medications should be individually reviewed for safety during breast-feeding.

- Newborns should be fed at least every 3 hours during the day and every 4 hours during the night.
- Breast-fed infants can go up to 10 days between stools. This is a normal stooling pattern so long as the infant shows no signs of distress or illness.

The newborn period is defined as birth through the 28th day of life. During this time, newborns primarily feed, grow, and sleep. Therefore adequate nutrition carries special significance during this phase of life. This chapter focuses on available options for newborn nutrition (e.g., breast milk and commercial formulas), information medical caregivers can use when counseling families, definitions of adequate quality and quantity of nutritional sources, and assessing for appropriate intake in terms of growth.

Breast-feeding and Breast Milk

Breast-feeding is the nutritional source of choice as recommended by the American Academy of Pediatrics (AAP), the Canadian Pediatric Society, and the American Academy of Family Physicians. Caregivers should always respect the choice of the mother and support her during her bonding period with her newborn infant. However, because many misconceptions exist regarding breast-feeding, it is practical for caregivers to inquire about a mother's reasons if she chooses to use formula to feed her infant. She may have several concerns about breast-feeding including returning to work, the logistics of pumping, or her modesty, or she may consider breast-feeding to be "antiquated." Breast-feeding may be contrary to cultural and ethnic beliefs of the mother. For example, some Hispanic women are concerned that when breast-feeding they might inadvertently pass on negative emotions to their newborn. Because Somali mothers attribute special powers to Western medicine and infant formulas, they often breast-feed but supplement with formula to ensure their infant gets everything that modern medicine can offer. With proper education and support, many mothers find breast-feeding to be a more reasonable option than they first thought.

Thanks to the efforts of several organizations promoting the health benefits of breast-feeding, even mothers who choose to formula feed recognize breast milk as the best nutritional option for their infant. But even after making the decision to breast-feed, some mothers continue to struggle with the actual undertaking of breast-feeding. There remains in our culture the inaccurate belief that something so "natural" must be easy to do. Many first-time mothers are easily frustrated and discouraged during the first few attempts at breast-feeding because they have unreasonable expectations based on the media and popular culture. With more and more women willing to try breast-feeding after delivery, adequate support and teaching should be provided by the entire medical team.

Healthy People 2010 established a national breast-feeding initiation goal of 75%, and in 2003 and 2004 reported rates for all US women were at 70.9% and 70.3%, respectively. These rates are the highest reported since before World War II and are largely the result of improved public knowledge. Unfortunately, other *Healthy People 2010* breast-feeding goals fell short. Despite a goal of 50% breast-feeding at 6 months, only 36% of infants were still receiving any human milk at this age, and only 14% were exclusively being breast-fed. Only 17% of babies are breast-fed at 1 year, despite a goal of 25%. The biggest disparities in breast-feeding rates are among racial and ethnic minorities. Special attention should be made by medical teams to provide sufficient support and education to these women.

Breast milk is considered the ideal source of nutrition for all newborns, including premature infants, in a large part owing to its contents. There is a greater ratio of whey to casein in breast milk than in formula. Whey is associated with better absorption and digestion, as well as faster gastrointestinal transit times. There are also several specific proteins found only in breast milk, such as lactoferrin, lysozyme, and secretory immunoglobulin A, that aid

contraction, is not effective in treating monosymptomatic nocturnal enuresis. The medication can be added, however, as a second-line drug in the treatment of children with both diurnal and nocturnal enuresis. The dose is 5 mg administered 1 hour before bedtime.

Enuretic alarm is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with a small bladder capacity or nocturnal detrusor overactivity. Randomized controlled trials have demonstrated that the enuretic alarm has greater efficacy than other forms of treatment. The enuretic alarm is triggered when a sensor in the sheets or night clothes gets wet; a bell or buzzer is thereby activated. Presumably, alarm therapy startles the child and improves arousal from sleep either by classical conditioning or avoidance conditioning. A disadvantage of alarm therapy is that it takes a couple of weeks to take effect. As such, alarms should be used for at least 6 weeks in children who do not respond before discontinuing their use. Because success depends on a cooperative, motivated child, conditioning therapy with an alarm device is generally used in children over 6 years of age.

It has been shown that combination of alarm and desmopressin works better than either treatment alone. Such treatment may be considered for children with refractory nocturnal enuresis.

When an anatomic abnormality or defect in urinary concentration ability is present, the underlying problem may require specific dietary, pharmacologic, or surgical treatment. Any underlying constipation should also be treated.

- Maternal medications should be individually reviewed for safety during breast-feeding.

- Newborns should be fed at least every 3 hours during the day and every 4 hours during the night.
- Breast-fed infants can go up to 10 days between stools. This is a normal stooling pattern so long as the infant shows no signs of distress or illness.

The newborn period is defined as birth through the 28th day of life. During this time, newborns primarily feed, grow, and sleep. Therefore adequate nutrition carries special significance during this phase of life. This chapter focuses on available options for newborn nutrition (e.g., breast milk and commercial formulas), information medical caregivers can use when counseling families, definitions of adequate quality and quantity of nutritional sources, and assessing for appropriate intake in terms of growth.

Breast-feeding and Breast Milk

Breast-feeding is the nutritional source of choice as recommended by the American Academy of Pediatrics (AAP), the Canadian Pediatric Society, and the American Academy of Family Physicians. Caregivers should always respect the choice of the mother and support her during her bonding period with her newborn infant. However, because many misconceptions exist regarding breast-feeding, it is practical for caregivers to inquire about a mother's reasons if she chooses to use formula to feed her infant. She may have several concerns about breast-feeding including returning to work, the logistics of pumping, or her modesty, or she may consider breast-feeding to be "antiquated." Breast-feeding may be contrary to cultural and ethnic beliefs of the mother. For example, some Hispanic women are concerned that when breast-feeding they might inadvertently pass on negative emotions to their newborn. Because Somali mothers attribute special powers to Western medicine and infant formulas, they often breast-feed but supplement with formula to ensure their infant gets everything that modern medicine can offer. With proper education and support, many mothers find breast-feeding to be a more reasonable option than they first thought.

Thanks to the efforts of several organizations promoting the health benefits of breast-feeding, even mothers who choose to formula feed recognize breast milk as the best nutritional option for their infant. But even after making the decision to breast-feed, some mothers continue to struggle with the actual undertaking of breast-feeding. There remains in our culture the inaccurate belief that something so "natural" must be easy to do. Many first-time mothers are easily frustrated and discouraged during the first few attempts at breast-feeding because they have unreasonable expectations based on the media and popular culture. With more and more women willing to try breast-feeding after delivery, adequate support and teaching should be provided by the entire medical team.

Healthy People 2010 established a national breast-feeding initiation goal of 75%, and in 2003 and 2004 reported rates for all US women were at 70.9% and 70.3%, respectively. These rates are the highest reported since before World War II and are largely the result of improved public knowledge. Unfortunately, other *Healthy People 2010* breast-feeding goals fell short. Despite a goal of 50% breast-feeding at 6 months, only 36% of infants were still receiving any human milk at this age, and only 14% were exclusively being breast-fed. Only 17% of babies are breast-fed at 1 year, despite a goal of 25%. The biggest disparities in breast-feeding rates are among racial and ethnic minorities. Special attention should be made by medical teams to provide sufficient support and education to these women.

Breast milk is considered the ideal source of nutrition for all newborns, including premature infants, in a large part owing to its contents. There is a greater ratio of whey to casein in breast milk than in formula. Whey is associated with better absorption and digestion, as well as faster gastrointestinal transit times. There are also several specific proteins found only in breast milk, such as lactoferrin, lysozyme, and secretory immunoglobulin A, that aid

in immune defense in the gut. Breast milk also contains long-chain polyunsaturated fatty acids (PUFAs) that aid in neural and visual development. Infants given formulas that contain long-chain PUFAs have serum concentrations that never match those of breast milk-fed infants, but there is also no known minimum amount needed to achieve benefit.

There is also a difference in the intestinal microflora seen in infants fed breast milk versus those fed formula. Larger percentages of *Lactobacillus* and *Bifidobacterium* species are found in infants fed breast milk, whereas *Bacteroides* spp and enterobacteria are in more abundance in formula-fed counterparts. Newer evidence suggests this difference in the diversity of gut microflora accounts for the stronger immune systems seen in breast-fed infants.

Breast milk has the benefit of containing several nonnutritive substances that are advantageous for young infants including maternal antibodies, growth regulators, digestive enzymes, and hormones. Breast milk has been associated with a reduced risk for many chronic illnesses including asthma, food and environmental allergies, diabetes mellitus, eczema, cardiovascular disease, and obesity. There is a reduction in the number of short-term illnesses of childhood including acute respiratory and gastrointestinal illnesses, as well as otitis media.

Newer research shows an association between being fed breast milk and having higher IQ scores later in childhood.

The act of breast-feeding offers several benefits to the infant. There is a sense of security and closeness that comes from skin-to-skin contact and the resultant interaction between infant and mother. Nursing can also reduce the opportunities and risk for bottle-propping and overfeeding. Breast-feeding allows nutrition to be more immediately available with minimal preparation work compared to the mixing and warming of formula. Breast milk is a much cheaper alternative to supplemental formulas. Breast-feeding can also lead to health benefits for the mother such as decreased risk of ovarian and breast cancers, as well as diabetes mellitus type II.

There are very few contraindications to breast-feeding. Contraindications include maternal HIV, active herpetic lesions on the breast (herpetic lesions elsewhere are not a contraindication), maternal use of illicit drugs, women undergoing chemotherapy with antimetabolite agents, and mothers with active tuberculosis. Nearly all over-the-counter medications are safe to take during breast-feeding. Some prescription medications are contraindicated, although safe substitutes are usually available. Providers can use the online National Library of Medicine's Drugs and Lactation Database (LactMed) to check safety and provide up-to-date counseling. Infants with galactosemia should not be breast-fed or bottle fed with milk products.

Infant Formulas

Commercially available infant formulas became widely used during World War II when there was a large influx of women into the national workforce. Since that time, infant formulas have been continuously improved upon and contain all the necessary energy and nutrient requirements for full-term infants up to the age of 6 months. According to the AAP there are three indications for the use of formulas:

- An alternative primary nutritional source for infants whose mothers choose not to or are unable to breast-feed
- A supplementary nutritional source for mothers with an inadequate supply of breast milk
- A nutritional source in infants with a medical condition in which breast-feeding is contraindicated (e.g., galactosemia)

Commercial formulas usually come in three distinct preparations, including ready-to-feed, concentrated liquid, and powder. All three preparations yield 20 kcal per fluid ounce when prepared correctly, the same amount of energy per volume found in breast milk. Powder preparations are generally the least expensive. An advantage to formulas over breast-feeding is the ability to increase caloric density for an infant with increased metabolic needs (e.g., infants with congenital heart defects). Breast-feeding mothers have the option to breast pump and add a fortifier if needed to achieve similar increases in caloric density.

Formulas carry the risk of improper preparation, whether intentional or accidental. Caregivers might choose to dilute the formula secondary to financial pressures or to concentrate formula preparations in a desire to have a larger infant, because some cultures equate larger infant size and weight with better health. Either change can be dangerous to the infant. Diluting leads to an excess of free water with an insufficient solute load (e.g., hyponatremia) and concentrating can conversely lead to hypernatremia. Nevertheless, formulas remain an appropriate alternative when desired by the infant's mother or when medically indicated (Table 1).

Micronutrients

Both breast milk and formula contain most of the micronutrients needed by infants. Calcium and phosphorus are found in lower concentrations in breast milk but are more bioavailable than the minerals present in formulas. Therefore there is no difference in bone mineral concentrations in both sets of infants. Iron, zinc, and copper serum levels are sufficient during the first 6 months of life in breast-fed infants, although tissue stores are gradually depleted. After 6 months breast-feeding should be supplemented with complementary foods to prevent outcomes such as iron deficiency anemia.

Vitamin K, necessary to prevent hemorrhagic disease, is produced by the digestive actions of intestinal flora. For this reason, most infants at the time of birth are given a single intramuscular dose to provide adequate amounts until intestinal flora concentrations are more mature and dietary supplementation with solid food begins at 6 months.

Vitamin D needs historically have been achieved with adequate sunlight exposure. However, with appropriate use of sunscreens and sunlight avoidance, most infants are at risk for vitamin D deficiency. Vitamin D is not passed in sufficient quantities in breast milk, and the content in formulas is so low that the daily recommended amount of 400 IU is only achieved when infants are consuming a volume typical of a 6-month old. Therefore supplementation should be recommended for all infants regardless of skin color and nutritional source to help prevent rickets. The recommendation is 400 IU of vitamin D for all pediatric age groups beginning after the first 2 weeks of life.

Neither formula-fed nor breast-fed infants usually require supplementation with water. In fact, providing infants with excess free water can lead to hyponatremia, seizures, and death. If there is concern that the infant is constipated or overheated, caregivers can provide up to a tablespoon of water daily to infants younger than 4 months old.

Defining Adequate Intake

To determine whether a newborn is receiving adequate nutrition, physicians should ask the caregiver how often feedings are occurring, for how long (for breast-fed infants), and how much is eaten (for formula-fed infants) and should assess the number of wet diapers and stools daily. Initially infants should consume 10 to 15 mL per feeding for the first 24 to 36 hours, gradually increasing to 30 to 45 mL by the fourth day of life. Breast-fed infants should feed 15 to 20 minutes each side. At the time of discharge to home, all newborns should be feeding 8 to 12 times a day, or every 2 to 3 hours. This interval can be increased to every 4 hours at night, and parents should be encouraged to wake any infants who sleep for longer than this duration. If an infant has lost more than 10% of his or her birth weight, the care team should consider delaying discharge to review the infant's nutritional status and feeding habits. Caregivers should be attentive to infant cues of hunger and satiety to provide an ideal feeding pattern for each infant.

Voiding and stooling patterns change with age and can also be influenced by the infant's diet. All newborns should have at least one wet diaper and one stool within the first 24 hours of life. If this does not occur, close observation and further workup are indicated to rule out structural or metabolic abnormalities. During the first week of life, infants usually void and stool with every feeding or even more often. Beyond the first week, infants should have at least 4 to 6 voids daily regardless of diet. Formula-fed infants might have one stool every other day up to 2 to 3 stools daily. Because of the

TABLE 1 Infant Formulas and their Indications

CLASS	BRAND NAMES	CALORIES (KCAL PER OZ)	CARBOHYDRATE SOURCE	PROTEIN SOURCE	INDICATIONS
Breast milk	—	20	Lactose	Human milk	Preferred for all infants
Term formula	Gerber Good Start Gentle	20	Lactose	Cow's milk	Appropriate for most infants
Term formula with DHA and ARA	Enfamil Premium Infant; Good Start Protect; Similac Advanced	20	Lactose	Cow's milk	Marketed to promote eye and brain development
Preterm formula	Enfamil Premature; Similac Special Care 24 with Iron	24	Lactose	Cow's milk	<34 wk gestational age Weight <1800 g
Enriched formula	Enfacare; Similac Neosure	22	Lactose	Cow's milk	34–36 wk gestational age Weight ≥1800 g
Soy formula	Enfamil Prosobee; Good Start Soy; Similac Isomil	20	Corn-based	Soy	Congenital lactase deficiency, galactosemia
Lactose-free formula	Similac Sensitive	20	Corn-based	Cow's milk	Congenital lactase deficiency, primary lactase deficiency, galactosemia
Hypoallergenic formula	Similac Alimentum; Enfamil Nutramigen; Enfamil Pregestimil	20	Corn or Sucrose	Hydrolyzed proteins	Milk protein allergy
Nonallergenic formula	Elecare; Neocate Infant; Nutramigen AA	20	Corn or Sucrose	Amino acids	Milk protein allergy
Antireflux formula	Enfamil AR; Similac Sensitive for Spit-Up	20	Lactose (thickened with rice starch)	Cow's milk	Gastroesophageal reflux

Abbreviations: ARA = arachidonic acid; DHA = docosahexaenoic acid.

higher percentage of protein that is absorbed in breast milk, breast-fed infants can go up to 10 days between stools. Physicians should review with families the signs and symptoms (emesis, refusal to feed, lethargy, inconsolability, and abdominal distention) that indicate an infant with infrequent stooling should be medically evaluated. Breast-fed infants also have stools that are described as loose, yellow, and seedy. Caregivers should be educated that this is a normal stool color and consistency and is not considered diarrhea.

Medical providers can also calculate an infant's nutritional needs and compare to the actual intake. Nutritional needs are represented as kcal/kg per day (KKD). The following formula can be used:

$$KKD = \frac{\text{Volume in mL consumed in 24h}}{\text{Weight in kg}} \times \frac{20 \text{ kcal/oz}}{30}$$

During the first 3 months of life, infants should consume an intake that equals 90 to 135 kcal/kg per day. This intake goal should lead to a weight gain of approximately 25 to 30 g daily. From 3 to 6 months of age, infants gain at a slightly slower rate of approximately 15 to 20 g per day (Table 2). For example, a 2-month-old who weighs 6 kg should consume between 810 mL to 1215 mL daily.

At subsequent visits an infant can be assessed for adequate growth using standardized, gender-specific growth curves.

Attention should be paid to growth parameters including weight, length, head circumference, and weight-for-length. Weight-for-length charts are used during the first 2 years of life as a gross equivalent to body-mass-index charts used for children older than 2 years. For years, practices defined adequate weight gain using growth charts as designed by the National Center for Health Statistics (NCHS), a branch of the Centers for Disease Control and Prevention (CDC). These charts were last updated in 2000 and unfortunately still reflect means for a population with a predominance of formula-fed infants. The World Health Organization (WHO) has since completed the Multi-Centre Growth Reference Study to better establish growth norms for infants and children who are breast-fed throughout the first year of life. A provider who is uncertain whether an exclusively breast-fed infant is meeting minimum growth requirements should refer to these charts before automatically encouraging caregivers to begin formula supplementation. Growth failure is usually considered a weight less than the third percentile or a drop of two or more percentiles in a short time (Figures 1 to 8, available on Expert Consult).

Overfeeding of newborns is unfortunately common, although bottle-fed infants are at a greater risk compared with breast-fed infants. Several factors can contribute to overfeeding, including lack of caregiver experience and support, as well as cultural biases such as the desire to have a chubbier infant. Many caregivers are unable to recognize infant cues for hunger and satiety and misinterpret cries or other vocalizations as a request for food. Medical providers should teach families about the rooting and sucking reflex and explain that some forms of sucking provide the infant with a means for self-soothing and are not signals that the infant is hungry (nonnutritive vs nutritive sucking).

Introduction of Complementary Foods

It remains controversial when solid foods should be added to the diet of an infant. The WHO recommends waiting until 6 months old. The AAP encourages waiting until an infant is 4 months old before adding solids and encourages continued breast-feeding until

TABLE 2 Expected Growth Velocities during Infancy

at least 1 year of age. However, some families want to start solids sooner than 4 months of age for a variety of reasons. A common explanation is “helping the baby sleep better at night.” Only by 4 months will infants have attained sufficient muscle strength and coordination to keep their head upright when seated and to protect their own airway during feedings that contain solid foods. Families should be encouraged to wait at least until 4 months old before introducing solids, usually starting with rice cereal. Introduction of solids should not be delayed for much longer than 6 months, especially for breast-fed infants, because this is typically when micronutrient stores have been depleted and dietary supplementation with solid foods is needed. Only one new solid should be introduced every 3 to 5 days so infants can be monitored for adverse food reactions.

Either formula or breast milk should continue to be offered until 12 months old, at which time infants can be transitioned to whole-fat cow's milk. Low-fat milk does not provide toddlers with sufficient lipid concentrations for adequate brain development or the required caloric density for general growth. Large quantities of fruit juices should be avoided throughout infancy and childhood because they provide little nutritional value.

Summary

The majority of term infants are born ready and able to begin feeding, but it is up to providers to know available nutritional options, normal feeding patterns, and means for measuring adequate intake and growth. Providers and other members of the care team also need to be able to counsel caregivers about best practices when feeding infants. When infants are suspected to be overfed or underfed, it may take a multidisciplinary approach by physicians, nurses, dietitians, speech therapists, lactation counselors, and social workers to help patients and their families.

PARENTERAL FLUID THERAPY FOR INFANTS AND CHILDREN

Method of

Aaron Friedman, MD

CURRENT DIAGNOSIS

- Maintenance fluid therapy is designed to replace the next 24 hours' anticipated losses from sensible and insensible losses in an otherwise healthy, euvoletic patient with normal kidney function.
- In a patient with extracellular volume loss, the percentage of body weight lost should be used as a guide to the volume needed for restoration.
- Serum sodium in patients with dehydration should be measured at the time of presentation and also after restoration fluid has been provided. The further correction of serum sodium will be much easier in a patient with a normalized extracellular volume.

CURRENT THERAPY

- Maintenance fluid therapy should not be used as a restoration or replacement fluid.
- Restoration fluid therapy can be given over short periods with a plan for complete restoration, in the majority of patients, within 24 hours.
- When treating hyponatremia or hypernatremia, the goal should be to change the serum sodium by *no more than* 10 mmol/L in a 24-hour period.
- When calculating how much water (in the case of hypernatremia) or how much sodium (in the case of hyponatremia) to provide a patient in order to restore sodium into the normal range, remember the calculation is based on the *total body water*, which is 60% of body weight, and the aim is to get to the closest serum sodium considered normal; for example, sodium 135 mmol/L for hyponatremia and sodium 145 mmol/L for hypernatremia.
- Replacement fluid therapy for patients with abnormal losses—gastrointestinal or urinary losses—should be based on measurement of the lost fluid volume and fluid electrolyte content.

Children receive three types of parenteral fluid therapy: maintenance therapy, restoration therapy, and replacement therapy. Maintenance fluid therapy provides the typical anticipated fluid and electrolyte losses seen in otherwise normal, euvoletic children. Restoration fluid therapy restores fluid volume previously lost. Replacement fluid therapy keeps up with ongoing abnormal fluid losses, such as ongoing losses from the gastrointestinal tract or abnormal urinary losses.

Maintenance Fluid Therapy

In 1957, Holliday and Segar proposed an approach to providing parenteral fluids and electrolytes to hospitalized children who are not permitted to eat or drink. The formulation was based on calories expended, presumed the patient did not have previous fluid losses (was euvoletic), and had normal kidney function. The surrogate for calories is weight because calories expended correlates to weight in grams. Therefore, the anticipated fluid losses for the upcoming 24 hours would come from urine excreted, water lost during breathing, and fluids lost from sweating. The prescription includes two components: water and electrolytes. [Table 1](#) describes the approach recommended by Holliday and Segar to determine parenteral fluids and electrolytes for a 24-hour period. It includes determining the amount of water to be provided based on weight as a surrogate for calories expended and it includes electrolytes to be provided. The electrolytes are sodium and potassium. Sodium is given at 2 to 3 mmol per 100 mL water provided, and potassium is given at 2 mmol per 100 mL water provided, with each provided as the chloride salt. Once the amount is calculated, the hourly rate can be determined by dividing the final calculation by 24.

The prepared solution that most closely resembles this maintenance prescription is 0.2 NS (0.2 normal saline, or 154 mmol sodium and chloride per liter) with 20 mEq KCl/L of fluid. Often glucose is added at 50 g/L (D₅W) or 5 g/100 mL. This provides some readily available calories to reduce catabolism. Note also that D₅W has an osmolality of nearly 300 mOsm/kg H₂O, essentially the same as plasma. This allows safe administration of the solution, because a markedly hypotonic solution administered into a vein could result in lysis of cells (especially red cells) in the vicinity of the infused hypotonic solution.

Another approach for calculating the water with the appropriate electrolytes to be provided is 1500 mL/m²/24 hours. This approach requires measuring the child's height and weight to determine square meters and is less convenient. The volume provided by the approach in [Table 1](#) and the 1500 mL/m² calculation are equivalent.

Another approach is to determine the hourly need of water bearing the electrolytes to be provided, the same as Holliday and Segar.

at least 1 year of age. However, some families want to start solids sooner than 4 months of age for a variety of reasons. A common explanation is “helping the baby sleep better at night.” Only by 4 months will infants have attained sufficient muscle strength and coordination to keep their head upright when seated and to protect their own airway during feedings that contain solid foods. Maintenance fluid therapy provides the typical anticipated fluid and electrolyte losses seen in otherwise normal, euvoletic children. Restoration fluid therapy restores fluid volume previously lost. Replacement fluid therapy keeps up with ongoing abnormal fluid losses, such as ongoing losses from the gastrointestinal tract or abnormal urinary losses.

Maintenance Fluid Therapy

In 1957, Holliday and Segar proposed an approach to providing parenteral fluids and electrolytes to hospitalized children who are not permitted to eat or drink. The formulation was based on calories expended, presumed the patient did not have previous fluid losses (was euvoletic), and had normal kidney function. The surrogate for calories is weight because calories expended correlates to weight in grams. Therefore, the anticipated fluid losses for the upcoming 24 hours would come from urine excreted, water lost during breathing, and fluids lost from sweating. The prescription includes two components: water and electrolytes. [Table 1](#) describes the approach recommended by Holliday and Segar to determine parenteral fluids and electrolytes for a 24-hour period. It includes determining the amount of water to be provided based on weight as a surrogate for calories expended and it includes electrolytes to be provided. The electrolytes are sodium and potassium. Sodium is given at 2 to 3 mmol per 100 mL water provided, and potassium is given at 2 mmol per 100 mL water provided, with each provided as the chloride salt. Once the amount is calculated, the hourly rate can be determined by dividing the final calculation by 24.

The prepared solution that most closely resembles this maintenance prescription is 0.2 NS (0.2 normal saline, or 154 mmol sodium and chloride per liter) with 20 mEq KCl/L of fluid. Often glucose is added at 50 g/L (D₅W) or 5 g/100 mL. This provides some readily available calories to reduce catabolism. Note also that D₅W has an osmolality of nearly 300 mOsm/kg H₂O, essentially the same as plasma. This allows safe administration of the solution, because a markedly hypotonic solution administered into a vein could result in lysis of cells (especially red cells) in the vicinity of the infused hypotonic solution.

Another approach for calculating the water with the appropriate electrolytes to be provided is 1500 mL/m²/24 hours. This approach requires measuring the child's height and weight to determine square meters and is less convenient. The volume provided by the approach in [Table 1](#) and the 1500 mL/m² calculation are equivalent.

Another approach is to determine the hourly need of water bearing the electrolytes to be provided, the same as Holliday and Segar.

TABLE 1 Approach to Determine Parenteral Fluids and Electrolytes for a 24-Hour Period

WEIGHT (kg)	WATER (mL)	NA (mEq/L)	K (mEq/L)
0–10	100/kg	3/100 mL	2/100 mL
11–20	1000 + 50/kg 11–20 kg	3/100 mL	2/100 mL
>20	1500 + 20/kg >20 kg	3/100 mL	2/100 mL
Examples			
15-kg child	1250	37 mEq/1250 mL	25 mEq/1250 mL
30-kg child	1700	51	34

Note: For sodium, potassium, and chloride, milliequivalents (mEq) and milliosmoles (mOsm) are the same.

TABLE 2 Hourly Administration of Fluids

CHILD'S WEIGHT (kg)	VOLUME OF WATER PER HOUR
≤10	4 mL/kg
11–20	40 mL + 2 mL/kg for every kilogram 11–20
>20	60 mL + 1 mL/kg for every kilogram >20

The hourly approach to determining volume is shown in [Table 2](#). Using this approach, maintenance fluid therapy for a 15-kg child would be infused at a rate of 50 mL/hour:

$$(4 \text{ mL/kg/h} \times 10 \text{ kg}) + (2 \text{ mL/kg/h} \times 5 \text{ kg})$$

Maintenance fluid therapy was designed to provide water and electrolytes to cover *future* (anticipated) loss, particularly from urine, expired air, and sweat. Unfortunately, since the publication of maintenance fluid therapy guidelines by Holliday and Segar, the formulation has often been misused. Maintenance fluid therapy should *not* be used as a fluid prescription for *restoring* extracellular fluid volume previously lost, for example, as a result of vomiting, diarrhea, or burns. It is almost always *not* an appropriate solution for *replacing* abnormal losses from the gastrointestinal tract, urinary tract, and so on. The volume calculation and the electrolyte concentrations are *not* appropriate to calculate a restoration solution or replacement solution.

The primary reason that a hypotonic solution such as maintenance fluids, as described by Holliday and Segar, is problematic for use as a restoration solution is the nonosmotic release of antidiuretic hormone (ADH, also called AVP [arginine vasopressin]). Since the mid 1950s it has been known that ADH is released from the hypothalamus under two different physiologic stimuli. One is an increase in serum and extracellular osmolality, usually greater than 290 mOsm/kg H₂O, termed *osmotic stimulus*. The other is a nonosmotic stimulus, usually the result of a fall in extracellular fluid volume or the perception of such a fall by volume receptors mainly in the thorax.

Since the 1950s we have come to learn that a large number of other stimuli can act as a nonosmotic stimulus to ADH release. These include, but are not limited to, a wide range of medications (antihypertensives, some antineoplastics, barbiturates), stress, central nervous system (CNS) injury or surgery, positive pressure ventilation, malignancy, and intrathoracic infection or malignancy. Under these conditions, ADH levels will be high and the administration of a hypotonic solution even at calculated maintenance doses could result in a fall in serum sodium and serum osmolality, on occasion to levels that might cause serious CNS injury, seizures, and even CNS herniation and death. Even in the early 1960s, when the precise reasons for the nonosmotic release of ADH were not well known, the risk of developing hyponatremia when providing the full volume prescribed in maintenance fluid therapy in the face of a concentrated urine and low urine volumes (signaling ADH release) was well known. The recommendation was to reduce the volume of fluid provided to approximately 50% of the standard calculated amount.

More recently, some have recommended, to prevent the development of hyponatremia, that all maintenance fluid therapy should be delivered as isotonic (normal) saline. The volume portion of the Holliday–Segar formulation is not altered, but the solution recommended in this approach is isotonic saline. The full impact of this approach on all types of hospitalized children is still unknown. It seems clear that patients in the perioperative period should receive normal saline in anticipation of the potential need for extracellular volume restoration. This approach does not guarantee that hyponatremia or hypernatremia will be totally prevented.

Restoration Fluid Therapy

Many children require parenteral fluids because of an inability to take fluids by mouth or due to abnormal fluid losses, such as from vomiting and diarrhea, excessive urinary losses, burns (excessive fluid losses from skin), or third spacing (the extravasation of fluid from the extracellular spaces such as the abdominal or thoracic cavity). In these situations, patients are at risk for serious extracellular volume depletion and even plasma volume depletion, which, left untreated, can result in hypotension or shock.

The parenteral fluid therapy for volume depletion should aim to first replace extracellular volume depletion. How much fluid to provide can be estimated by a long-standing approach using clinical signs to estimate the percentage of reduction in body weight associated with fluid losses ([Table 3](#)). In general, these losses can be replaced with a solution that restores extracellular fluid (isotonic saline or lactated Ringer's solution). In situations of

TABLE 3 Signs of Volume Depletion

SIGN	DEGREE OF DEPLETION		
	MILD (1%–4%)	MODERATE (5%–7%)	SEVERE (>7%)
Skin	Normal	Cool	Cool, mottled
Capillary refill	Normal	Decreased	Markedly decreased
Skin turgor	Normal	Loose	Tenting
Buccal mucosa	Slightly dry	Dry	Parched
Eyes	Normal	Sunken	Markedly sunken
Fontanel*	Normal	Sunken	Markedly sunken
Pulse	Normal (full)	Rapid	Rapid, thready
Urine output	Normal	Decreased	Oliguria (<1 mL/kg/h)
Systolic blood pressure	Normal	Normal, low	Low, shock

*Infants <9 mo of age.

prolonged fluid losses (more than 7 days), partial replacement with isotonic saline followed by a slower replacement with a more hypotonic solution with added potassium may be warranted. Table 3 outlines the clinical approach to assessing a patient's degree of volume depletion as a percentage of body weight.

Once the percentage of volume depletion is determined and the decision is made to use parenteral fluids based on moderate to severe volume depletion and ongoing vomiting, thus decreasing the effectiveness of oral rehydration, then rapid parenteral volume repletion is usually safe and effective. Replacing 50% of the determined volume depletion in 1 to 4 hours is appropriate, with the remaining replacement in the subsequent 4 to 16 hours. This should result in restored volume and improvement in the signs and symptoms demonstrated or reported by the patient. Often, partial restoration of extracellular volume depletion improves gastrointestinal symptoms and allows a switch to the oral route for completing volume restoration.

Example: A 15-kg patient presents with a 3-day history of vomiting and diarrhea. Physical examination suggests 5% volume depletion. The patient has ongoing vomiting, and parenteral fluids will be started. Volume depletion of 5% is 750 mL of fluid:

$$0.5 \times 15 \text{ kg (body weight)}$$

A commonly used volume expansion technique is to provide isotonic saline, 20 mL/kg, in a bolus (over 30 minutes to 1 hour). This amount of 300 mL (15 kg \times 20 mL/kg) is approximately 2% of body weight and in this example is less than 50% of the determined volume depletion. The plan, therefore, is 375 mL (50%) over 1 to 2 hours of isotonic saline (or lactated Ringer's solution) parenterally, then 375 mL of the same solution over the next 4 to 6 hours.

Replacement Fluids

As a general rule of thumb, unusual losses—gastrointestinal or renal, for example—should be replaced with a solution of comparable electrolyte concentration and of comparable volume. The most precise way to determine the needed solution is to measure the concentration of solutes such as sodium, potassium, chloride, or bicarbonate lost in emesis, diarrhea, or urine. Emesis contains sodium at 10 to 40 mmol/L and even less potassium (5–20 mmol/L) but large amounts of chloride (90–150 mmol/L). Diarrheal fluid typically contains sodium at 40 to 90 mmol/L, potassium at 10 to 50 mmol/L, and up to 40 or 50 mmol/L of bicarbonate. Cholera patients can excrete sodium up to 140 mmol/L. When possible, the volume of loss should be measured so a replacement fluid solution volume can be planned.

The safe approach to the patient with ongoing losses is first to restore extracellular volume to normal using normal saline or lactated Ringer's solution as noted earlier. During extracellular volume restoration, measure the output and electrolyte content of abnormal losses, preferably over a 12- to 24-hour period. Once this is known, then replacement of ongoing losses should be provided as a separate solution, the volume and electrolyte concentration determined by the measurements of each. Provide the replacement solution over the next 12 to 24 hours. For example, a patient with diarrhea is found to be producing 300 mL of diarrheal fluid over 12 hours. The measured sodium concentration is 80 mmol/L, potassium is 20 mmol/L, and bicarbonate is 40 mmol/L. The solution that will nearly approximate the losses is 0.2 NS (34 mmol/L of sodium and of chloride) with 20 mmol/L of potassium and 40 mmol/L of sodium bicarbonate. The solution will contain 74 mmol/L of Na, 20 mmol/L of K and 40 mmol/L of bicarbonate. The solution would be infused at a rate of 25 mL/hour. The advantage of providing this separately from maintenance or restoration fluids is that the rate of infusion or even the electrolyte content can be changed to address just the replacement needs without having to change all the intravenous solutions.

Hyponatremia and Hypernatremia

Hyponatremia (serum sodium <135 mmol/L) and hypernatremia (serum sodium >145 mmol/L) are often associated with volume depletion. Hypernatremia is nearly exclusively associated with volume depletion, and hyponatremia can be seen in situations of

volume expansion such as vasopressin excess (syndrome of inappropriate antidiuretic hormone [SIADH]) or congestive heart failure, kidney failure, or liver failure. At times, the need to normalize the serum sodium concentration requires parenteral intervention.

Approach to Hyponatremia

Symptomatic hyponatremia can occur if the serum sodium falls rapidly, but usually not until the serum sodium falls below 125 mmol/L. The symptoms associated with hyponatremia include anorexia, anxiety, agitation, ataxia, weakness, lethargy, disorientation, depressed deep tendon reflexes, seizures, coma, and death (usually the result of CNS herniation).

In situations where hyponatremia is associated with volume depletion, restoration of volume with isotonic saline often raises the serum sodium. When extracellular fluid volume is normal or expanded (such as situations when SIADH is at play), a four-fold approach to hyponatremia should be considered:

1. Treat the underlying condition.
2. Reduce water intake. In particular, if parenteral fluids are being provided, reduce or eliminate the use of hypotonic fluids.
3. Increase water excretion. This is usually done with loop diuretics such as furosemide (Lasix 0.5–1 mg/kg IV) to achieve a more rapid response.
4. Hypertonic saline IV is a step reserved for symptomatic patients. The most readily available hypertonic saline solution is 3% normal saline (sodium concentration of 513 mmol/L or approximately 0.5 mmol/mL). The desired outcome is to raise the serum sodium sufficiently to improve symptoms, but never more than 10 mmol/L in a 24-hour period. There is no need to raise the serum sodium beyond the lower limit of normal or 135 mmol/L. The desired increase in the serum sodium concentration should not exceed a maximum of 10 mmol/L.

The addition of sodium into the extracellular space will result in a shift of water from the intracellular to the extracellular space. Thus, the entire water space will be affected. The following example demonstrates how to calculate the amount of hypertonic saline to infuse in the face of severe hyponatremia:

A patient weighing 15 kg has a serum sodium of 125 mmol/L and experiences a seizure. The patient is felt to be euvolemic. Thus, hypertonic saline infusion is being considered. How should this be prescribed? Raise the serum sodium to 135 mmol/L from 125 mmol/L:

$$\begin{aligned} &\text{Change in serum sodium (mmol/L)} \times \text{body weight (kg)} \\ &\quad \times 0.6(\text{total body water space}) \\ &= 10 \times 15 \times 0.6 = 90 \text{ mmol} \end{aligned}$$

Because hypertonic saline is approximately 0.5 mmol/mL, if 90 mmol is the amount of sodium calculated to raise the serum sodium and osmolality, then 180 mL of 3% saline is needed.

An alternative way to calculate the maximum 3% saline to use is: The maximum change in serum sodium is 10, the body weight is 15 kg, the water space is 1.2 (0.6 \times 2 = 1.2; i.e., 2 mL/mmol sodium in 3% saline), so:

$$10 \times 15 \times 1.2 = 180 \text{ mL of 3\% saline}$$

Once the amount is calculated, the rate of administration should be no more than 2 to 4 mL/kg/hour, with measurements of the serum sodium at 2-hour intervals. Usually symptoms improve before there is a full 10-mmol rise in serum sodium. This rate should not result in a change of greater than 1 to 2 mmol/hour. If a change faster than this is seen, slow or stop the infusion immediately.

Approach to Hypernatremia

Hypernatremia (serum sodium >145 mmol/L) is seen with volume depletion. The extremely rare situation of pure salt overload is seen in babies receiving improperly mixed formula or intensive care patients receiving concentrated blood products and IV solutions. In these situations the patients do not show evidence of volume depletion, and urinary sodium excretion (and fractional excretion of sodium) is very high. In the overwhelming majority of patients

who are volume depleted, hypernatremia signals volume losses of *at least* 10% of body weight. The classic teaching is that hypernatremic patients appear less-severely volume depleted than they actually are. This is attributed to the increased osmolality protecting the extracellular space at the cost of intracellular space. Intracellular volume contains two thirds of total body water, and the decreased volume in the intracellular space means nearly all cells in the body (importantly, including in the brain) are smaller than normal.

The approach to hypernatremia is first to restore volume using isotonic saline. Providing 40 to 50 mL/kg of isotonic saline over 4 hours will improve extracellular volume and is unlikely to markedly reduce the serum sodium. Restoring extracellular volume will improve organ perfusion, especially perfusion of the gut and the kidney. This will improve the likelihood of being able to use the gut for fluid replacement and improve glomerular filtration rate and overall kidney function so as to be able to restore volume and safely return serum sodium and osmolality to normal. The major consequence of a too-rapid fall in serum sodium or osmolality is cerebral edema, the result of smaller-than-normal cell volume too rapidly expanded by IV (especially hypotonic) fluids.

Following the first infusion, as noted earlier, consider providing 30 to 40 mL/kg of isotonic fluid over the next 20 hours (to complete a 24-hour treatment plan) to continue replenishing extracellular volume. Check the serum sodium and serum osmolality frequently, at 2- to 4-hour intervals in the first 24 to 48 hours if the serum sodium is greater than 155 mmol/L at presentation. As with hyponatremia, it is important not to change (in this case, drop) the serum sodium by more than 10 mmol/L in 24 hours or to change the serum osmolality by more than 20 mOsm/kg H₂O in 24 hours. To determine how much water is necessary to lower the serum sodium, the following formula is often used:

$$\text{Actual serum sodium} - \text{desired serum sodium (not to exceed 10)} \\ \times \text{body weight in kg} \times 4 \text{ mL}$$

For a 15-kg child with a serum sodium of 155:

$$10 \times 15 \times 4 = 600 \text{ mL of water}$$

The safe approach to reducing the water deficit is to provide no more than half of the water deficit in the first 24 hours as a solution of 5% dextrose (D₅W) with potassium of 20 to 30 mmol/L. The intracellular fluid compartment is rich in potassium, and patients with hypernatremic dehydration have had considerable intracellular volume loss and have lost potassium, usually through urinary losses. The same approach may be considered in day 2 and following. Certain caveats are important here. First, as noted earlier, frequent measurements of serum sodium and serum osmolality are necessary to prevent too rapid a decline. Because the maintenance prescription is very hypotonic in the first 24 hours, at least, replacing volume loss should be the first priority. Once the patient approaches a normal volume status and serum sodium, providing maintenance *may* be appropriate. Patients with hypertonicity (hypernatremic dehydration) are very thirsty. Any fluid they consume by mouth must be measured and monitored lest their oral consumption along with parenteral fluids exceed the safe amount recommended.

Intravenous Electrolyte Replacements

At times, IV replacement of other electrolytes may be necessary. The IV replacement of potassium, in situations where the serum potassium concentration falls below 2.5 mmol/L or where oral replacement cannot be used, can be given as potassium chloride or potassium phosphate at a dose of no more than 0.5 mmol/kg/hour. The concentration of potassium in the solution infused should not exceed 40 mmol/L in a peripheral vein because potassium infusions are painful and sclerosing. Higher concentrations under the appropriate circumstances could be given through a central vein.

On occasion, IV administration of calcium or phosphate (or both) is clinically indicated. IV calcium is considered in patients with tetany, usually a serum calcium <6.5 mg/dL with a normal serum albumin. For IV calcium administration to correct symptomatic hypocalcemia, in older children the recommendation is 10 to

20 mL of a 10% calcium gluconate solution over 15 minutes to reduce or stop symptoms such as tetany or seizures. In neonates and young children, 10 to 20 mg/kg or 1 to 2 mL/kg of a 10% calcium gluconate solution administered at a rate of 1 mL/min with cardiac monitoring is recommended. For more chronic administration, 50 to 75 mg/kg/24 hours of calcium gluconate is recommended. Rapid calcium administration temporarily lowers the serum phosphate and can lead to arrhythmia, hence the cardiac monitoring.

Hypophosphatemia might require parenteral administration of phosphate. This approach is usually reserved for patients with a serum phosphate less than 1 mg/dL. The recommended dosage of elemental phosphorus is 2.5 to 5 mg/kg (0.08 to 0.16 mmol/kg) over 6 to 8 hours. This administration can lower serum calcium, so frequent testing of both the serum phosphorus and calcium is appropriate.

Finally, bicarbonate may be given intravenously. Usually the IV solution of bicarbonate should not exceed a concentration of 45 mmol/L. For example, in certain clinical conditions alkalinization of the urine is desired to prevent crystal or stone formation. The usual prescription is 1 to 2 mmol/kg body weight in 24 hours. Higher infused concentrations of bicarbonate (seen in patients with proximal tubule disease or injury as noted with certain chemotherapeutic agents) should be given into a central vein under careful monitoring. Calcium and bicarbonate should not be given in the same solution.

PEDIATRIC FAILURE TO THRIVE

Method of
Gretchen Homan, MD

CURRENT DIAGNOSIS

- Pediatric failure to thrive (PFTT), also known as weight faltering, refers to failure to gain weight at an appropriate rate over time.
- History taking, physical examination, and growth chart data are used to identify PFTT.
- Weight below the fifth percentile with a negative growth trend over time indicates potential PFTT.
- Weight measurements declining across two major percentiles may indicate PFTT.
- Failure to gain or maintain weight is the earliest indication of PFTT, but length and head circumference may be impacted and should always be monitored.

CURRENT THERAPY

- Successful treatment includes addressing all causes, including underlying medical problems.
- Hospitalization is generally not indicated, and serial clinic visits can be used to monitor weight gain and maintenance.

who are volume depleted, hypernatremia signals volume losses of *at least* 10% of body weight. The classic teaching is that hypernatremic patients appear less-severely volume depleted than they actually are. PEDIATRIC FAILURE TO THRIVE

Method of
Gretchen Homan, MD

CURRENT DIAGNOSIS

- Pediatric failure to thrive (PFTT), also known as weight faltering, refers to failure to gain weight at an appropriate rate over time.
- History taking, physical examination, and growth chart data are used to identify PFTT.
- Weight below the fifth percentile with a negative growth trend over time indicates potential PFTT.
- Weight measurements declining across two major percentiles may indicate PFTT.
- Failure to gain or maintain weight is the earliest indication of PFTT, but length and head circumference may be impacted and should always be monitored.

CURRENT THERAPY

- Successful treatment includes addressing all causes, including underlying medical problems.
- Hospitalization is generally not indicated, and serial clinic visits can be used to monitor weight gain and maintenance.

- Growth chart parameters can help set a goal weight. Daily weight gain goals can be identified to monitor treatment over weeks to months.
- The majority of patients respond to generalized techniques for increased calories combined with frequent outpatient monitoring of progress.
- Consulting with a dietitian or using detailed nutrition calculations can provide specific guidance for protein and calorie goals in complicated cases.

In pediatric failure to thrive (PFTT), also known as weight faltering, the child fails to gain weight at an appropriate rate; this failure is documented over time. The concept has been recognized for over a century, but there is still no consensus on terminology or a definition. Historically, the terms *organic* and *nonorganic* were used to identify PFTT, and they were attributed to medical conditions and psychosocial causes, respectively. Insufficient usable nutrition is now regarded as the underlying cause of PFTT. It can be due to problems with calorie intake or absorption or both. Approximately 80% of children with PFTT are diagnosed by age 18 months. For older children, the preferred term is *poor weight gain*.

Epidemiology

In the United States, PFTT occurs in approximately 5% to 10% of children seen in primary care and in up to 5% of children admitted to the hospital. An estimated 20% to 30% of cases are undiagnosed. PFTT is a condition rather than a specific diagnosis, and imprecise diagnostic criteria complicate estimating its incidence and prevalence. Some children show a decrease in their weight curves followed by weight maintenance on the new curve; although this occurs in approximately 25% of children, it is not considered weight faltering.

Risk Factors

Risk factors for PFTT can be medical and/or psychosocial. In up to 80% of cases, no obvious medical etiology is identified. Any disease process has the potential to cause PFTT. Prenatal disposing factors include exposure to toxins, intrauterine growth retardation, and poor maternal nutrition. Infants born prematurely are at high risk for PFTT. Premature infants need to catch up in growth over months to years and should not be expected to reach normal peer percentiles too quickly, as this could have negative implications for healthy weight in adult life. Any medical problem that interferes with or inhibits calorie intake and absorption of nutrients can cause PFTT, as can any condition that creates increased caloric demand. Leading medical causes include development delay, congenital anomalies such as cleft lip and/or palate, genetic conditions such as cystic fibrosis or celiac disease, and childhood cancers and related treatments.

Poverty is the most powerful psychosocial risk factor for PFTT, as it limits access to appropriate nutrition. Healthcare providers should be aware of “food deserts” in their communities as well as families within their practice that are food insecure. Children of families with increased life stresses, social isolation, poor parenting skills, or substance abuse are at increased risk for PFTT. Personal nutritional beliefs and practices can also limit nutrition, leading to PFTT. Examples include prolonged exclusive breast feeding or avoidance of multiple food categories for cultural or religious reasons.

Pathophysiology

Inadequate caloric intake, malabsorption, or increased metabolic demand, either as isolated entities or concurrently, can lead to PFTT. Caloric intake may be impaired by use of diluted formula, poor feeding habits, neglect, or mechanical feeding difficulties. Inadequate nutrient absorption can be caused by a range of diseases or conditions that affect the gastrointestinal tract, including celiac disease, cystic fibrosis and other pancreatic diseases, milk protein allergy, inborn errors of metabolism, and chronic infections. Increased energy needs and potential caloric deficit leading to PFTT can occur in children with chronic infections, congenital heart or lung disease, hyperthyroidism, malignancy, renal failure, inflammatory conditions, and HIV.

Prevention

Prevention of PFTT begins with prenatal care and maternal health, especially limiting potential exposure to toxins, optimizing maternal nutrition, and conducting routine pregnancy screenings. Being aware of potential genetic conditions facilitates planning appropriate support for the family. State-mandated newborn screening tests provide opportunities for early intervention in patients at risk for PFTT. Routine well-child visits in the first 2 years of life provide surveillance for growth and anticipatory guidance regarding nutrition to support development. Connecting families with appropriate community resources can help provide high-risk children and families with access to nutritional resources. Supporting overall good health with patient education and general preventive services, including oral health and immunization, is essential to reducing the risk of FTT.

Clinical Manifestations

PFTT is defined by problems with weight as a documented trend over time. The Centers for Disease Control and Prevention (CDC) recommend that the World Health Organization growth charts be used to document growth for children under age 2 years and that the CDC growth charts be used for children ages 2 years and older. The majority of PFTT patients show at least one of three characteristics: weight below the 5th percentiles for age and sex, weight drop of two major percentiles, or weight less than the 80th percentile of ideal body weight. Some infants may benefit from a PFTT evaluation when their daily weight gain is less than expected for age and sex but does not yet meet these criteria. If weight faltering persists, length and then head circumference are impacted, and these indicate severe PFTT.

Patients with PFTT can generally be diagnosed as outpatients. Laboratory evaluation or imaging is not generally required. Detailed history taking and physical examination, along with the growth chart information, are sufficient to identify PFTT. A delay in development coupled with weight faltering noted on the growth chart comprise the clinical presentation of severe or prolonged PFTT. The aim of the physical examination is to identify any underlying or contributing medical condition that could impair nutrition and/or increase metabolic demands. The clinician should observe for any dysmorphic features and look for signs of abuse or neglect. Signs of malnutrition may become evident when PFTT is allowed to persist. The most severely affected children show edema, wasting, hepatomegaly, rash, or skin and hair changes.

Differential Diagnosis

Prematurely born infants and those with intrauterine growth retardation may be mistaken for patients with PFTT. These infants and children may meet the diagnostic criteria for delay on standard growth charts (values less than the 5th percentile) for age and sex. Ongoing monitoring for underlying medical conditions, regular developmental assessments, and evaluation of the social support network for each patient can provide reassurance that the child does not have PFTT and is expected to “catch up” in growth parameters within 18 to 36 months.

Genetic short stature and constitutional growth delay should be ruled out by reviewing the midparental height and growth patterns for delays. Radiologic testing for bone age may be helpful when confirming constitutional growth delay.

Therapy

PFTT can have one or multiple causes or complicating factors. Each issue should be addressed in the context of the overall health of the child and family. Any underlying medical condition must be diagnosed and treated. Hospitalization is rarely indicated but may be helpful if there are complicating medical or social problems or if outpatient treatment has failed. Outpatient therapy is centered on increasing calorie intake with appropriate food options (Table 1). Equations can be used to calculate estimated calorie and protein needs by age and sex for both normal and catch-up growth. To simplify this process, a generalized list of targets is provided in Table 2. When available, a dietitian can define the required protein and calorie goals for catch-up growth initially and over the remaining treatment period. Alternatively, the primary care physician can use the growth chart to determine the desired weight goal for age and plan

TABLE 1 Techniques to Increase Calories

AGE	CALORIE SOURCE ADJUSTMENT	FEEDING TECHNIQUE
Infant – breast fed	<ul style="list-style-type: none"> • Increase feeds up to 12 in 24 hours • Pump after feeds and use expressed breast milk (EBM) to supplement nursing; add formula powder to EBM 	<ul style="list-style-type: none"> • Evaluate and ensure proper latch/position • Feed both breasts with each feeding • Work to keep baby awake for complete feeding • Do not allow feeds to persist beyond 30 minutes total
Infant – formula fed	<ul style="list-style-type: none"> • Increase calorie concentration by mixing formula powder with less water, from 19/20 to 24/26 kcal; monitor for tolerance • Evaluate feeding volume and frequency to avoid over- or underfeeding; rule of thumb feeds average 1 oz/h (e.g., 3 oz/3 h) 	<ul style="list-style-type: none"> • Evaluate for intolerance and change formula if needed; consider predigested proteins • Use proper bottle nipple speed • Avoid bottle propping
Toddler	<ul style="list-style-type: none"> • Add butter, dips such as ranch or mayonnaise, and cheese to foods • Use high-calorie foods and offer proteins such as cheese, peanut butter, avocados, and high-fat yogurts • Encourage a variety of healthy foods such as fruits, vegetables, proteins, and grains • Consider supplement shake or drink 1–2 times/day 	<ul style="list-style-type: none"> • Structured mealtimes in a high chair with adult supervision and without distractions (e.g., television, other children) • Evaluate toddler's ability to self-feed effectively; intervene and teach if needed • Aim for 3 meals with 3 snacks daily • Minimize fruit juices • Offer water with meals and offer foods before milk or supplement drinks

TABLE 2 Estimated Calorie Needs by Age

AGE	KCAL/KG/DAY
Preterm infant	115–130; up to 150 for very low birth weight infants
Full-term infant	
• 0–2 months	• 104–107
• 3 months	• 95
• 4–35 months	• 82
Toddler	70–80

Add 5–20 kcal/kg/day for catch-up growth, depending on tolerance and desired rate of recovery.

for a daily weight gain goal over weeks or months. The techniques described in [Table 1](#) can be used to initiate treatment. Frequent visits are necessary. At each visit, the child's measurements should be done on the same well-calibrated scale to provide reliable data for clinical decision making about appropriate weight gain and maintenance. Patients who are unable to grow with these interventions may benefit from either short-term nasogastric tube feedings or more long-term gastric tube feedings.

Monitoring

Children with PFTT may require more frequent monitoring than the scheduled routine well-child visits. Young infants can be seen weekly or monthly and older patients every 2 to 4 months. At these visits, patients should be weighed and measured, preferably without clothing, by trained staff using routinely calibrated devices and

standardized techniques to ensure the most accurate measurements. The clinician should review the patient's growth charts, diet and activity history, any changes in the social and medical history, and perform a physical examination. Recent acute illness may slow or reverse growth progress and should be addressed. It may take months for malnourished patients to show and maintain growth recovery. Patients who were born prematurely or with intrauterine growth retardation may require years to catch up. Depending on the underlying cause of PFTT, relapse is possible.

Complications

Weight loss or deceleration is the earliest clinical indicator for PFTT; if allowed to persist, height and length can be affected. Eventually, head size and brain growth can be impaired. At this level of severity, PFTT puts cognitive development and achievement of milestones in jeopardy. Immune system function may be impaired during a malnourished state, thus putting affected patients at risk for infections. Social and emotional health may also be impacted. Research is ongoing with the hope of yielding more data on the long-term effects of PFTT.

PEDIATRIC SLEEP DISORDERS

Method of

Julie M. Baughn, MD

CURRENT DIAGNOSIS

- Sleep disorders are common in children.
- Evaluation of pediatric sleep disorders in children begins with a thorough sleep history.
- Overnight polysomnography is most commonly used to evaluate for sleep-disordered breathing
- Other diagnostic tools include the multiple sleep latency test (MSLT), oximetry, sleep logs, and actigraphy.
- Common sleep disorders in children include obstructive sleep apnea, insomnia, restless legs syndrome, and delayed sleep phase syndrome.

CURRENT THERAPY

- For most children tonsillectomy and adenoidectomy are an effective treatment for obstructive sleep apnea.
- Behavioral therapy is essential to treating insomnia.
- Only in select circumstances are medications used to treat children with sleep disorders.

PEDIATRIC SLEEP DISORDERS

Method of

Julie M. Baughn, MD

CURRENT DIAGNOSIS

- Sleep disorders are common in children.
- Evaluation of pediatric sleep disorders in children begins with a thorough sleep history.
- Overnight polysomnography is most commonly used to evaluate for sleep-disordered breathing
- Other diagnostic tools include the multiple sleep latency test (MSLT), oximetry, sleep logs, and actigraphy.
- Common sleep disorders in children include obstructive sleep apnea, insomnia, restless legs syndrome, and delayed sleep phase syndrome.

CURRENT THERAPY

- For most children tonsillectomy and adenoidectomy are an effective treatment for obstructive sleep apnea.
- Behavioral therapy is essential to treating insomnia.
- Only in select circumstances are medications used to treat children with sleep disorders.

Introduction

Pediatric sleep medicine has grown as the importance of sleep in the developing child has been recognized along with the impact that insufficient or disrupted sleep can have on cognitive development and behavior. The American Academy of Sleep Medicine (AASM) and the American Academy of Pediatrics (AAP) have recently published guidelines and practice parameters addressing several aspects of pediatric sleep medicine. Pediatric sleep disorders have unique societal impact; both the child's and the family's sleep can be affected when a disorder is present. The aim of this chapter is to offer a practical approach to the diagnosis and treatment of the most common pediatric sleep disorders, discuss diagnostic tools available, and discuss recommended treatment.

Developmental Aspects of Sleep

Pediatric sleep disorders also have the unique challenge of dealing with sleep issues that are subject to change based on the child's developmental age. The amount of sleep required by age has been described in a recent AASM consensus statement (Table 1). The sleep architecture of the child characteristically changes as he or she develops. The portion of rapid eye movement (REM) sleep declines from 50% at birth to 25% to 30% in adolescence. The proportion of slow-wave sleep is highest in early childhood and

continues to decline throughout life. The pattern of sleep and sleep requirement also change. Neonates may not develop a regular sleep-wake pattern until about 3 months of age. Most infants are capable of sleeping through the night by about 6 months of age, but many may continue to awaken. Naps are typically given up somewhere between 3 and 5 years of age. Most adolescents, due to many societal and social constraints, do not get a requisite 8 to 10 hours of sleep at night.

Clinical Approach

Taking a Sleep History

There are several key elements to obtaining a sleep history in children. The mnemonic BEARS (Bedtime problems, Excessive daytime sleepiness, Awakenings during the night, Regularity and duration of sleep, and Sleep-disordered breathing) has been offered as a practical starting point for obtaining a history, tailoring questions to both parent and child where appropriate (Table 2).

The primary sleep complaint should be obtained in the child's or parent's own words. Once the primary complaint is detailed, the presence/absence of snoring, the presence of restlessness at sleep initiation and during sleep, and the child's sleep-wake patterns during school should be gathered. The presence or absence of a bedtime routine and the details of that routine should be noted. A child's sleep environment should be carefully queried. A child who shares his or her bedroom, sleeps in his or her parents' bed, or ends up sleeping on a couch in front of the television may lead to specific sleep complaints. A history of whether there is more than one household involved (i.e., shared custody) is particularly important.

Sleepiness in children can be a particularly challenging symptom to evaluate. It is normal physiologically for children to nap until age 5. Other clues to daytime sleepiness that can be obtained in children include behavior issues, hyperactivity, excessive napping, or napping after age 5 years (intentionally or unintentionally). School-age children often display symptoms of behavioral problems or inattentiveness rather than sleepiness. Sleep-wake patterns on school days, weekends, and vacations need to be detailed. Often the child's most natural sleep pattern will emerge over the summer months.

Determining the child's sleep hygiene or good sleep practices is important in diagnosing and treating sleep disorders. Principles of good sleep hygiene are listed in Table 3.

TABLE 1 Sleep Requirements in Children by Age

AGE	AVERAGE SLEEP DURATION IN 24 HOURS (OVERNIGHT AND NAPS)
Infants (4 to 12 months)	12 to 16 hours
Children (1-2 years)	11-14 hours
Children (3-5 years)	10-13 hours Most give up naps between 3 and 5 years
Children (6-12 years)	9-12 hours
Teenagers (> 12 years) 13-18 years)	9 hours8-10 hours

Paruthi S, Brooks LJ, D'Ambrosio C, et al. Consensus Statement of the American Academy of Sleep Medicine on the Recommended Amount of Sleep for Healthy Children: Methodology and Discussion, *J Clin Sleep Med* 2016; 12 (11):1549-1561.

TABLE 2 BEARS Mnemonic: A Screening Tool for Sleep Disorders in Children

	PRESCHOOL (2-5 YEARS)	SCHOOL-AGE (6-12 YEARS)	ADOLESCENT (13-18 YEARS)
Bedtime problems	Does your child have any problems going to bed? Falling asleep?	Does your child have any problems at bedtime? (P) Do you have any problems going to bed? (C)	Do you have any problems falling asleep at bedtime? (C)
Excessive daytime sleepiness	Does your child seem overly tired or sleepy during the day? Does your child still take naps?	Does your child have difficulty waking in the morning, seem sleepy during the day, or take naps? (P) Do you feel tired a lot? (C)	Do you feel sleepy a lot during the day? In school? While driving? (C)
Awakenings during the night	Does your child wake up a lot at night?	Does your child seem to wake up a lot at night? Any sleepwalking or nightmares? (P) Do you wake up a lot at night? Have trouble getting back to sleep? (C)	Do you wake up a lot at night? Have trouble getting back to sleep? (C)
Regularity and duration of sleep	Does your child have a regular bedtime and wake time? What are they?	What time does your child go to bed and get up on school days? Weekends? Do you think your child is getting enough sleep? (P)	What time do you usually go to bed on school nights? Weekends? How much sleep do you usually get? (C)
Sleep-disordered breathing	Does your child snore a lot or have difficulty breathing at night?	Does your child have loud or nightly snoring or any breathing difficulties at night? (P)	Does your teenager snore loudly or nightly? (P)

Abbreviations: C = child; P = parent.

From Owens JA, Dalzell V: Use of the "BEARS" sleep screening tool in a pediatric residents' continuity clinic: A pilot study. *Sleep Med* 2005;6:63-69.

TABLE 3 Principles of Sleep Hygiene in Children

The child's bedroom should be dark and quiet.
Bedtime routines should be strictly enforced. Routines should be relaxing and only 20 to 30 minutes in length.
The time of morning awakening should be firmly and consistently structured.
Bedroom temperatures should be kept comfortably cool (< 75 °F).
Environmental noise should be minimized as much as possible.
Background music and/or white noise may inhibit extraneous noise.
Children should not go to bed hungry and may have a snack before bedtime.
Excessive fluids before bedtime may result in bladder distention and arousal and disrupt sleep.
Children should learn to fall asleep alone (i.e., without their parents' presence in the room).
Vigorous activity should be avoided before bedtime.
A bath is often a stimulating activity for children. If bedtime struggles are present after a child's bath, it may be moved to the morning or separated from the child's bedtime by at least 2 hours.
Methylxanthine-containing beverages and food (e.g., caffeinated beverages/colas, tea, chocolate) should be avoided several hours before bedtime.
Parents should read labels on all over-the-counter and prescription medications. Some may contain alcohol or caffeine and may disrupt sleep.
Naps should be developmentally appropriate. Brief naps may be refreshing, but prolonged naps or napping too frequently may result in significant accumulation of sleep during the day and make it more difficult to fall asleep at night.

Modified from Sheldon SH, Ferber R, Kryger M (eds): Principles and Practice of Pediatric Sleep Medicine. Philadelphia: Elsevier Saunders, 2005.

Past Medical History/Family History

A history of prematurity, trisomy 21, velopharyngeal cleft palate repair, or hypotonia is each associated with an increased risk of sleep-disordered breathing. A past history of adenotonsillectomy for snoring is important information to obtain. Chronic nasal obstruction can cause maxillary hypoplasia. Arnold-Chiari malformation, myelomeningocele, or a brainstem lesion can predispose to central sleep apnea due to impaired central respiratory drive. Chronic health issues can also be associated with sleep disruption and consequently with behavioral problems associated with sleep.

A family history of obstructive sleep apnea (OSA), insomnia, or restless legs syndrome (RLS) is important; a family history of RLS can be used to support a diagnosis of RLS in the child. In particular, questioning the mother if she had symptoms of RLS during any of her pregnancies can be helpful because this is a common time for RLS to present or worsen. Morning or evening preferences (i.e., "night-owl" or "lark" tendencies) can also have a familial element. In addition, sleepwalking can be found to occur in families.

Focused Physical Examination

The physical examination in a child presenting with a sleep complaint should include a general assessment. Presence/absence of sleepiness, fatigue, and irritability/hyperactivity are all important. Height, weight, and body mass index (BMI) should be recorded. Children with OSA can have poor growth and even failure to thrive. Obesity is a risk factor for OSA. Special attention to a child's craniofacial features is important because these may make a child more at risk for sleep-disordered breathing. Assessment of tonsil size, oropharyngeal crowding (using the Mallampati or Friedman classification systems can be useful), and presence of maxillary/mandibular hypoplasia can all offer clues to an airway that may predispose to OSA. The practitioner should evaluate for evidence of nasal obstruction by noting mouth breathing and signs of allergy (i.e., allergic shiners, nasal crease).

Diagnostic Tools

Polysomnography

The AASM has published practice parameters on both the respiratory and nonrespiratory indications for polysomnography (PSG) in pediatric patients. In this chapter, a sleep study or PSG will refer only to an in-laboratory attended study, because home monitoring currently has not been sufficiently evaluated in the pediatric population. PSG in children entails spending the night at a sleep center. A parent or caregiver must also spend the night. During the night, the child's sleep characteristics, respiratory function, and movement are analyzed. This is done by the following measures: electroencephalography (EEG), electromyography (EMG) of chin and limbs, airflow by thermistor and nasal pressure, end-tidal or transcutaneous carbon dioxide measurements, and induction plethysmography to measure respiratory effort. Scoring of a PSG performed on a child is done using pediatric scoring rules set forth by the AASM.

The most common indication for a sleep study in children is OSA. PSG can be used to both diagnose OSA and treat sleep apnea with continuous positive airway pressure (CPAP). PSG can also be used to evaluate for elevated periodic limb movements of sleep, and in rare cases to characterize abnormal nocturnal behavior such as evaluation of parasomnias or nocturnal seizures.

Overnight Oximetry

The gold standard for diagnosis of pediatric OSA is PSG. Overnight oximetry has been suggested as an alternative screening tool for pediatric sleep-disordered OSA. Although an abnormal oximetry will suggest OSA, a normal oximetry does not rule out OSA. Children can have sleep apnea that is severe and still maintain normal oxygenation. In a study by Brouillette and colleagues (2000), when a positive oximetry graph was present (defined by three or more desaturation clusters and at least three desaturations < 90%) in a referred population, the positive predictive value for OSA on PSG was 97%. A negative or inconclusive oximetry by this definition did not rule out OSA and there was still a 47% chance OSA was present on PSG.

Sleep Logs/Actigraphy

Sleep logs can be effective in demonstrating a child's sleep-wake patterns. Actigraphy is often done in conjunction with a sleep log. Actigraphy is a portable wristband that measures movement. The absence of movement over a certain time period is used as a surrogate marker of sleep, and the presence of movement over a certain time period is used as a surrogate for wakefulness. Some devices also measure ambient light exposure. Used in conjunction with actigraphy sleep logs can be extremely helpful in demonstrating discrepancies between perceived and actual sleep, and are helpful in demonstrating insufficient sleep and circadian rhythm disorders. Those that measure light as well can aid in uncovering sleep hygiene issues.

Multiple Sleep Latency Test

The multiple sleep latency test (MSLT) is a daytime study used to objectively measure sleepiness. It is often used to aid in the diagnosis of narcolepsy or hypersomnia. It is a set of four to five scheduled naps that typically occur the day after an overnight sleep study. Often 2 weeks of actigraphy are done before the MSLT to determine sleep-wake patterns.

Common Pediatric Sleep Diagnoses and Treatment

Obstructive Sleep Apnea

Epidemiology

Up to one-fifth of children can have intermittent snoring. Prevalence rates of OSA range from 1.2% to 5.7%. OSA is most common in children 2 to 8 years of age corresponding to the peak age of adenotonsillar hypertrophy. Due to the rise in childhood obesity there is now a corresponding rise in older children diagnosed with OSA.

Pathophysiology

The pharynx has many roles, including swallowing, speaking, and maintaining airway patency. Pharyngeal size is determined by the bones and soft tissue. The soft tissue is affected by the size of the tonsils and adenoids, as well as adipose tissue. Airway patency is maintained during wakefulness; a small airway can become vulnerable during sleep resulting in partial or total closure of the airway, hypoxemia, hypercapnia, and an arousal that results in opening of the airway and termination of the obstructive event. This leads to sleep disruption and daytime consequences. OSA in children likely results from a combination of narrowing of the upper airway, abnormal upper airway tone, and genetic factors.

Clinical Manifestation

OSA in adults is typically associated with daytime sleepiness. Associations have been made with hypertension, stroke, and metabolic syndrome. In children, OSA may not present with daytime sleepiness. Children may present with daytime inattention and/or neurocognitive and behavioral issues. Symptoms include snoring with or without apneic pauses or gasps. Restless sleep or secondary enuresis may also be noted. Parents may comment on increased work of breathing while sleeping. Other associations include poor growth, obesity, hypertension, and systemic inflammation.

Diagnosis

The gold standard for diagnosis of pediatric OSA is an in-laboratory attended PSG by an accredited sleep laboratory. History and physical examination lack sensitivity and specificity in predicting which children with snoring have OSA. However, a history of loud snoring, tonsillar hypertrophy, and abnormal oximetry is strongly suggestive of the diagnosis of OSA (see above). History alone cannot distinguish children with OSA from those with primary snoring. Criteria for the diagnosis of OSA in children are met when there is one or more apnea or hypopnea events per hour identified using scoring criteria by the AASM.

Differential Diagnosis

Other forms of sleep-disordered breathing are not as common as OSA. Sleep-related hypoventilation can occur in patients with neuromuscular weakness. Central hypoventilation syndromes are rare, but should be considered in children with persistent gas exchange abnormalities without additional explanation. Sleep-related hypoxemia can be present in pediatric patients with chronic lung disease. Central sleep apnea should be thought of in patients with brainstem abnormalities or Arnold-Chiari malformation. Sleep-related seizures may be difficult to differentiate from OSA in infants and an extended EEG montage may be necessary during their sleep study. Normal breathing patterns of infants and children should also be identified; brief (less than 10 seconds), central respiratory pauses that are self-resolving (and without significant desaturation) are common in normal children in either REM sleep or post-arousal/post-sigh.

Treatment

Treatment of OSA in most children is adenotonsillectomy. Recent guidelines from the AAP recommend an overnight sleep study in children where the practitioner had a clinical suspicion of OSA before adenotonsillectomy. Children with mild OSA preoperative can be monitored clinically postoperatively. Children with moderate to severe OSA, as well as children with craniofacial abnormalities, neurologic disorders, and obesity, should have a follow-up PSG to demonstrate resolution of OSA after surgery. Children who are not candidates for adenotonsillectomy may be treated with CPAP and use may have an impact on neurobehavioral outcomes. Treatment with CPAP therapy in children requires close follow-up because pressure needs may change with growth.

Difficulty with Sleep Initiation and Night Wakings

Epidemiology

Bedtime problems and night wakings occur in up to 30% of children.

Clinical Manifestations

The diagnosis of insomnia includes difficulty going to sleep and/or staying asleep, the complaint that sleep is not of good quality, and the report of poor daytime functioning. The sleep complaints of infants and young children are often in the words of their parent or caregiver.

In preschool-age children both bedtime problems and night wakings are common and characterized by two types of behavioral insomnia of childhood: sleep-onset association type and limit-setting type. The definition of the *sleep-onset association type*, as defined in the ICDSD-2, includes the following: sleep initiation is an extended process, associations are demanding, if the associations are not present sleep onset is delayed, and awakenings require caregiver intervention. The *limit-setting type* involves difficulty initiating or maintaining sleep, there is bedtime stalling or refusal, and the caregiver does not set sufficient and appropriate limits around this behavior. Children with frequent and prolonged night wakings have the sleep-onset association type. They often require an intervention by the caretaker to reinitiate sleep. Both problems can be present at once. Children who have difficulty going to sleep and provide resistance to bedtime have the limit-setting type. Parents of these children may complain of daytime behavioral issues due to the parent's inability to set limits during the day as well.

Diagnosis

Diagnosis is made from the history in the majority of cases. An overnight sleep study may be indicated in cases where another sleep disorder is suspected.

Differential Diagnosis

The differential diagnosis of insomnia or behavioral insomnia of childhood includes sleep disorders such as OSA, RLS, or nocturnal seizures. These disorders can prompt nocturnal awakenings or make sleep initiation difficult. If there is clinical suspicion of one of these disorders, an overnight sleep study may be indicated.

Treatment

Behavioral interventions have been shown to be effective in treating all forms of insomnia. In older children, primary and secondary insomnia can be effectively treated with cognitive-behavioral therapy. This often includes stimulus control and sleep restriction. Stimulus control includes maintaining a regular sleep-wake pattern and using the bed and bedroom only for sleeping. It involves getting out of bed if sleep is not initiated within about 20 minutes. Sleep restriction includes minimizing the time in bed to be only sleeping. It often includes delaying bedtime to the child's actual sleep onset, and then over time gradually advancing the bedtime. Sleep hygiene should be effectively addressed, including development of a relaxing bedtime routine, maintaining a regular sleep-wake pattern, and eliminating electronic use before bedtime.

There are several treatments of behavioral insomnia of childhood sleep-onset association type. No one treatment has been found to be superior. The goal of all of these methods is for the child to fall asleep in his or her crib or bed on the child's own. These include extinction (i.e., "cry it out"), which is often not palatable to caregivers. There is the graduated extinction method, which has parents ignoring crying or protests for specified periods of increasingly longer intervals. Some prefer an even more gradual approach of sitting next to the child's bed in a chair and over several days to weeks moving that chair across the room and out of the room. A consistent bedtime routine should also be implemented. Use of a transitional object can be helpful. Treatment of the limit-setting type includes firm limit setting. Positive reinforcement and limiting negative reinforcement should be used. The use of a reward system can be helpful. Effectively addressing behavioral treatment of sleep issues can be challenging for the primary care provider because of time constraints.

Restless Legs Syndrome/Willis Ekblom Disease

Epidemiology

Prevalence rates for pediatric RLS/WED have ranged from 1% to 6%.

Risk Factors

Risk factors include a family history and a history of anemia or iron deficiency. Attention-deficit/hyperactivity disorder (ADHD) is associated with RLS.

Pathophysiology

Decreased dopamine has been suggested in the pathophysiology of RLS/WED. Iron is a cofactor in the synthesis of dopamine and treatment of iron deficiency or low ferritin, if present, may improve symptoms.

Diagnosis

Diagnosis of pediatric RLS/WED is a clinical diagnosis. It is made using the adult criteria set forth in the ICSD-3 but with some modification for children due to developmental issues. It consists of the child reporting an urge to move the legs, usually accompanied by an uncomfortable sensation; this urge or sensation worsens during rest or inactivity; the sensations are improved or resolved by movement; the sensations are present or worsen in the evening or night. If a child cannot express a description in his or her own words, diagnosis can be made using two out of the following three criteria: a sleep disturbance for age, a family history of RLS, and a periodic limb movement index on PSG of > 5 per hour. Because of this last criterion, a sleep study can be helpful in children to make this diagnosis. There can be an association with sleep initiation and maintenance difficulties.

Differential Diagnosis

Differential diagnosis of RLS should include insomnia, sleep-disordered breathing, or neurologic or musculoskeletal etiologies for the discomfort.

Treatment

Nonpharmacologic treatment of RLS includes good sleep hygiene, moderate exercise a few hours before bedtime, and avoidance of substances that are associated with worsening of RLS symptoms, including caffeine, alcohol, antihistamines, and antiemetics. A serum ferritin should be drawn in all children with RLS and if < 50 ng/mL, treatment with 6 mg/kg/day of oral elemental iron should be considered. Oral iron absorption is enhanced by vitamin C and impaired by calcium. Gastrointestinal upset and constipation can be common side effects. Compliance can be difficult. A serum ferritin should be rechecked at 3 months to evaluate therapy. Referral to a sleep medicine specialist should be made if lifestyle and oral iron therapy have been unsuccessful. There are no FDA-approved medications for the treatment of RLS in children. Dopamine agonists, gabapentin (Neurontin),¹ clonazepam (Klonopin)¹, and clonidine (Catapres)¹ have been used to treat pediatric RLS.

Delayed Sleep Phase Syndrome

Epidemiology

Delayed sleep phase syndrome (DSPS) occurs most commonly in adolescents and young adults.

Clinical Manifestations

Symptoms usually present in adolescents but can occur in younger children. Adolescents with DSPS consistently have sleep onset at a later time, typically after midnight. They have difficulty initiating sleep earlier. They do not have difficulty maintaining sleep. They have difficulty waking in the morning unless able to sleep until their preferred time, which is typically after 10 AM. They may have sleepiness during the daytime if forced to rise early (i.e., for school); however, during long vacations or summer breaks when allowed to sleep to preferred wake time they feel refreshed. Children who already have a preferred evening preference may find this exacerbated in adolescence. Poor school performance can be present.

Diagnosis

Diagnosis is made from history; actigraphy and sleep logs are also useful. An overnight sleep study may be indicated if another sleep disorder is suspected (e.g., OSA).

Differential Diagnosis

The differential diagnosis includes insomnia, poor sleep hygiene, insufficient sleep, mood disorder, OSA, and RLS.

Treatment

Treatment is typically behavioral and includes good sleep hygiene. Typically either the patient's sleep-wake schedule is advanced (if there is less than 3 hours between actual and desired bedtime) by 15 minutes every 2 to 3 days until the goal bedtime is achieved. Rise time is advanced as well and if set at the desired wake time initially it should facilitate the advancement of the bedtime by increasing sleep drive. If the desired bedtime of the adolescent is greater than 3 hours from the current bedtime, phase delay can be considered. Bedtime is delayed by 2 to 3 hours each day until the target bedtime is reached. Timing of this therapy should be considered, because it will interfere with school or other daytime activities. Parental or caregiver support is necessary, as well as commitment by the adolescent.

Once the new pattern is established weekends must not differ from weekdays by more than 1 to 2 hours. This is particularly important for the rise time. Relapse is common if strict sleep-wake patterns are not adhered to, a problem common on vacations.

Both bright light exposure and melatonin⁷ have been used to help reset the circadian rhythm. Exposure to bright light in the morning is encouraged and can be as simple as increasing sun exposure in the morning. Light boxes using 2500 to 10,000 lux can be used in the morning for 20 to 30 minutes. Exposure to light in the evening should be limited. A small dose of melatonin (0.5 mg) can be used in the early evening (about 5 hours before desired bedtime) to attempt to physiologically advance sleep onset. If the timing is not optimal for both light and melatonin, the phase delay can be worsened; consultation with a sleep physician should be considered.

Parasomnias

Parasomnias can occur out of both non-REM (NREM) and REM sleep. Those occurring out of NREM sleep include sleepwalking, sleep terrors, and confusional arousals. They typically occur in the first one-third of the night, when NREM-3 sleep is most prevalent, and are not recalled the next day. They can be part of normal development, but depending on their nature, they can be distressing to caregiver and child. Parasomnias occurring out of REM sleep include nightmares and REM-sleep behavior disorder (RBD). Nightmares are commonly recalled and have been associated with anxiety in children. Nightmares typically peak in the school-age child. RBD is rare in children but has been reported; it involves the loss of atonia that occurs in REM sleep and consequently dreams are "acted out."

Risk Factors

Poor sleep hygiene, insufficient sleep, irregular sleep-wake patterns, and a positive family history are all risk factors. Sleep disruption from sleep-disordered breathing or periodic limb movements of sleep can exacerbate parasomnias.

Differential Diagnosis

The differential diagnosis should include nocturnal seizures. In addition, if another sleep disorder is present, parasomnias can be exacerbated.

Treatment

Safety is most important in children with parasomnias, and it is important that the child's sleep environment is kept clear of things that could cause injury. Door alarms can be effective. The child

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

should not be awakened during the episode. The event should not be referred to the next morning because this can cause distress for the child. Maintaining good sleep hygiene and regular sleep-wake patterns is important. If the events occur at a predictable time each night, the caregiver can do planned awakenings 30 minutes before the event typically occurs for several weeks. This may abolish the episodes. It can also have the effect of pushing the episode to later in the night. Pharmacologic treatment with a small dose of a benzodiazepine (e.g., 0.5 mg of clonazepam [Klonopin]¹ at bedtime) may be indicated in severe cases with the drug tapered slowly after episodes are suppressed.

Hypersomnias

A full discussion of primary hypersomnias (including narcolepsy) in children is beyond the scope of this chapter. Consideration for a primary hypersomnia should be made in a child who is sleepy after common causes of sleepiness such as insufficient sleep and obstructive sleep apnea have been ruled out. Symptoms of narcolepsy include disrupted nocturnal sleep, hallucinations on going to sleep or waking up, and sleep paralysis. Daytime sleepiness is present with "sleep attacks" both during quiet activities and while active. Cataplexy may also be present and is defined by loss of muscle tone without loss of consciousness. It should be noted that onset of narcolepsy is often in adolescence or as a young adult. Diagnosis is often delayed because the symptoms are attributed to other conditions. Treatment of pediatric hypersomnia is done under the supervision of a sleep specialist and often involves use of stimulants.

¹Not FDA approved for this indication.

RESUSCITATION OF THE NEWBORN

Method of

Stacey A. Hinderliter, MD; and David Gregory, MD

CURRENT DIAGNOSIS

- The transition from intrauterine to extrauterine life at birth requires effective breathing by the infant to expand the lungs and oxygenate the blood. All newborn infants are at risk for delays in this process, prompting a need for resuscitation.
- The fetal and newborn response to hypoxia is to develop apnea. If primary apnea is diagnosed, it can be corrected by gentle stimulation and oxygen delivery. If hypoxia persists, secondary apnea will occur. It is not readily apparent whether a newborn has primary or secondary apnea, and the approach to resuscitation therefore requires that any apneic event be treated using the same sequence of interventions.
- The initial steps of newborn resuscitation include drying the infant, providing warmth, suctioning the airway, and providing gentle stimulation. Infants who do not respond to these interventions need more assistance. Establishment of effective ventilation spontaneously by the newborn or with assistance by positive-pressure ventilation is the most important step in newborn resuscitation.
- Reassessment of the infant's heart rate, respiratory effort, pulse oximeter reading or color, and tone every 30 seconds during resuscitation is crucial to determine the next appropriate intervention. Apgar scoring should *not* be used to guide newborn resuscitation. Pulse oximetry in the delivery room should be used to guide oxygen therapy. Temperature of the infant should be monitored.
- If application of positive-pressure ventilation does not improve the infant's heart rate, chest compressions or drug therapy, or both, may be required. A team approach is needed to coordinate these interventions, and ongoing reassessment is necessary to determine cardiorespiratory and hemodynamic status. Subsequent assessment and treatment should be performed in an intensive care setting.

CURRENT THERAPY

- Term gestation infants who are breathing and crying with good muscle tone do not need newborn resuscitation.
- Initial resuscitation includes drying the infant, providing warmth, suctioning the mouth and nose, and giving gentle stimulation.
- If the infant is breathing vigorously but has central cyanosis, oxygen should be administered. Pulse oximetry should be used to guide oxygen therapy.
- If the infant is apneic, breathing slowly, or gasping, positive-pressure ventilation (PPV) with a mask and bag should be administered.
- If the infant's heart rate drops below 60 beats/min, chest compressions should be initiated using the two-thumb technique.
- If the heart rate remains less than 60 beats/min despite PPV and chest compressions, IV epinephrine (Adrenalin) should be given using an umbilical venous catheter.

should not be awakened during the episode. The event should not be referred to the next morning because this can cause distress for the child. Maintaining good sleep hygiene and regular sleep-wake patterns is important. If the events occur at a predictable time each night, the caregiver can do planned awakenings 30 minutes before the event typically occurs for several weeks. This may abolish the episodes. It can also have the effect of pushing the episode to later in the night. Pharmacologic treatment with a small dose of a benzodiazepine (e.g., 0.5 mg of clonazepam [Klonopin]¹ at bedtime) may be indicated in severe cases with the drug tapered slowly after episodes are suppressed.

Hypersomnias

A full discussion of primary hypersomnias (including narcolepsy) in children is beyond the scope of this chapter. Consideration for a primary hypersomnia should be made in a child who is sleepy after common causes of sleepiness such as insufficient sleep and obstructive sleep apnea have been ruled out. Symptoms of narcolepsy include disrupted nocturnal sleep, hallucinations on going to sleep or waking up, and sleep paralysis. Daytime sleepiness is present with "sleep attacks" both during quiet activities and while active. Cataplexy may also be present and is defined by loss of muscle tone without loss of consciousness. It should be noted that onset of narcolepsy is often in adolescence or as a young adult. Diagnosis is often delayed because the symptoms are attributed to other conditions. Treatment of pediatric hypersomnia is done under the supervision of a sleep specialist and often involves use of stimulants.

RESUSCITATION OF THE NEWBORN

Method of

Stacey A. Hinderliter, MD; and David Gregory, MD

CURRENT DIAGNOSIS

- The transition from intrauterine to extrauterine life at birth requires effective breathing by the infant to expand the lungs and oxygenate the blood. All newborn infants are at risk for delays in this process, prompting a need for resuscitation.
- The fetal and newborn response to hypoxia is to develop apnea. If primary apnea is diagnosed, it can be corrected by gentle stimulation and oxygen delivery. If hypoxia persists, secondary apnea will occur. It is not readily apparent whether a newborn has primary or secondary apnea, and the approach to resuscitation therefore requires that any apneic event be treated using the same sequence of interventions.
- The initial steps of newborn resuscitation include drying the infant, providing warmth, suctioning the airway, and providing gentle stimulation. Infants who do not respond to these interventions need more assistance. Establishment of effective ventilation spontaneously by the newborn or with assistance by positive-pressure ventilation is the most important step in newborn resuscitation.
- Reassessment of the infant's heart rate, respiratory effort, pulse oximeter reading or color, and tone every 30 seconds during resuscitation is crucial to determine the next appropriate intervention. Apgar scoring should *not* be used to guide newborn resuscitation. Pulse oximetry in the delivery room should be used to guide oxygen therapy. Temperature of the infant should be monitored.
- If application of positive-pressure ventilation does not improve the infant's heart rate, chest compressions or drug therapy, or both, may be required. A team approach is needed to coordinate these interventions, and ongoing reassessment is necessary to determine cardiorespiratory and hemodynamic status. Subsequent assessment and treatment should be performed in an intensive care setting.

CURRENT THERAPY

- Term gestation infants who are breathing and crying with good muscle tone do not need newborn resuscitation.
- Initial resuscitation includes drying the infant, providing warmth, suctioning the mouth and nose, and giving gentle stimulation.
- If the infant is breathing vigorously but has central cyanosis, oxygen should be administered. Pulse oximetry should be used to guide oxygen therapy.
- If the infant is apneic, breathing slowly, or gasping, positive-pressure ventilation (PPV) with a mask and bag should be administered.
- If the infant's heart rate drops below 60 beats/min, chest compressions should be initiated using the two-thumb technique.
- If the heart rate remains less than 60 beats/min despite PPV and chest compressions, IV epinephrine (Adrenalin) should be given using an umbilical venous catheter.

- Reassessment of the newborn every 30 seconds during resuscitation is required to adjust therapy as indicated. The best indicator of successful resuscitation is an increase in heart rate.

The changes that occur in the transition from fetus to newborn are unmatched in any other time of life. Most newborns manage to make this transition on their own, but about 10% require some assistance. Approximately 1% of newborns require extensive resuscitative measures to survive. The approach to resuscitation in infants is similar to that in adults, consisting of evaluation and intervention when needed for the infant's airway, breathing, and circulation. Every birth should be attended by personnel trained in neonatal resuscitation. Specific training and certification are offered by the American Academy of Pediatrics/American Heart Association's Neonatal Resuscitation Provider (NRP) course. This chapter has been updated based on the NRP 7th edition.

Transition from Fetal to Extrauterine Life

The environment of the fetus differs greatly from that of the infant after birth. The fetus depends on receiving oxygen and nutrients from the mother through the placental circulation. The fetus experiences relative hypoxia and almost constant body temperature in the amniotic fluid. The fetal lungs are filled with fluid and do not participate in the exchange of oxygen and carbon dioxide. Several adaptations in the fetus permit survival in this environment.

Oxygenated blood from the mother enters the fetus by means of the placenta through the umbilical vein. Most of this oxygenated blood bypasses the liver through the ductus venosus and enters the inferior vena cava. On entering the right atrium, this oxygenated blood is directed toward the patent foramen ovale into the left atrium, bypassing the fetal lungs. Fetal blood also passes through the right atrium into the right ventricle and then into the pulmonary artery. The vascular resistance and blood pressure of the pulmonary vessels in the fetal lung are higher than in the aorta and systemic circulation; most of the blood is therefore shunted away from the lungs through the ductus arteriosus into the ascending aorta. Only a small amount of fetal blood passes through the lungs to the left atrium and then to the left ventricle. The umbilical arteries branch off from the internal iliac arteries and return fetal blood to the placenta. The functional organ for gas exchange of oxygen and carbon dioxide in the fetus is the placenta.

At birth, the newborn is no longer connected to the placenta, and the lungs become the only source of oxygen. The first breaths of the infant cause the fluid in the lung alveoli to be replaced with air. The umbilical arteries and veins constrict at birth and are eventually clamped. This increases the vascular resistance and blood pressure of the systemic circulation. As the oxygen level in the alveoli increases, the blood vessels in the lung start to relax, decreasing pulmonary vascular resistance. Blood in the pulmonary artery travels toward the lung and away from the ductus arteriosus because the blood pressure in the systemic circulation is higher than that in the pulmonary circulation. Increased blood flow to the lungs allows the oxygen from the alveoli to enter the infant's blood, increasing the PO_2 . Oxygenated blood enters the left heart through the pulmonary vein and is delivered to the rest of the infant's tissues through the aorta.

Although the initial steps in this transition occur within a few minutes of birth, the entire process may not be completed for several hours to days. The ductus venosus, foramen ovale, and ductus arteriosus remain potentially patent and do not completely involute for days or weeks. Changes in the infant's systemic and pulmonary pressures can result in blood flow through these channels in the infant.

Transition can be prevented or delayed in several circumstances. The infant may not breathe adequately, in which case the lung fluid is not forced out of the alveoli. Material such as meconium may block air from entering the alveoli. If the lungs do not fill with air, hypoxia will quickly develop. Systemic hypotension due to excessive blood loss, poor cardiac function, or bradycardia prevents the change in the direction of blood flow that is necessary to promote

blood flow into the lungs. Failure of the lungs to expand or hypoxia can prevent relaxation of the pulmonary blood vessels, resulting in a high pulmonary vascular resistance. This leads to decreased blood flow to the lungs and worsening of hypoxia.

Risk Factors for Newborn Resuscitation

A number of prenatal and intrapartum factors are associated with a higher chance that the infant will have a delay in transition and require resuscitation (Table 1). However, some infants *with no risk factors* need resuscitation; therefore, preparations for neonatal resuscitation should be made during all deliveries.

Reaction to Hypoxia and Asphyxia

Normally at birth, the newborn makes vigorous efforts to breathe. The process of leaving the warm, dark, and liquid environment in utero is replaced by cold air, dryness, and bright lights. Drying the infant with towels and wiping the mouth and nose are all the assistance that most newborns require. The end result of any mechanism that delays transition is a period of hypoxia for the fetus or newborn infant. Laboratory studies have shown that the first sign of oxygen deprivation in the newborn is a change in the breathing pattern. After an initial period of rapid breathing attempts, cessation of breathing occurs. This is called *primary apnea*. Stimulation by drying the infant or slapping the feet can cause breathing to resume. If hypoxia continues after primary apnea has occurred, the infant will make attempts at gasping and then stop breathing. This is called *secondary apnea*. Stimulation does not affect secondary apnea. Assisted ventilation is necessary to provide breaths to the newborn to reverse the hypoxia. The infant's heart rate starts to decrease when primary apnea occurs. The heart rate increases with stimulation if the infant has primary apnea, and blood pressure is maintained. With continued hypoxia, the heart rate continues to drop, and hypotension develops. If assisted ventilation

TABLE 1 Risk Factors for Newborn Resuscitation

PRENATAL FACTORS	INTRAPARTUM FACTORS
Maternal	Placental
Diabetes, preexisting	Placenta previa
Chronic hypertension	Abruption of the placenta
Infection	Premature or prolonged rupture of membranes
Cardiac, renal, pulmonary, thyroid, or neurologic disease	Chorioamnionitis
Drug therapy	Fetal
Substance use	Macrosomia
Lack of prenatal care	Low birth weight
Age <16 or >35 years	Breech or other abnormal presentation
Previous fetal or neonatal death	Persistent fetal bradycardia
Pregnancy	Non-reassuring fetal heart rate patterns
Bleeding in second or third trimester	Labor
Pregnancy-induced hypertension	Premature labor
Toxemia	Precipitous labor
Gestational diabetes	Prolonged labor (>24 h)
Fetal anemia or isoimmunization	Prolonged second stage of labor (>2 h)
Polyhydramnios	Prolapsed cord
Oligohydramnios	Emergency cesarean section
Fetal hydrops	Forceps or vacuum-assisted delivery
Postterm gestation	Other
Multiple gestation	Meconium-stained amniotic fluid
Size-date discrepancy	General anesthesia
Diminished fetal activity	Narcotics given within 4 h of delivery
Fetal malformation or abnormality	Uterine hyperstimulation
	Severe intrapartum bleeding

is not adequate to increase the infant's heart rate, chest compressions will be required.

When a newborn becomes apneic, it is not readily apparent whether the infant has primary or secondary apnea. The approach to resuscitation therefore requires that any apneic event in a newborn be treated using the same sequence of interventions. If the apneic infant responds to simple stimulation, the diagnosis is primary apnea, and no further intervention is required. If the infant does not improve with stimulation, secondary apnea has occurred, and more intensive intervention is needed.

Sequence of Newborn Resuscitation

Initial Steps and Basic Resuscitation

Resuscitation of the newborn starts the rapid assessment of three characteristics: Is the infant at term gestation, does the infant have good tone, and is the infant crying and breathing? The answers to these questions will affect the approach to care. Resuscitation when fluid is meconium stained is discussed later in this chapter. The information presented here refers to term infants with clear amniotic fluid. More information regarding the care of premature infants is discussed in a later section.

The infant at term who is crying and breathing with good muscle tone does not need resuscitation and should not be separated from the mother. Current evidence suggests cord clamping should be delayed for at least 30–60 seconds for most vigorous term and preterm infants unless there is evidence of placental abruption or bleeding. The baby should be dried, placed skin-to-skin with the mother, and covered with dry linen to maintain temperature. Ongoing observation for breathing, activity, and color should continue while the infant is with the mother. If the infant is not term, is not crying and breathing, or does not have good muscle tone, newborn resuscitation should begin with the initial steps: providing warmth, positioning and clearing (if needed) the airway, drying and stimulating the infant.

The newborn should be placed under a radiant warmer to prevent heat loss and to allow easy observation. Although warm blankets or towels can be used to dry the infant, they should not be left in place to cover the infant. The newborn should be placed on the back with the neck slightly extended in the “sniffing” position (Figure 1). This facilitates air entry into the lungs by lining up the posterior pharynx, larynx, and trachea.

If the newborn is crying vigorously, secretions can be removed by wiping the nose and the mouth with a towel. Routine suctioning should be avoided. Gentle suctioning of the mouth and nose with a bulb syringe or suction catheter is *only* indicated when there is obvious obstruction to spontaneous breathing or when there is a need for positive-pressure ventilation. Deep or vigorous suctioning can be detrimental to the infant because of stimulation of the vagus nerve, causing bradycardia or apnea. The mouth should be

suctioned before the nose to prevent aspiration if the infant gasps during suctioning.

Drying the infant, slapping the feet, and rubbing the back are appropriate forms of stimulation. More forceful methods of stimulation can harm the infant. Primary apnea, if present, will respond to stimulation in less than 30 seconds. Prolonged apnea will require positive-pressure ventilation (PPV).

Evaluating the infant's response to resuscitation is essential. The Apgar score is a traditional method for evaluating newborn status at 1 and 5 minutes after delivery. However, effective resuscitation demands that evaluation of the newborn's status not be delayed until 1 minute of age, and Apgar scores therefore should *not* be used to guide resuscitative efforts. Within 30 seconds of delivery, the infant's need for PPV must be assessed. Establishment of effective ventilation spontaneously by the newborn or with assistance by PPV is the most important step in newborn resuscitation. The respiratory status, heart rate, and color or oximetry reading should be determined. The chest wall should move with each breath, and the newborn should be breathing spontaneously. Although heart rate can be assessed by feeling for a pulse at the base of the umbilical cord, this method can be unreliable. Auscultation with a stethoscope is the preferred method during initial resuscitation. The heart rate should be greater than 100 beats/min. Peripheral cyanosis (i.e., blueness of the hands and feet) is acceptable in the initial period after delivery. Central cyanosis in which the lips and trunk are blue indicates hypoxemia and the need for more resuscitation efforts. A pulse oximeter can provide continuous assessment of the oxygen saturation and is the optimal method for monitoring the infant's state of oxygenation. Pulse oximetry often displays lower heart rate readings during the first 2 minutes of life. Placement of 3-lead ECG as soon as possible to monitor the infant's heart rate during resuscitation may be beneficial. The initial steps of stabilization, reassessment, and establishing ventilation should be completed within the first minute of life (the “Golden Minute”). The oximeter probe should be placed on the newborn's right wrist or hand to detect preductal saturation. A pulse oximeter should be used to confirm the perception of central cyanosis. Temperature should be monitored during newborn resuscitation. The normal range is an axillary temperature of 36.5–37.5°C.

Respiratory Support and Positive-Pressure Ventilation

If the infant is breathing with a heart rate higher than 100 beats/min but has central cyanosis, free-flowing oxygen delivery is indicated. This can be administered with a facemask or by holding oxygen tubing or a flow-inflating bag and mask close to the infant's face. *A self-inflating bag and mask cannot be used to give free-flowing oxygen.* If the newborn is apneic, not breathing effectively, or has a heart rate less than 100 beats/min, PPV using a self-inflating bag, flow-inflating (or anesthesia) bag, or a T-piece resuscitator is required. Use of a flow-inflating bag requires a compressed gas source and considerable practice to be used effectively. A T-piece resuscitator needs special equipment and a compressed gas source. Most delivery rooms are equipped with self-inflating bags (Figure 2) because they are easy to use and can be fitted with a pressure-release valve to decrease overinflation. A reservoir must be used with a self-inflating bag to provide 100% oxygen.

Positive pressure ventilation (PPV) should begin using room air for term newborns. The facemask should cover the infant's nose, mouth, and tip of chin, but not the eyes (Figure 3). Multiple sizes should be available. A tight seal between the infant's skin and the facemask is needed, but excessive pressure can bruise the face. The mask can be held in place using the thumb and index finger in a C-shaped position on top of the mask, with the remaining fingers in an E-shaped position below the infant's chin (Figure 4). Inspiratory pressures of 20 to 25 cm H₂O are usually needed when squeezing the bag to make the infant's chest rise. A pressure gauge can be connected to the self-inflating bag for monitoring inspiratory pressure. The heart rate and color of the infant should rapidly improve if enough pressure is being given. An assistant can also use a stethoscope to listen to breath sounds for air movement. Breaths should be given at a rate of 40 to 60 breaths/min.

Figure 1 The sniffing position. Positioning the infant on the back with the neck slightly extended brings the posterior pharynx, larynx, and trachea in line (white line) to facilitate air entry into the lungs.

Figure 2 Self-inflating bag with infant mask and reservoir. This type of device is available in most delivery rooms.

Figure 3 Facemask. Choose a size that covers the infant's mouth and nose.

Figure 4 Facemask placement. The thumb and index finger are held in a C-shaped position on top of the mask, and the remaining fingers are held in an E-type position under the chin.

Traditionally, 100% oxygen has been used in newborn resuscitation. However, several randomized, controlled studies enrolling term and near-term infants have shown that room air can be used initially with oxygen as a backup if room air fails. A meta-analysis of these trials showed a benefit for the use of room air. Providing oxygen at concentrations between room air and 100% requires the use of compressed air, oxygen, and blenders by experienced personnel. A pulse oximeter with a probe designed for use in newborns can be used to guide oxygen administration during newborn resuscitation. It will take 1 to 2 minutes to apply the pulse oximeter

TABLE 2 Titrated Oxygen Saturations After Birth

1 minute	60-65%
2 minutes	65-70%
3 minutes	70-75%
4 minutes	75-80%
5 minutes	80-85%
10 minutes	85-90%

probe to the infant's right palm or wrist (preductal site) and get a consistent reading. The pulse oximeter may not function during states of very poor cardiac output or perfusion. In these situations, observation for central cyanosis will be necessary. The infant's oxygen saturation may remain in the 70% to 80% range for several minutes after birth. Oxygen may be titrated to the interquartile range of preductal saturations measured in healthy babies following vaginal birth at sea level (see [Table 2](#)). If blended oxygen is not available, room air should be used for resuscitation. If the infant's heart rate does not respond to positive pressure ventilation with room air after 90 seconds, 100% oxygen should then be used.

After 30 seconds of PPV, the infant should be reevaluated. Once PPV is started, an electronic cardiac monitor is the preferred method to measure heart rate. Ventilation with a bag and mask can be stopped when the newborn has a heart rate higher than 100 beats/min, spontaneous breathing, improved color, and good muscle tone. Supplemental oxygen should still be given to the infant. If the newborn is not improving, use the acronym "MR SOPA" to correct the technique of PPV: M=mask adjustment to check seal, R=reposition head in sniffing position, S=suction mouth and nose, O=open mouth with infant's jaw lifted forward, P=increase pressure up to 30-40 cm H₂O, A=consider using an alternative airway such as endotracheal (ET) intubation.

ET intubation is a technical skill that must be learned and practiced to maintain competency. Effective ventilation can be given with a bag and mask approach to most newborns. This skill is easily mastered and maintained. If an infant is responding well to bag and mask ventilation, it can be continued for longer periods; however, some air may escape into the esophagus and into the stomach. This may cause gastric distention, which can prevent full expansion of the lungs and cause vomiting and aspiration. An orogastric tube can be placed in the stomach and left open to air to vent any air introduced into the infant's stomach during bag and mask ventilation.

Chest Compressions

Before beginning chest compressions, intubation is strongly recommended to provide effective ventilation. After 30 seconds of effective PPV, the heart rate should be assessed. If the heart rate dips below 60 beats/min, chest compressions are needed to support the circulation. The two-thumb technique ([Figure 5](#)) is recommended. The two-thumb technique generates higher blood pressure and coronary perfusion with less rescuer fatigue. It can also be continued with the rescuer at the head of the bed if access to the abdomen is needed. If chest compressions are required, 100% oxygen should be given by PPV. Two people are required to give PPV and chest compressions effectively. To coordinate the breaths and chest compressions, three compressions are given followed by one breath, and this sequence is repeated to give the infant 90 compressions and 30 breaths/min. The thumbs are placed on the lower third of the infant's sternum but above the xyphoid process. The sternum is depressed to a depth of one third of the infant's anteroposterior chest diameter. The purpose of chest compressions is to squeeze the heart between the sternum and the spine, forcing blood in and out of the heart and to the body. The direction of the compressions should be perpendicular to the chest surface, and the thumbs should not be lifted off of the chest after the correct placement is obtained. Incorrect methods during chest compressions can cause rib fracture and liver laceration.

Figure 5 Two-thumb technique. The hands encircle the torso, and the thumbs are placed on top of the lower sternum above the xiphoid process and below a line drawn between the nipples (*white line*).

After 60 seconds of chest compressions, the infant's heart rate, breathing, pulse oximeter reading or color, and tone are reassessed. If the heart rate is higher than 60 beats/min, chest compressions can be stopped, although PPV may still be needed. If the heart rate is not improving, the following problems must be considered: ventilation is not adequate, 100% oxygen concentration is not being given, or the compressions may not be deep enough or well coordinated with the breaths. If the arrest is suspected to be of primary cardiac etiology, a compression ratio of 15 compressions to 2 breaths may be more effective.

Medications for Newborn Resuscitation

If the newborn heart rate remains below 60 beats/min despite 30 seconds of effective PPV and 60 seconds of chest compressions, epinephrine (Adrenalin) can be used to stimulate the newborn heart. Fewer than 2 of 1000 infants will require this step in resuscitation. *IV administration of epinephrine is preferred.*

A catheter can be quickly inserted into the umbilical vein for intravenous access. A 3.5 or 5 F catheter prefilled with saline and connected to a 3-way stopcock is inserted about 2 to 4 cm into the umbilical vein using sterile technique. After blood is aspirated, insertion of the catheter is stopped, and the epinephrine is given rapidly, followed by a saline flush. The concentration of epinephrine used in neonatal resuscitation is 1:10,000. The intravenous dose is 0.01 to 0.03 mg/kg (0.1 to 0.3 mL/kg) ([Table 3](#)). A dose of epinephrine may be considered through the ET tube during the umbilical vein catheterization process but there is no evidence of benefit. The ET dose of epinephrine is 0.05 to 0.1 mg/kg (0.5 to 1 mL/kg).¹ *These higher doses are for ET use only.* Because lung absorption of epinephrine varies, the intravenous route using the umbilical vein is preferred. The intraosseous route can also be used.

During umbilical vein cannulation, PPV and chest compressions are continued. More personnel will be needed to place the catheter

and draw up the medications and saline flushes. After an intravenous dose of epinephrine, the infant's heart rate, respirations, color or oximeter reading, and tone are reevaluated. The heart rate should increase to more than 60 beats/min. If the heart rate does not respond, the dose of epinephrine can be repeated every 3 to 5 minutes. The effectiveness of ventilation and compressions should be reassessed. If the infant appears pale, has delayed capillary refill, or decreased pulses, shock may be present. Infant blood loss might have occurred during delivery from placental problems or other sources. Administration of an isotonic crystalloid solution such as normal saline or Type O negative blood at 10 mL/kg over 5 to 10 minutes can improve circulation. Ringer's lactate is no longer recommended for newborns. Volume expansion should be used cautiously because there is evidence from animal studies for poorer outcomes when it is used in the absence of hypovolemia. Rapid infusion of large volumes has been associated with intraventricular hemorrhage in premature infants.

Newborns, especially premature infants, are at risk for hypoglycemia. Blood from the infant's heel or the umbilical vein can be tested at the bedside and intravenous 10% dextrose (2 to 5 mL/kg) given for low blood glucose. No specific glucose level has been associated with a poorer outcome. There is no evidence that use of sodium bicarbonate benefits the neonate, and its use during resuscitation in the delivery room is not recommended.

After resuscitation, newborns should be monitored in an intensive care setting. These infants are at risk for several complications, such as infection, metabolic abnormalities, and seizures. Infants of 36 weeks' gestation or older with moderate to severe hypoxic-ischemic encephalopathy may benefit from induced hypothermia under clearly defined protocols.

Special Considerations

Some newborns do not respond to resuscitation because of specific problems. Infants with upper airway obstruction from micrognathia can be helped by a nasopharyngeal airway and placement of the infant in the prone position. Choanal atresia can be treated by placing an oral airway. Absence of breath sounds on one side of the chest can indicate a pneumothorax, requiring needle aspiration of the chest. An infant with a scaphoid abdomen and decreased breath sounds may have a diaphragmatic hernia. These infants should be intubated, and PPV by mask and bag should not be used. If the mother has received narcotics shortly before the delivery, the narcotic may be the cause of respiratory depression in the infant. These infants need *PPV and respiratory support*. Naloxone is no longer recommended as part of initial resuscitative efforts in the delivery room. Heart rate and oxygenation should be supported by PPV.

Endotracheal Intubation

During neonatal resuscitation, endotracheal intubation may be indicated in the following circumstances: cases in which bag and mask ventilation is ineffective or prolonged, if chest compressions are performed, and in special situations such as congenital diaphragmatic hernia or extremely low birth weight infants.

TABLE 3 Drugs for Newborn Resuscitation

DRUG	CONCENTRATION	DOSE	INDICATIONS	COMMENTS
Epinephrine	1:10,000	0.01–0.03 mg/kg IV = 0.1–0.3 mL/kg IV route preferred 0.05–0.1 mg/kg ETT ¹	Asystole Bradycardia that does not improve with PPV and chest compressions Shock	May repeat every 3–5 min. No evidence for giving epinephrine via ETT.
Volume expanders	Normal saline O negative blood	10 mL/kg IV	Hypovolemia	Crossmatch blood to mother if possible Repeat if needed
Glucose	10% Dextrose	2–5 mL/kg IV	Hypoglycemia	Monitor glucometer or venous glucose levels

¹Not FDA approved for this indication.

Abbreviations: ETT = endotracheal tube; IV = intravenous.

Intubation of the newborn requires preparation that can be performed while the infant is being ventilated by bag and mask. The ET tube should not be placed unless the glottis is visualized by direct laryngoscopy. To ensure that the tube is in the trachea, a carbon dioxide (CO₂) detector should be used. Listening for equal breath sounds and looking for vapor condensation in the ET tube during exhalation can help, but an increase in the infant's heart rate or a positive detection of CO₂ is most reliable. It should be noted that poor or absent pulmonary blood flow may result in the absence of CO₂ detection despite tube placement in the trachea. The best indicator for effective ventilation is an increase in the newborn's heart rate.

Intubation should be performed as quickly as possible, with a goal of 30 seconds from insertion of the laryngoscope to the connection of the ET tube to the resuscitation bag. Complications of intubation include worsening of hypoxia and bradycardia, pneumothorax, contusions, perforation of the trachea or esophagus, and infection. After the infant has been intubated, deterioration in the infant's status should prompt an organized sequence to assess the adequacy of ventilation using the mnemonic DOPE:

Dislodged (D): Is the tube in the right bronchus or out of the trachea?

Obstructed (O): Is the tube obstructed by secretions or blood?

Pneumothorax (P) and esophagus (E): Is the tube in the esophagus?

An alternative to intubation for infants ≥ 34 weeks gestation and ≥ 2000 grams is placement of a laryngeal mask airway. This type of airway does not require laryngoscopy. A soft inflatable mask that is attached to a flexible airway tube is placed in the hypopharynx such that the air in the tube is directed into the larynx and away from the esophagus. However, this type of airway cannot be used to suction the trachea nor to give endotracheal drugs. Its use has not been evaluated during chest compressions.

Premature Infants

Infants born before 37 weeks' gestation are at increased risk for complications and the need for resuscitation. Premature lungs may lack surfactant, making ventilation difficult. Very low birth weight (less than 1500 g) infants will need additional warming techniques such as prewarming the delivery room, covering the baby in plastic wrapping, and placing the baby under a radiant warmer and/or an exothermic mattress; however, iatrogenic hyperthermia (axillary temperature $>38^{\circ}\text{C}$) should be avoided. Immature brain development may decrease the drive to breathe. Weak muscles make respiratory efforts less effective. Thin skin and decreased subcutaneous fat make temperature regulation a challenge. Premature infants often have infections such as pneumonia or sepsis. The blood vessels in their brains are fragile and can easily bleed during periods of blood pressure variation. The lower birth weights of premature newborns also require smaller sizes of equipment for resuscitation such as facemasks, suction catheters, endotracheal tubes, and umbilical catheters. Initial oxygen concentrations between room air and 30% should be used to protect the premature infant from oxygen toxicity. The use of continuous positive airway pressure (CPAP) in premature infants who are breathing spontaneously but with difficulty following birth may reduce the need for intubation, mechanical ventilation, and surfactant use. If PPV is needed, it is preferable to use a device that can deliver positive end expiratory pressure (PEEP). Many personnel trained in newborn resuscitation should be present at the delivery of a high-risk premature infant.

Meconium Staining of the Amniotic Fluid

Meconium is formed in the newborn gastrointestinal system during gestation. Intrauterine stress can cause release of meconium into the amniotic fluid. Aspiration of meconium-stained amniotic fluid into the lungs can result in severe pneumonitis and lung injury. The approach to resuscitation for an infant born in meconium stained amniotic fluid (MSAF) has been revised. There is no evidence that the consistency of meconium-stained fluid (i.e., thick or thin) has an effect on the outcome of the newborn.

Crying and Vigorous Infant

If the newborn born in MSAF has normal respiratory effort and muscle tone with a heart rate higher than 100 beats/min, *gentle* mouth and nose suctioning can be performed using a bulb syringe or suction catheter. Deep and prolonged suctioning should be avoided. ET intubation is not required for vigorous infants with meconium-stained amniotic fluid.

Nonvigorous Infant

Routine endotracheal intubation and tracheal suctioning is no longer recommended for nonvigorous newborns born in MSAF, however, the resuscitation team should include someone skilled in endotracheal intubation. If the newborn is gasping or apneic and has poor muscle tone, the initial steps of routine resuscitation should be started—provide warmth, dry the infant, position the airway, and provide gentle mouth and nose suctioning. If there is no response, PPV should be started using a bag and mask. If bag and mask ventilation is not effective, intubation should be performed. There is no evidence that suctioning the trachea of nonvigorous newborns born in MSAF prevents morbidity or mortality. It is possible that the main cause of meconium aspiration into the lungs is due to intrauterine fetal gasping.

Newborn Resuscitation Outside of the Delivery Room

Resuscitation of infants born at home, in an emergency room, in an ambulance, or otherwise outside of a delivery room setting should proceed according to the same principles as in the delivery room. Providing warmth, wiping the airway, and providing stimulation are usually adequate measures. Establishing effective ventilation using a bag and mask is the most important step if the infant fails to breathe on its own. Emergency providers should be familiar with resuscitation of the newborn, and basic equipment (Table 4) should be available.

TABLE 4 Equipment for Newborn Resuscitation

TYPE OF USE	EQUIPMENT
General	Sterile towels Radiant warmer or heat lamps Pulse oximeter Cardiorespiratory monitor Sterile gowns, gloves
Airway	Bulb syringe Suction catheters (5, 8, 10, 12, 14 F) Suction source with manometer Oral and nasopharyngeal airways (newborn sizes) Laryngoscope and straight blades sizes 0 and 1 Endotracheal tubes (sizes 2.5, 3.0, 3.5)
Ventilation	Face masks (premature, newborn, and infant sizes) Self-inflating bag (450–750 mL) with oxygen reservoir and manometer Oxygen source Orogastric tubes (8, 10 F) Carbon dioxide (CO ₂) indicator Chest tubes (8 and 10 F)
Circulation	Umbilical catheters (3.5 and 5 F) Umbilical catheter tray (sterile scissors, scalpel, forceps, umbilical tape) Three-way stopcock Syringes (1, 3, 5, 10 mL) No 88.5679 Normal saline Epinephrine 1:10,000 10% Dextrose

TABLE 5 Important Changes in Newborn Resuscitation based on Neonatal Resuscitation Program 7th edition.

1. Delayed cord clamping of 30-60 seconds is recommended for vigorous term and preterm infants.
2. Routine intubation and tracheal suctioning is no longer recommended for nonvigorous infants born in MSAF.
3. Positive pressure ventilation of term newborns begins in room air. For preterm newborns, oxygen should be started between room air and 30%.
4. Oxygen therapy should be titrated using pulse oximeter readings of the preductal oxygen saturation on the right hand.
5. The most important indicator of effective PPV is a rising heart rate.
6. Once PPV is started, an electronic monitor should be used to assess heart rate.
7. Intubation to provide effective PPV is strongly recommended prior to starting chest compressions.
8. The preferred technique for chest compressions is the two thumb method.
9. Epinephrine should not be given until after the infant has received 30 seconds of PPV that inflates the lungs and 60 seconds of chest compressions, and the heart rate is still <60 beats/minute.
10. Ringer's lactate is no longer recommended to treat hypovolemia during newborn resuscitation.
11. Temperature should be monitored during resuscitation with a goal of axillary temperature between 36.5°C and 37.5°C.

Withholding and Withdrawing Newborn Resuscitation

Newborns should be offered resuscitation at delivery except in extreme circumstances. Newborn resuscitation should not be used if the infant has a condition that is incompatible with survival, such as a confirmed gestational age of less than 22 completed weeks, birth weight less than 400 g, or congenital anomalies associated with certain death or extreme morbidity.

In most situations, initial resuscitation can provide time to observe the infant's response to interventions and to discuss the infant's condition with the parents. Techniques for obstetric dating of pregnancies are accurate only to ± 1 to 2 weeks, and estimates of fetal weight are accurate only to ± 100 to 200 g. Care must be taken before deciding to withhold resuscitation from a newborn. Ongoing conversation between parents and medical caregivers allows mutual decision making. Withdrawal of care is indicated if continued support is futile. After 10 minutes of asystole (heart rate of 0), newborns are very unlikely to survive.

TRAUMATIC BRAIN INJURY IN CHILDREN

Method of

Peter D. Patrick, PhD

CURRENT DIAGNOSIS

Acute:

- Comorbid medical complications.

Rehabilitation:

- Functional activities of daily living.
- Neuropsychological status.

Community:

- School-based/learning issues.
- Social learning problems.
- Neuropsychiatric disorders.
- Monitor for mood disorders/anxiety.
- Monitor for personality changes.

CURRENT THERAPY

Acute:

- Need for Level I trauma services.

Rehabilitation:

- Multidisciplinary team, organized rehabilitation program.
- Functional therapies for communication, self-care, and self-protection.
- Organized comprehensive rehabilitation program.
- Neuropsychological baseline assessment.
- Cognitive remediation.
- Neurobehavioral monitoring.

Community:

- Psychoeducational assessment.
- Group participation/socialization opportunities.
- Longitudinal neuropsychological or neuropsychiatric monitoring.

Epidemiology and Risk Factors

Pediatric traumatic brain injury (TBI) has been called the "silent epidemic." Each year TBI accounts for more mortality and morbidity in children from birth to young adulthood than any other childhood illness or disease. TBI accounts for more deaths, emergency department visits, and hospitalizations than any other disorder confronting children and teenagers. According to the Centers for Disease Control and Prevention, children from birth to 4 years of age and adolescents from 15 to 19 years of age represent the highest-incidence groups. Children from birth to 14 will account for 473,947 emergency department visits. Of these visits, approximately 35,000 will be hospitalized and over 2000 will die. With age comes the higher likelihood (percentage) of a death resulting from TBI, with the senior citizen population most at risk. Between 2002 and 2006 children 0 to 4 years had the highest rate of TBI with approximately 1300/100,000, with teenagers second with approximately 800/100,000. The rate of TBI then declines until ages 60 to 65 where there is once again an increase in emergency department visits. Males tend to outnumber females at all three peak episodes. By comparison, TBI causes 6 times the death rate of HIV/AIDS, 20 times the death rate of asthma, and 38 times the death rate of cystic fibrosis.

Causes of TBI vary over the life span. During infancy and early childhood falls are the number one cause, followed by "be struck by/against," and then automobile accidents. According to current statistics, infants and preschool infants incur the highest rate of TBI due to abuse and inflicted injuries. During the adolescent years

TRAUMATIC BRAIN INJURY IN CHILDREN

Method of

Peter D. Patrick, PhD

CURRENT DIAGNOSIS

Acute:

- Comorbid medical complications.

Rehabilitation:

- Functional activities of daily living.
- Neuropsychological status.

Community:

- School-based/learning issues.
- Social learning problems.
- Neuropsychiatric disorders.
- Monitor for mood disorders/anxiety.
- Monitor for personality changes.

CURRENT THERAPY

Acute:

- Need for Level I trauma services.

Rehabilitation:

- Multidisciplinary team, organized rehabilitation program.
- Functional therapies for communication, self-care, and self-protection.
- Organized comprehensive rehabilitation program.
- Neuropsychological baseline assessment.
- Cognitive remediation.
- Neurobehavioral monitoring.

Community:

- Psychoeducational assessment.
- Group participation/socialization opportunities.
- Longitudinal neuropsychological or neuropsychiatric monitoring.

Epidemiology and Risk Factors

Pediatric traumatic brain injury (TBI) has been called the "silent epidemic." Each year TBI accounts for more mortality and morbidity in children from birth to young adulthood than any other childhood illness or disease. TBI accounts for more deaths, emergency department visits, and hospitalizations than any other disorder confronting children and teenagers. According to the Centers for Disease Control and Prevention, children from birth to 4 years of age and adolescents from 15 to 19 years of age represent the highest-incidence groups. Children from birth to 14 will account for 473,947 emergency department visits. Of these visits, approximately 35,000 will be hospitalized and over 2000 will die. With age comes the higher likelihood (percentage) of a death resulting from TBI, with the senior citizen population most at risk. Between 2002 and 2006 children 0 to 4 years had the highest rate of TBI with approximately 1300/100,000, with teenagers second with approximately 800/100,000. The rate of TBI then declines until ages 60 to 65 where there is once again an increase in emergency department visits. Males tend to outnumber females at all three peak episodes. By comparison, TBI causes 6 times the death rate of HIV/AIDS, 20 times the death rate of asthma, and 38 times the death rate of cystic fibrosis.

Causes of TBI vary over the life span. During infancy and early childhood falls are the number one cause, followed by "be struck by/against," and then automobile accidents. According to current statistics, infants and preschool infants incur the highest rate of TBI due to abuse and inflicted injuries. During the adolescent years

motor vehicle accidents are first, followed by assaults. Likelihood of death from a TBI also rises with age, with the senior citizen most likely to die from a TBI. Although automobile accidents are the leading cause of death due to TBI, falls overall contribute to the highest number of emergency department visits. From 2002 to 2006 there was an increase in emergency department visits due to TBI overall and more specifically there was an increase in fall-related TBIs in children 14 years of age and younger. The literature would also suggest that the earlier the injury, the more significant the mortality and morbidity. Children and infants who suffer moderate to severe TBI not only have neurologically confirmed injury to the brain but also lose the opportunity of experience and education that are important in the development of overall brain function. Based on Levin's 1992 study, children from birth to 4 years have the lowest survival rate and highest morbidity, followed by 11- to 15-year-olds. Interestingly, the children injured from 5 to 10 years of age tended to have better survivor rates over the first year, and also may have less morbidity.

Pathophysiology

Pediatric brain injury is made up of a heterogeneous array of injuries that can be classified according to severity, location, and nature of insults, with each injury existing within the context of a person's array of premorbid characteristics and talents. Some insults to the brain are localized/focal (hematomas, ischemia) and others are diffuse/generalized (hypoxia, diffuse axonal injury). Physiologic changes from TBI include alterations in metabolism and changes in energy consumption. The scope of injuries can range from alteration in anatomic structures to the alteration in physiologic functioning at the microscopic level.

Structural changes at the time of injury are due to the biomechanics of blunt trauma to the head and/or acceleration/deceleration shear forces. The child's, especially the very young child's, biomechanics are magnified due to head-to-body size ratios, as well as lack of neck and shoulder girdle strength. In addition, the child may be more vulnerable to "rotational forces" that have been associated with greater likelihood of unconsciousness. Resulting changes include immediate and delayed/prolonged edema. Intracranial pressure is a significant result of edema, as well as inflammatory response, which sets up the conditions for brainstem herniation. In addition, supporting blood vessels and glial cells are compromised. Blood vessel compromise can lead to hemorrhagic events or subdural and subarachnoid hematomas (which can be fast or slow developing). Hydrocephalus or isolated compromise to cerebrospinal flow can also be more immediate or slow to develop.

Microscopic and secondary injury is associated with the alteration in cellular environment. Cytotoxic cascade includes excessive neurotransmitter release (e.g., glutamate cascade) or "neurotransmitter storm," as well as alteration in electrolyte balances, magnesium, sodium/potassium balance, and calcium influx. Furthermore, there is an "energy crisis" in the brain based on reduction/compromise in oxygenation/perfusion rates, as well as metabolic changes, resulting in both hypoglycemic and hyperglycemic episodes. The microscopic crisis taking place can extend the primary injury over hours and days and set up the conditions for further cell injury and/or cell death.

Clinical Manifestations and Diagnosis

The clinical picture of injury is dictated by severity, location, and nature of the brain injury, as well as presence or absence of multiple trauma. The clinical picture in moderate to severe injuries is an unfolding presentation that starts prehospital and continues through return to home and community.

Acute Trauma Care

During the acute phase the primary goals are to preserve life and prevent/minimize secondary injury. Moderate to severe TBI can directly and indirectly affect every organ system of the body negatively. Trauma services with emphasis on managing intracranial pressure, monitoring for herniation, and maintaining

oxygenation/perfusion rates to vital organs/brain are all seen as contributing to improved outcomes. In some children surgical intervention for evacuation of hematoma, decompression, and/or managing hydrocephalus are important in effecting long-term outcomes. In addition, addressing seizures, hypoglycemic and hyperglycemic episodes ("energy crisis"), and hyponatremia and anemia are equally important. Anti-inflammatory management, including steroid treatments, and hypothermia have been used effectively, and the literature continues to grow regarding their utility and impact. Management of hyperglycemic episodes is important and is associated with improved outcomes. During acute care, seizure management and other comorbid conditions are addressed as the team works toward establishing medical stability. This is especially true for children with multiple traumas. In addition to addressing structural lesions and injury, the trauma team prevents secondary injury by addressing physiologic changes at the microscopic level. Managing sodium/potassium balance and calcium levels has become a part of managing secondary injury, which is also addressed by reducing free radical and excitotoxicity ("glutamate cascade"). The role of adenosine metabolite has become more understood as a possible "retaliatory metabolite" against cytotoxic reaction. Adenosine levels appear to be higher in children and especially in severely injured children. The pediatric intensive care unit then takes over, further addressing primary injuries, preventing secondary injuries, and further supporting a road back to medical stability.

During the acute phase, measures that are associated with later outcomes are (1) length of unconsciousness (Box 1), (2) Glasgow Coma Scale scores, and (3) measures of posttraumatic amnesia. Disorders of consciousness applies to those children with prolonged low-response states that include coma, vegetative state, and minimally conscious state. Although no one instrument is available for the infant with a disorder of consciousness, the Coma-Near-Coma Scale, Coma Recovery Scale, and Western NeuroSensory Profile have all been used with children to serially assess the slow to recover.

The Glasgow Coma Scale for Infants and Children is composed of a score for each of three domains (Table 1): eye opening, best verbal response, and best motor response. In younger children their ability to communicate and respond to instructions requires a modified reading that includes response to consoling and use of facial grimace in place of the older child's ability to talk and respond to instruction. Based on the total score of 15, 3 to 8 is severe, 9 to 13 is moderate, and 14 to 15 is mild.

As a neuropsychological marker associated with severity of cognitive injury, the serial assessment of posttraumatic amnesia (PTA) has been used. Following the lead from adult literature, the Children's Orientation and Amnesia Test (COAT) was published and is composed of 16 items that assess orientation, temporal orientation, and memory for children 3 to 15 years old. At the younger age temporal orientation items may not be age appropriate so a prorated score can be used. An early study by Ewing-Cobbs concluded that the COAT was a better predictor of verbal and nonverbal memory skills at 6 and 12 months after injury than the Glasgow Coma Scale. In a related study the number of days until a score of 75% accuracy was reached further strengthened the prognostic powers of the COAT when assessing neurocognitive return. Even the use of the COAT in later stages of recovery has been positive. A 1994 article by Iverson and colleagues found that the COAT score was associated with special services in school and rating the student as "impaired."

BOX 1

Length of Unconsciousness

Mild	15–30 minutes
Moderate	15 minutes–24 hours
Severe	1–90 days
Profound	90 days or longer

TABLE 1 Glasgow Coma Scale

EYE OPENING		VERBAL RESPONSE		MOTOR RESPONSE	
Spontaneous	4	Infant and young child Oriented to sound, visual stimuli; interacts	Older child/adolescent Oriented to person, place, and time	5	Normal spontaneous movement/follows commands
To verbal or touch	3	Cries but consolable	Converses but may be confused	4	Withdraws to touch
To painful stimuli	2	Inconsistent consolable, moaning	Replies with inappropriate words	3	Withdraws to pain
None	1	Inconsolable, agitated	Makes incomprehensible sounds	2	Flexion to pain
		None	None	1	Extension to pain
				None	1

Medical Aspects During Inpatient Rehabilitation

Once medically stable and the child's survival is established, most children with moderate to severe TBI will move on to inpatient rehabilitation. The new focus will be around skill reacquisition, remedial care that strongly emphasizes mobility (physical therapy), activities of daily living (occupational therapy), and communication (speech/language therapy). In addition, neuropsychological monitoring will continue and cognitive return will be monitored. However, there continues to be a significant need for medical intervention that addresses primary problems (e.g., spasticity, seizures) and secondary/comorbid (e.g., fractures) medical conditions. Delayed seizure onset is of particular importance given that seizure onset can occur over the next 2 to 5 years of life. The younger child is reportedly more vulnerable to seizure onset. During inpatient rehabilitation the therapists begin to address relearning skills while the medical team addresses medical and health care needs (Table 2).

Differential Diagnosis and Interventions

During inpatient and outpatient rehabilitation, sensory/motor deficits continue to be addressed. However, over time with moderate to severe TBI neurocognitive and neurobehavioral issues require diagnostic attention and services. Medical and health monitoring continues throughout recovery and ongoing professional assessments are indicated. The role of neuropsychologists, educators, and mental health professionals increases as medical stability and acute/emergent health issues resolve.

Neurocognitive Consequences of TBI

We now know that changes in mental skills for problem solving, learning, and adaptive skills can be transient or enduring consequences of TBI in children. Mental support skills such as attention/concentration, processing speed, mental fluency, and working memory can all be affected and in some cases in spite of preserved intellectual skills. Some children will demonstrate an acquired form of attention-deficit/hyperactivity disorder (ADHD) called secondary attention-deficit/hyperactivity disorder (SADHD). In addition to being inattentive, the child will present as impulsive and hyperactive, thereby meeting the diagnostic criteria for ADHD. Preinjury characteristics can contribute to risk factors for SADHD. Also, unlike primary ADHD, SADHD typically occurs within the context of other cognitive and neuropsychological difficulties. Treatments include environmental management, cognitive remediation, and use of psychostimulant medications (however, there is a lack of clinical trials in children with TBI).

We also know that memory deficits are common. Early assessment and monitoring of retrograde and posttraumatic amnesia has become standard even in the young child. Resolution of PTA is a milestone in recovery, setting the stage for cognitive return. Short-term memory deficits in some children and historical memory deficits can persist beyond the inpatient hospitalization. The disturbances in memory make new learning difficult if not impossible. Consequently, over time not only does the child struggle with memory limitations, but also suffers the consequences of poor achievement of basic educational skills and knowledge due to poor learning. The natural course of memory disorder starts with early assessment of retrograde amnesia and serial assessment of PTA. As the amnesia resolves and/or shrinks the child is left with a permanent loss of recall for specific events surrounding the injury. Many times the child will have a disturbance to short-term memory recall, with retrieval error and lesser decline in historical memory (although in severe injuries there can be a loss of historical memory, and more specifically memory of personal history). Global memory disturbance is less likely; instead, more specific changes in domains of memory may occur, such as auditory/verbal short-term memory or visual/perceptual short-term memory. Typically the memory disorder is characterized by poor storage and retrieval of main ideas and details. Those factors appear to benefit from cueing and prompting techniques in order to assist recall.

Children on examination can have an array of information processing deficits that, on examination, profile much like verbal or nonverbal learning disability. In most children the learning disability occurs in parallel to difficulties with mental support skills, memory, and behavior problems. In particular, delayed expression of neurocognitive difficulties may not be symptomatic until operational or computational skills are required. Therefore it is not uncommon for moderate or even severe brain injuries to only

TABLE 2 Common Medical Aspects to Moderate/Severe TBI during Rehabilitation

REVIEW BY SYSTEMS	CONDITIONS
Neurologic	Seizures, pain, hydrocephalus, movement disorders
Respiratory	Tracheotomy care
Cardiovascular	Autonomic instability/"storming"
Fluid, electrolytes, and nutrition/gastrointestinal	Nutrition
Head/eyes/ears/nose/throat	Neuro-ophthalmology examination, vision, hearing acuity disorders
Hematology	Deep vein thrombosis prophylaxis

Genitourinary	Incontinence
Skin	Decubitus ulcers
Psychiatric	Delirium, agitation, depression, anxiety, neurobehavioral disorders

become symptomatic at the time of school entry or when particular types of social learning challenges arise. Unfortunately, the emergence of late TBI effects, especially in moderate injury, may not be associated with the antecedent TBI. The symptoms may be inaccurately diagnosed resulting in misguided interventions.

Complex reasoning is frequently affected due to poor mental organization skills, lack of ability to sequence information, and poor mental abstraction skills. Also, in addition to specific compromise within learning domains, the child's "mental support skills" can be limited and have a more global impact on problem solving. For example, poor processing speed, poor working memory, and limitations in mental fluency can all undermine preserved and at times average intellectual skills following injury.

Executive, self-guiding skills are among the most complex of injuries. Poor goal maintenance and limits in initiation, persistence, and follow-through can be severe. Also, the child's loss of age-appropriate self-control and inability to set problem-solving strategies or maintain mental set contribute to both academic and social learning problems (Figure 1).

Neurobehavioral/Neuropsychiatric Limitations following Moderate and Severe TBI

"Socialization behavior is the supreme achievement of the cortex."

—Floyd Allport

In 1978 Muriel Lezak brought to light the "characterological alterations following traumatic brain injury." She made clear that alterations in complex behaviors, temperament, and personality could be direct sequelae of TBI and not a reaction to or premorbid characteristics of the person injured. With this came a greater appreciation that TBI alters who people are. Children also suffer these changes in "nature" (personality/temperament). Changes in behavior and "nature" limit successful social reentry and result in the child's being marginalized and excluded from group membership. Ultimately the changes in conduct disqualify full participation as a citizen. These changes included impaired social perceptiveness, impaired capacity for self-regulation (limited reflective thought,

limited self-critical capacity, stimulus-bound behavior), emotional alterations (apathy, silliness, lability, irritability, altered libido), and the inability to profit from learning (poor use of feedback). Prigatano in later years published a report regarding changes in conduct due to "frustration and limitations" versus changes due to neurologic injury.

In 2001 Max and colleagues studied a sample of 94 children 5 to 14 years of age. These children were diagnosed with mild/moderate (57) and severe (37) TBI. Personality changes were reported in 59% of those with severe TBI (22/37), but in only 5% of those with mild/moderate TBI (3/57). Children with severe TBI were most likely to have the "labile subtype" (49% of severe), with aggressive (38%) and disinhibited (38%) most likely next and apathy subtype at 14%.

A follow-up study looked at predictors of personality change in children and adolescents. The report concluded that severity of injury predicted the initial changes in personality and that preinjury adaptive skills predicted changes in the second year after injury. There were also findings to magnetic resonance imaging (MRI) localization of injury. The study revealed that lesions of the

superior dorsal lateral frontal gyrus were associated with personality changes taking place from 6 months to 1 year after injury. Changes in the second year were more closely associated with lesions of the frontal white matter.

Interventions

Treatment intervention for the array of cognitive changes includes cognitive remediation and special education services. Cognitive remediation is an instructional intervention that attempts to isolate specific skills and then practice, strengthen, and/or restore them. These efforts depend on the brain's ability to compensate, learn, and utilize underlying inherent plasticity. Review of the literature on cognitive remediation has evolved, but it is still in need of investigation for the young and very young child with TBI.

Currently the literature supports cognitive remediation for mild memory disturbance and recommends compensatory training for more severe forms of memory disturbance. Severe forms of memory disorder have been studied regarding psychopharmacologic

intervention (e.g., donepezil/Aricept¹) in children and adults. There is class II support for attention retraining, and auditory processing training is frequently mentioned. Disorders of executive function have been addressed programmatically with multimodal techniques, including social discourse training, coupled with cognitive remediation and neurobehavioral care. Specific programmatic elements include self-managing skills, goal setting, and strategic problem-solving skills for social transactions. Feehey and Ylvisaker's work has greatly contributed to the positive behavioral intervention strategies used across multiple environments. The works of Lucia Braga (Brazil) and Jennie Ponsford (Australia) included family training and education, which appeared to greatly improve outcomes.

Mental Health Services

Psychotherapy

Traditional modes of counseling and psychotherapy may need adaptation, due to cognitive and communication limitations. Emphasis on complex skills that require self-reflection, self-assessment, and the ability to identify deficits may not be available for therapy either due to developmental appropriateness of these skills and/or due to consequences of brain injury. Also, social discourse skills may not be strong enough to support maximum participation in counseling or psychotherapeutic exchange. In addition, impulsivity and adynamic/areactivity (poor initiation, persistence, and follow-through) can undermine full participation in psychotherapy. It is not uncommon for there to be a need for "precounseling" training that addresses needed cognitive and emotional skills in order to participate in counseling/psychotherapy.

Medications

Much of the literature about medications following TBI is in the adult population. There is no level I class evidence for children or the very young. However, increasing interest and research over the past 5 to 10 years has explored the relationship between recovery in children and medication use. In general, case studies, retrospective studies, and small observational trials have begun to explore effectiveness/safety and what the rules of application would look like with children following TBI. Currently medications are typically used off label to address arousal, agitation, cognitive impairment, and depression/anxiety. Impaired arousal has focused on the use of dopamine agonist agents (e.g., amantadine [Symmetrel],¹ methylphenidate [Ritalin],¹ bromocriptine [Parlo-del]¹), and for a small group of individuals with impaired arousal omega-1 specific indirect GABA agonists (e.g., Zolpidem [Ambien]¹), has been investigated. Based on current reviews, most of the attention to address disorders of consciousness in children has focused on dopaminergic functioning. Intrathecal baclofen [Lioresal]¹ has been reported to have clinical benefit.

The medications for agitation have included benzodiazepines, beta-blockers (e.g., propranolol [Inderal]¹), some antidepressants (selective serotonin reuptake inhibitors [SSRIs]) and second-generation antipsychotic agents (e.g., risperidone [Risperdal]¹), and even anticonvulsant agents (e.g., valproic acid [Depakene]¹). Anxiety and depression have been treated with SSRIs in children (with some indication of increased side effects and tendency toward activation). In general with children, older tricyclic medications are not as effective and have a more negative side-effect profile. In the area of cognitive enhancement the dopamine agonists have been again included but acetylcholine agonists (e.g., nACh-r) have also been explored, including donepezil (Aricept).¹ Much still needs to be learned regarding use of psychotropic agents with this population of children. However, increasing effort and resources are being committed to the safe exploration of agents and possible uses with children.

Educational Service

The child with TBI presents a unique combination of learning problems, behavior problems, and emotional reactivity. Poor reading, writing, and arithmetic skills, as well as poor communication skills, all undermine speed of learning and the rate, pace, and load of academic challenge the child can tolerate. Unique disturbances to memory skills are most noteworthy, wherein short-term memory problems, difficulty encoding, and retrieval of new learning add to the poor achievement. Although special education services provide remedial services, there is also a significant need to manage educational exchange between child and instructor. In particular, there is a need for guiding and supporting positive instruction, utilizing strengths, and compensating for limitations in order to make best use of existing skills while remedial services progress. Behavior management programs that focus on improving social discourse, pragmatic language, and communications would be most beneficial to establish positive and productive exchange between student and instructor.

At an organizational level, improved communication and synergy of action between medical/rehabilitative community and educational institutions is important. Savage and DePompei recommended the following: (1) Involve the special education and school-based team in the hospital or rehabilitation center. (2) Train all school-based staff who will have contact with the child with TBI. (3) Plan for the short- and long-term support and services needed. (4) Continue follow-up and coordination with the rehabilitation team.

Family Reentry

Successful return to home and community depends on multiple factors. Both clinical and nonclinical factors play a part in success. There are child-specific factors, family-specific factors, and community-specific factors. Return to an increasingly more complex array of challenges marks recovery. As changes in the environment and demands increase, secondary mental health issues emerge for the injured as well as the family members.

Child-Specific Factors

Reentry to home and community is a major milestone in recovery. Successful reentry is due to an interaction of child-specific factors, family-specific factors, and community-specific factors. Child-specific factors include the severity of cognitive changes. More important, family and educators report changes in behaviors, personality, and emotional regulation that mostly disqualify children for participation opportunities. Prigatono reported that changes in personality/behaviors in part are due to the child's reaction to limitation and loss of function. He suggested that irritability, increased distress, and increased sensitivity to distress that affects the child's psychological resilience may contribute to the "catastrophic reaction" (Goldstein, 1952). The child's neuropsychological profile of poor awareness of deficits, poor episodic dyscontrol/aggression/anger, and emotional lability are neurobiologic factors that negatively affect participation. In some children the inability to initiate, lack of persistence, and lack of follow-through create an adynamic/areactive profile that also undermines participation.

Family-Specific Factors

Family-specific factors include health of remaining members of the family, family style of coping, patterns of communication, and available resources (financial, social resources) and innovativeness. Characteristics that appear to predict positive family outcomes include the family's resilience and preinjury traits. Higher levels of communication, expressiveness, and role flexibility and a greater orientation to activities are all associated with successful return home. Low levels of family control also appear to be related to positive outcomes. Other factors predicting a successful living environment include age of injury (younger children more successful), similarity to preinjury living environment, time after injury, and family educational level, as well as current monthly income.

Community-Specific Factors

Community-specific factors are also important in supporting and encouraging social participation. For example, how good is the

¹Not FDA approved for this indication.

community at recognizing the needs of children with TBI? Can the community provide a pattern of support beyond the family's ability? Can the community provide "meaningful activities"? Do community members sponsor group membership and help "bring children into the group"? And ultimately, how does the community support full citizenship as much as it is possible for the individual with TBI?

Pediatric Concussion

In more recent years there has been increasing interest and need to learn more about concussions in children. It appears that incidence rates have increased and/or concussions have increasingly been reported in clinical practice. During the young and very young years, males and females appear to be equally represented. During preadolescent and adolescent years there is a shift toward a higher incidence in males. With increased awareness of the long-term consequences of concussion and more female athletes being active, older male and female athletes are equally represented. There is some literature supporting differences in the clinical presentations, magnitude, and time line of symptoms between males and female athletes.

The cause of concussion can vary by age, despite similar clinical presentation. Younger children and the very young may present after a fall or auto accident. While somewhat less well studied, children of all ages can present after a violent or inflicted injury. Older children, preadolescents, and teens are exposed to more sports-related concussions, yet other etiologies persist, with auto accidents being associated with the more severe head injuries.

Myths

Prior beliefs about concussions have been challenged. For example, many concussions are not associated with loss of consciousness. In fact, many children report alterations in consciousness which can range from minor/major disorientation and/or immediate and delayed confusion and difficulty with memory. Frequently the most prominent features of a concussion are alterations in cognitive function and/or alteration in temperament and behaviors. For example, children may be irritable, emotional, moody, anxious, depressed, forgetful, or tired.

Another myth is that there must be clinical or focal signs on neurologic examination. Not only does this belief not hold true but frequently there are no findings on clinical examination and with further testing there may not be positive findings on computed tomography or MRI. Probably the greatest myth is that it is important for the child to get right back into a daily routine. In fact, return to usual daily activities should follow a graded and individually timed increase in level of activity, maintaining a symptom-free state at each level.

Defining the Problem

The operational definition of concussion has proven to be difficult but has the following characteristics. Concussion is a rapid onset condition caused by an impact effecting the head, neck, or other part of the body. A fall, a blow to the head, or an identified sports-related injury all carry the potential of resulting in a concussion. The quick onset produces alterations in behavior (irritability), cognitive functioning (forgetfulness), sensory-motor functioning (balance, sensory hypersensitivity), and psychophysiologic functioning (sleep disturbances, circadian rhythm changes). Typically, concussion is associated with pathophysiologic changes that effect energy systems of the brain and may not include structural changes to the brain. Typically, with supportive care, concussion is finite with a beginning, middle, and end over the course of 1 to 2 weeks. While there is a small proportion of children/adolescents with symptoms of concussion at 30 days, an even smaller portion of concussions will be more persistent. The later represent a complex form of injury and recovery that in the past has frequently been referred to as "post-concussion syndrome." In each case, there are modifying factors that should be considered when making a diagnosis. Is there a history of repeated concussion? Were previous concussions close together or years apart? Are there comorbid

factors that conflate with concussion (i.e., depression, learning disability, medical comorbidity, ADHD)? Are there differences in the type of event that preceded the concussion (high impact sport vs. low impact event)? Was the loss of consciousness prolonged? Did the individual suffer retrograde versus anterograde amnesia?

Collateral Tools for Identification

More aggressive medical examination is required for children with worsening symptoms, suspicion of structural changes due to presence of focal neurologic signs on examination, or having had a prolonged alteration in consciousness. As of yet, no valid, reliable biomarker of concussion is presently in use. Research is being conducted on a number of possible biomarkers (e.g., S-100, IGF-1, nerve growth factor etc.). Electrophysiologic studies have not proven reliable or valid though cortical magnetic stimulation and evoked response potential (ERPs) show some promise. Consequently, the diagnosis of concussion remains a clinical assessment with multiple rule-outs.

In addition to clinical examination, there a number of other tools to help with the diagnosis. Symptom checklists by self-report and parent/teacher report are useful observational tools.

These tools are particularly useful for assessing symptom presentation across environments outside the clinical examination suite. Use of computer-based neurocognitive testing has been routinely used in sports medicine (e.g., ImPact). Formal neuropsychological examination has been used for children and adolescents, especially when there is a complicated recovery and/or need for assistance on returning to school and meeting academic demands. With young and very young children, reporting symptoms may be difficult. Younger children may lack adequate verbal skills to self-report and instead demonstrate their symptoms behaviorally, or with increased somatic complaints such as headaches and body aches. Children and adolescents with premorbid cognitive, mental health, and medical conditions may warrant more formal examination given the interaction of the comorbid conditions with the concussion.

Return to Activities

Return to activities has proven to be a clinically determined path. The balance between rest and activities should be individualized and requires a surveillance and monitoring system which can be time and labor intensive. The goal is to attain a symptom-free gradual increase in activities. Many symptoms are subjective which makes it challenging for the clinician to assess. The use of objective markers along with symptom reports is a useful approach. The combination of clinical system review and patient, family, and teacher reports of behaviors is the most commonly used approach.

A good rule is having a successfully return to school precede the return to sports. The gradual return to play should follow a successful graded return to academic challenges. Overall a gradual return to physical activity is recommended. Either too much or too little activity, especially during initial phases of return, is negatively associated with outcomes. There are developmental differences in the management of the return to usual activities. Young and very young activities are more likely to be under parental control and supervised, while the older child and/or adolescent may have less supervision. Management of the return to activity for older children/adolescents has to be collaborative and requires more systematic contracting and agreement. Taking the time to have the older child/adolescent provide consent to cooperate with the plan is recommended.

While graded return to activities is agreed upon, the specifics for each individual child may vary. Most of the current research has been centered around graded activity with return to sports. In 2013, Halstead et al. specifically addressed this in an article titled, "Clinical Report: Returning to Learning following a Concussion." The authors discuss mobilizing school-based resources (e.g., 504 Plan, Individual Educational Plan, individualized health care plan). Written plans may help guide the child/teen on increasing participation in school. Use of these various instruments varies depending on state law, resources, and the nature of cooperation between the medical, family, and school systems. However, all are supported by

federal law as viable instruments to help children. While much of the monitoring and testing for return to activity has been centered around sports activities, the authors point out the need to focus on the relationship between symptoms and level of cognitive activity/participation. For example, poor sleep impacts on memory, concentration, and cognitive endurance and headaches impact on attention/concentration. As with sports activity, the demand on the brain to perform and participate in purely cognitive activities can be problematic. A concussion may strain the child's ability to handle the pace, rate, and load of cognitive demands. A rule of thumb is that a *successful return to school should precede a return to sports*. Return to school should include serial monitoring through use of symptom checklists, interviews, and/or observation. A well thought out surveillance plan of the child's expression of symptoms compared to his or her level of participation serves to guide clinical decision making.

Strategies to guide school reentry requires the interface and coordination of the medical team and the educational team. While this can be time and resource demanding, the collaboration must be given some priority and support and requires family participation. The majority of concussions which resolve within a 3-week window are best addressed by classroom adjustments that are monitored by both the medical and educational teams. Children with "prolonged symptoms" must first be identified and addressed in a separate ongoing pathway of reentry. The child with "prolonged symptoms" would best be served by additional testing (medical and cognitive) to better identify and track possible causes of unresolved symptoms. The medical team may order additional medical and neuropsychological assessments. In parallel, the educational team, which is composed of teachers, school nurses, and school psychologists, monitor symptoms and pace of reentry.

Prolonged Symptoms of Concussion

The child with prolonged symptoms presents a complex clinical challenge. One group of children at risk for symptom prolongation are those with comorbid medical, psychosocial and/or mental health problems. The interaction of concussion with pre-existing conditions can amplify and change the trajectory of recovery from the concussion. For this and other reasons, prolonged symptomatology requires that the child who is not on the typical spontaneous path of recovery is identified and a decision to employ additional resources made. Worsening symptoms require additional medical exploration as well as cognitive/neuropsychological fact finding.

While the category "*post-concussion syndrome*" no longer is included in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, (DSM-5), the DSM-5 has introduced a diagnosis of neurocognitive disorders due to brain trauma. The category of *mild neurocognitive disorder* due to traumatic brain injury is now used to describe consequences of mild/concussive head injury. This diagnosis applies to children without critical medical risk who grossly maintain life activities. This nomenclature allows clinicians to appropriately classify changes in neurocognitive and neurobehavioral integrity from baseline that would warrant clinical attention. It must be pointed out that the ICD-10 has maintained the diagnosis of "post concussive syndrome."

The DSM-5 criteria for mild neurocognitive disorder requires evidence of a modest decrease (i.e., standardized cognitive test decline equivalent to $Z = -1$ to -2) from previous cognitive performance in one of the following six domains: complex attention, executive function, learning and memory, language, perceptual-motor, or social cognition. The individual or a knowledgeable informant may report the decline or there may be a substantial impairment in cognitive performance on a quantified clinical assessment or on standardized neuropsychological testing. The impairment cannot be from delirium or another mental disorder such as depression. The impairment cannot interfere with independence in everyday activity though greater effort, accommodation, or other compensatory strategy may be required to accomplish the task.

When a concussion should be classified as a mild traumatic brain injury (mTBI) is still in discussion. If there are neuroradiologic

findings, the injury moves into the category of mTBI. Based on DSM-5 criteria, a neurocognitive disorder due to traumatic brain injury requires at least one of the following four features: loss of consciousness, posttraumatic amnesia, disorientation and confusion, or neurological signs, such as neuroimaging findings, seizures, visual field cuts, anosmia, or hemiparesis. The neurocognitive disorder due to traumatic brain injury must have its onset immediately following the trauma or after recovery from consciousness and must persist past the immediate postinjury period.

In prolonged concussion, the concept of primary and secondary influences can be helpful to the clinician. Continued symptom expression with gradual extension of exertion and activity can be seen as an extension of the primary concussive event and warrants ongoing monitoring and use of rest and gradual exposure therapies. However, for many children co-morbid conditions can complicate the initial symptoms, making it difficult to maintain a natural recovery curve and may even influence the morphing of symptoms into ongoing difficulty getting back to school and play. The secondary influences can range from comorbid medical conditions to psychological/mental health issues or even ongoing situational distress responses. In this later case, identification of secondary influences warrants further assessment (e.g., medical, mental health, psycho-social) and a plan of action that addresses the interaction of the primary event and secondary influences.

Prolonged symptom expression may require additional medical assessments as well as standardized neuropsychological testing and/or mental health assessment. Access to additional services at school (e.g., 504 plan, Individual Educational Plan) may be necessary. More intensive treatments including remedial therapy (e.g., OT, PT, Speech) and/or mental health interventions (e.g., counseling, psychiatric intervention) may be required.

Summary

Increased reporting and/or incidence of childhood concussion has necessitated that the clinician become more aware of clinical presentation and options for care. The young and very young child are particular clinical challenges given that they frequently "act out" their symptoms in the absence of the ability to report subjective changes. Symptoms of concussion may include alterations in consciousness, sensory hypersensitivity and changes in conduct and mental skills. Concussion may occur in the absence of loss of consciousness or focal neurologic signs or clear neuroradiologic findings. The typical period of resolution in the majority of children is 2 to 3 weeks. A graded recovery trajectory depends upon increasing levels of activity in the absence of worsening symptoms. Successful return to school and its attendant requirements for cognitive and mental endurance improvement is the initial stepping stone followed by return to athletic activities. A number of symptom checklists and observational tools are available to guide the clinician. In addition, computerized neuropsychological testing has been used, although standardized use in the young and very young is not fully developed. Returning to school may require adaptive teaching and/or compensatory support.

Particular challenges are seen with the slow to recovery or children with prolonged concussive symptoms. Detection and treatment of pediatric concussion can be difficult and prolonged. Identifying both primary and secondary factors that may be contributing to the stubbornness of recovery is important. The ongoing presentation will require medical, neuropsychological/mental health, and educational assessment and tracking. Return to activities may require personalized incremental rest-to-activity approaches depending on what additional examinations reveal. Pediatric concussion places added pressures on the clinician to detect symptom changes, especially in the young and very young as well as establish ongoing monitoring and surveillance activities for safe and productive return to activities.

Monitoring

Moderate to severe TBI is a chronic condition that extends over years. Prolonged health concerns, cognitive factors, and emotional factors change over the years as the child meets increasing

demands. Routine health monitoring might include a developmental pediatrics consultation, as well as the conventional medical point of view (e.g., delayed onset of seizures). School-based monitoring for delayed onset of cognition and neurobehavior may be helpful. Extended surveillance is necessary given delayed onset of difficulties and the emergence of late-onset problems. Late onset of difficulties is particularly important when monitoring frontal cortex injuries. Injuries to the body and white matter frontal lobe are particularly important, with bilateral injury being higher risk than unilateral. This is especially true in the lack of detection of late-onset behavior and cognitive problems in children injured very early in life. When there is relative lack of sensory motor or communication difficulties, the original brain injury event is not apparent and goes underappreciated over time. Instead, late-onset cognitive and neurobehavioral problems are mislabeled and given a new diagnosis such as bipolar disorder, ADHD, or personality disorder, when in fact this is a late expression of the early brain injury. Conceptually and in terms of what resources are mobilized, it is important to understand the child in terms of the contribution that childhood and infant brain injury brings.

Complications

Medical complications can burden the recovery process from the beginning. Given the incidence of comorbid medical conditions (e.g., diabetes insipidus, seizures, pituitary disorders), ongoing medical monitoring and treatment are common. Later complications typically emerge as the child reenters home, school, and community. The increased challenge the community brings can unmask latent or late-stage limitations that the pediatricians or family practice physicians need to be aware of. In addition, the interaction of negative life events, family stress, and the challenge of meeting developmental demands can all negatively interact with a child who has cognitive and neurobehavioral limitations. Late-onset mental health needs, neuropsychiatric and neuropsychological services, and special education and medical specialties may be needed over time as the child and family confront long-term recovery challenges.

URINARY TRACT INFECTIONS IN INFANTS AND CHILDREN

Method of

Ellen R. Wald, MD

The urinary tract is the most common site for serious bacterial infections in infants and young children. Urinary tract infections (UTIs) are more common than bacterial meningitis, bacterial pneumonia, and bacteremia.

Infection of the urinary tract may involve only the bladder, or only the kidney, or both. In general, infections of the bladder (cystitis), while causing substantial morbidity, are not regarded as serious bacterial infections. In contrast, infections that involve the kidney (pyelonephritis) can cause acute morbidity and lead to scarring with the consequences of hypertension, preeclampsia, and chronic renal disease.

Diagnosis

The diagnosis of UTI may be suggested by certain signs and symptoms, but culture of the urine is the gold standard. Because culture results are not available for at least 24 hours, there has been considerable interest in evaluating tests that may predict the results of urine culture, so that appropriate therapy can be initiated at the first encounter with the symptomatic patient. The tests that have received the most attention are urine microscopy for white blood cells and bacteria and biochemical analysis of leukocyte esterase and nitrite, which can be assessed rapidly by dipstick.

Several studies have concluded that both the presence of any bacteria on Gram staining of an uncentrifuged urine sample and dipstick analysis for leukocyte esterase perform similarly in children from birth through 12 years of age and are helpful in identifying individuals with UTI. Other recent studies done involving young infants (<2 months of age) and older infants (<12 months and 1–24 months) concluded that a hemocytometer white blood cell count of 10 or more cells/ μ L provides the most valuable cutoff point for identifying infants for whom urine culture is warranted.

The definition of a positive urine culture depends on the method used to collect the specimen. This variable definition reflects the fact that urine that has passed through the urethra may be contaminated by bacteria present in the distal urethra. If the urine is obtained by the clean-catch method, a positive culture is defined as equal to or greater than 10^5 colony-forming units (CFU)/mL. If the specimen is obtained by catheterization of the urethra, a positive culture is defined as equal to or greater than 5×10^4 CFU/mL. Finally, if a urine culture is obtained by suprapubic aspiration, a method that bypasses the potential source of contamination, a positive culture is defined as recovery of any bacteria from the urine.

Imaging

Imaging studies have been the standard of care for young children with a first UTI for the past decade. Commonly, a renal ultrasound study is performed to evaluate the gross anatomy of the urinary tract (size and shape of the kidneys, duplication or dilatation of the ureters). A voiding cystourethrogram (VCUG) is done to determine whether vesicoureteral reflux is present. This practice

demands. Routine health monitoring might include a developmental pediatrics consultation, as well as the conventional medical point of view (e.g., delayed onset of seizures). School-based monitoring for delayed onset of cognition and neurobehavior may be helpful. Extended surveillance is necessary given delayed onset of difficulties and the emergence of late-onset problems. Late onset of difficulties is particularly important when monitoring frontal cortex injuries. Injuries to the body and white matter frontal lobe are particularly important, with bilateral injury being higher risk than unilateral. This is especially true in the lack of detection of late-onset behavior and cognitive problems in children injured very early in life. When there is relative lack of sensory motor or communication difficulties, the original brain injury event is not apparent and goes underappreciated over time. Instead, late-onset cognitive and neurobehavioral problems are mislabeled and given a new diagnosis such as bipolar disorder, ADHD, or personality disorder, when in fact this is a late expression of the early brain injury. Conceptually and in terms of what resources are mobilized, it is important to understand the child in terms of the contribution that childhood and infant brain injury brings.

Complications

Medical complications can burden the recovery process from the beginning. Given the incidence of comorbid medical conditions (e.g., diabetes insipidus, seizures, pituitary disorders), ongoing medical monitoring and treatment are common. Later complications typically emerge as the child reenters home, school, and community. The increased challenge the community brings can unmask latent or late-stage limitations that the pediatricians or family practice physicians need to be aware of. In addition, the interaction of negative life events, family stress, and the challenge of meeting developmental demands can all negatively interact with a child who has cognitive and neurobehavioral limitations. Late-onset mental health needs, neuropsychiatric and neuropsychological services, and special education and medical specialties may be needed over time as the child and family confront long-term recovery challenges.

URINARY TRACT INFECTIONS IN INFANTS AND CHILDREN

Method of

Ellen R. Wald, MD

The urinary tract is the most common site for serious bacterial infections in infants and young children. Urinary tract infections (UTIs) are more common than bacterial meningitis, bacterial pneumonia, and bacteremia.

Infection of the urinary tract may involve only the bladder, or only the kidney, or both. In general, infections of the bladder (cystitis), while causing substantial morbidity, are not regarded as serious bacterial infections. In contrast, infections that involve the kidney (pyelonephritis) can cause acute morbidity and lead to scarring with the consequences of hypertension, preeclampsia, and chronic renal disease.

Diagnosis

The diagnosis of UTI may be suggested by certain signs and symptoms, but culture of the urine is the gold standard. Because culture results are not available for at least 24 hours, there has been considerable interest in evaluating tests that may predict the results of urine culture, so that appropriate therapy can be initiated at the first encounter with the symptomatic patient. The tests that have received the most attention are urine microscopy for white blood cells and bacteria and biochemical analysis of leukocyte esterase and nitrite, which can be assessed rapidly by dipstick.

Several studies have concluded that both the presence of any bacteria on Gram staining of an uncentrifuged urine sample and dipstick analysis for leukocyte esterase perform similarly in children from birth through 12 years of age and are helpful in identifying individuals with UTI. Other recent studies done involving young infants (<2 months of age) and older infants (<12 months and 1–24 months) concluded that a hemocytometer white blood cell count of 10 or more cells/ μ L provides the most valuable cutoff point for identifying infants for whom urine culture is warranted.

The definition of a positive urine culture depends on the method used to collect the specimen. This variable definition reflects the fact that urine that has passed through the urethra may be contaminated by bacteria present in the distal urethra. If the urine is obtained by the clean-catch method, a positive culture is defined as equal to or greater than 10^5 colony-forming units (CFU)/mL. If the specimen is obtained by catheterization of the urethra, a positive culture is defined as equal to or greater than 5×10^4 CFU/mL. Finally, if a urine culture is obtained by suprapubic aspiration, a method that bypasses the potential source of contamination, a positive culture is defined as recovery of any bacteria from the urine.

Imaging

Imaging studies have been the standard of care for young children with a first UTI for the past decade. Commonly, a renal ultrasound study is performed to evaluate the gross anatomy of the urinary tract (size and shape of the kidneys, duplication or dilatation of the ureters). A voiding cystourethrogram (VCUG) is done to determine whether vesicoureteral reflux is present. This practice

has rested on the assumption that continuous prophylactic antimicrobial therapy is effective in reducing the incidence of reinfection of the kidney and renal scarring that may occur in children with vesicoureteral reflux. The 2011 guidelines on diagnosis and management of urinary tract infection in infants and children 2–24 months of age issued by the American Academy of Pediatrics recommend postponing performance of the VCUG until the second infection (unless there is a major abnormality of the renal ultrasound).

Treatment

In general, there are many choices for the antibiotic treatment of UTIs in children. If a child is toxic in appearance or vomiting (thereby precluding oral antimicrobials), admission to the hospital for parenteral therapy is appropriate. Many would recommend a third-generation cephalosporin, such as ceftriaxone (Rocephin) 50 mg/kg/d given once daily or cefotaxime (Claforan) 25 mg/kg/dose every 6 hours, until the emesis has resolved and the patient can be treated orally. Otherwise, children, even those with presumed pyelonephritis, do well on oral therapy.

For the child who is to receive oral therapy, the choices are amoxicillin potassium clavulanate (Augmentin) 30 mg/kg/dose given every 12 hours³; a second- or third-generation cephalosporin such as cefuroxime (Ceftin)¹ 50 mg/kg/dose twice daily,³ cefpodoxime (Vantin)¹ 5 mg/kg/dose given twice daily, cefdinir (Omnicef)¹ 7 mg/kg/dose given twice daily, or cefixime (Suprax) 10 mg/kg/dose once daily³; or sulfamethoxazole-trimethoprim (Bactrim) 6 mg/kg/day of trimethoprim given once daily. There has been a tendency during the past several years for the prevalence of antimicrobial resistance to increase. The overall resistance to antibiotics varies geographically, and it is essential for the practitioner to be familiar with local antibiotic resistance patterns. In patients with suspected acute pyelonephritis, amoxicillin (Amoxil), cephalixin (Keflex), and sulfamethoxazole-trimethoprim should be avoided as presumptive therapy because of the potentially high rate of antibiotic resistance.

The optimal duration of therapy for children with UTI has been somewhat controversial. If the diagnosis of pyelonephritis is known or suspected, 10 days of treatment is conventional. Shorter courses of therapy have been successful in adult women with infection of the lower urinary tract. A recent meta-analysis conducted by the Cochrane Database of Systematic Reviews evaluated 10 trials (652 children) with lower-tract UTI. There was no significant difference in frequency of positive urine cultures between short-term (2–4 days) and standard (7–14 days) duration of oral antibiotic therapy for cystitis in children, either early after treatment or at 1 to 15 months after treatment. Furthermore, there was no difference between groups in the development of resistant organisms at the end of treatment or in the incidence of recurrent UTIs. Accord-

ingly, in cases in which the diagnosis of cystitis is assured, 4 days of antimicrobial therapy is sufficient.

Voiding Dysfunction

Voiding dysfunction is a broad term indicating a voiding pattern that is abnormal for the child's age. This is a condition that should be considered in all children who are diagnosed as having a UTI after toilet training has been accomplished. Constipation plays a significant role in some children with voiding dysfunction, and attention to this comorbidity sometimes results in resolution of recurrent UTIs.

Prophylaxis

For children who are thought to be at very high risk for recurrent UTIs and potential scarring, prophylactic treatment with sulfamethoxazole-trimethoprim or nitrofurantoin (Macrochantin) should be considered. These groups include children with high degrees of vesicoureteral reflux (grades 4 and 5), those with frequent and closely spaced UTIs without reflux, and, occasionally, those who have urologic abnormalities.

The RIVUR study, Randomized Intervention for Children with Vesicoureteral Reflux (VUR), was undertaken in 2007 to determine whether antimicrobial prophylaxis with SMX-TMP is effective in preventing recurrent UTI in infants and children with reflux of any grade. The study showed a modest benefit of prophylaxis with regard to febrile episodes of UTI but no difference in scarring. There is no question of the biologic plausibility of prophylactic antimicrobial therapy in preventing recurrent UTI; however, adverse effects, emergence of antimicrobial resistance, and difficulties with long-term adherence to prophylactic strategies present barriers to effectiveness.

- Cyanide exposure – check for and treat cyanide toxicity in victims of structure fires

**CURRENT THERAPY**

- The first, immediate treatment is to stop the burning
- Cool water irrigation (NOT ice or ice water)
- Standard airway, breathing, and circulation resuscitation applies
- Resuscitation fluids should be calculated on the basis of surface area of deep partial and deeper burns (does not include superficial burns)
- Topical treatment is the mainstay for most wounds
- Update tetanus vaccination if needed
- Consult poison control center for chemical injuries or toxic gas exposure
- Hydroxocobalamin (CYANOKIT) is the treatment of choice for cyanide exposure
- Develop transfer relationship with burn center

Epidemiology

Annually in the United States, there are nearly 500,000 burns that are significant enough to require emergency treatment or admission to the hospital, and about 4000 deaths attributable to fire or fire-related inhalation injuries. The vast majority of the annual 40,000 injuries that require admission to the hospital are treated in a specialized burn center. Worldwide there are over 265,000 deaths annually due to fire-related injuries, with over 90% of these occurring in low- and middle-income countries.

Risk Factors

Burns are distributed across the spectrum of age, although their types and mechanisms vary with age. Burns tend to be more common in males. Males tend to get burned by flames, while females are more likely to sustain scald or heat contact wounds. Old and very young persons are more likely to sustain injury due to inability to get away from either a flame or heat contact. Alcohol use and other substance use are associated with an increased risk of burn injury. Burns tend to cluster in lower socioeconomic groups and are much more common in countries with lower incomes.

Pathophysiology

The injuries that result from burns are thought to be due to a combination of immediate tissue injury, the resulting inflammatory cascade, immediate and delayed cellular and humoral effects, and the delayed effects of changes in gene expression induced by the earlier injuries. The immediate injury is divided into three zones. The most severely injured is the central zone of necrosis; this area is surrounded by the zone of stasis, which is surrounded by the zone of hyperemia ([Figure 1](#)). The zone of necrosis is composed of coagulated tissue that will progress to rapid cell death and eschar formation. The outer zone of hyperemia has increased blood flow and minimal tissue damage and will almost certainly heal. The middle zone of stasis is the region where blood flow has ceased within the capillary bed. Depending on subsequent actions over the next 24 to 48 hours, this area either will worsen to necrotic tissue or may re-epithelialize to healing. The immediate postinjury efforts are focused on salvaging this area.

Burning Tissue

As heat transfers to tissue, damage begins to occur as cellular temperature rises above 44 °C. Once the internal cellular temperature reaches 60 °C, the cell will die. Generally, once the heat source is removed from the skin, the tissue temperature rapidly returns to normal, but the tissue injury does not stop at that point. Within seconds of the injury, arterioles begin to spasm, and red blood cells aggregate within the tissues. Histologic changes are visible within 15 minutes, and tissue edema begins. Tissue edema typically peaks 6 to 12 hours postinjury.

It is much easier for a burn injury to penetrate through the dermal layers in thin skin than in thick skin, leading to more severe injury in the former with a similar degree of heat transfer. These injuries pose a particular risk in infants and children as well as the elderly.

Shortly after the burning stops, processes of both inflammation and healing begin. There is a complex interplay of inflammatory mediators, immune cell action, and changes in gene expression that will continue over the following weeks to months and will play a role in how the wound heals.

Prevention

Public safety initiatives have done a great deal to decrease the risk of burn injury in the developed world. Often patient visits provide opportunities for educational interventions, especially if for a minor burn. Campaigns to decrease hot water heater temperatures in homes have helped reduce scald injuries. Safety plugs for electrical outlets decrease the risk of electrical injury in children. Smoke detectors and planned and practiced escape routes increase the likelihood of escaping from structure fires. Reminders to check smoke detectors and to change the batteries with the seasonal clock change ensure that devices are functional. Child-resistant lighters and safety matches, especially when stored out of reach of children, increase fire safety. Keeping screens or safety devices around fireplaces and fire pits may decrease injuries as well. Avoiding activities with fuel and flames, especially while intoxicated, will also decrease fire injuries.

Clinical Manifestations

Descriptions of burns are based on the depth of the injury and the extent of coverage ([Table 1](#)). Superficial burns involve the epidermis alone. These injuries are typically painful and erythematous,

Figure 1 Burn injury.

TABLE 1 Types of Burns					
DEPTH	ANATOMY	APPEARANCE	SENSATION	TIME	TREATMENT
Superficial	Epidermis only	Pink or red and dry, blanches	Painful	Days	Topical
Superficial partial thickness	Epidermis and upper papillary dermis	Pink, clear blisters, moist surface, blanches	Painful	14–21 days	Debride and topical medication
Deep partial thickness	Epidermis, papillary dermis, and lower reticular dermis	Pink or red, moist surface, blisters, may be hemorrhagic, does not blanch	Painful, may have decreased sensation	Weeks or may progress to full thickness	Debride, topical medication, possible surgery
Full thickness	Epidermis, dermis, and into underlying tissue	White or brown, dry, leathery, does not blanch	Insensate	Weeks, and heals by contraction and scarring	Surgical

and they will heal without scarring. These injuries are not included in calculations of the percentage total body surface area (TBSA) burned. Superficial partial thickness burns involve the entire epidermis and extend down to the papillary region of the upper dermis. These injuries are painful, erythematous, and moist, and they form blisters. Deep partial thickness burns involve the entire epidermis and extend deeper into the lower reticular dermis. These wounds are typically painful and whitish, and they have less weeping and blanching than superficial partial thickness wounds. Full-thickness burns extend through the entire dermis and destroy nerves and other deep structures. These wounds are insensate, stiff, and white or tan, and they do not blanch. Wounds of this depth cannot heal spontaneously and will have significant scarring and contracture if not surgically managed.

Areas of burn that have extensive or circumferential deep partial thickness or full-thickness burns are at risk for development of restrictive eschars. Thickened areas of eschar can restrict circulation, leading to compartment syndrome; in areas of the neck and chest, they can restrict respiration, leading to hypoventilation. Ideally, burn patients can reach burn centers before an escharotomy is

required, but an escharotomy will be required emergently in some cases.

Inhalation injury is a source of significant morbidity in burn patients. The initial injury may not seem particularly severe, but edema can develop rapidly in the airway, which makes delayed airway management perilous. Early intubation may be necessary.

Special Situations

Ocular Injuries

Patients with any signs of burns to the face, complaints of eye pain, or inability to communicate should undergo eye examinations with fluorescein staining. If corneal burns are identified, appropriate antibiotic ointment should be started, and consultation with an eye specialist should be obtained.

Nonaccidental Trauma

Up to 6% of burns in children are secondary to physical abuse. Burns caused by abuse are more likely to occur in males and children with developmental delays and may result in a delay in seeking care. Other concerning findings are burns that have clear lines of

demarcation (e.g., cigarette burns, dunking, radiator, grill, curling iron), that are symmetric on both extremities, or spare the flexor creases with deep surrounding burns. If nonaccidental trauma is suspected, it must be reported, and the child must be kept in a safe place until authorities have cleared the child to go home.

Chemical Burns

The risk and degree of injury caused by chemical burns vary greatly, depending on the substance involved as well as on the concentration of the material and the duration of exposure. The Centers for Disease Control and Prevention has a website that provides information on treatment for chemical injuries: <http://www.atsdr.cdc.gov/mmg/index.asp>. General precautions for chemical burns are to decontaminate as quickly as possible while avoiding rescuer contamination or injury. For dry or powdered chemicals, remove as much chemical physically while it is still in the dry form by brushing or other mechanical removal. After mechanical removal, or for liquid contamination, dilute the chemical and continue the removal process by using water. Water should be used via copious, high-flow, low-pressure irrigation for at least 20 minutes. If feasible, check the pH of the contaminated area and continue irrigation until it returns to normal. In most cases, removal and irrigation are more important to neutralizing the chemical because using neutralizing agents can make the injury worse in some cases. Evaluate the patient for possible inhalation or ocular injury as well. There are important exceptions to typical management, some of which are listed in Table 2.

Electrical Injuries

Injuries with electrical sources vary based on the type of circuit (alternating vs direct current), amperage, voltage, tissue resistance, duration of exposure, and path of current through the body. High voltage (≥ 1000 V) tends to cause more thermal tissue injury and often causes concomitant traumatic injuries. Depending on the path of electricity, there may be significant internal injuries beneath normal-appearing skin, especially in high-voltage cases. Significant injuries should be treated more like crush injuries, as the extent of the internal injuries is difficult to assess. Cutaneous burns due to electrical injury can be treated similarly to thermal burns. During the initial evaluation of electrical injury, patients should undergo electrocardiography and cardiac monitoring, and obtaining serum levels of myoglobin, creatine kinase, and troponin, as well as

coagulation studies, should be considered, in addition to liver and pancreas enzyme levels in patients with intra-abdominal injuries. In cases of multiple victims of a lightning strike, a reverse triage process occurs whereby care is provided first to the patients who appear to be in cardiac arrest, as cardiopulmonary resuscitation and defibrillation may save their lives if applied early enough.

Therapy (or Treatment)

First Aid and Office Management

The initial management for burn injuries consists of stopping further injury by removing the heat source and providing cooling. Remove the patient from the burning area in the event of flame injury. If the patient's clothing is on fire, it is important to stop the burning and remove hot clothing as quickly as possible. Hot liquid or scald injuries especially require prompt removal of overlying clothing, as the clothing will trap the heat, which will continue the burning damage. After the heat source is removed, copious cool water should be used to irrigate the injured area, and any constricting jewelry should be removed immediately. The ideal temperature for cool water irrigation is not clear, but it is likely between 15 °C and 25 °C (59 °F–77 °F); colder temperatures can be damaging. The cooling irrigation can be continued for up to 20 minutes. Early wound cooling decreases the temperature of the injured area quickly to halt the burning process, but irrigation has been shown to be beneficial even after the wound has returned to a normal temperature. Cooling the wound is thought to be effective up to 3 hours after the injury. It is unclear why cool water irrigation improves burn outcomes; heat removal and edema prevention appear to play a role, but they also appear to lead to alterations in gene expression that decrease injury and improve healing. After cooling the injured area, the initial treatment is to cover the wounds with a clean, thin cloth or sterile sheets while the patient awaits further care. Ensure that the patient's tetanus vaccination is up to date.

Superficial burns or superficial partial thickness burns can generally be treated on an outpatient basis, with important exceptions ($>10\%$ TBSA; very young or old patient, circumferential injury; hand, face, or genital area burns). Debride any ruptured blister tissue, clean the wounds with mild soap and water or dilute antiseptic solution, and dress the wound. Wound dressings may include topical antibiotic cream or ointment, silver impregnated nylon or bismuth tribromophenate, and petrolatum impregnated gauze

TABLE 2 Chemical Burns*

CHEMICAL	TREATMENT	SPECIAL NOTES
Dry chemical	Brush or remove as much chemical as possible, then copious irrigation	Obtain material safety data sheet information on exposure
Liquid chemical	Copious irrigation	
Ocular injury	Copious irrigation with Lactated Ringer's solution, measure pH early and repeat frequently	
Elemental metals (e.g., sodium, magnesium)	Cover with mineral oil if available, physically remove as soon as possible, irrigate with water if no other options	Water causes an intense exothermic reaction, but tissue damage occurs with continued contact
Strong alkalis (pH 10–12; e.g., lye, bleach, cement [calcium oxide], ammonia)	Copious irrigation, continue until pH normalizes, but at least 1 hour; may require 12 or more hours	Current recommendations are not to try to neutralize, but research is continuing
Petroleum	Irrigation, mild soap solution	May be seen in vehicle trauma patients
Hydrofluoric acid	Irrigation, topical calcium gluconate (Calgonate) mixed with water-based lubricant (e.g., K-Y jelly), intradermal or intravenous calcium gluconate	Associated with pain out of proportion to appearance, fluoride ion can cause hypocalcemia and death
Phenol	Polyethylene glycol (PEG) (Miralax) ¹ stops phenol burn more quickly than water; if PEG is not available, use high-flow, low-pressure, copious irrigation	

*Consider contacting a burn center or poison control center for assistance with chemical injury treatment.

¹Not FDA approved for this indication.

(Xeroform). Topical bacitracin or triple-antibiotic ointment is often used. Silver sulfadiazine cream 1% (Silvadene) is also commonly used, but avoid use on the face as it can lead to pigmented scarring. The management of intact blisters is controversial; however, if a blister appears fragile or likely to rupture, unroof and debride the wound before dressing the wound. If the blister is in thicker skin or appears stable, most recommendations are to aspirate the blister fluid and dress the wound. Occlusive dressings over mild burns have also been shown to improve healing. Dressings should be changed as dictated by the dressing choice. Some silver products and occlusive bandages may be left in place for several days; most traditional dressings need to be changed daily, or more frequently if needed.

Burns are painful injuries and often require early, aggressive pain control, such as with nonsteroidal anti-inflammatory medications, opioid medications, and acetaminophen. It is important to remember to provide additional analgesia as needed for dressing changes and wound care. Pruritus and neuropathic pain may occur as the wound heals, these are often treated with adjunct pain medications such as gabapentin (Neurontin),¹ and diphenhydramine (Benadryl).¹

Wounds that are of deep partial thickness or deeper usually require some form of surgical management and should be referred for specialized care. Early surgical management has been demonstrated to be beneficial. Prophylactic antibiotics should not be used for burn management, as they have been shown to be harmful.

Hospital Management

For patients with more severe injuries, follow the traditional algorithm of assessing and stabilizing the respiratory and circulatory system first, then proceeding with a complete history and physical examination, including comorbid conditions, allergies, medications, and other past medical history. If possible, identify the mechanisms and circumstances surrounding the injury, including agents involved, duration of exposure, and situation, including possibility of inhalation injury or enclosed space involvement. Assess whether there are chemical or electrical burns and any associated trauma. The social history may play an important role in disposition and management decisions.

Patients who were in an enclosed space or structure fire or who were otherwise exposed to high levels of smoke or toxins should be assessed for carbon monoxide and cyanide injuries. Lactate, troponin, and carboxyhemoglobin levels should be checked in patients at risk for carbon monoxide or cyanide exposure. A patient at risk for cyanide exposure who has a decreased level of consciousness, hypotension, or a lactate level greater than 9 should receive 5 g (or 70 mg/kg to a maximum of 5 g) of hydroxocobalamin (Cyanokit) intravenously. If the patient is in cardiac arrest or does not improve with the initial dose, a total of 10 g should be given.

A patient with carbon monoxide exposure should have a carboxyhemoglobin level obtained and be placed on 100% oxygen as soon as possible, typically delivered via a non-rebreather face mask. Carbon monoxide binds tightly to hemoglobin, and by increasing the oxygen concentration in the lungs and blood, the half-life of carboxyhemoglobin is greatly reduced. With oxygen levels typically delivered by non-rebreather face mask, the half-life of carboxyhemoglobin is 74 minutes. This leads to the recommendation that after 6 hours on 100% oxygen, if the patient is asymptomatic, treatment can be stopped. It is unnecessary to use arterial blood or to repeat carboxyhemoglobin levels. Patients with carbon monoxide poisoning may experience delayed neurologic sequelae. Hyperbaric oxygen therapy may reduce the risk of delayed neurologic sequelae in appropriately selected patients. Although controversial, this therapy is thought to be most helpful if it occurs within 12 hours after the end of the patient's exposure, but patients may benefit up to 24 hours after exposure. If possible, consult with a physician capable of providing hyperbaric oxygen therapy or with a poison control center for patients with carboxyhemoglobin levels greater than 10, symptoms consistent with carbon monoxide exposure, or pregnant patients (Table 3).

¹Not FDA approved for this indication.

TABLE 3 Symptoms of Carbon Monoxide Exposure*

Headache
Dizziness
Nausea
Vomiting
Confusion
Fatigue
Chest pain
Shortness of breath
Loss of consciousness

*It is important to note that carboxyhemoglobin levels do not correlate well with symptoms or with severity of exposure. Arterial blood gas samples are not superior to venous blood samples.

Patients with inhalation injuries can develop rapidly progressing airway swelling. The initial evaluation of burn patients should include assessment for perioral injury, singed facial or nasal hair, and soot or swelling in the oral or hypopharyngeal cavities. These findings, other indications of airway swelling, or difficulty breathing should prompt early placement of a definitive airway. Delay may make placement of an endotracheal tube difficult or impossible.

Burn Management

After evaluation and stabilization of the respiratory and circulatory status of the patient, and after stabilizing acute traumatic injuries, the next step is to evaluate the extent of the burn injuries. Removing the heat source and cooling the injured areas remain a priority. Burned areas can be cooled with cool water irrigation or saline-soaked gauze. Because patients with extensive wounds can be at risk of developing hypothermia during this phase, it is important to raise the ambient temperature in the resuscitation room or use warm blankets to maintain normothermia. The extent of the burns should be determined. The "rule of nines" diagram is an accepted mechanism for approximating the percentage of TBSA burned in adults, but it tends to overestimate. Because children have a proportionally larger head and torso, diagrams have been adapted for use in pediatric populations. The Lund-Browder chart has been adapted for use with patients of all ages (Figure 2). It can also be useful to diagram the areas of burn by estimated depth. For determination of burn severity, calculation of transfer criteria, and fluid resuscitation, only the areas of deep partial thickness and deeper burns are added together to determine TBSA. Use of a diagram is recommended because TBSA is frequently overestimated when providers estimate the extent of burned areas. Overestimating TBSA burned leads to excessive fluid administration and the complications that accompany fluid overload.

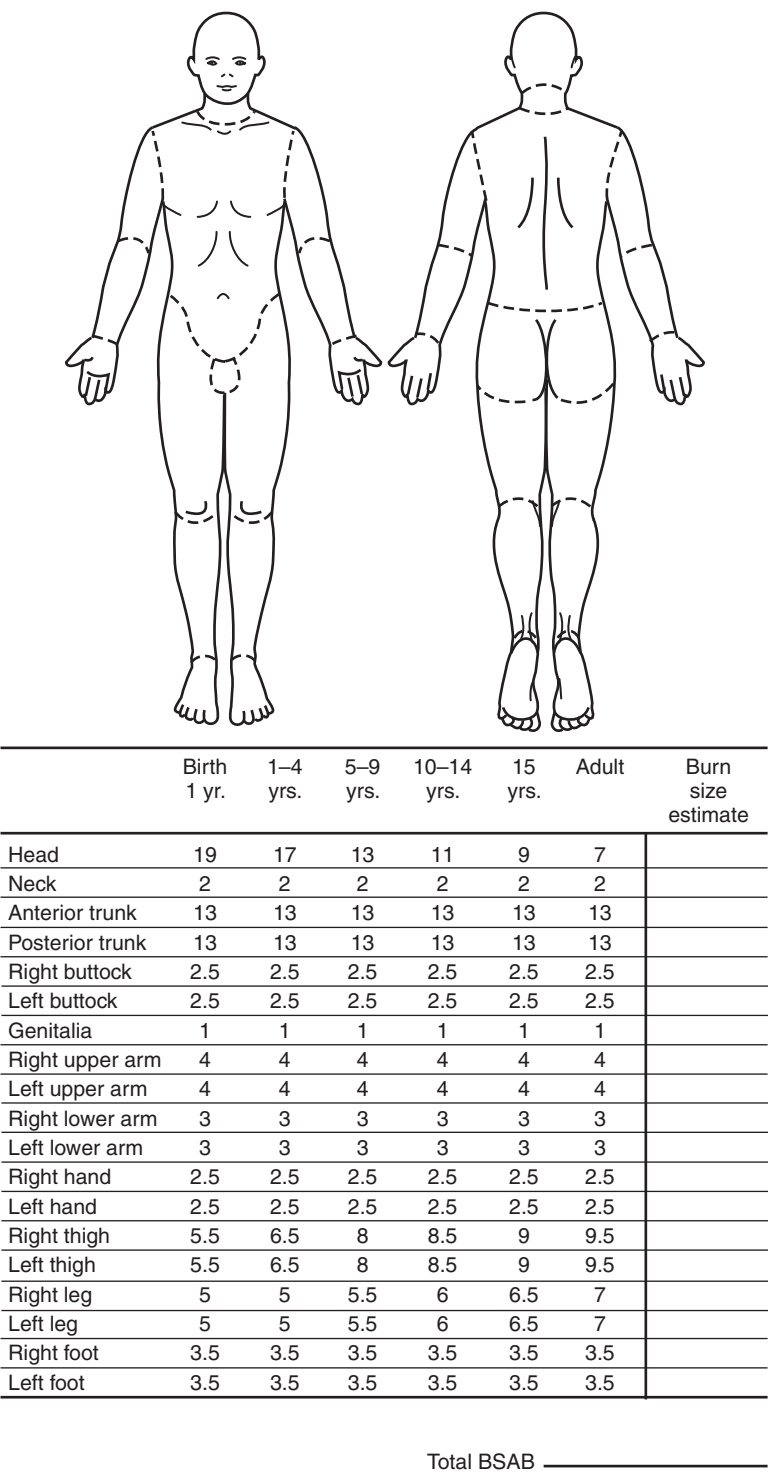

Burn Center Referral Criteria

It is important to identify the regional burn referral center and to establish a line of communication with it before a burn patient is encountered, in order to know of the center's suggested criteria for transfer (Table 4). In general, the following criteria are recommended for transfer to a burn center: burns greater than 10% of TBSA; inhalation injury; burns with significant associated mechanical injury; burns of the face, hands, feet, perineum, or genitalia or across major joints; full-thickness burns of any size; and circumferential burns. Burns that warrant a discussion with a burn center for possible transfer or outpatient follow-up include burns in children; patients with comorbid conditions that will impact healing; and patients with special social, emotional, psychological, or rehabilitative needs.

Monitoring

Critically ill burn patients should be monitored in an intensive care setting while awaiting transfer to a burn center. In addition to

Figure 2 Lund-Browder classification of burn size.

monitoring of respiratory and circulatory status, a Foley catheter should be placed to monitor urinary output and for intermittent assessment of bladder pressure to evaluate for the development of intra-abdominal compartment syndrome.

Because burned tissue increases insensible fluid losses, burn victims have increased fluid requirements. Various formulas are available for calculating approximate fluid requirements, but all require careful monitoring of the results and progress of fluid resuscitation. Patients who receive more than 250 mL/kg in the first 24 hours are at increased risk of developing fluid-related complications. The American Burn Association Consensus Statement formula is used to guide initial fluid management. The starting fluid requirements are 2 to 4 mL/kg of Lactated Ringer solution per TBSA percent value, with half given in the first 8 hours and the rest over the next 16 hours

(e.g., for an 80-kg patient with a 35% TBSA deep and deep partial burn, the calculation would be $3 \text{ mL/kg} \times 80 \text{ kg} \times 35 = 8400 \text{ mL}$, for a rate of 525 mL/h in first 8 hours, followed by 265 mL/h for the next 16 hours). Urine output should be monitored hourly and maintained between 0.5 and 1 mL/kg/h. If a patient's urine output is greater than 1 mL/kg/h, the rate of fluid administration should be decreased by 20% and continued to be monitored hourly. If the urine output is less than 0.5 mL/kg/h, the rate of fluid administration should be increased by 20% and continued to be monitored (Table 5).

Unfortunately, ensuring adequate urine output does not necessarily guarantee adequate fluid resuscitation. In addition to using urine output as an indicator of resuscitation adequacy, other modes of monitoring can be used to help guide fluid resuscitation (hemodynamic monitoring, echocardiography, gastric tonometry,

TABLE 4 Burn Center Referral Criteria

Partial thickness burns greater than 10% TBSA
Full-thickness burns
Burns to high-risk areas, such as the face, hands, feet, genitals, perineum, or major joints
Circumferential burns
Electrical burns, including lightning strikes
Chemical burns
Inhalation injury
Preexisting conditions known to impair healing and increase risk of mortality
Burns in combination with traumatic injury (e.g., fracture, traumatic brain injury) whereby the burn is the leading risk for patient mortality
Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention
Burns in a setting unequipped (personnel, equipment, or unit) to care for critically ill children
Available from: http://www.ameriburn.org/BurnUnitReferral.pdf . Accessed June 19, 2016.

Abbreviation: TBSA = total body surface area.

TABLE 5 Fluid Administration and Calculation

80-kg male patient with a burn of 35% TBSA full-thickness and partial thickness burns:
$80 \text{ kg} \times 35 \times 3 \text{ mL/kg} = 8400 \text{ mL}$ in first 24 hours
$8400 \text{ mL}/24 \text{ hours} \div 2 = 4200 \text{ mL}$ in first 8 hours, 4200 mL in next 16 hours
Initial rate of 525 mL/h over first 8 hours, then switching to a rate of 265 mL/h over next 16 hours
Expected urine output is 0.5–1 mL/kg/h
$80 \text{ kg} \times 0.5 \text{ mL/kg/h} = 40 \text{ mL/h}$
$80 \text{ kg} \times 1 \text{ mL/kg/h} = 80 \text{ mL/h}$
So, for our 80-kg patient, we would expect 40–80 mL of urine every hour. In hours 1 and 2 of resuscitation, the patient has 65 mL of urine per hour. In hour 3 of resuscitation, the patient has 90 mL of urine per hour. We would then decrease the fluid administration rate by 20%, or
$525 \text{ mL/h} - (0.20 \times 525) = 420 \text{ mL/h}$
Thus, the rate of administration of lactated Ringer solution would change from 525 mL/h to 420 mL/h and continue to be monitored and recorded hourly, with continued adjustments based on hourly urine output.

Abbreviation: TBSA = total body surface area.

or other devices). Whether they lead to any increased improvement or survivability is not clear, however.

Transfer

Burn centers typically manage more than 200 burn patients annually and have specially trained physicians, nurses, and ancillary personnel who are focused on treating burn patients. Severely burned patients who are treated at specialized centers have better outcomes. It is recommended that hospitals and clinics have agreements with burn centers for the management of complicated patients and patients who meet criteria for burn center transfer.

Complications

Pain management for burns may require multiple modalities because the type of pain varies, depending on where the patient is in the cycle of treatment and healing. There are three types of pain that need to be treated during the care of a burn patient: background pain, breakthrough pain, and long-term pain. Background pain is present from the onset of the injury, and the pain is typically intensified during procedures. There will also be episodes of breakthrough pain. Depending on the severity of the injury, initial pain and background pain may be treated with acetaminophen, nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen sodium), or opioids. Procedural pain may require bolus dosing of opioids or other adjunctive medications such as ketamine¹ (0.1–0.2 mg/kg IV). Long-term pain may respond to medications such as gabapentin, clonidine, or others.

Psychosocial recovery from burns is impacted by the preexisting conditions and the resilience of the patient. Preexisting mental health, substance abuse, and other medical and psychosocial issues complicate the patient's recovery from burns. Risk factors for burn injury include poverty, a history of abuse or neglect, substance abuse, serious mental illness, and risk for suicide or assault. Psychiatric recovery is negatively affected by posttraumatic stress disorder, depression, learning disorders, substance abuse, stigma, and disability. Individual resilience, social support, and education or occupation also impact patient outcomes.

The patient's age and stage of life at the time of injury impact recovery as well. Younger victims have a longer remaining lifespan to live with the scarring and disfigurement. Pediatric patients often have fewer comorbid medical conditions, which can speed their recovery and limit disability, and they tend to heal more quickly, but their injuries may have a significant impact on their body image development, self-confidence, and interpersonal relationship building. The family may be of assistance in recovery from the injury, but family members, too, may experience stress and psychological concerns related to the injury to a child. Adults and older patients have to deal with the impact of the injury on their identity and their ability to return to their preinjury roles.

Some patients and caregivers may develop posttraumatic stress disorder related to the injury or to postinjury treatment. It is thought that early multidisciplinary interventions may decrease this risk, but the research is unclear. Some patients will require long-term, continued outpatient treatment.

Hypertrophic scarring is the most common complication related to healing of burn wounds, but scar contracture and pruritus are common complications as well. It is thought that hypertrophic scarring may be decreased with early, appropriate surgical repair, but it still can occur. The development of hypertrophic scarring is multifactorial; it is likely a result of a complex interplay of humoral and cellular immunity causing an inappropriate response to healing tissue. Multiple host and injury factors contribute, but protracted healing of a partial thickness injury is a common theme. There are some experimental therapies for manipulating different components of the host response, but none has clearly proven to be beneficial.

Scar contracture results from tissue loss at the time of injury and tissue-healing properties. Burn injuries are more complicated than other traumatic wounds because the destroyed tissue is surrounded by profoundly damaged tissue. As a result of this tissue injury, there is increased collagen deposition resulting from changes in inflammation, proliferation, and remodeling at the cellular and extracellular matrix levels. Hypertrophic scars tend to form within the first month after injury and may improve over the first 6 months, but then tend not to show significant changes after that time. Burn treatment and scar prevention consist of tissue replacement, tissue rehabilitation, and tension release. Early and existing scars are often treated with compression garments and silicone sheets. It is thought that these may alter and improve remodeling of the extracellular matrix and thereby improve scarring. In some cases, surgical release of tension may be necessary.

DISTURBANCES DUE TO COLD¹

Method of

Jerrold B. Leikin, MD; Scott M. Leikin, DO; Frederick K. Korley, MD; and Ernest Wang, MD

CURRENT DIAGNOSIS

- Accidental hypothermia may be classified as mild, moderate, or severe.
- The measured temperature should be the core body temperature.
- The method of rewarming depends on the severity of the temperature drop.
- The complications of rewarming include arrhythmias, rewarming-related hypotension, core temperature after drop, and rhabdomyolysis.
- Patients can be declared dead only after they are warm.

CURRENT THERAPY

Mild Hypothermia: 32.2 °C (90 °F) to 35 °C (95 °F)

- Start passive external rewarming; remove wet clothing.
- Ambient temperature should exceed 21.0 °C (70.0 °F).
- Cover patient with insulating material.

Moderate Hypothermia: 28 °C (82.4 °F) to 32.2 °C (90 °F)

- Start active external rewarming; use radiant heat.
- Use thermal mattresses and electric heating blankets.
- Use forced-air heating blankets.
- Perform active core rewarming; use warmed humidified oxygen.

- Give warmed intravenous saline.
- Give bladder, colonic, and gastric irrigation.
- Start pleural cavity lavage.
- Avoid alcohol, caffeine, and nicotine (tobacco).

Severe Hypothermia: Less than 28 °C (82.4 °F)

- Begin aggressive active core rewarming; use warmed, humidified oxygen.
- Give warmed intravenous saline.
- Give bladder, colonic, and gastric irrigation.
- Start pleural cavity lavage.
- Perform peritoneal lavage or dialysis.
- Perform extracorporeal warming or heated cardiopulmonary bypass.

CURRENT THERAPY

Frostnip

- Gentle rewarming, generally in a water bath of 104 °F to 108 °F (40 °C to 42 °C).
- It is usually self-resolving.

Frostbite

- Immerse in warm (not hot) water.
- Débride broken vesicles.
- Do not débride hemorrhagic or intact blisters
- Apply topical aloe vera⁷ or antibiotic ointment.
- Use NSAIDs for pain.
- Update tetanus status.
- Do not rub or massage the affected area.
- Do not use a heating pad or heat lamp; affected areas can be easily burned.
- Avoid alcohol and tobacco products.

Chilblain

- Rewarm gently.
- Nifedipine (Procardia)¹ may be useful.

Trench foot

- Dry the foot.
- Rewarm gently.
- Use NSAIDs for pain.

¹Not FDA Approved for this indication.

⁷Available as dietary supplement.

Accidental Hypothermia

Hypothermia is classically defined as a reduction in the body's core temperature below 95.0 °F (35.0 °C). Most reported cases of hypothermia are due to environmental exposure to low ambient temperatures (accidental hypothermia). Other causes of hypothermia include sepsis, severe hypothyroidism (myxedema coma), acute spinal cord injury, diabetic ketoacidosis, multisystem trauma, and prolonged cardiac arrest.

Epidemiology

Risk factors for developing hypothermia include extremes of age (elderly people might not be able to remove themselves from cold environments, and young children lose heat more rapidly because of their increased total body surface area), major trauma, homelessness, psychiatric illness, and drug and alcohol abuse (Box 1). Cold-related deaths also are reported in military combatants and outdoor winter sports participants. Several drugs and chemicals can predispose to hypothermia (Box 2). Alcohol is the most common intoxicant associated with hypothermia because of its ability to cause cutaneous vasodilation, impairment of shivering, and impairment of adaptive behavior.

DISTURBANCES DUE TO COLD¹

Method of

Jerrold B. Leikin, MD; Scott M. Leikin, DO; Frederick K. Korley, MD; and Ernest Wang, MD

CURRENT DIAGNOSIS

- Accidental hypothermia may be classified as mild, moderate, or severe.
- The measured temperature should be the core body temperature.
- The method of rewarming depends on the severity of the temperature drop.
- The complications of rewarming include arrhythmias, rewarming-related hypotension, core temperature after drop, and rhabdomyolysis.
- Patients can be declared dead only after they are warm.

CURRENT THERAPY

Mild Hypothermia: 32.2 °C (90 °F) to 35 °C (95 °F)

- Start passive external rewarming; remove wet clothing.
- Ambient temperature should exceed 21.0 °C (70.0 °F).
- Cover patient with insulating material.

Moderate Hypothermia: 28 °C (82.4 °F) to 32.2 °C (90 °F)

- Start active external rewarming; use radiant heat.
- Use thermal mattresses and electric heating blankets.
- Use forced-air heating blankets.
- Perform active core rewarming; use warmed humidified oxygen.

- Give warmed intravenous saline.
- Give bladder, colonic, and gastric irrigation.
- Start pleural cavity lavage.
- Avoid alcohol, caffeine, and nicotine (tobacco).

Severe Hypothermia: Less than 28 °C (82.4 °F)

- Begin aggressive active core rewarming; use warmed, humidified oxygen.
- Give warmed intravenous saline.
- Give bladder, colonic, and gastric irrigation.
- Start pleural cavity lavage.
- Perform peritoneal lavage or dialysis.
- Perform extracorporeal warming or heated cardiopulmonary bypass.

CURRENT THERAPY

Frostnip

- Gentle rewarming, generally in a water bath of 104 °F to 108 °F (40 °C to 42 °C).
- It is usually self-resolving.

Frostbite

- Immerse in warm (not hot) water.
- Débride broken vesicles.
- Do not débride hemorrhagic or intact blisters
- Apply topical aloe vera⁷ or antibiotic ointment.
- Use NSAIDs for pain.
- Update tetanus status.
- Do not rub or massage the affected area.
- Do not use a heating pad or heat lamp; affected areas can be easily burned.
- Avoid alcohol and tobacco products.

Chilblain

- Rewarm gently.
- Nifedipine (Procardia)¹ may be useful.

Trench foot

- Dry the foot.
- Rewarm gently.
- Use NSAIDs for pain.

¹Not FDA Approved for this indication.

⁷Available as dietary supplement.

Accidental Hypothermia

Hypothermia is classically defined as a reduction in the body's core temperature below 95.0 °F (35.0 °C). Most reported cases of hypothermia are due to environmental exposure to low ambient temperatures (accidental hypothermia). Other causes of hypothermia include sepsis, severe hypothyroidism (myxedema coma), acute spinal cord injury, diabetic ketoacidosis, multisystem trauma, and prolonged cardiac arrest.

Epidemiology

Risk factors for developing hypothermia include extremes of age (elderly people might not be able to remove themselves from cold environments, and young children lose heat more rapidly because of their increased total body surface area), major trauma, homelessness, psychiatric illness, and drug and alcohol abuse (Box 1). Cold-related deaths also are reported in military combatants and outdoor winter sports participants. Several drugs and chemicals can predispose to hypothermia (Box 2). Alcohol is the most common intoxicant associated with hypothermia because of its ability to cause cutaneous vasodilation, impairment of shivering, and impairment of adaptive behavior.

BOX 1 Factors Predisposing to Hypothermia or Frostbite**Physiologic****Decreased Heat Production**

Age extremes (infants, elderly)
 Dehydration or malnutrition
 Diaphoresis or hyperhidrosis
 Endocrinologic insufficiency
 Hypoxia
 Insufficient fuel
 Overexertion
 Physical conditioning
 Prior cold injury
 Trauma (multisystem or extremity)

Increased Heat Loss

Burns
 Dermatologic malfunction
 Cold infusions
 Emergency resuscitation
 Poor acclimatization or conditioning
 Shock
 Vascular diseases

Impaired Thermoregulation

Central nervous system trauma or disease
 Metabolic disorders
 Pharmacologic or toxicologic agents
 Sepsis
 Spinal cord injury

Psychological

Fatigue
 Fear or panic
 Hunger
 Intense concentration on tasks
 Intoxicants
 Mental status or attitude
 Peer pressure

Environmental

Altitude with or without associated conditions
 Ambient temperature or humidity
 Duration of exposure
 Heat loss (conductive, evaporative, radiative, convective)
 Quantity of exposed surface area
 Wind chill factor

Mechanical

Constricting or wet clothing or boots
 Inadequate insulation
 Immobility or cramped positioning

Between 1979 and 2002, 16,555 deaths in the United States, an average of 689 per year, were attributed to exposure to low environmental temperatures. In 2002, of the 646 hypothermia-related deaths reported, 66% occurred in male patients, 52% of all decedents were aged 65 years or younger, 45% of the deaths occurred among white male patients, and 14% occurred among black male patients. The states of Alaska, New Mexico, North Dakota, and Montana had the largest overall death rates from hypothermia in 2002. The lowest recorded core temperature in a pediatric survivor of accidental hypothermia is 57.9 °F (14.4 °C) and the lowest in an adult survivor is 56.7 °F (13.7 °C).

Pathophysiology

The normal range of human core temperature is 97.5 °F (36.4 °C) to 99.5 °F (37.5 °C). Humans are thus warm-blooded and are normally able to maintain their body temperature by heat-generating mechanisms and heat-conserving behavior. These compensatory

responses, however, can be overwhelmed under extreme environmental conditions, leading to hypothermia.

The anterior hypothalamus coordinates the nonshivering heat conservation and dissipation mechanisms, and the posterior hypothalamus coordinates shivering thermogenesis. Heat loss usually occurs by four mechanisms: About 55% to 65% of heat is lost by radiation, 25% to 30% by evaporation from the skin and respiratory tract, and 10% to 15% by conduction and convection. The amount of heat lost via conduction is markedly increased in cold-water immersion (by about 32-fold). Each organ system is affected uniquely by hypothermia.

Skin

Cutaneous blood flow is regulated by the individual's thermoregulatory needs, modulated by neural control through the arteriovenous anastomoses located in the extremities. Sympathetic tone is increased, which leads to arteriovenous constriction, which is maximum at 59 °F (15 °C). Cold-induced dermal vasodilatation can occur at 50 °F (10 °C).

Cardiovascular System

One of the initial heat-conserving mechanisms is peripheral vasoconstriction to decrease blood flow to the skin. There are also initial increases in heart rate and blood pressure owing to a catecholamine surge. At core temperatures below 82.4 °F (28.0 °C), bradycardia can result from a decrease in spontaneous depolarization of the pacemaker cell firing. The myocardium also becomes irritable, predisposing it to bradyarrhythmias and hypotension. Cardiac output decreases to approximately 45% at 77 °F (25 °C).

Atrial arrhythmias can occur with a slow ventricular response, and they can precede ventricular arrhythmias and asystole at core temperatures below 77.0 °F (25.0 °C). The characteristic Osborn or J waves (a hump seen at the QRS-ST junction) may be seen on the electrocardiogram (ECG) at core temperatures below 89.6 °F (32.0 °C). Orthostasis also commonly occurs.

Renal System

Renal blood flow is affected by peripheral vasoconstriction, causing the glomerular filtration rate to fall and contributing to metabolic acidosis. Antidiuretic hormone activity is usually inhibited. This can result in intravascular volume depletion, subsequent vasodilation, increased renal blood flow, and, ultimately, acute renal failure. Urinary output can increase threefold, and this may be accentuated with concomitant ethanol use.

Respiratory System

At core temperatures below 82.4 °F (28 °C), minute ventilation, tidal volume, respiratory rate, and thoracic elasticity all are reduced; bronchorrhea can occur, with a loss of cough and gag reflexes leading to an increased risk for aspiration. Carbon dioxide production drops by one-half for every 14 °F (8 °C) drop in temperature, and oxygen consumption is reduced by 75% at 72 °F (22 °C). Apnea can then result.

Central Nervous System

Cerebral metabolism is depressed 6% to 7% per 1 °C decrease in core temperature. Cerebrovascular autoregulation remains intact until below 77.0 °F (25.0 °C), which helps maintain cortical blood flow. Electroencephalographic activity is clearly not prognostic, but it is abnormal below 92 °F (33 °C); burst suppression can occur at 71.6 °F (22 °C) and it silences around 66.2 °F to 68.0 °F (19.0 °C to 20.0 °C). Most patients are unconscious at a core temperature of 82.4 °F to 86 °F (28 °C to 30 °C).

Coagulation

Because of depression of enzymatic activity of the activated clotting factors, clotting time (particularly partial thromboplastin time [PTT]) is prolonged. At 84 °F (29 °C), a 50% increase of PTT can be expected. Thrombocytopenia also commonly occurs due to bone marrow suppression along with splenic and hepatic platelet sequestration, which can be exacerbated by cryoglobulinemia.

Medicinals

Acetaminophen (Tylenol)

²Not available in the United States.

Clinical Presentation

Accidental hypothermia is classified as mild at body temperatures of 90 °F (32.2 °C) to 95 °F (35 °C), moderate at body temperatures of 82.4 °F (28.0 °C) to 90 °F (32.2 °C), or severe at body temperatures less than 82.4 °F (28 °C).

In general, a patient's symptoms depend on the severity of the temperature drop. Patients with mild hypothermia can develop vigorous shivering and cold diuresis. Those with moderate hypothermia can have a paradoxical decrease in shivering, slurred speech, hyporeflexia, and confusion. They might have Osborn J waves on the ECG. They are also at risk for intravascular thrombosis. Splanchnic vasoconstriction, gastric erosions, hepatic necrosis, and pancreatitis can occur. Prominent laboratory abnormalities include leukopenia (from splenic sequestration), thrombocytopenia (during rewarming), hypoglycemia, respiratory or metabolic acidosis, and hyperkalemia. Fetal bradycardia can occur in response to maternal hypothermia, but long-term sequelae are unknown.

During severe hypothermia, shivering gives way to rigor, minute ventilation decreases, and heart rate and cardiac output decrease. Cardiac instability can be seen at this stage and can manifest in the form of arrhythmias, heart blocks, and eventually asystole. Neurologically, the patient's mental status declines. The patient might attempt to undress (paradoxical undressing) and might respond only to painful stimuli, have decreased gag reflexes, and eventually become apenic. Generally, at about 68.0 °F (20.0 °C), patients become totally neurologically unresponsive, lose corneal and ocular reflexes, and can have a flat electroencephalogram (EEG).

Emergency Department Evaluation

Typically, the source of hypothermia is revealed from the patient's history; however, it is very important to rule out secondary causes of hypothermia, such as sepsis, hypothyroidism, central nervous system lesions, and hypoglycemia, among others. All patients arriving in the emergency department with hypothermia need a complete evaluation to rule out traumatic injuries and drug or toxin ingestion or overdose.

As in all resuscitation, attention should be paid to the ABCs (airway, breathing, and circulation). Successful neurologic recovery has been documented following five hours of cardiopulmonary resuscitation (CRP) in the setting of profound accidental hypothermia (62.4 °F or 16.9 °C). Ideally, in patients in cardiac arrest, CPR should be maintained throughout the pre-hospital period. In a patient with a core temperature of under 28 °C, evidence supports alternating 5 minutes of CPR with less than or equal to 5 minutes without CPR, if feasible. With a core temperature under 20 °C, data supports alternating 5 minutes of CPR with less than or equal to 10 minutes without CPR. Respiratory failure should be treated with endotracheal intubation and mechanical ventilation. Hypotension can be treated initially with warmed fluids. Placing the patient in a warm environment, removing all cold and wet clothes, and remembering to cover up the patient after he or she has been exposed should help prevent further heat loss.

The temperature should be confirmed by checking a core temperature (e.g., rectal, bladder, or esophageal), using a thermometer capable of recording very low temperatures. Patients should be placed on a cardiac monitor and an ECG should be obtained. Laboratory testing is especially useful in the postresuscitative period, when complications begin. Laboratory tests should include a complete blood count (CBC), a chemistry panel, creatine phosphokinase (CPK) to evaluate for rhabdomyolysis, a coagulation profile, blood type and screen, an arterial blood gas, and a drug screen. A Foley catheter should be placed to assess urinary output.

Rewarming Strategies

There are several methods of rewarming. The method of choice usually depends on the severity of hypothermia. During rewarming, the patient should be placed on a cardiac monitor with frequent measurements of blood pressure and temperature (via a rectal probe) for easy detection of complications of rewarming, such as rewarming-related hypotension, arrhythmias, and core

temperature after-drop. It should be noted that the human body is capable of raising the body temperature through heat generation by approximately 1 °C per hour.

Passive External Warming

Passive external warming is ideal for patients with mild hypothermia (greater than 93 °F or 34 °C) who are otherwise healthy. It uses the patient's endogenous heat production for rewarming and it involves simple, logical passive maneuvers that minimize heat dissipation. When using this method, all wet clothing should be removed and the patient should be covered with insulating materials. Patients warmed easily using this method can be safely discharged.

Active External Rewarming

Active external rewarming should be considered for patients with core temperatures between 86 °F and 92 °F (30 °C to 34 °C). It involves exposing the patient's skin to exogenous heat sources. Radiant heat, thermal mattresses, electric heating blankets, and forced-air heating blankets are some of the available techniques. The rate of temperature rise is approximately 2.7 °F to 7.2 °F (1.5 °C to 4 °C) per hour.

This method has several disadvantages. First, burn injuries can occur to the vasoconstricted skin. Second, any sort of immersion can hinder monitoring and other resuscitative activities. Finally and most important, active external rewarming produces a phenomenon called *core-temperature after-drop*. This refers to a drop in core temperature resulting from sudden peripheral vasodilation. This causes cold, acidic blood to return to the core. Hypotension and potentially fatal dysrhythmias can result. Focusing on rewarming the trunk only (rather than the trunk and extremities) can prevent these temperature gradients. In general, active external rewarming is used in conjunction with active core rewarming.

Active Core Rewarming

Active core rewarming involves techniques to deliver direct heat internally. It should be used in patients with moderate to severe hypothermia (under 86 °F or 30 °C). The simplest method entails the administration of heated, humidified oxygen at 107.6 °F to 114.8 °F (42.0 °C to 46.0 °C) and intravenous saline solution warmed to 109.4 °F (43.0 °C). Saline should be administered via a central line at 150 to 200 mL/h. Gastric, bladder, and colonic irrigations have been used, but their relatively small surface areas usually limit their effect. Urinary bladder or gastric lavage (which is rarely used due to aspiration potential and electrolyte shifts) can rewarm at an hourly rate of 0.9 °F to 1.8 °F (0.5 °C to 1 °C).

Another method of active core rewarming is pleural irrigation using two large-bore (36 °F or greater) thoracostomy tubes. One tube is placed at the midclavicular line and is connected to saline at 107.6 °F (42.0 °C). The other tube is placed at the posterior axillary line and connected to a chest tube drainage kit.

A more-aggressive method of active core rewarming is via peritoneal lavage and dialysis. This can be accomplished using a standard diagnostic peritoneal lavage kit and introducing an 8-F catheter into the peritoneum using Seldinger's technique. The crystalloid dialysate should be warmed at 104.0 °F to 113.0 °F (40.0 °C to 45.0 °C). This method affords the added advantage of allowing the serum potassium level to be adjusted.

The most efficient and physiologic active core rewarming method is via extracorporeal warming or heated cardiopulmonary bypass. This is the method of choice for the most-severe cases, patients with severe rhabdomyolysis, and patients who require cardiopulmonary resuscitation. Survival rates with no chronic neurological sequelae as high as 75% have been documented. Excellent recovery has been documented from a nasopharyngeal temperature of 13.8 °C (and a serum potassium of 11.3 mmol/L) due to drowning with a submersion time of at least 83 minutes in icy sea water) with slow rewarming with extra corporeal membrane oxygenation. Extra corporeal life support can be an effective rewarming tool in patients with prolonged cardiac arrest from accidental hypothermia, particularly in the absence of asphyxia,

Atropine
 Digoxin
 Fentanyl (Sublimaze, Duragesic)
 Gentamicin (Garamycin)
 Lidocaine (Xylocaine)
 Phenobarbital
 Procaine
 Propranolol (Inderal)
 Sulfanilamide (AVC cream)
 Suxamethonium (succinylcholine, Anectine)
 D-Tubocurarine
 Brain natriuretic peptide

trauma, or severe hyperkalemia. Survival rates as high as 40% (with good neurologic outcome) have been documented.

Most arrhythmias are corrected by rewarming. Atrial dysrhythmias often occur during rewarming and generally resolve without treatment. Atropine is typically ineffective for cold-associated bradycardias. Ventricular tachycardia and fibrillation require electrocardioversion and the use of bretylium (not available in the United States) if it is available. Dopamine, epinephrine¹, and vasopressin (Pitressin)¹ may be effective vasopressors. External pacing may be ineffective. Empiric antibiotics may be given. However, the empiric use of levothyroxine (Synthroid)¹ and corticosteroids may be hazardous. Phenytoin (Dilantin) might have cardiac-depressant qualities in the moderately hypothermic patient. Box 3 demonstrates drugs with possible decreased metabolism or clearance with resultant increase in toxicity in hypothermia.

Indicators of grave prognosis include development of profound hyperkalemia (serum potassium greater than 10 mEq/L), elevated serum creatinine, serum sodium, serum lactate concentration, or lower prothrombin time, underlying medical conditions, intravascular thrombosis (fibrinogen less than 59 mg/dL), pH less than 6.5, and a core temperature less than 8.4 °F (28.0 °C). Submersion in cold water for over 10 minutes is associated with a poor prognosis; if the water is less than 43 °F (6 °C), survival is unlikely to occur if submerged for over 90 minutes.

Peripheral Cold Injuries

Peripheral cold injuries span a spectrum ranging from minimal to severe tissue damage. Freezing and nonfreezing syndromes can cause these injuries. About 500 patients with frostbite are hospitalized yearly in the United States, with about an 80% male demographic and lower extremity predominance. The average length of stay in critical care units and total hospital stay is approximately 7 and 10 days, respectively. Frostnip and frostbite are caused by exposure to freezing temperatures. *Frostnip* refers to the numbness and blue-white discoloration of the face and extremities that occur during exposure to freezing temperatures. It is a precursor to frostbite. It is characterized by reversible skin changes, including blanching and numbness with no permanent tissue damage, unlike frostbite. Nonfreezing injuries depend on whether the ambient environment during exposure was wet (trench or immersion foot) or dry (pernio or chilblain).

Pathophysiology

During exposure to cold temperatures, the core body temperature is preserved to the detriment of the extremities. Frostbite occurs in four stages: prefreeze, freeze-thaw, vascular stasis, and late ischemic stages. The prefreeze phase occurs when the temperature of the extremities falls below 50.0 °F (10.0 °C) and cutaneous sensation is lost. Vasoconstriction also occurs along with leakage of intracellular fluid into the interstitium.

¹Not FDA approved for this indication.

The freeze-thaw phase begins at the freezing point of water (32.0 °F or 0 °C) with the formation of ice crystals extracellularly. This further enhances the exit of water from the intracellular space under osmotic forces, resulting in cell shrinkage and, ultimately, damage. During the vascular stasis phase, plasma leakage and formation of ice crystals continue. Arachidonic acid breakdown products are then released from underlying damaged tissue. Both prostaglandin F_{2α} and thromboxane A₂ produce platelet aggregation, leukocyte immobilization, and vasoconstriction.

Endothelial cells are sensitive to cold injury, and the microvasculature becomes distorted and clogged, leading to tissue ischemia. The late ischemic phase is characterized by ischemia, thrombosis, continued shunting, gangrene, autonomic dysfunction, and denaturation of tissue proteins. The tissue can eventually mummify and demarcate more than 60 to 90 days later.

Clinical Presentation of Local Extremity Issues

Frostnip and Frostbite

The face and ears are the most common sites prone to cold injury, followed by the hands and feet. Patients with frostnip usually have blanching and numbness of their fingertips. The skin has a firm or waxy texture. Often the patient is unaware of these changes. Frostnip is usually reversible. Frostbite has been classified as superficial, affecting the skin and subcutaneous tissue, or deep, affecting the bones, joints, and tendons. When a superficial frostbite is rewarmed, the skin can form a clear blister; however, when a deep frostbite is rewarmed, it can form a hemorrhagic blister. This classification, however, has no therapeutic or prognostic value given that frostbites can initially appear benign. Many weeks can pass before the demarcation between viable and nonviable tissues becomes apparent. Facial frostbite, with skin blistering, can also occur following halogenated (especially fluorinated) hydrocarbon inhalation abuse. This can appear initially as angioneurotic edema if it involves the oral mucosa membranes. Acute compartment syndrome of the foot and ankle, associated with gangrenous toe changes, have been described.

Although no prognostic factors can be entirely predictive, favorable factors include retained sensation, normal skin color, and clear rather than cloudy fluid in the blisters, if present. Poor prognostic features include nonblanching cyanosis, firm skin, and dark, fluid-filled blisters. Patients can present with pain, numbness, and a clumsy “chunk of wood” sensation in the affected extremity. The pain is initially described as a dull ache and evolves to become a throbbing sensation in about 48 to 72 hours.

Chilblain

Chilblain, also referred to as pernio, results from repetitive exposure to cold, dry air. It manifests as painful erythematous nodules or cyanotic lesions often referred to as cold sores. These lesions usually develop on exposed surfaces after a delay of 12 to 14 hours and are characterized by pruritus and burning paresthesias. Young women, especially those with Raynaud's phenomenon and/or a low body mass index, are at risk.

Chilblains are located on acral skin associated with cold exposure. They are usually located on the dorsum of the fingers, toes, and thighs, where blisters or ulcerations can develop in very severe cases. Perivascular lymphocytic infiltration with vacuolation of the basal layer is often seen on histologic analysis, especially when it is associated with an autoimmune disease (particularly lupus erythematosus).

Susceptibility to chilblains increases when the ambient temperature is less than 10 °C and relative humidity is 60%.

Trench Foot and Immersion Foot

Trench foot occurs as a result of prolonged exposure (about 10 to 15 hours) to a damp, cold, nonfreezing environment (with temperature as high as 15 °C or 59 °F). It has been classically described among soldiers in World War I, many of whom were confined to cold and damp trenches for prolonged periods. Symptoms include numbness and painful paresthesias that can progress to a throbbing and burning sensation. Initial evaluation reveals a cold, pale extremity, with or without vesicles or bullae. Inflammatory

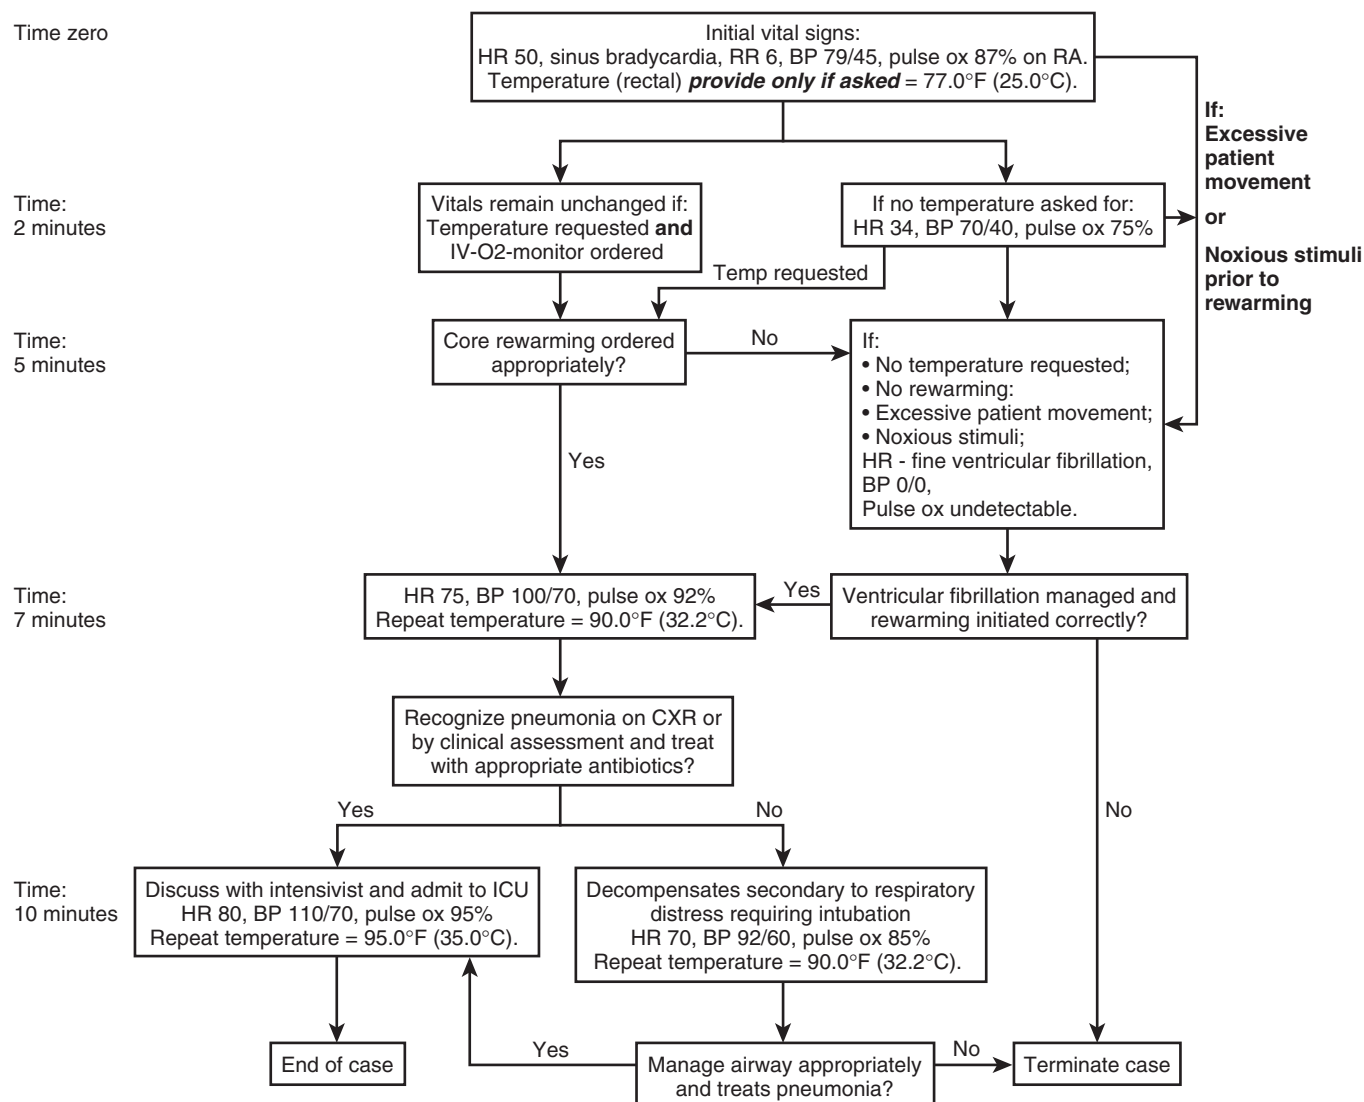

Figure 1 Hypothermia simulation flow diagram.

serum markers, such as erythrocyte sedimentation rate (ESR) or C-reactive Protein (CRP), may be elevated.

Immersion foot may be considered the sailor's counterpart to trench foot. It occurs after prolonged immersion in cold water at temperatures above freezing.

Treatment

Treatment of frostbite should begin with removing all wet or frozen clothing. For patients with moderate or severe hypothermia, initial resuscitative efforts should be geared toward raising their core temperature. The patient should be moved to a warm environment and all wet clothing should be removed. The frozen extremity should be rewarmed by immersion in circulation water at 104.0 °F to 108.0 °F (40.0 °C to 42.0 °C) for about 15 to 30 minutes. Given the risks of thermal injury, the frozen parts should not be exposed to direct or dry heat (such as hair dryers, heating pads, or heat lamps). Do not rub or massage the affected area. The process should be continued until the extremity appears warm and well perfused. Following rewarming, the extremity should be air dried and elevated. Because of the pain associated with reperfusion, there may be the temptation to abruptly abort the rewarming process. This can, however, promote further tissue damage.

Because the pain is usually prominent at night, amitriptyline (Elavil®)¹ at an initial dosage of 10 to 25 mg and a maximum of

100 mg may be helpful. Gabapentin (Neurontin®)¹ also may be an alternative therapy. Parenteral analgesic medications—nonsteroidal antiinflammatory drugs (NSAIDs) and opioids—may be administered as needed to make this process more tolerable. Ibuprofen at a dose of 12 mg/kg twice daily (400 mg in adults twice daily, which can be increased to a maximum of 600 mg daily) may be helpful for its analgesic and anti-inflammatory effects.

Almost all authors agree that hemorrhagic blisters should not be débrided because of the risk of secondary desiccation of deep dermal layers, extending the injury. Débriding broken vesicles or bullae is also widely accepted; however, clear, intact vesicles may be broken and débrided or left intact. Topical aloe vera ointment (Dermaide Aloe)⁷ or topical antibiotic ointments may be applied. Cold extremity wounds are not considered tetanus prone.

The injured tissue should be loosely covered with sterile, dry, nonadherent dressing. Hands and feet may be splinted and elevated to reduce edema. Because the damaged tissue is tetanus prone, patients whose tetanus status has not been updated may require a tetanus booster (Td).

Adjunctive agents that have been used for their antithrombotic and vasodilative properties with varying success include heparin¹, steroids¹, NSAIDs¹, dimethylsulfoxide (DMSO, Rimsso-50)¹,

⁷Available as dietary supplement.

nonionic detergents¹, dipyridamole (Persantine)¹, calcium channel blockers¹, thrombolytics¹, pentoxifylline (Trental)¹, and phenoxybenzamine (Dibenzylamine).¹ Hyperbaric oxygen with thrombolytic therapy has been used to treat severe frostbite of the hand. Negative pressure wound therapy, following blister excision, has been demonstrated to be beneficial in treating infant frostbite hand injuries. Following rewarming, intravenous Tissue Plasminogen Activator (TPA, Activase)¹ with an initial bolus followed by a 6- to 12-hour infusion has been utilized effectively with systemic anticoagulation and/or anti-platelet therapy to follow. Intra-arterial TPA (Activase)¹ has also been utilized. Surgical consultation is appropriate for guiding long-term management, because some patients might need débridement of infections or skin grafts for nonhealing wounds. A sympathetic nerve block can relieve painful and refractory vasospasms.

For hypothermia due to myxedema coma, levothyroxine (Synthroid) should be administered intravenously (at a dose of 250 to 500 µg over 30 to 60 seconds). Daily intravenous injections of 100 µg may be required for up to 7 days. A familial association of chilblain (associated with contractual arachnodactyly) has been described in Italy. Chilblain (pernio) may be treated with nifedipine¹ at an oral dose of 20 to 60 mg daily. Oral prednisolone (Millipred)¹, 0.5 mg/kg in two divided doses over 2 weeks, and topical glucocorticoids have been used to treat perniosis; pentoxifylline¹ (1200 mg/day in three divided doses for 2 weeks) has also been demonstrated to be effective. Acupuncture treatments (once weekly for 12 weeks) has been used to decrease cold sensitivity due to second-degree frostbite in the fingertips.

Sequelae

Late sequelae of frostbite include cold hypersensitivity, arthritis, numbness, chronic pain, ulceration, decreased sensation, and functional loss of the extremity. This is a result of early neuronal damage and abnormal sympathetic tone. Patients with chronic symptoms should be advised to avoid nicotine and cold exposure while using NSAIDs. Tissue demarcation can occur 60 to 90 days after initial injury. Amputation decisions should be deferred unless there is supervening sepsis or gangrene. The ultimate tissue salvage after a spontaneous slough usually far exceeds the most optimistic initial estimates. A medical simulation flow diagram is presented in Figure 1.

¹Not FDA approved for this indication.

HEAT-RELATED ILLNESS

Method of
Paul Cleland, MD

CURRENT DIAGNOSIS

- Heat illness is a spectrum of illnesses usually seen among athletes in hot and humid environments.
- Children, elderly, and poorly acclimatized individuals are at increased risk for developing exertional heat illness (EHI).
- Exercise-associated cramps are intense, prolonged, painful muscle spasms that occur during physical activity.
- Heat exhaustion is an elevation in core temperature (<104°F) without central nervous system (CNS) dysfunction resulting in collapse or difficulty continuing activity.
- Heat stroke is a life-threatening illness characterized by elevation in core temperature (≥104°F) with CNS dysfunction (e.g., altered consciousness, seizure, coma) and usually end-organ damage.

CURRENT THERAPY

- Acclimatization is key for prevention of EHI.
- Heat illness is most effectively managed by immediate recognition of the signs and symptoms and proper diagnosis.

nonionic detergents¹, dipyridamole (Persantine)¹, calcium channel blockers¹, thrombolytics¹, pentoxifylline (Trental)¹, and phenoxybenzamine (Dibenzylamine).¹ Hyperbaric oxygen with thrombolytic therapy has been used to treat severe frostbite of the hand. Negative pressure wound therapy, following blister excision, has been demonstrated to be beneficial in treating infant frostbite hand injuries. Following rewarming, intravenous Tissue Plasminogen Activator (TPA, Activase)¹ with an initial bolus followed by a 6- to 12-hour infusion has been utilized effectively with systemic anticoagulation and/or anti-platelet therapy to follow. Intra-arterial TPA (Activase)¹ has also been utilized. Surgical consultation is appropriate for guiding long-term management, because some patients might need débridement of infections or skin grafts for nonhealing wounds. A sympathetic nerve block can relieve painful and refractory vasospasms.

For hypothermia due to myxedema coma, levothyroxine (Synthroid) should be administered intravenously (at a dose of 250 to 500 µg over 30 to 60 seconds). Daily intravenous injections of 100 µg may be required for up to 7 days. A familial association of chilblain (associated with contractual arachnodactyly) has been described in Italy. Chilblain (pernio) may be treated with nifedipine¹ at an oral dose of 20 to 60 mg daily. Oral prednisolone (Millipred)¹, 0.5 mg/kg in two divided doses over 2 weeks, and topical glucocorticoids have been used to treat perniosis; pentoxifylline¹ (1200 mg/day in three divided doses for 2 weeks) has also been demonstrated to be effective. Acupuncture treatments (once weekly for 12 weeks) has been used to decrease cold sensitivity due to second-degree frostbite in the fingertips.

Sequelae

Late sequelae of frostbite include cold hypersensitivity, arthritis, numbness, chronic pain, ulceration, decreased sensation, and functional loss of the extremity. This is a result of early neuronal damage and abnormal sympathetic tone. Patients with chronic symptoms should be advised to avoid nicotine and cold exposure while using NSAIDs. Tissue demarcation can occur 60 to 90 days after initial injury. Amputation decisions should be deferred unless there is supervening sepsis or gangrene. The ultimate tissue salvage after a spontaneous slough usually far exceeds the most optimistic initial estimates. A medical simulation flow diagram is presented in Figure 1.

HEAT-RELATED ILLNESS

Method of
Paul Cleland, MD

CURRENT DIAGNOSIS

- Heat illness is a spectrum of illnesses usually seen among athletes in hot and humid environments.
- Children, elderly, and poorly acclimatized individuals are at increased risk for developing exertional heat illness (EHI).
- Exercise-associated cramps are intense, prolonged, painful muscle spasms that occur during physical activity.
- Heat exhaustion is an elevation in core temperature (<104°F) without central nervous system (CNS) dysfunction resulting in collapse or difficulty continuing activity.
- Heat stroke is a life-threatening illness characterized by elevation in core temperature (≥104°F) with CNS dysfunction (e.g., altered consciousness, seizure, coma) and usually end-organ damage.

CURRENT THERAPY

- Acclimatization is key for prevention of EHI.
- Heat illness is most effectively managed by immediate recognition of the signs and symptoms and proper diagnosis.

- Core temperature measurement **MUST** be performed with a rectal thermometer.

Exercise-associated collapse (EAC)

- Continue walking after the race to prevent development.
- Position the patient in a Trendelenburg position and start fluid administration.

Heat exhaustion

- Use rapid cooling with ice bags to areas adjacent to large vasculature (groin, neck, axilla).
- Administer oral or IV fluids to correct hydration deficit.

Heat stroke

- Ensure the ability to maintain adequate circulation, airway, and breathing.
- Rapid cooling with ice-water immersion is the most effective way to cool.
- Goal of cooling is to reduce and maintain temperature below 101°F.
- Heat stroke may require transport to hospital if temperature-lowering interventions are not effective or mental status does not return to normal after 30 minutes of medical treatment.

Heat illness is a continuum of disease that can affect a wide array of individuals including athletes, firefighters, construction workers, military personnel, and others. Exertional heat illness is a leading cause of death among young athletes and may be on the rise owing to possible climate change and increasing popularity of mass-participation events such as marathons. Recognizing patient-specific and environmental risk factors will allow clinicians to prevent heat-related illness. Early recognition and treatment of EHI can lead to significant reduction in the morbidity and mortality associated with this condition.

In the United States, most cases of EHI occur in summer months. Elevations in the ambient temperature and humidity, as well as athletic deconditioning, are predominant contributing factors. Heat illness is associated with inadequate heat acclimatization and elevated wet bulb globe temperatures (WBGTs). The WBGT measurement takes into account the temperature, humidity, wind speed, sun angle, and cloud cover. High school and collegiate athletic programs that have protocols in place to stop practice or reduce the duration or frequency of practice when the WBGT is high have shown a decreased incidence of heat illness compared to those that do not.

Pathophysiology

It is important to understand the pathophysiology of heat regulation within the body to gain an accurate picture of heat illness. The human body has a substantial capacity to withstand drastic reductions in temperature. However, only mild increases in core temperature can result in severe consequences. Heat is generated by normal metabolic processes that occur continuously in our bodies and is also absorbed from the environment. Exercise generates additional heat from the skeletal muscles. An increase in core temperature is detected in the hypothalamus, and signals are sent out to induce cutaneous vasodilation and sweating. Blood is shunted to the skin and exercising skeletal muscle. Under normal conditions the body is able to dissipate heat through evaporation, radiation, convection, and conduction. Evaporation is the primary means of heat dissipation and occurs as water is converted from its liquid to its vapor form. But evaporation is ineffective above a relative humidity of 75%. Radiation, convection, and conduction are also methods to dissipate heat but are decreasingly effective as the ambient temperature approaches the skin's temperature. When physiologic cooling mechanisms fail and heat continues to be produced, the body's core temperature increases. As the temperature rises, cell damage occurs and a systemic inflammatory response ensues, releasing cytokines throughout the body. Blood is shunted to the peripheral circulation, leading to organ hypoperfusion and ischemia. Organ failure and disseminated intravascular coagulation (DIC) develop and eventually result in death.

The injuries that occur as a result of heat illness can be mitigated by acclimatization of the patient. Acclimatization to environmental stress is the most important factor to thrive in hot and humid conditions. Acclimatization occurs as the body, repeatedly exposed to certain levels of stress, makes compensatory adjustments that ultimately result in improved performance the next time the body is under duress. This process occurs over 1 to 2 weeks of exposure to new conditions and appears to be lost over the same period of time. There are several key changes that occur as the body is exposed to heat, including production of heat shock proteins that give cells the ability to resist heat stress, a decreased sweat temperature threshold, increased sweat production, decreased salt concentration in sweat, and increased skin blood flow. These factors all serve to aid the athlete under high-risk heat conditions to improve performance and alleviate potential heat illness. It is recommended that the athlete spend at least 2 weeks acclimatizing to the environment mimicking both temperature and humidity for maximal outcome. If an athlete returns to a more temperate environment after training, such as an air-conditioned room, he or she will not experience the same benefit as he or she would with exposure to the conditions for 24 hours a day. If possible, air conditioning should be restricted to nighttime only when the athlete is resting.

Risk Factors

Although each person has unique genetic traits that determine how his or her body reacts to specific conditions, there are known congenital and acquired risk factors that may preclude an individual toward development of EHI. Exposure to a hot and humid environment may be the most obvious risk factor as ambient heat is transferred to the body and elevated humidity impairs the body's ability to dissipate heat. Poor conditioning, lack of acclimatization, obesity, and dehydration are all contributors that have been shown to increase the risk of EHI. The use of prescription medications, supplements, and recreational drugs (Table 1) may cause disturbances in the capacity to dissipate heat or cause production of heat. Creatine supplementation does not appear to impose a risk of heat generation, although this is a topic of ongoing research.

Children are at increased risk of developing heat illness for several physiologic reasons. A larger surface area-to-mass ratio allows for more heat absorption from the environment. Children also produce more heat compared to their adult counterparts owing to higher basal metabolic rates. Fluid is conserved more efficiently than adults and children depend more on nonevaporative forms of heat transfer for cooling. Consequently, children have lower sweat rates. Children can make the same physiologic changes of acclimatization that adults can, though it appears to occur at a slower rate.

TABLE 1 Drugs That Place Individuals at Risk for Heat Illness

- Amphetamines
- Anticholinergic agents
- Antiepileptic agents
- Antihistamines
- Benzodiazepines
- Beta-blockers
- Calcium channel blockers
- Cocaine
- Decongestants
- Diuretics
- Ergogenic stimulants
- Ethanol
- Laxatives
- Lithium
- Phenothiazines
- Tricyclic antidepressants

Data from Bouchama A, Knochel JP. Heat stroke. *N Engl J Med* 2002;346[25]:1978–1988, and Wexler RK. Evaluation and treatment of heat-related illnesses. *Am Fam Physician* 2002;65:2307–2314.

Environmental characteristics such as heat and humidity may play the largest role in development of heat illness. The WBGT can accurately predict the development of EHI in a particular setting and allows for modification of work or athletic events. The WBGT is recommended over use of the heat index. A dangerous clinical situation is likely to develop when physical activities are performed with an elevated WBGT. It is recommended that endurance events be adjusted when the WBGT exceeds 82°F (28°C) and that only events where adequate rest and recovery is observed are allowed to continue.

Heat Edema

Heat edema is caused by vasodilation of blood vessels, resulting in swelling that is typically observed in the hands and feet. The core temperature of the body is not elevated. Treatment begins with removal from the hot environment and elevation of the extremities, and may involve use of compression with stockings or wrapping. Diuretics are not recommended.

Heat Cramps

Also known as exercise-associated cramps, heat cramps present as intense pain, spasm, and prolonged muscle contraction as athletes undergo high-intensity activity. Although they are termed “heat cramps,” they are known to occur in cool settings as well, such as swimming and winter sports. The pathophysiology has not been entirely agreed upon but seems to stem from a neurogenic response to muscle fatigue in conjunction with fluid and electrolyte losses. To make the diagnosis, no signs of other illness may be present such as rhabdomyolysis, sickle cell disease or trait, or heat stroke. It is important to take a thorough medical history to avoid pitfalls in the diagnosis.

Management consists of stretching and massaging the affected muscle and oral replacement of fluids and electrolytes. IV fluids and benzodiazepines may be used for refractory cases. One study has shown that ingestion of pickle juice at 1 mL/kg may cause a faster recovery from muscle cramps when compared to deionized water. Discontinuation of cramping occurred at an average of 85 seconds with pickle juice compared to deionized water at 134 seconds. This may support the theory that heat cramps are a neurogenic-mediated process as cessation of cramping occurred before the contents of the pickle juice had time to reach the sites of action in the skeletal muscle.

Exercise-Associated Collapse

Also termed exercise-associated postural hypotension, exercise-associated collapse (EAC) is a relatively commonly occurring inability of the athlete to maintain a standing posture owing to hypotension that develops *after* an endurance event. Blood that is in circulation pools in the lower extremities as the athlete finishes the event and discontinues exercising. The skeletal muscles in the lower extremities normally exert a pressure on the corresponding vasculature, but as exercise ceases, the blood pools, causing an unexpected drop in cranial blood pressure, triggering collapse. Heat may play an indirect role in the development of EAC, but the terms “heat syncope” and “heat collapse” incorrectly describe the condition because there is no elevation in the athlete’s core temperature. Athletes may develop dizziness, nausea, and vomiting as a result of the rapid drop in blood pressure.

Athletes should be encouraged to continue activity such as walking at the end of events (rather than abruptly stopping or standing in place) to continue normal blood flow in order to avoid a sudden collapse and resultant injury. If an athlete does collapse, treatment should begin with laying the patient supine in the Trendelenburg position, keeping the legs and pelvis elevated. Administration of oral fluids containing glucose and electrolytes is helpful. IV fluid administration should be reserved for those with an elevated pulse (>100 bpm) or hypotension (systolic blood pressure <110 mm Hg) who are not responding to oral fluid intake. Generally these athletes will respond favorably within 10 to 30 minutes and may be allowed to leave under their own power.

Heat Exhaustion

Heat exhaustion occurs when the core body temperature measured rectally is elevated between 98.6°F and 104°F and the cardiovascular system is unable to generate the cardiac output necessary for the patient to complete the intended physical activity. This is clinically manifested most often by collapse or difficulty continuing activity *before* the event has finished. Heat exhaustion may be accompanied by nausea, vomiting, diarrhea, headache, muscle cramping, tachycardia, hypotension, weakness, dehydration, and electrolyte depletion. The level of dehydration can be difficult to judge clinically as the only reliable assessment of dehydration is measurement of water loss that occurs through preweight and postweight measurements. The distinction between heat exhaustion and heat stroke is the development of CNS dysfunction such as an altered level of consciousness, delirium, or seizure in heat stroke. Confusion may be present in heat exhaustion but should be mild and resolve quickly with treatment measures.

Athletes with heat exhaustion should be removed from the heat and placed in a cool, shaded, or air-conditioned environment. Vital signs including a rectal temperature should be measured to ensure that the proper diagnosis is made and to monitor the adequacy of cooling. Any excess clothing should be removed and the athlete should be placed in the Trendelenburg position. Cooling may be performed initially with placement of ice bags over the groin, axilla, and neck and water or ice-soaked towels over the head, trunk, and extremities. Immersion in an ice bath or tub of cold water or simply running cold water from a hose over the athlete may be necessary, but these measures tend to be more for comfort as heat exhaustion is not life threatening. Oral administration of an electrolyte-containing solution is helpful to restore adequate hydration and assists in returning the cardiac output to normal. IV fluid would be beneficial to individuals who do not respond or are not able to take oral fluids. Athletes who do not respond to these measures should be transported to a hospital to monitor for other developing conditions.

Heat Stroke and Heat Injury

Heat stroke is defined as a core body temperature elevated above 104°F associated with CNS dysfunction and end-organ damage. The CNS dysfunction can be observed in several ways including confusion, delirium, aggression or irritability, seizures, altered consciousness, and coma. Heat stroke can occur as classic heat stroke (nonexertional) or exertional heat stroke. Classic heat stroke usually afflicts the elderly population in the summer season and can be related to a lack of access to adequate air conditioning. Heat is continually absorbed from the environment and may be poorly dissipated secondary to underlying medical conditions and medications that preclude cooling. Exertional heat stroke is seen in younger and more athletic populations and does not necessarily occur in hot and humid environments. Other signs and symptoms of heat stroke are similar to those seen in heat exhaustion, but vital sign abnormalities are more likely to be present. Contrary to popular belief, the presence or absence of sweating does not diagnose heat stroke. Examination of a collapsed individual on the athletic field can be difficult and the differential diagnosis can extend beyond heat exhaustion and heat stroke to include cardiac arrhythmia and exercise-associated hyponatremia. It is important to maintain a degree of diagnostic suspicion for those athletes who present with collapse but do not have an elevated core temperature.

The term “heat injury” is not currently recognized by the World Health Organization as a diagnosis but was created by U.S. military physicians to categorize patients suffering from heat illness. Heat injury is diagnosed as an elevation in core temperature above 104°F with associated end-organ damage, with the exception of CNS dysfunction that defines heat stroke. The organs most commonly affected by heat stroke or injury include the liver, kidneys, and skeletal muscle (rhabdomyolysis).

Individuals who present with heat stroke should be treated with basic life support measures. Secure the airway and make sure adequate circulation and breathing are maintained. An initial set of vital signs including a rectal temperature should be performed

and repeated throughout the course of treatment. If a rectal thermometer is not available, do not use other methods to determine the temperature as they inaccurately measure core temperature in athletes who have been exercising. If available, rapid assessment of serum electrolytes including sodium and glucose should be done, especially with longer endurance events such as marathons. Rapid cooling should commence as soon as possible after the diagnosis is made as the prognosis worsens the longer the core temperature is elevated. The most effective cooling measure is ice-water immersion. Expected cooling rates are about 1°F per 3 minutes or 1°C per 5 minutes of immersion. Measurement with a rectal thermistor allows for continuous monitoring, but if this is not available, measurement by a rectal thermometer should be done approximately once every 10 minutes. Cooling should continue until the core temperature reaches 101°F. If no rectal thermometer is available, cool until the athlete begins to shiver, or about 15 to 20 minutes. If other interventions need to be performed (intubation, administration of IV medications or fluid) and ice-water immersion is not practical, other cooling tactics such as ice bags to the groin, axilla, and neck and placement of ice- or water-soaked towels to the rest of the body should be performed. Fluid resuscitation should be performed, but careful attention should be paid to fluid overload as pulmonary edema can develop with rapid administration of IV fluids. Despite rapid reduction in core temperature, these individuals are still at risk for organ damage. In cases where the core temperature does not decrease as expected or starts to rise after initial decline, transport to the hospital by emergency medical services is necessary for appropriate monitoring and lab evaluation. Transport to the hospital is always required in patients who do not regain consciousness within 30 minutes of appropriate cooling and medical intervention.

Return to Play

The prognosis for returning to physical activity after an episode of EHI is dependent upon the individual and the severity of the illness incurred. Athletes who develop heat cramps or EAC should be allowed to return to activity as soon as they feel capable. Decisions about return to play for those who develop heat exhaustion or heat stroke are more complicated. These athletes should avoid physical activity for at least 7 days. All lab abnormalities should be corrected and the athlete should feel physically and psychologically capable of returning. Once these conditions are met, a gradual progression of activity can begin in a cool or temperate environment. Acclimatization occurs over a period of approximately 2 weeks as activity is increased in duration and intensity and the individual is gradually reexposed to heat. Once the athlete is able to perform full-intensity workouts for 2 to 4 weeks in the heat, he or she may be returned to competition. For individuals who fail to acclimatize at 4 weeks or who have had multiple episodes of EHI, an exercise-heat tolerance test should be performed. An exercise-heat tolerance test consists of walking on a treadmill at 5.0 km/h with a 2% grade for 120 minutes at 40°C and 40% relative humidity while testing for elevated pulse and temperature and signs of nausea, dizziness, or weakness or a request for early termination of the test.

HIGH ALTITUDE ILLNESS

Method of

Adrienne N. Kovalsky, DO, MPH; and Ryan M. Commins, MD

CURRENT DIAGNOSIS

Acclimatization

- Symptoms include exertional dyspnea, increased respiratory rate, polyuria, peripheral edema, and insomnia.

High Altitude Headache (HAH)

- New-onset headache that fulfills at least two of the following:
 - Develops in temporal relation to altitude gain above 2500 m (8000 ft)
 - Worsens in conjunction with continued ascent and/or resolves within 24 hours of descent below 2500 m (8000 ft)
 - Includes at least two of the following characteristics: bilateral; mild or moderate intensity; aggravated by exertion, movement, straining, coughing, and/or bending

Acute Mountain Sickness (AMS)

- New-onset headache occurs within 12 hours of altitude gain above 2500 m (8000 ft)
- Anorexia, nausea, vomiting, fatigue, weakness, dizziness, or lightheadedness (see Box 3).

High Altitude Cerebral Edema

- Mental status changes or ataxia with preexisting AMS
- Mental status changes and ataxia without a prodrome of AMS

High Altitude Pulmonary Edema

- Relative hypoxemia in the setting of at least two signs or symptoms from each of the following lists:
 - Resting dyspnea, cough, weakness, decreased exercise performance, and chest tightness or congestion
 - Wheezing, rales, tachypnea, tachycardia, or central cyanosis

CURRENT THERAPY

Insomnia or Sleep Disturbance

- Acetazolamide (Diamox)¹ 125 mg PO at bedtime is recommended.
- Consider diphenhydramine (Benadryl) 50 mg at bedtime, zolpidem (Ambien) 5–10 mg at bedtime, or temazepam (Restoril) 15 mg at bedtime for patients with no history of altitude illness.

High Altitude Headache

- Medications for headache include ibuprofen (Advil) 600–800 mg PO every 8 hours, acetaminophen (Tylenol) 650–1000 mg PO every 6 hours, enteric-coated aspirin (Ecotrin) 325–650 mg PO every 4 hours, oxygen by nasal cannula at 1–2 L/min, or acetazolamide¹ 125 mg PO twice daily.

and repeated throughout the course of treatment. If a rectal thermometer is not available, do not use other methods to determine the temperature as they inaccurately measure core temperature in athletes who have been exercising. If available, rapid assessment of serum electrolytes including sodium and glucose should be done, especially with longer endurance events such as marathons. Rapid cooling should commence as soon as possible after the diagnosis is made as the prognosis worsens the longer the core temperature is elevated. The most effective cooling measure is ice-water immersion. Expected cooling rates are about 1°F per 3 minutes or 1°C per 5 minutes of immersion. Measurement with a rectal thermistor allows for continuous monitoring, but if this is not available, measurement by a rectal thermometer should be done approximately once every 10 minutes. Cooling should continue until the core temperature reaches 101°F. If no rectal thermometer is available, cool until the athlete begins to shiver, or about 15 to 20 minutes. If other interventions need to be performed (intubation, administration of IV medications or fluid) and ice-water immersion is not practical, other cooling tactics such as ice bags to the groin, axilla, and neck and placement of ice- or water-soaked towels to the rest of the body should be performed. Fluid resuscitation should be performed, but careful attention should be paid to fluid overload as pulmonary edema can develop with rapid administration of IV fluids. Despite rapid reduction in core temperature, these individuals are still at risk for organ damage. In cases where the core temperature does not decrease as expected or starts to rise after initial decline, transport to the hospital by emergency medical services is necessary for appropriate monitoring and lab evaluation. Transport to the hospital is always required in patients who do not regain consciousness within 30 minutes of appropriate cooling and medical intervention.

Return to Play

The prognosis for returning to physical activity after an episode of EHI is dependent upon the individual and the severity of the illness incurred. Athletes who develop heat cramps or EAC should be allowed to return to activity as soon as they feel capable. Decisions about return to play for those who develop heat exhaustion or heat stroke are more complicated. These athletes should avoid physical activity for at least 7 days. All lab abnormalities should be corrected and the athlete should feel physically and psychologically capable of returning. Once these conditions are met, a gradual progression of activity can begin in a cool or temperate environment. Acclimatization occurs over a period of approximately 2 weeks as activity is increased in duration and intensity and the individual is gradually reexposed to heat. HIGH ALTITUDE ILLNESS

Method of

Adrienne N. Kovalsky, DO, MPH; and Ryan M. Commins, MD

CURRENT DIAGNOSIS

Acclimatization

- Symptoms include exertional dyspnea, increased respiratory rate, polyuria, peripheral edema, and insomnia.

High Altitude Headache (HAH)

- New-onset headache that fulfills at least two of the following:
 - Develops in temporal relation to altitude gain above 2500 m (8000 ft)
 - Worsens in conjunction with continued ascent and/or resolves within 24 hours of descent below 2500 m (8000 ft)
 - Includes at least two of the following characteristics: bilateral; mild or moderate intensity; aggravated by exertion, movement, straining, coughing, and/or bending

Acute Mountain Sickness (AMS)

- New-onset headache occurs within 12 hours of altitude gain above 2500 m (8000 ft)
- Anorexia, nausea, vomiting, fatigue, weakness, dizziness, or lightheadedness (see Box 3).

High Altitude Cerebral Edema

- Mental status changes or ataxia with preexisting AMS
- Mental status changes and ataxia without a prodrome of AMS

High Altitude Pulmonary Edema

- Relative hypoxemia in the setting of at least two signs or symptoms from each of the following lists:
 - Resting dyspnea, cough, weakness, decreased exercise performance, and chest tightness or congestion
 - Wheezing, rales, tachypnea, tachycardia, or central cyanosis

CURRENT THERAPY

Insomnia or Sleep Disturbance

- Acetazolamide (Diamox)¹ 125 mg PO at bedtime is recommended.
- Consider diphenhydramine (Benadryl) 50 mg at bedtime, zolpidem (Ambien) 5–10 mg at bedtime, or temazepam (Restoril) 15 mg at bedtime for patients with no history of altitude illness.

High Altitude Headache

- Medications for headache include ibuprofen (Advil) 600–800 mg PO every 8 hours, acetaminophen (Tylenol) 650–1000 mg PO every 6 hours, enteric-coated aspirin (Ecotrin) 325–650 mg PO every 4 hours, oxygen by nasal cannula at 1–2 L/min, or acetazolamide¹ 125 mg PO twice daily.

Acute Mountain Sickness, Mild

- Avoid respiratory depressants, strenuous activity, or further ascent until the patient is asymptomatic.
- Acetazolamide 125–250 mg PO twice daily may be tried.
- Symptomatic treatment as for headache and nausea.

Acute Mountain Sickness, Moderate to Severe

- Stop ascent and rest until asymptomatic AND:
 - Administer acetazolamide 250 mg PO twice daily.
 - Oxygen (1–2 L) or hyperbaric chamber 2–4 psi may be used if available.
 - Consider dexamethasone (Decadron)¹ 4 mg PO or IM every 6 hours as an adjunct or if acetazolamide is contraindicated.
 - Monitor for mental status changes, confusion, or ataxia and descend immediately at onset.
- If symptoms are severe, or if there is no response to 24 hours of therapy, immediate descent of at least 500 m or to last asymptomatic altitude is the definitive treatment.

High Altitude Cerebral Edema

- Prepare for evacuation or emergent descent of at least 1000 m (3,280 ft).
- Administer dexamethasone¹ 8 mg PO, IM, or IV once followed by 4 mg every 6 hours.
- Consider adding acetazolamide¹ 250 mg PO twice daily as an adjunct.
- Early recognition and treatment are essential.

High Altitude Pulmonary Edema

- Bed rest with oxygen 4–6 L by nasal cannula.
- If the patient is not improving or if HACE is severe, descend at least 500 m, avoiding exertion.
- Use a hyperbaric chamber at 2–4 psi if oxygen is unavailable or the patient is unable to descend.
- If oxygen is unavailable or the patient is unable to descend, or if the patient is not responding to either:
 - Give nifedipine (Procardia)¹ 10 mg PO once and 30 mg extended-release PO every 12 to 24 hours³ (contraindicated in HACE).
 - Consider adding tadalafil (Adcirca, Cialis)¹ 10 mg PO twice daily³, sildenafil (Revatio, Viagra)¹ 50 mg PO thrice daily³, or salmeterol (Serevent)¹ 125 µg inhaled twice daily³.
 - It is not advisable to use both nifedipine and a phosphodiesterase inhibitor; if this becomes necessary, carefully monitor blood pressure and stagger doses to prevent potential cerebral hypoperfusion.

Concurrent High Altitude Pulmonary and Cerebral Edema

- As always, immediate descent and supplemental oxygen therapy are critical.
- Treatment as for HACE with the addition of dexamethasone.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

The appeal of travel to high altitude is vast. For many it is tourism, skiing, or mountaineering, but for others it is far more fundamental, as many travel to high altitudes for work. The number of people residing at elevations higher than 1500 m has risen significantly in the last two decades, and is approximately 440 million worldwide. While elevation greater than 1500 m (5000 ft) is generally considered high altitude (Denver, for example, is 1609 m or 5,278 ft), most high altitude illness occurs above 2500 m or 8000 ft. It is at these altitudes that the effects of hypoxia and decreasing barometric pressure start to be seen. Elevation greater than 5500 m (18,000 ft) is considered extreme altitude. Many persons become symptomatic during the adaptive process known as acclimatization, and some develop acute high altitude syndromes, including acute mountain sickness (AMS), high altitude cerebral edema

(HACE), and high altitude pulmonary edema (HAPE). These syndromes are often preventable, but they have the potential to cause significant morbidity and mortality for the patient and for those involved in risky rescue efforts by land or air.

Epidemiology and Risk Factors

The incidence of altitude illnesses is highly variable and commonly idiosyncratic. At 3000 m (~10,000 ft) the incidence of AMS ranges from 4% to 58%, whereas the incidence of HAPE and HACE generally is less than 1%. The occurrence of altitude illness depends on the rate of ascent, altitude of residence, exertion, prior history of altitude illness, and individual susceptibility. For each 1000 m (3,280 ft) above 2500 m (8,000 ft) the rate of AMS increases 13%. The most predictive risk factor for AMS is previous AMS, and the risk of recurrence in similar elevations is as high as 60%. Physical fitness does not alter susceptibility, whereas obesity is a risk factor. Tobacco smoking, asthma, and diabetes do not confer any additional risk. Certain medical conditions including chronic obstructive pulmonary disease, pulmonary hypertension, congestive heart failure, coronary artery disease, sickle cell disease, and sleep apnea increase risk of developing altitude illness. Stable and well-controlled conditions such as hypertension and diabetes do not appear to increase the risk for altitude illness. A more detailed discussion of some of these diseases is included later in the text.

Physiologic Adaptation and Pathophysiology

Hypoxia inducible factors (HIFs) are a family of transcription regulators that respond to level of oxygenation and ultimately control the physiologic response to hypoxia. In hypoxic conditions, they are able to increase transcription of hypoxia-responsive genes. The HIFs have a wide range of effects including increasing glycolysis and angiogenesis, stimulating erythropoiesis, regulating endothelial nitric oxide synthase, and controlling ventilation.

The physiologic response to altitude rests along one end of a spectrum of compensatory mechanisms that can evolve into high altitude syndromes. The pathophysiology of AMS and HACE is incompletely understood, but hypoxemia and changes in the brain itself have been implicated. Hypoxemia is thought to increase cerebral blood flow though it is unclear whether there is a true difference in cerebral blood flow in patients with and without AMS. Hypoxemia may also increase vascular permeability through various mechanisms. Changes that occur in the brain include edema, increased ICP, vascular distention due to increased intravascular pressure, and release of nociceptive chemicals or substances. The development of HAPE is usually preceded by an excessive rise in the pulmonary artery pressure in response to hypoxic vasoconstriction. However, other factors including alveolar inflammation, impaired sodium and water reabsorption by the alveolar epithelium and uneven hypoxic vasoconstriction may also play a role.

In the first few hours at high altitude, peripheral chemoreceptors are activated by hypoxia, leading to an increased respiratory rate. The increased minute ventilation reduces the dilutional effects of CO₂ in the alveolar air and causes a respiratory alkalosis. This subsequent alkalosis also improves oxygen binding in the lung but ultimately slows respiration. After 24 to 48 hours the kidneys excrete excess bicarbonate, normalizing the elevated pH that would otherwise prevent an adequate increase in respiration. This is the basis for acclimatization.

Periodic breathing is also more likely to occur at higher elevations owing to hypoxia and the resulting respiratory alkalosis. Altitude-dependent diuresis causes transient hemoconcentration in the first 1 to 2 days, with true erythropoiesis starting at 4 to 5 days. Long-term residence at altitude can cause polycythemia, increasing the risk for tissue infarction. With permanent residence at high altitude there is evidence that cognitive development may be slowed in children and that neuropsychological function is impaired in adults. Permanent residents will see improved maximal oxygen consumption at lower elevations. The most complex effects of hypobaric hypoxia are seen in the lung and the brain and are not completely understood.

Prevention

High altitude illness is a morbid and potentially fatal disease, and preventive measures should be employed. The most reliable way to prevent altitude illness is through graded ascent, thereby allowing sufficient time for acclimatization. A conservative guideline for activities above 2500 m (8,000 ft) is increasing sleep altitude by no more than 300 m (1000 ft) in a 24-hour period and with an additional rest day every 1000 m (3,280 ft). If symptoms of AMS are noted, no further ascent should be attempted until they resolve in order to prevent more severe illness or evolution of HACE or HAPE. Additional preventive measures should be taken and are of particular importance for persons planning rapid ascent, whether on foot or flying directly into altitudes of 2500 m (8,000 ft) or greater. Light activity can accelerate acclimatization, but strenuous exertion should be avoided in the first 2 days. Pre-exposure of 5 days of comparable altitude within 2 months of ascent is protective. CNS depressants such as alcohol are thought to worsen effects of altitude, particularly overnight when respiration is already more depressed, and they should be avoided. Abrupt cessation of caffeine intake in chronic users may provoke withdrawal symptoms that can mimic AMS. If available, residing and working in an oxygen-enriched environment may also help reduce the incidence of AMS. Refer to [Box 1](#) for a summary.

Medical prophylaxis should be considered when graded ascent is not possible, whether on foot or flying directly into altitudes of 2500 m (8,000 ft) or greater, and for persons with any history of prior altitude illness returning to the same elevation. Prophylaxis is also advised for ascent profiles that are considered moderate to high risk in patients with unknown susceptibility, including planned ascent to more than 3000 m (10,000 ft) in one day, rapid ascent greater than 500 m (1,640 ft) per day above 3000 m (10,000 ft), or very rapid ascent to a final altitude greater than 4000 m (13,000 ft). This should be started the day prior to beginning ascent and continue until at a stable altitude for at least 2 to 4 days. If further ascent is undertaken, or if symptoms recur, prophylaxis can be restarted at any point.

BOX 1 Prevention of High Altitude Sickness

Ascent above 2500 m (8,000 ft) should be at a gradual rate of 300 m per 24 hours, with an additional rest day for every 1000 m (3,280 ft) gain.

With rapid ascent above 2500 m (8,000 ft), light activity may be helpful with acclimatization, but strenuous activity should be avoided for at least 48 hours.

Avoid respiratory depressants such as alcohol until acclimatized. Five days of comparable altitude exposure should be undertaken within 2 months of ascent.

For AMS or HACE, begin prophylaxis 1 or 2 days before starting ascent:

- Acetazolamide 125 mg PO bid
- Dexamethasone¹ 2 mg q6 or 4 mg q12 h for patients with sulfa allergy
- Prophylaxis is strongly recommended for patients with a history of AMS or HACE or for rapid ascent.

For persons with a history of HAPE, begin prophylaxis 1 day before starting ascent:

- Nifedipine¹ 30 mg BID³
- Salmeterol¹ (adjunct) 125 µg inhaled bid³
- Dexamethasone¹ 8 mg PO bid
- Tadalafil (Adcirca, Cialis)¹ 10 mg PO bid³
- Sildenafil (Revatio, Viagra)¹ 50 mg PO tid³

Stop ascent with onset of even mild AMS to prevent evolution to HACE.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Abbreviations: AMS = acute mountain sickness; HACE = high altitude cerebral edema; HAPE = high altitude pulmonary edema.

BOX 2 Medications for AMS, HACE, and HAPE

Acetazolamide

Acetazolamide (Diamox) is a central-acting respiratory stimulant that causes a metabolic acidosis and ultimately facilitates acclimatization. It is effective in preventing and treating AMS and HACE.¹ Patients should be warned about side effects, including paresthesias, flat taste of carbonated beverages, and polyuria, particularly at night. Persons with a history of asthma, sulfonamide allergy, anaphylaxis, or penicillin allergy should try this medication under the supervision of a medical professional prior to departure. It should not be used in type 1 diabetics due to the risk for ketoacidosis. It also should not be used in chronic lung disease if FEV₁ is less than 25% predicted, in patients on potassium-wasting diuretics, or on long-term high doses of aspirin.

Dexamethasone

Dexamethasone (Decadron)¹ is also effective in the prevention and treatment of AMS and HACE, though its mechanism is not completely understood. Unlike with acetazolamide, symptoms can recur after stopping treatment, and it does not facilitate acclimatization. It is not recommended for prophylaxis of AMS unless acetazolamide is contraindicated, though it is the drug of choice for treatment of HACE. Use is cautioned in diabetics due to hyperglycemia and in patients at risk for amebiasis or strongyloidosis.

Nifedipine

Nifedipine (Procardia)¹ is a calcium channel blocker that inhibits pulmonary vasoconstriction secondary to hypoxia at high altitude and is used in treatment and prevention of HAPE. Caution should be used with other antihypertensives due to risk for hypotension. Medications that inhibit the cytochrome P450 3A4 pathway, including macrolides, doxycycline, and azoles, may increase plasma concentrations and also precipitate hypotension. Ginkgo biloba⁷ may also increase levels of nifedipine and cause hypotension and should be avoided.

Tadalafil (Cialis) and sildenafil (Viagra)

These are phosphodiesterase inhibitors¹ that cause pulmonary vasodilation and are used in preventing HAPE. They should not be used in conjunction with nitrates due to risk for significant hypotension, nor with alpha-blockers due to orthostatic hypotension. Medications that inhibit the cytochrome P450 3A4 pathway, including macrolides, doxycycline, and azoles, may increase plasma concentrations and also precipitate hypotension.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

Abbreviations: AMS = acute mountain sickness; HACE = high altitude cerebral edema; HAPE = high altitude pulmonary edema

The most effective medication for prophylaxis of AMS and HACE is acetazolamide (Diamox) 125 mg PO twice daily starting 1–2 days before ascent. This is a central-acting respiratory stimulant that causes a metabolic acidosis and ultimately facilitates acclimatization. Patients should be warned about side effects and possible allergy ([Box 2](#)). Dexamethasone (Decadron)¹ 2 mg every 6 hours or 4 mg every 12 hours also is effective, though its mechanism is not completely understood. Unlike with acetazolamide, symptoms can recur after stopping dexamethasone, and it does not facilitate acclimatization. It is not recommended for prophylaxis unless acetazolamide is contraindicated, and it is best saved for treatment of severe AMS or HACE. Ginkgo biloba⁷ is no better

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

than placebo at preventing AMS. Ibuprofen (Advil)¹ has not been shown to prevent AMS but does prevent high altitude headache.

Prophylaxis of HAPE has been studied in preventing recurrence in persons with a history of HAPE, though it also would be prudent to consider prophylaxis for anyone undertaking very rapid ascent. Numerous agents have been evaluated in patients with history of HAPE and are listed in [Box 1](#). Nifedipine (Procardia)¹ is the preferred medication for prevention, with salmeterol (Serevent)¹ as a potential adjunct if there is significant history of HAPE and anticipated rapid ascent profile.

Symptomatic Acclimatization and Disrupted Sleep

Many people experience symptoms of normal adaptation that do not always herald illness, but they should nonetheless always be completely evaluated. Expected symptoms include exertional dyspnea, polyuria, peripheral and facial edema, and nocturnal awakenings and insomnia. The most common side effects of normal acclimatization are disrupted sleep and mild peripheral edema. Acetazolamide¹ 125 mg at bedtime has been shown to decrease nocturnal oxygen saturation and lessen awakenings (see [Box 2](#)). Diphenhydramine (Benadryl)¹ 25 to 50 mg may also be used, but it does not have the same benefits. Studies have shown that zolpidem (Ambien)¹ 10 mg and temazepam (Restoril)¹ 15 mg are probably safe, but because studies have been small and targeted, these medications probably should be avoided whenever possible, particularly in persons with a history of altitude illness.

High Altitude Headache

Headache is a common occurrence and does not always evolve into AMS. The headache is generally bilateral, and throbbing is exacerbated with coughing, bending, straining, and exertion, and is often worst early in the morning. There should be no other associated symptoms. Onset can occur within 1 hour but usually begins within 6 to 10 hours. Numerous medications are effective for treatment, including analgesics and medications used in prophylaxis of AMS. See the Current Therapy box for a complete listing.

High Altitude Syndromes

Acute Mountain Sickness

In the setting of a recent gain in altitude, AMS is defined as headache with at least one of the following: anorexia, nausea, or vomiting; fatigue or weakness; or dizziness or lightheadedness. Clinically, a lack of headache with otherwise suggestive symptoms should not rule out AMS. As with high altitude headache, onset can occur within 1 hour but usually begins within 6 to 10 hours. Other symptoms can include decreased urine output, lassitude, and ataxia. All symptoms typically resolve within 2 to 3 days, though on occasion at higher altitudes symptoms can persist for days or weeks without progression or resolution. Examination is normal and no diagnostic studies are indicated. The differential includes dehydration, exhaustion, hangover, viral illness, carbon monoxide poisoning, caffeine withdrawal, migraine, and meningitis. Early recognition of AMS is essential in order to begin appropriate measures that might help prevent evolution to the potentially fatal HACE, which exists along the same spectrum.

If mild, AMS can be monitored at a stable altitude with no further ascent undertaken. Analgesics and antiemetics are effective for managing symptoms. Acetazolamide may be considered for mild AMS and is recommended for moderate to severe symptoms. Dexamethasone¹ may be added, or used in substitution if intolerant of or allergic to acetazolamide, for a short course (less than 5 days) while acclimatizing. Low-flow supplemental oxygen and hyperbaric chambers can be used as an adjunct for moderate to severe symptoms. Descent is advised for symptoms that progress after 24 hours of rest or treatment or for symptoms that are severe or stable but prolonged in order to prevent evolution to HACE, but graded ascent can be resumed once symptoms resolve. Immediate descent should be undertaken for ataxia, altered mental status, or

any signs or symptoms of pulmonary edema. Refer to the Current Therapy box for dosing and summary.

High Altitude Cerebral Edema

In the setting of a recent gain in altitude, HACE is defined as a change in mental status and/or ataxia in a person with AMS, or both mental status changes and ataxia in a person without AMS. There may be changes in mood or hallucinations. It generally progresses over 1 to 3 days, but it can also cause loss of consciousness within 12 hours. Examination has nonfocal neurologic findings with confusion. Papilledema may be seen, and rales are often present from concurrent HAPE. If computed tomography (CT) or magnetic resonance imaging (MRI) is available acutely, findings would be consistent with vasogenic edema. If a lumbar puncture is performed, increased opening pressure is usually present.

Differential diagnosis is similar to that for AMS but should be expanded to include diabetic ketoacidosis, hypoglycemia, electrolyte imbalances, brain tumor, stroke, acute psychosis, and seizure. After a long term at altitude or any length of time at very high altitudes blood can become hyperviscous and increasingly thrombogenic, so in these circumstances stroke should rise on the differential.

Early recognition is crucial in management of HACE to prevent evolution to irreversible disease. The most important element of treatment is descent of at least 1000 m (3,280 ft). Supplemental oxygen and hyperbaric bags may be used during descent and are imperative if descent is not possible. Dexamethasone¹ should be initiated, and should be continued after descent if symptoms persist. Acetazolamide¹ may be added. Dosages are listed in the Current Therapy box.

High Altitude Pulmonary Edema

In the setting of a recent gain in altitude, HAPE is diagnosed with at least two of resting dyspnea, cough, weakness or decreased exercise performance, and chest tightness or congestion and two of wheezing or rales, tachypnea, tachycardia, or central cyanosis. There may also be an associated low-grade temperature elevation. Cough is initially dry but in late stages is productive of pink or bloody sputum. Onset often occurs during sleep, usually the second night at altitude, and often after the use of sleep aids that cause respiratory depression. It rarely occurs after 4 or 5 days at a stable altitude and should resolve within 48 hours of descent.

Examination is significant for rales that can begin in the right axilla and progress diffusely and for low-grade temperature elevation. Hypoxia, often very pronounced, is noted on pulse oximetry; oxygen levels will be disproportionately low for a given elevation. If available, chest radiography typically demonstrates bilaterally diffuse patchy opacities without pulmonary vascular changes, though initially they may be seen in the right middle lobe. Computed tomography of the chest typically shows a patchy peripheral and nodular distribution of edema. Ultrasound may be more readily available than radiography in remote locations and through the use of the comet-tail technique may be helpful in identifying HAPE and differentiating from pneumonia or other conditions.

HAPE can occur in conjunction with severe AMS or HACE. Differential includes heart failure, acute myocardial ischemia, pulmonary embolus, asthma, bronchitis, and pneumonia. Among the altitude illnesses, HAPE is associated with the highest rate of mortality but, unlike HACE, it is unlikely to cause long-term sequelae if treated appropriately. As with all altitude illness, removing the hypoxic stimulus is the central principle in management, and with HAPE it is also the most effective. This can be done with descent, supplemental oxygen, or a hyperbaric chamber. If available, supplemental oxygen and bed rest may be sufficient. If the pulmonary edema is severe, descent is the definitive treatment and should be undertaken without delay. Exertion and cold stress should be avoided during descent. Nifedipine (Adalat, Procardia)¹ and salmeterol (Serevent)¹ may be of benefit in treatment of HAPE, but they

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

are not as effective as oxygen or descent and should be used as an adjunct or if no other alternatives exist. Dual vasodilating agent use (nifedipine¹ and a phosphodiesterase inhibitor¹) is not recommended, but if attempted when no alternatives exist, doses should be staggered and blood pressure carefully monitored to prevent potentially disastrous hypotension and cerebral hypoperfusion. Refer to the Current Therapy box for dosing. Reascent may be considered 2 to 3 days after resolution, but risk of recurrence is significantly higher.

Other High Altitude Disorders

Upper Respiratory Disorders

Rhinorrhea, chronic cough, and noninfectious pharyngitis and bronchitis are commonly seen at high altitude and very prevalent at extreme altitude. Sputum is often purulent. Onset of high altitude bronchitis and chronic cough is generally after strenuous activity, and use of a balaclava to increase humidification of inhaled air may help prevent this. Symptoms may become severe enough to cause rib fracture. Comprehensive studies on the most effective treatment are lacking, but symptomatic therapies may be helpful, including decongestant nasal sprays, inhaled corticosteroids and beta agonists, and codeine-based cough medications; the latter should never be used in the pediatric population or in combination with other opiate medications or benzodiazepines. Infectious upper respiratory syndromes should remain in the differential; however, viral etiologies are most common with judicious consideration of antibiotic therapy.

High Altitude Retinopathy (HAR)

Hypoxia is known to cause hyperemia and engorgement of the retinal vessels at any elevation, and will be seen above 2500 meters (8,000 ft) in the setting of hypobaric hypoxia. Evolution to retinal hemorrhage indicates the presence of high altitude retinopathy (HAR) and may occur above 4000 meters (13,000 ft). Macular or vitreous hemorrhage, disc edema, and cotton wool spots can be seen in more severe HAR. There may be a delay between ascent and onset of hemorrhage. The retinopathy is generally asymptomatic; however, scotomas and visual field deficits may occur, particularly with macular hemorrhage.

Lower oxygen saturation, higher ascent, strenuous exertion, and longer duration at high altitude are associated with HAR. Higher baseline intraocular pressure, hypercoagulable disorders, and aspirin and NSAID use also appear to be risk factors. Slower ascent and improved acclimatization are protective. Acetazolamide does not appear to affect incidence. Recent research has not shown a definitive correlation between HAR and AMS or HACE.

Most HAR will resolve within days to weeks of descent. Rarely visual deficits have persisted longer. Descent is recommended for any premacular hemorrhage due to higher risk to central vision and unclear long-term prognosis, as well as any new visual deficits. Given the potential risk of worsening retinopathy, diabetics and other patients with risk for or preexisting retinopathy should avoid travel to elevations greater than 4000 meters (13,000 ft), and consult with their ophthalmologist if such travel is unavoidable or if any travel is intended above 2500 meters (8,000 ft).

Chronic High Altitude Diseases

Residence above 2500 meters (8,000 ft) in the United States is rising, and numbers in the hundreds of millions worldwide. Prevalence is dependent on many factors, most notably residence altitude and ethnicity. Ethnic groups with longer history of high altitude residence, such as Tibetans, have improved adaptation and lower prevalence compared to other ethnic groups at the same elevation. Prevalence increases with increasing altitude, even among more adapted ethnic groups.

Chronic Mountain Sickness (CMS). Symptoms include headache, dizziness, dyspnea, palpitations, insomnia, fatigue, arthralgias, myalgias, distal peripheral paresthesias, anorexia, and

cognitive dysfunction. Diagnosis is made by excessive erythrocytosis (hemoglobin greater than 19 g/dL in women or 21 g/dL in men) in the setting of severe hypoxemia (there is not yet consensus on threshold value, but less than <85% is highly suggestive), normal pulmonary function tests, and chronic residence above 2500 meters (8,000 ft). Pulmonary hypertension and heart failure may also be present. Patients with a history of antecedent chronic pulmonary disease such as COPD or other medical condition that may account for hypoxia are excluded from this diagnosis, as the presentation cannot be fully attributed to altitude, though consideration for a diagnosis of secondary CMS may be made. Phlebotomy, optimally with isovolemic hemodilution, provides temporary benefit and may result in more significant recurrence and is not recommended as a long-term solution. Consideration may be made for severe symptoms or as a short-term bridge to permanent resettlement at lower elevation. Supplemental oxygen, slow breathing technique, a supervised mild to moderate exercise regimen, and intermittent pulses of acetazolamide¹ 250 mg per day for three weeks have all been found to help. Other medications are still being studied. Strenuous activity should be avoided. Definitive therapy is migration to lower elevations, upon which CMS will slowly resolve, but will reappear upon return to high altitude. Periodic travel to lower altitude is recommended if permanent migration is not possible.

High Altitude Pulmonary Hypertension (HAPH). Symptoms include cough, dyspnea, cyanosis, and insomnia, and may include physical findings of right heart failure. Diagnosis is made by a mean pulmonary artery pressure greater than 30 mmHg or systolic pulmonary artery pressure greater than 50 mmHg measured at altitude of residence with moderate hypoxemia, absence of excessive erythrocytosis, and chronic residence above 2500 meters (8,000 ft) after the exclusion of chronic lung disease and other causes of pulmonary hypertension. Screening diagnosis should be made by echocardiography and confirmed via invasive measurement. As with CMS, definitive therapy is migration to low altitude. If this is not feasible, calcium channel blockers and phosphodiesterase inhibitors may be of benefit. Early referral to a pulmonary hypertension specialist is recommended.

Additional Considerations

Traveling to high altitude with children, during pregnancy or in the setting of chronic medical conditions includes additional considerations, some of which are summarized below. Patients should include consultation with the patient's pediatrician, obstetrician, or specialist prior to travel. Complete medication list, including as-needed prescriptions for travel, such as antibiotics, should be carefully reviewed for interactions, contraindications, and dose adjustments prior to prescribing medications for prevention or treatment of altitude illness. Refer to [Box 2](#) for a limited summary.

Children

Susceptibility of the pediatric population to altitude illness is comparable to that of the adult population. Travel to high altitude should not be undertaken in first 4 to 6 weeks or in prematurity. It should also be avoided in any children with history of cardiopulmonary conditions, Down syndrome, at increased risk for pulmonary hypertension, or a recent upper respiratory illness. Presentation will generally mimic that in adults; however, assessment of nonverbal children is more complicated with criteria including fussiness, decreased playfulness, decreased appetite, and sleep disturbance. Physical findings are similar to the adult population and may also include agitation, productive cough, cyanosis, and tachycardia. Management and prevention are comparable with the following dosage adjustments: acetazolamide* 2.5 mg/kg every 12 hours can be used for prevention and treatment of both AMS and HACE¹. Dexamethasone¹ 0.15 mg/kg every 6 hours

¹Not FDA approved for this indication.

*Acetazolamide is approved for use in children aged 12 years and older only.

¹Not FDA approved for this indication.

should be used for treatment of severe AMS and HACE, in conjunction with descent. Medications to prevent and treat HAPE have not been adequately studied in the pediatric population.

Pregnant Women

Women who travel to high altitude during pregnancy are at higher risk for preterm labor, but the rate of complications does not appear to be significantly changed in the setting of uncomplicated low-risk pregnancy, and travel to 2500 meters (8,000 ft) is likely safe. While exercise during pregnancy is associated with better outcome, it should be minimized the first few days at high altitude while acclimatizing, and strenuous exertion should be avoided. Most medications used for the treatment of high altitude illness are rated category C for pregnancy, and priority should be made for descent rather than medical management of altitude illness. Travel to high altitude should be avoided in any pregnancy that is complicated or not low risk. Residence at high altitude during pregnancy is associated with a decrease in birth rate in proportion to the increase in altitude, as well as increased complications, although highland ancestry is protective.

Hypertension

Blood pressure response to high altitude is variable. Adequately controlled hypertension should not confer any additional risk for altitude illness. Any patient requiring more than one medication or maximum dose of one medication should travel with a blood pressure cuff and monitor their blood pressure. These patients should also develop an algorithm with their physician for how to manage elevated blood pressure and when to decrease or hold doses.

Coronary Artery Disease (CAD)

All patients with known history or antecedent symptoms should undergo risk stratification, cardiac stress testing, and consult with their cardiologist. Patients with stable CAD who are able to exercise will likely tolerate travel to high altitude. It is advisable to avoid exertion until acclimatized, or for at least 4 to 5 days. Subsequent exertion should be below tolerated exertion at their elevation of residence, and strenuous exercise should be avoided. Other patients, including those with abnormal stress tests, angina, or acute coronary syndrome within six months without revascularization, should not travel to altitude.

Heart Failure

High altitude may increase risk for decompensation of chronic heart failure, and patients with poorly compensated heart failure should avoid travel. If heart failure is stable and controlled, patients may tolerate travel to altitude less than 3000 meters, but physical activity should remain below what is tolerated at their altitude of residence. These patients should monitor their body weight and develop an algorithm with their physician for how to adjust diuretics for increasing edema or weight gain.

Respiratory Conditions

Asthma. Allergic asthma will likely improve at high altitude, but asthma that is exercise- or cold-induced may be made worse. An optimized pre-travel medical regimen should be continued, and these patients should travel with additional rescue medications, including bronchodilators and corticosteroids. Patients should travel with an up-to-date asthma action plan and know where to seek medical attention for an exacerbation that cannot be managed independently. Travel should be avoided in moderate persistent or severe asthma, history of hospitalization, or recent exacerbation.

Chronic Obstructive Pulmonary Disease (COPD). Studies evaluating patients with COPD at high altitude are limited, and data from commercial flights assess exposure of insufficient duration to evaluate risk for high altitude illness. Those who are chronically hypoxemic may have some tolerance to hypobaric hypoxia due to their adaptations to chronic hypoxia. Data is more limited on patients with chronic carbon dioxide retention, and these patients should avoid travel to high altitude. Those with an FEV₁ < 1 liter

should travel with supplemental oxygen. If FEV₁ is 1–1.5 liters, patients should be assessed by their pulmonologist for possible initiation of supplemental oxygen after arrival at altitude. If supplemental oxygen is already being utilized, the anticipated increase in flow rate may be estimated by the ratio of higher to lower barometric pressure. Patients who have dyspnea at rest or with minimal exertion should not travel to altitudes higher than residence. High-altitude travel also should be avoided if there is a history of frequent recurrent exacerbations or hospitalizations. The home medical regimen should be optimized, and patients should travel with additional rescue medications and inhalers. All patients should travel with a pulse oximeter and seek medical attention for new persistent respiratory symptoms, hypoxia, or fatigue. Acetazolamide should not be used in patients with severe COPD or history of CO₂ retention.

Pulmonary Hypertension. Patients with pulmonary hypertension are at increased risk for developing HAPE and should be educated about the clinical presentation and treatment of HAPE. If mean pulmonary arterial pressure is 35 mm Hg or greater, or if systolic pulmonary arterial pressure is 50 mm Hg or greater, patients should travel with supplemental oxygen. If not on vasodilator therapy, these patients should also be started on nifedipine¹ 30mg SR BID. Those with milder pulmonary hypertension should monitor oxygen saturation and consider prophylaxis with nifedipine¹ 30mg SR BID. Pre-travel evaluation by a pulmonary hypertension specialist is recommended.

Sleep Apnea. Patients with obstructive sleep apnea tend to do better at high altitudes than those with central sleep apnea, but both of these populations should continue CPAP while at altitude. Older machines may lack pressure-compensating features and thus need intended CPAP pressure adjusted at high altitude. In patients not using CPAP, acetazolamide prophylaxis is recommended.

Other Considerations. Travel to high altitude should be avoided in patients with obesity hypoventilation or bilateral carotid body resection. If such travel is unavoidable, supplemental oxygen should be used and any home use of CPAP should be continued while at altitude.

Diabetes Mellitus

Patients with controlled type 1 diabetes do not appear to be at higher risk for AMS. Those with type II diabetes may be at higher risk for AMS, possibly related to other underlying risk factors and the metabolic syndrome. The elevated risk for cerebrovascular accident in diabetics may be further increased at high altitude. The prevalence of diabetes is lower at higher altitudes.

Metabolism and glucose control will change at altitude. Basal metabolic rate will increase, appetite may be suppressed, and absorption may be slowed, but hypoxia also causes hyperglycemia. Close glucose monitoring is imperative. Glucose-monitoring devices may lose accuracy, though glucose dehydrogenase-based glucometers may have more reliable performance. Malfunction risk is decreased if devices are kept warm. Acetaminophen may cause hyperglycemia, and care should be taken in use for HAH. Hydration is also particularly important for diabetic patients, particularly type 1, which can be self monitored by urine output and color.

Despite the above changes at altitude that suggest later administration of prandial insulin, there may also be a delay in the effects of rapid-acting insulin with increasing elevation, which may require earlier administration. This will also be affected by rate of ascent, acclimatization, exertion, and of course diet. Given this variability and individual response, patients should track their specific responses upon ascent and factor this in during descent, particularly if rapid, as is often the case. Glucose should be checked at a greater frequency to assess response, and any insulin administration should be adjusted accordingly. Continuous glucose monitoring may help track trends but, given the lag time compared to

¹Not FDA approved for this indication.

capillary testing and lack of studies at high altitude, probably only be used in conjunction with capillary testing.

In Type 1 diabetes, travel to altitude induces hyperglycemia initially and with any acute hypoxia or further ascent. After acclimatization there is a decrease in fasting glucose, and a further drop with exertion. The initial hypoxia-induced hyperglycemia may contribute to ketonuria as well as ketoacidosis, particularly with rapid ascent. This is particularly notable at very high to extreme elevations, and increased exertion and decreased appetite at these elevations may not be adequate to compensate for this hyperglycemia. Risk for DKA is increased due to these metabolic effects of altitude as well as the increased risk infectious diarrhea in some high-altitude regions, changes in diet, and certain medications. As symptoms of AMS, HACE, and diarrheal illness may mimic DKA, onset of symptoms of AMS or HACE, diarrhea in the setting of hyperglycemia, or suspected DKA warrants immediate descent.

Use of an insulin pump at altitude in controlled type 1 diabetics appears safe without significant pump dysfunction, though with rapid pressure changes such as cabin pressurization during air travel there have been reports of bubble formation affecting insulin delivery. It is advisable to also carry injectable insulin in case of pump failure. Use of acetazolamide is not advisable for type 1 diabetics due to increased risk for acidosis and diuresis increasing risk for dehydration. Dexamethasone should also be avoided due to the risk for hyperglycemia. This should be reserved for treatment of severe AMS, HACE, or if descent is not possible but emergent descent is a priority.

Type 2 diabetics do not appear to have the same extent of glycemic changes, though they may also experience hyperglycemia with initial ascent and hypoxia. Once acclimatized, they may need to decrease doses of sulfonylurea medications and insulin due to increased basal metabolic rate. It may be safe to use acetazolamide with caution in type 2 diabetes if not on insulin. Dexamethasone will cause hyperglycemia.

All travel companions should be educated on the signs and symptoms of hyper- and hypoglycemia, diabetic ketoacidosis (DKA) if applicable, overlap between these and AMS, HACE, and gastrointestinal illness, and how these conditions should be managed. Patients with poorly controlled or brittle diabetes should not travel to high altitude. Sedentary patients are advised to discuss cardiac stress testing with their physician.

MARINE POISONINGS, ENVENOMATIONS, AND TRAUMA

Method of

Allen Perkins, MD, MPH

CURRENT DIAGNOSIS

- History of exposure is necessary for diagnosis.
- Ingested toxins can cause unusual symptoms, predominately gastrointestinal.
- Jellyfish envenomation is very painful but almost always self-limited.
- Trauma management follows principles of dirty wounds.
- Specific marine pathogens should be covered if contamination is suspected.

CURRENT THERAPY

Ingestions

- Avoidance is the best strategy.
- Early decontamination with activated charcoal (Actidose-Aqua) can reduce duration of symptoms.
- Symptomatic care is generally sufficient.

Jellyfish

- Remove visible stingers.
- Control pain with topical analgesia.

Trauma

- Avoiding water at feeding time can help avoid injury.
- If envenomation is suspected, consider hot water immersion.
- Tetanus status should be checked.
- Antibiotic coverage should take marine pathogens into account.

The United States has more than 80,000 miles of coastline, and more people are enjoying water-dependent recreation activities such as scuba diving, snorkeling, and surfing. As a consequence, people are more likely to suffer trauma, envenomation, or poisoning related to an encounter with a marine creature, which will come to the attention of a physician. The science of marine medicine is limited; hence, treatment of these conditions is largely based on case reports and expert opinion; very few randomized, controlled studies are available. Misdiagnosis is common, especially when the

capillary testing and lack of studies at high altitude, probably only be used in conjunction with capillary testing.

In Type 1 diabetes, travel to altitude induces hyperglycemia initially and with any acute hypoxia or further ascent. After acclimatization there is a decrease in fasting glucose, and a further drop with exertion. The initial hypoxia-induced hyperglycemia may contribute to ketonuria as well as ketoacidosis, particularly with rapid ascent. This is particularly notable at very high to extreme elevations, and increased exertion and decreased appetite at these elevations may not be adequate to compensate for this hyperglycemia. Risk for DKA is increased due to these metabolic effects of altitude as well as the increased risk infectious diarrhea in some high-altitude regions, changes in diet, and certain medications. As symptoms of AMS, HACE, and diarrheal illness may mimic DKA, onset of symptoms of AMS or HACE, diarrhea in the setting of hyperglycemia, or suspected DKA warrants immediate descent.

Use of an insulin pump at altitude in controlled type 1 diabetics appears safe without significant pump dysfunction, though with rapid pressure changes such as cabin pressurization during air travel there have been reports of bubble formation affecting insulin delivery. It is advisable to also carry injectable insulin in case of pump failure. Use of acetazolamide is not advisable for type 1 diabetics due to increased risk for acidosis and diuresis increasing risk for dehydration. Dexamethasone should also be avoided due to the risk for hyperglycemia. This should be reserved for treatment of severe AMS, HACE, or if descent is not possible but emergent descent is a priority.

Type 2 diabetics do not appear to have the same extent of glycemic changes, though they may also experience hyperglycemia with initial ascent and hypoxia. Once acclimatized, they may need to decrease doses of sulfonylurea medications and insulin due to increased basal metabolic rate. It may be safe to use acetazolamide with caution in type 2 diabetics if not on insulin. Dexamethasone will cause hyperglycemia.

All travel companions should be educated on the signs and symptoms of hyper- and hypoglycemia, diabetic ketoacidosis (DKA) if applicable, overlap between these and AMS, HACE, and gastrointestinal illness, and how these conditions should be managed. Patients with poorly controlled or brittle diabetes should not travel to high altitude. Sedentary patients are advised to discuss cardiac stress testing with their physician.

MARINE POISONINGS, ENVENOMATIONS, AND TRAUMA

Method of

Allen Perkins, MD, MPH

CURRENT DIAGNOSIS

- History of exposure is necessary for diagnosis.
- Ingested toxins can cause unusual symptoms, predominately gastrointestinal.
- Jellyfish envenomation is very painful but almost always self-limited.
- Trauma management follows principles of dirty wounds.
- Specific marine pathogens should be covered if contamination is suspected.

CURRENT THERAPY

Ingestions

- Avoidance is the best strategy.
- Early decontamination with activated charcoal (Actidose-Aqua) can reduce duration of symptoms.
- Symptomatic care is generally sufficient.

Jellyfish

- Remove visible stingers.
- Control pain with topical analgesia.

Trauma

- Avoiding water at feeding time can help avoid injury.
- If envenomation is suspected, consider hot water immersion.
- Tetanus status should be checked.
- Antibiotic coverage should take marine pathogens into account.

The United States has more than 80,000 miles of coastline, and more people are enjoying water-dependent recreation activities such as scuba diving, snorkeling, and surfing. As a consequence, people are more likely to suffer trauma, envenomation, or poisoning related to an encounter with a marine creature, which will come to the attention of a physician. The science of marine medicine is limited; hence, treatment of these conditions is largely based on case reports and expert opinion; very few randomized, controlled studies are available. Misdiagnosis is common, especially when the

patient has returned from vacationing or when the patient has been poisoned by improperly handled seafood. This article describes common ailments and injuries occurring as a consequence of direct contact with sea creatures and discusses management and prevention.

Ingestions

Ciguatera

Epidemiology

Ciguatera poisoning is the most commonly reported marine toxin disease in the world. It is caused by human ingestion of reef fish that have bioaccumulated sufficient amounts of the dinoflagellate *Gambierdiscus toxicus*, either through direct ingestion or through ingestion of smaller reef fish. Although limited to tropical regions, it is heat and cold tolerant, is lipid soluble, and can survive transport to other areas. The toxin becomes more concentrated as it passes up the food chain; fish such as amberjack, grouper, and snapper pose less of a risk than predatory fish such as barracuda and moray eel. Ciguatera poisoning affects at least 50,000 people worldwide annually, and there are several thousand cases of poisoning in Puerto Rico, the U.S. Virgin Islands, Hawaii, and Florida each year.

Clinical Features

Patients can exhibit a primarily gastrointestinal (diarrhea, abdominal cramps, and vomiting), neurologic (parasthesias, diffuse pain, blurred vision), cardiac (bradycardia), or mixed pattern of symptoms. Additionally, a cold sensation reversal, in which a patient perceives the cold temperatures as a hot sensation and vice versa, occurs in 80% of patients and is considered pathognomonic for ciguatera poison (Box 1).

The attack rate is high. As many as 80% to 100% of people who ingest affected fish develop symptoms depending on the size of the fish and the toxin load. Ingestion of internal organs where the toxin accumulates (e.g., liver, roe) is associated with more severe symptoms, but avoiding these organs is not protective. The symptoms are also related to the number of exposures over time, and patients typically have more severe symptoms with subsequent exposures. There is no age-related susceptibility, and no immunity is acquired through exposure.

BOX 1 Symptom Patterns Associated With Ciguatera Poisoning

Gastrointestinal Pattern

Onset 15 minutes to 24 hours, typically worsens, lasts 1–2 days and resolves

- Nausea and/or vomiting
- Profuse, watery diarrhea
- Abdominal pain

Neurologic Pattern

Onset up to 24 hours after ingestion, commonly nonphysiologic pattern, can last several months

- Numbness and paresthesias
- Vertigo
- Ataxia
- Severe weakness or lethargy
- Severe myalgia
- Decreased vibration and pain sensations
- Diffuse pain pattern
- Cold sensation reversal
- Coma

Cardiovascular Pattern

Onset up to 24 hours after ingestion is uncommon but occurs rapidly

- Bradycardia
- Hypotension
- Cardiovascular collapse

Symptoms typically begin 1 to 6 hours after ingestion, although a delay of 12 to 24 hours can occur. Duration is 7 to 14 days, and neurologic symptoms occasionally persist for months to years. Chronic ciguatera syndrome can also occur as a constellation of symptoms such as general malaise, depression, headaches, muscle aches, and dysesthesias in the extremities. Patients with chronic disease report recurrences with ingestion of fish, ethanol, caffeine, and nuts up to 6 months after the acute illness resolves.

Diagnosis

The diagnosis should be entertained in any patient who has neurologic, gastrointestinal, or cardiac symptoms and a history of ingesting predatory fish within the past 24 hours. The symptom constellation can be similar to other ingestions, such as certain shellfish toxins, and differentiation requires knowledge of the patient's diet for the previous day. Additionally, scombroid and type E botulinum poisoning should be considered, but these are unlikely if the patient did not ingest ill-appearing game. Other poisonings, such as organophosphates, can produce a similar symptom complex. There are no currently available clinical assays to assist in making the diagnosis, which is based on clinical suspicion and knowledge of the patient's diet history.

Treatment

If ciguatera poisoning is suspected soon after ingestion, I would consider gut decontamination with activated charcoal (Actidose-Aqua) because it can reduce the toxin load and subsequent symptoms. Initial symptomatic treatment typically consists of fluid replacement to replace gastrointestinal losses.

Atropine (AtroPen) is used in patients who have bradycardia. Temporary electrical pacing may be used for refractory symptoms, and pressors may be needed in cases of severe hypotension. Neurologic symptoms are problematic because of their extended course as well as their severity. Mannitol (Osmitol)¹ is often cited as effective in reducing the duration of neurologic symptoms, but I would use it with caution because the only double-blind trial failed to show any benefit. There are many local remedies used throughout the world that are said to be successful, which likely attests to the self-limited course of the ingestion in most cases. Table 1 offers more details regarding treatments currently used for ciguatera poisoning.

Prevention

Prevention is difficult except by avoiding ingestion of affected reef fish. The toxin is not deactivated by cooking, freezing, smoking, or salting. There are no outward signs of ciguatera: The fish look, taste, and smell normal. Although several commercial assays are available, they are neither sensitive nor specific enough to be relied on to prevent ciguatera poisoning.

To decrease the risk of ciguatera poisoning, I recommend the following steps: Avoid warm-water reef fish, especially those caught where ciguatera poisoning is known to occur; avoid moray eel injection; avoid ingesting large game fish; avoid consuming the internal organs; and limit the amount of initial ingestion if you are in an area where ciguatera is known to occur. Additionally, patients travelling to distant locales should be made aware that, although the vast majority of cases result from direct ingestion, there have been cases of ciguatera passed through sexual contact and through breast milk, so they should be wary of body fluid contact if ciguatoxin is endemic to the area, if for no other reasons.

Scombroid

Epidemiology

Scombroid poisoning (also known as histamine fish poisoning) results from improper handling of certain fish between the time the fish is caught and the time it is cooked. In the United States it is most common in Hawaii and California. Improper

¹Not FDA approved for this indication.

TABLE 1 Treatment for Ciguatera Poisoning

DRUG	DOSE	INDICATION
Activated charcoal (Actidose-Aqua)	Children <1 y: 1 g/kg Children 1–12 y: 25–50 g Adults: 25–100 g	Gut emptying and decontamination More effective in first hour
Antiemetics (no preference)	Administer per dosing recommendations	Intractable nausea and/or vomiting
Intravenous fluid bolus and infusion (normal saline or lactated Ringer's as initial)	Per volume replacement protocols	Hypovolemia
Atropine (AtroPen)	0.5–1.0 mg IV every 3–5 min to a maximum dose of 0.04 mg/kg per episode Maximum total dose: 3 mg for adults, 2 mg for adolescents, 1 mg for young children	Bradycardia
Pressors: Dopamine (Intropin), dobutamine (Dobutrex), epinephrine	Varies with clinical response	Hypotension, shock
Antihistamines (no preference)	Administer per dosing recommendations	Pruritus
Mannitol (Osmitol) ¹	1 g/kg of a 20% solution given IV over several h Adult dose: 25–100 g, titrate to urinary output of 100 mL/h	Neurologic symptoms, double-blind study did not show benefit
Amitriptyline (Elavil) ¹	25–75 mg PO bid for patients >25 kg	Pruritus, dysesthesias

¹Not FDA approved for this indication.

preservation and refrigeration lead to histamine and histamine-like substances being produced in the dark meat of certain fish through a conversion of histidine to histamine by bacterial decarboxylases. Members of the family Scombridae, such as tuna and mackerel, contain the highest amounts of this substance, but both scombroid and nonscombroid fish have been associated with the disease. The production of toxins requires the introduction of bacteria during the handling process, primarily during storage at high temperatures. It is the total amount of histamine, the presence of other biogenic amines, and individual susceptibility that determine the severity of the symptoms.

Clinical Features

The patient develops a histamine reaction 20 to 30 minutes after ingestion. Symptoms can be cutaneous, gastrointestinal, neurologic, or hemodynamic, or any combination of these. Cutaneous symptoms include flushing, urticaria and conjunctival injection, and localized edema; gastrointestinal symptoms include dry mouth, nausea, vomiting, diarrhea, and abdominal cramping; neurologic symptoms include severe headache and dizziness; and hemodynamic symptoms include palpitations and hypotension. In severe cases there can be bronchospasm and respiratory distress. These symptoms typically come on rapidly (within several minutes) and last less than 6 to 8 hours. Flushing is the most consistent clinical sign, occurring on exposed areas so it typically resembles sunburn. Diarrhea is also very common, occurring in 75% of symptomatic patients.

Diagnosis

As with ciguatera, the diagnosis is one of history. If the time between ingestion and illness is short and the patient has ingested a type of fish previously implicated in scombroid, then a tentative diagnosis can be made. The diagnosis is often confused with an allergic reaction. It can be distinguished from allergy by the lack of a previous allergic reaction as well as by testing the remaining fish for histamine, although testing is rarely warranted.

Treatment

Treatment is the same as for any histamine reaction, the cornerstone of which is antihistamine. Diphenhydramine (Benadryl) 50 mg for adults and 0.5–1 mg/kg/dose for children, repeated every 4 hours until symptoms abate, is delivered either intravenously or intramuscularly in severe cases and orally for milder cases.

For severe cases, cimetidine (Tagamet)¹ 300 mg for adults, 20 mg/kg for children, either orally or intravenously, might be added for more complete histamine-receptor blockade. In cases where ingestion was recent, consider induced emesis using syrup of ipecac: 15 mL for children younger than 12 years or 30 mL otherwise. Most patients require only reassurance, and pharmacologic treatment will be unnecessary. It should be stressed to the patient that this is not an *allergic* reaction to fish, because the histamine is exogenous. Prevention is possible in regions where food storage and preparation are monitored through identification and removal of suspect fish.

Other Ingested Toxins

In addition to the toxins just discussed, ingestion of certain other marine creatures can lead to problems.

Ingestion of bivalves harvested from contaminated waters has been associated with hepatitis A, Norwalk virus, *Vibrio parahaemolyticus* and *Vibrio vulnificans* infections, the latter two particularly problematic and occasionally fatal in immunocompromised patients. I counsel patients likely to be immunocompromised, including diabetics and those with known liver disease, to avoid uncooked bivalves.

Shellfish are occasionally known to contain one or more of several toxins acquired through bioaccumulation of certain algae. These dinoflagellates tend to bloom in summer months. The symptoms occur immediately after ingestion and last several hours and are typically neurologic or gastrointestinal, or both. The shellfish poisoning syndromes are known as paralytic, neurologic, diarrheal, or amnesic depending on the predominant symptom. The care is typically supportive. Public health officials typically monitor local mollusk populations fairly carefully and alert the public to possible hazards.

Ingestion of the flesh of certain puffer fish has been associated with tetrodotoxin poisoning. The flesh of the fish (fugu) is considered a delicacy. The toxin builds up in internal organs such as the liver and the roe. If the toxin is ingested, it is likely to be fatal, but there are certified chefs who are trained in avoiding the toxin when preparing the dish. Despite this precaution, as many as 50 deaths occur in Japan annually from exposure to this toxin. Avoiding this puffer fish and avoiding the ingestion of certain other exotic

¹Not FDA approved for this indication.

animals (such as the blue-ringed octopus) eliminate the risk of acquiring this toxin.

Envenomations

Many marine creatures are venomous, and beachgoers experience clinically significant envenomations with some regularity. Jellyfish and related creatures (Cnidarians), sea urchins (Echinodermata), and stingrays (Chondrichthyes) are some of the more commonly identified marine animals involved with envenomations.

Jellyfish

These invertebrates have stinging cells called *nematocytes*, which carry nematocysts that continue to function when separated from the larger organism. For example, jellyfish nematocysts can sting if the tentacle is separated and after the jellyfish is dead. The venom is antigenic and causes a reaction of a dermatonecrotic, hemolytic, cardiopathic, or neurotoxic nature. The severity of the reaction depends on several variables, including the number of nematocysts that discharge, the toxicity of the coelenterate involved, and each patient's unique antigenic response.

Clinical Features

Although occasionally fatal as a consequence of an anaphylactic response in the United States and Caribbean, the primary concern in these areas with contact is pain, which is almost always self-limiting. Other, less common symptoms include parasthesias, nausea, headaches, and chills. The symptoms may last up to 2 to 3 days. Certain Pacific jellyfish primarily found in the waters around Australia have a more potent toxin and are much more likely to cause death (which is still very uncommon). Additionally, the Irukandji syndrome, which occurs in the Pacific, is a suite of symptoms including muscle spasms, vomiting, hypertension, incessant coughing, and occasionally heart failure and brain hemorrhage. Almost all exposed people, regardless of the geographic location, do not have a severe reaction, and the principles of first aid are primarily the same throughout the world.

Treatment

In my experience, treatment is mostly concerned with limiting pain and neurologic symptoms, because anaphylaxis and other severe reactions are rare, and the following general guidelines can be applied. In the field, either the victim or a companion should remove any visible tentacles. To do so requires using care, with gloves or forceps being optimal to prevent further stings. If a towel is used, any nematocysts remaining on the towel can still discharge. Salt water can be used to wash off the nematocysts. Urine, household vinegar, fresh water, and rubbing with sand should be avoided.

Should the victim present to the physician's office or emergency department, topical lidocaine (4%)¹ should be liberally applied for 30 minutes or until the pain subsides, followed by removal of the nematocysts, usually through use of the gloved hand or with forceps. Another method for removing the nematocysts is to apply shaving cream or baking soda slurry to the area and scrape off the nematocysts with a razor. Applications of cold, in the form of an ice pack, and immersion in hot water have variously been shown to improve pain, but because of the self-limited nature of the discomfort, it is hard to gauge an optimum therapy. Either is probably acceptable until the patient is comfortable. Meat tenderizer has been found to be ineffective. Local anesthetics, antihistamines, and steroids are all used to control prolonged symptoms, based on anecdotal experience. Antibiotics are not generally necessary. In the rare cases of cardiovascular collapse, supportive care and principles of treatment of anaphylaxis should be followed. A delayed hypersensitivity reaction can occur 1 to 3 days out, which will almost certainly be self-limited and can be treated with oral antihistamines and topical steroids if symptoms are severe.

Sea bather's itch is a form of jellyfish sting caused by the larvae of the thimble jellyfish. It is characterized by a painful, itchy rash

under the edges of the bathing suit or wet suit. It can occasionally progress to a papular rash. Topical steroids can be used to relieve symptoms.

Prevention

Prevention is mostly a matter of common sense. Staying away from the organism (the tentacles can extend several meters from the body of the organism) and staying out of the water when jellyfish are known to be present are the most effective. There is a commercially available product, Safe Sea, which has been shown to reduce the number of nematocyst discharges and thus the severity of the sting should a swimmer need to be in the water when jellyfish are present. Wetsuits and other protective gear are ineffective.

Echinoderms

The Echinoderm family includes sea urchins. Urchins have toxin-coated spines that break off, leaving calcareous material in the wound, which can potentially cause infection. Symptoms include local pain, burning, and local discoloration. The discoloration is thought to be a temporary tattooing of the skin resulting from dye in the spines; absence of a spine is indicated if the discoloration spontaneously resolves within 48 hours. Theoretically, hot water disables the toxin, although there is no evidence in humans that it is effective. If a spine is present and easily accessible, it should be removed with fingers or forceps. If it is close to a joint or neurovascular structure, it should be surgically removed. If the spines do not cause symptoms, retained pieces will likely reabsorb into the skin.

Stingrays

Although many fish are venomous, stingrays are the most clinically important, accounting for an estimated 1500 mostly minor injuries in the United States annually. These creatures partially bury themselves in the shallow, sandy bottom of the ocean, leading water enthusiasts to accidentally step on them or grab at what they think is a seashell.

Clinical Features

Stingrays have a spine at the base of their tail, which contains a venom gland. The spine, including the venom gland, is broken off and may be left in the resulting wound. The venom has vasoconstrictive properties that can lead to cyanosis and necrosis with poor wound healing and infection. Symptoms can include immediate and intense pain, salivation, nausea, vomiting, diarrhea, muscle cramps, dyspnea, seizures, headaches, and cardiac arrhythmias. Fatalities are rare and mostly a consequence of exsanguination at the scene or penetration of a vital organ.

Treatment

Home care should include rinsing the area thoroughly with fresh water if available (salt water if not) and removing any foreign body. If the damage is minimal, the victim may soak the wound in warm water at home. The victim should watch for signs of infection and seek care for excessive bleeding, retained foreign body, or infection.

For severe wounds that lead the victim to seek medical attention, treatment should include achieving hemostasis followed by submersion of the affected region in hot but not scalding water (42–45 °C, 108–113 °F) for 30 to 90 minutes or until the pain resolves. Spines and stingers are typically radiopaque, so radiographs or an ultrasound should be obtained if a retained spine is suspected. The wound should be thoroughly cleansed, and delayed closure should be allowed. Tetanus immunization status should be reviewed and updated as appropriate. Surgical exploration may be necessary to remove residual foreign bodies. Prophylactic antibiotics are typically not necessary unless there is a residual foreign body or if the patient is immunosuppressed. If the wound becomes infected, *Staphylococcus* and *Streptococcus* species are the most common pathologic organisms. Unique to the marine environment are *Vibrio vulnificus* and *Mycobacterium marinum*, and antibiotic coverage should include coverage for all of these (Table 2).

¹Not FDA approved for this indication.

TABLE 2 Antibiotic Choices in Marine Injuries

DRUG	DOSAGE	
	PEDIATRIC	ADULT
Outpatient Management		
Ciprofloxacin (Cipro) ¹	20–30 mg/kg/day PO × 14 d ¹	500 mg PO bid × 14 d
Levofloxacin (Levaquin) ¹		750 mg PO qd × 14 d
Doxycycline (Vibramycin, Doryx)	>8 y: 2.2 mg/kg PO qd × 14 d	100 mg bid × 14 d
Inpatient Management		
Preferred		
Ceftazidime (Fortaz, Tazicef) <i>plus</i>	150 mg/kg/d q8h	1 g IV q8h
PO or IV quinolone or doxycycline	150 mg/kg/d q8h	1 g IV q8h
Alternative		
Gentamicin <i>plus</i>	Typically based on institutional protocol and adjusted based on serum levels	Typically based on institutional protocol and adjusted based on serum levels
TMP-SMX (Bactrim, Cotrim, Septra)	8–10 mg/kg/d TMP	8–10 mg/kg (lean body mass)/d TMP

¹Not FDA approved for this indication.

Abbreviation: TMP-SMX = trimethoprim-sulfamethoxazole.

Other Venomous Sea Creatures

Seasnakes are venomous creatures found most commonly in the Indo-Pacific area. Bites are uncommon (and envenomation is even less common), but should they occur, the toxin is very potent. The care is supportive. There is antivenom, which may be available in areas where the snakes are endemic.

Certain other fish and octopi have been associated with envenomation and occasional death. Most are tropical such as the stonefish, scorpionfish, and rabbitfish and the blue-ringed octopus. Certain varieties of catfish have venom as well. Envenomations are rare, and if they occur, treatment is based on good first-aid principles and antivenom where available (mostly in tropical areas).

Certain cone shells contain a toxin that can be fatal. This toxin is injected by the mollusk into the victim from a proboscis, which it extends from the small end of the cone. Treatment is primarily supportive.

Trauma

Abrasions, bites, and lacerations are usually the result of a marine animal's instinct to protect itself against a perceived danger. The most commonly involved marine animals are octopi, sharks, moray eels, and barracuda. The trauma alone creates problems for patients, but the trauma can be further complicated by envenomation. It is often difficult to identify the marine animal involved in the attack. Treatment is for the most part symptomatic, with local cleansing and topical dressing usually sufficing. If the wound becomes infected, antibiotics should cover common organisms (see Table 2).

Environmental Hazards

Abrasions from the ambient environment are also common. These wounds should be thoroughly cleansed with soap and water and a topical antibiotic applied, because the wounds can contain toxins and are commonly contaminated with bacteria. Coral contains nematocysts and also has very sharp edges. Scuba divers in particular suffer from coral cuts in the course of their recreational diving. If these wounds become infected, coverage for *Vibrio* species should be included as well.

Sharks

Although shark attacks receive a lot of publicity, there are only around 50 such attacks worldwide annually and they result in fewer than 10 deaths. The majority of the deaths are in South Africa. Typically these attacks involve the tiger, great white, gray reef, and bull sharks. Attacks occur in shallow water within 100 feet of shore during the evening hours when sharks tend to feed.

BOX 2 Management of Marine Trauma

Remove the victim from the water.
 Ensure airway control.
 Control bleeding.
 Do not remove the wet suit if the victim is wearing one.
 Attempt to identify the animal involved in the injury.
 If the injury is severe, transport the victim to a hospital.
 If envenomation is suspected, consider hot water immersion.
 Irrigate the wound with normal saline.
 Perform surgical débridement of the wound as appropriate.
 If sutures must be placed, place them loosely and allow drainage.
 Primary suturing should be avoided in puncture wounds, crush injuries, and wounds in the distal extremities.
 Start appropriate antibiotics if indicated.

Common sense dictates avoiding areas where aggressive shark feeding has been noted.

Sequelae of a shark attack range from abrasions to death from hemorrhage. Abrasions and lacerations can occur when sharks brush or aggressively investigate humans. Soft tissue damage, fractures, and neurovascular damage result from such attacks. The majority of attacks result in minor injuries that require simple suturing. Morbidity increases in wounds that are greater than 20 cm or where more than one myofascial compartment is lost. General principles of first aid in marine animal injuries are found in Box 2. Although it would seem self-evident, practices such as urinating on the injury, applying oil or gasoline to injuries, and application of any strong oxidizing agents, such as strong bases or acids, should be counseled against when doing patient education regarding self-care.

MEDICAL TOXICOLOGY

Method of

Howard C. Mofenson, MD; Thomas R. Caraccio, PharmD;
Michael McGuigan, MD; and Joseph Greensher, MD

Introduction and Epidemiology

According to the national Toxic Exposure Surveillance System (TESS), over 2.4 million potentially toxic exposures were reported last year to Poison Control Centers throughout the United States. Poisonings were responsible for 1183 deaths and more than 500,000 hospitalizations. Poisoning accounts for 2% to 5% of pediatric hospital admissions, 10% of adult admissions, 5% of hospital admissions in the elderly (>65 years of age), and 5% of ambulance calls. In one urban hospital, drug-related emergencies accounted for 38% of the emergency department visits. An evaluation of a medical intensive care unit and step-down unit over a 3-month period indicated that poisonings accounted for 19.7% of admissions.

The largest number of fatalities resulting from poisoning reported to the TESS are caused by analgesics. The other principal toxicologic causes of fatalities are antidepressants, sedative hypnotics/antipsychotics, stimulants/street drugs, cardiovascular agents, and alcohols. Less than 1% of overdose cases reaching the hospitals result in fatality. However, patients presenting in deep

coma to medical care facilities have a fatality rate of 13% to 35%. The largest single cause of coma of inapparent etiology is drug poisoning.

Pharmaceutical preparations are involved in 50% of poisonings. The number one pharmaceutical agent involved in exposures is acetaminophen. The severity of the manifestations of acute poisoning exposures varies greatly depending on whether the poisoning was intentional or unintentional. Unintentional exposures make up 85% to 90% of all poisoning exposures. The majority of cases are acute, occurring in children younger than 5 years of age, in the home, and resulting in no or minor toxicity. Many are actually ingestions of relatively nontoxic substances that require minimal medical care. Intentional poisonings, such as suicides, constitute 10% to 15% of exposures and may require the highest standards of medical and nursing care and the use of sophisticated equipment for recovery. Intentional ingestions are often of multiple substances and frequently include ethanol, acetaminophen, and aspirin. Suicides make up 54% of the reported fatalities. About 25% of suicides are attempted with drugs. Sixty percent of patients who take a drug overdose use their own medication and 15% use drugs prescribed for close relatives. The majority of the drug-related suicide attempts involve a central nervous system (CNS) depressant, and coma management is vital to the treatment.

Assessment and Maintenance of the Vital Functions

The initial assessment of all patients in medical emergencies follows the principles of basic and advanced cardiac life support. The adequacy of the patient's airway, degree of ventilation, and circulatory status should be determined. The vital functions should be established and maintained. Vital signs should be measured frequently and should include body core temperature. The assessment of vital functions should include the rate numbers (e.g., respiratory rate) and indications of effectiveness (e.g., depth of respirations and degree of gas exchange). Table 1 gives important measurements and vital signs.

Level of consciousness should be assessed by immediate AVPU (Alert, responds to Verbal stimuli, responds to Painful stimuli, and Unconscious). If the patient is unconscious, one must assess the severity of the unconsciousness by the Glasgow Coma Scale (Table 2).

If the patient is comatose, management requires administering 100% oxygen, establishing vascular access, and obtaining blood for pertinent laboratory studies. The administration of glucose, thiamine, and naloxone, as well as intubation to protect the airway,

Data from Teasdale G, Jennett B: Assessment of coma impaired consciousness. *Lancet* 2:83, 1974; Simpson D, Reilly P: Pediatric coma scale. *Lancet* 2:450, 1982; Seidel J: Preparing for pediatric emergencies. *Pediatr Rev* 16:470, 1995.

should be considered. Pertinent laboratory studies include arterial blood gases (ABG), electrocardiography (ECG), determination of blood glucose level, electrolytes, renal and liver tests, and acetaminophen plasma concentration in all cases of intentional ingestions. Radiography of the chest and abdomen may be useful. The severity of a stimulant's effects can also be assessed and should be documented to follow the trend.

The examiner should completely expose the patient by removing clothes and other items that interfere with a full evaluation. One should look for clues to etiology in the clothes and include the hat and shoes.

Prevention of Absorption and Reduction of Local Damage

Exposure

Poisoning exposure routes include ingestion (76.8%), dermal (8%), ophthalmologic (5%), inhalation (6%), insect bites and stings (4%), and parenteral injections (0.5%). The effect of the toxin may be local, systemic, or both.

Local effects (skin, eyes, mucosa of respiratory or gastrointestinal tract) occur where contact is made with the poisonous substance. Local effects are nonspecific chemical reactions that depend on the chemical properties (e.g., pH), concentration, contact time, and type of exposed surface.

Systemic effects occur when the poison is absorbed into the body and depend on the dose, the distribution, and the functional reserve of the organ systems. Shock and hypoxia are part of systemic toxicity.

Delayed Toxic Action

Therapeutic doses of most pharmaceuticals are absorbed within 90 minutes. However, the patient with exposure to a potential toxin may be asymptomatic at this time because a sufficient amount has not yet been absorbed or metabolized to produce toxicity at the time the patient presents for care.

Absorption can be significantly delayed under the following circumstances:

1. Drugs with anticholinergic properties (e.g., antihistamines, belladonna alkaloids, diphenoxylate with atropine [Lomotil], phenothiazines, and tricyclic antidepressants).

2. Modified release preparations such as sustained-release, enteric-coated, and controlled-release formulations have delayed and prolonged absorption.
3. Concretions may form (e.g., salicylates, iron, glutethimide, and meprobamate [Equanil]) that can delay absorption and prolong the toxic effects. Large quantities of drugs tend to be absorbed more slowly than small quantities.

Some substances must be metabolized into a toxic metabolite (acetaminophen, acetonitrile, ethylene glycol, methanol, methylene chloride, parathion, and paraquat). In some cases, time is required to produce a toxic effect on organ systems (*Amanita phalloides* mushrooms, carbon tetrachloride, colchicine, digoxin [Lanoxin], heavy metals, monoamine oxidase inhibitors, and oral hypoglycemic agents).

Initial Management

1. Stabilization of airway, breathing, and circulation and protection of same.
2. Identification of specific toxin or toxic syndrome.
3. Initial treatment: D50W; consider thiamine, naloxone (Narcan), oxygen, and antidotes if needed.
4. Physical assessment.
5. Decontamination: Gastrointestinal tract, skin, eyes.

Decontamination

In the asymptomatic patient who has been exposed to a toxic substance, decontamination procedures should be considered if the patient has been exposed to potentially toxic substances in toxic amounts.

Ocular exposure should be immediately treated with water irrigation for 15 to 20 minutes with the eyelids fully retracted. One should not use neutralizing chemicals. All caustic and corrosive injuries should be evaluated with fluorescein dye and by an ophthalmologist.

Dermal exposure is treated immediately with copious water irrigation for 30 minutes, not a forceful flushing. Shampooing the hair, cleansing the fingernails, navel, and perineum, and irrigating the eyes are necessary in the case of an extensive exposure. The clothes should be specially bagged and may have to be discarded. Leather goods can become irreversibly contaminated and must be abandoned. Caustic (alkali) exposures can require hours of irrigation.

Dermal absorption can occur with pesticides, hydrocarbons, and cyanide.

Injection exposures (e.g., snake envenomation) can be treated with venom extractors. Venom extractors can be used within minutes of envenomation, and proximal lymphatic constricting bands or elastic wraps can be used to delay lymphatic flow and immobilize the extremity. Cold packs and tourniquets should not be used and incision is generally not recommended. Substances of abuse may be injected intravenously or subcutaneously. In these cases, little decontamination can be done.

Inhalation exposure to toxic substances is managed by immediate removal of the victim from the contaminated environment by protected rescuers.

Gastrointestinal exposure is the most common route of poisoning. Gastrointestinal decontamination historically has been done by gastric emptying: induction of emesis, gastric lavage, administration of activated charcoal, and the use of cathartics or whole bowel irrigation. No procedure is routine; it should be individualized for each case. If no attempt is made to decontaminate the patient, the reason should be clearly documented on the medical record (e.g., time elapsed, past peak of action, ineffectiveness, or risk of procedure).

Gastric Emptying Procedures

The gastric emptying procedure used is influenced by the age of the patient, the effectiveness of the procedure, the time of ingestion (gastric emptying is usually ineffective after 1 hour postingestion), the patient's clinical status (time of peak effect has passed or the patient's condition is too unstable), formulation of the substance ingested (regular release versus modified release), the amount ingested, and the rapidity of onset of CNS depression or stimulation (convulsions). Most studies show that only 30% (range, 19% to 62%) of the ingested toxin is removed by gastric emptying under optimal conditions. It has not been demonstrated that the choice of procedure improved the outcome.

A mnemonic for gathering information is STATS:

- S—substance
- T—type of formulation
- A—amount and age
- T—time of ingestion
- S—signs and symptoms

The examiner should attempt to obtain AMPLE information about the patient:

- A—age and allergies
- M—available medications
- P—past medical history including pregnancy, psychiatric illnesses, substance abuse, or intentional ingestions
- L—time of last meal, which may influence absorption and the onset and peak action
- E—events leading to present condition

The intent of the patient should also be determined.

The Regional Poison Center should be consulted for the exact ingredients of the ingested substance and the latest management. The treatment information on the labels of products are notoriously inaccurate.

Ipecac Syrup

Syrup of ipecac-induced emesis has virtually no use in the emergency department. Although at one time it was considered most useful in young children with a recent witnessed ingestion, it is no longer advised in most cases. Current guidelines from the American Association of Poison Control Centers have significantly limited the indications for inducing emesis because the risk most often exceeds the benefit derived from this procedure. The Poison Control Center should be called if inducing emesis is being considered.

Contraindications or situations in which induction of emesis is inappropriate include the following:

- Ingestion of caustic substance
- Loss of airway protective reflexes because of ingestion of substances that can produce rapid onset of CNS depression (e.g.,

short-acting benzodiazepines, barbiturates, nonbarbiturate sedative-hypnotics, opioids, tricyclic antidepressants) or convulsions (e.g., camphor [Ponstel], chloroquine [Aralen], codeine, isoniazid [Nydrizid], mefenamic acid, nicotine, propoxyphene [Darvon], organophosphate insecticides, strychnine, and tricyclic antidepressants)

- Ingestion of low-viscosity petroleum distillates (e.g., gasoline, lighter fluid, kerosene)
- Significant vomiting prior to presentation or hematemesis
- Age under 6 months (no established dose, safety, or efficacy data)
- Ingestion of foreign bodies (emesis is ineffective and may lead to aspiration)
- Clinical conditions including neurologic impairment, hemodynamic instability, increased intracranial pressure, and hypertension
- Delay in presentation (more than 1 hour postingestion)

The dose of syrup of ipecac in the 6- to 9-month-old infant is 5 mL; in the 9- to 12-month-old, 10 mL; and in the 1- to 12-year-old, 15 mL. In children older than 12 years and in adults, the dose is 30 mL. The dose can be repeated once if the child does not vomit in 15 to 20 minutes. The vomitus should be inspected for remnants of pills or toxic substances, and the appearance and odor should be documented. When ipecac is not available, 30 mL of mild dishwashing soap (not dishwasher detergent) can be used, although it is less effective.

Complications are very rare but include aspiration, protracted vomiting, rarely cardiac toxicity with long-term abuse, pneumothorax, gastric rupture, diaphragmatic hernia, intracranial hemorrhage, and Mallory-Weiss tears.

Gastric Lavage

Gastric lavage should be considered only when life-threatening amounts of substances were involved, when the benefits outweigh the risks, when it can be performed within 1 hour of the ingestion, and when no contraindications exist.

The contraindications are similar to those for ipecac-induced emesis. However, gastric lavage can be accomplished after the insertion of an endotracheal tube in cases of CNS depression or controlled convulsions. The patient should be placed with the head lower than the hips in a left-lateral decubitus position. The location of the tube should be confirmed by radiography, if necessary, and suctioning equipment should be available.

Contraindications to gastric lavage include the following:

- Ingestion of caustic substances (risk of esophageal perforation)
- Uncontrolled convulsions, because of the danger of aspiration and injury during the procedure
- Ingestion of low-viscosity petroleum distillate products
- CNS depression or absent protective airway reflexes, without endotracheal protection
- Significant cardiac dysrhythmias
- Significant emesis or hematemesis prior to presentation
- Delay in presentation (more than 1 hour postingestion)

Size of Tube. The best results with gastric lavage are obtained with the largest possible orogastric tube that can be reasonably passed (nasogastric tubes are not large enough to remove solid material). In adults, a large-bore orogastric Lavacuator hose or a No. 42 French Ewald tube should be used; in young children, orogastric tubes are generally too small to remove solid material and gastric lavage is not recommended.

The amount of fluid used varies with the patient's age and size. In general, aliquots of 50 to 100 mL per lavage are used in adults. Larger amounts of fluid may force the toxin past the pylorus. Lavage fluid is 0.9% saline.

Complications are rare and may include respiratory depression, aspiration pneumonitis, cardiac dysrhythmias as a result of increased vagal tone, esophageal-gastric tears and perforation, laryngospasm, and mediastinitis.

Activated Charcoal

Oral activated charcoal adsorbs the toxin onto its surface before absorption. According to recent guidelines set forth by the American Academy of Clinical Toxicology, activated charcoal should

TABLE 3 Substances Poorly Adsorbed by Activated Charcoal

C	Caustics and corrosives
H	Heavy metals (arsenic, iron, lead, mercury)
A	Alcohols (ethanol, methanol, isopropanol) and glycols (ethylene glycols)
R	Rapid onset of absorption (cyanide and strychnine)
C	Chlorine and iodine
O	Others insoluble in water (substances in tablet form)
A	Aliphatic hydrocarbons (petroleum distillates)
L	Laxatives (sodium, magnesium, potassium, and lithium)

not be used routinely. Its use is indicated only if a toxic amount of substance has been ingested and is optimally effective within 1 hour of the ingestion. Because of the slow absorption of large quantities of toxin, activated charcoal may be beneficial after 1 hour postingestion.

Activated charcoal does not effectively adsorb small molecules or molecules lacking carbon (Table 3). Activated charcoal adsorption may be diminished by milk, cocoa powder, and ice cream.

There are a few relative contraindications to the use of activated charcoal:

1. Ingestion of caustics and corrosives, which may produce vomiting or cling to the mucosa and falsely appear as a burn on endoscopy.
2. Comatose patient, in whom the airway must be secured prior to activated charcoal administration.
3. Patient without presence of bowel sounds.

Note: Activated charcoal was shown not to interfere with effectiveness of *N*-acetylcysteine in cases of acetaminophen overdose, so it is no longer contraindicated as was thought in the past.

The usual initial adult dose is 60 to 100 g and the dose for children is 15 to 30 g. It is administered orally as a slurry mixed with water or by nasogastric or orogastric tube. *Caution:* Be sure the tube is in the stomach. Cathartics are not necessary.

Although repeated dosing with activated charcoal may decrease the half-life and increase the clearance of phenobarbital, dapsone, quinidine, theophylline, and carbamazepine (Tegretol), recent guidelines indicate there is insufficient evidence to support the use of multiple-dose activated charcoal unless a life-threatening amount of one of the substances mentioned is involved. At present there are no controlled studies that demonstrate that multiple-dose activated charcoal or cathartics alter the clinical course of an intoxication. The dose varies from 0.25 to 0.50 g/kg every 1 to 4 hours, and continuous nasogastric tube infusion of 0.25 to 0.5 g/kg/h has been used to decrease vomiting.

Gastrointestinal dialysis is the diffusion of the toxin from the higher concentration in the serum of the mesenteric vessels to the lower levels in the gastrointestinal tract mucosal cell and subsequently into the gastrointestinal lumen, where the concentration has been lowered by intraluminal adsorption of activated charcoal.

Complications of treatment with activated charcoal include vomiting in 50% of cases, desorption (especially with weak acids in intestine), and aspiration (at least a dozen cases of aspiration have been reported). There are many cases of unreported pulmonary aspirations and "charcoal lungs," intestinal obstruction or pseudoobstruction (three case reports with multiple dosing, none with a single dose), empyema following esophageal perforation, and hypermagnesemia and hypernatremia, which have been associated with repeated concurrent doses of activated charcoal and saline cathartics. Catharsis was used to hasten the elimination of any remaining toxin in the gastrointestinal tract. There are no studies to demonstrate the effectiveness of cathartics, and they are no longer recommended as a form of gastrointestinal decontamination.

Whole-Bowel Irrigation

With whole-bowel irrigation, solutions of polyethylene glycol (PEG) with balanced electrolytes are used to cleanse the bowel without causing shifts in fluids and electrolytes. The procedure is not approved by the US Food and Drug Administration (FDA) for this purpose.

Indications. The procedure has been studied and used successfully in cases of iron overdose when abdominal radiographs reveal incomplete emptying of excess iron. There are additional indications for other types of ingestions, such as with body-packing of illicit drugs (e.g., cocaine, heroin).

The procedure is to administer the solution (GoLYTELY or Colyte), orally or by nasogastric tube, in a dose of 0.5 L per hour in children younger than 5 years of age and 2 L per hour in adolescents and adults for 5 hours. The end point is reached when the rectal effluent is clear or radiopaque materials can no longer be seen in the gastrointestinal tract on abdominal radiographs.

Contraindications. These measures should not be used if there is extensive hematemesis, ileus, or signs of bowel obstruction, perforation, or peritonitis. Animal experiments in which PEG was added to activated charcoal indicated that activated charcoal-salicylates and activated charcoal-theophylline combinations resulted in decreased adsorption and desorption of salicylate and theophylline and no therapeutic benefit over activated charcoal alone. Polyethylene solutions are bound by activated charcoal in vitro, decreasing the efficacy of activated charcoal.

Dilutional treatment is indicated for the immediate management of caustic and corrosive poisonings but is otherwise not useful. The administration of diluting fluid above 30 mL in children and 250 mL in adults may produce vomiting, reexposing the vital tissues to the effects of local damage and possible aspiration.

Neutralization has not been proven to be either safe or effective.

Endoscopy and surgery have been required in the case of body-packer obstruction, intestinal ischemia produced by cocaine ingestion, and iron local caustic action.

Differential Diagnosis of Poisons on the Basis of Central Nervous System Manifestations

Neurologic parameters help to classify and assess the need for supportive treatment as well as provide diagnostic clues to the etiology. Table 4 lists the effects of CNS depressants, CNS stimulants, hallucinogens, and autonomic nervous system anticholinergics and cholinergics.

CNS depressants are cholinergics, opioids, sedative-hypnotics, and sympatholytic agents. The hallmarks are lethargy, sedation, stupor, and coma. In exception to the manifestations listed in Table 4, (a) barbiturates may produce an initial tachycardia; (b) convulsions are produced by codeine, propoxyphene (Darvon), meperidine (Demerol), glutethimide, phenothiazines, methaqualone, and tricyclic and cyclic antidepressants; (c) benzodiazepines rarely produce coma that will interfere with cardiorespiratory functions; and (d) pulmonary edema is common with opioids and sedative-hypnotics.

The CNS stimulants are anticholinergic, hallucinogenic, sympathomimetic, and withdrawal agents. The hallmarks of CNS stimulants are convulsions and hyperactivity.

There is considerable overlapping of effects among the various hallucinogens, but the major hallmark manifestation is hallucinations.

Guidelines for In-Hospital Disposition

Classification of patients as high risk depends on clinical judgment. Any patient who needs cardiorespiratory support or has a persistently altered mental status for 3 hours or more should be considered for intensive care.

Guidelines for admitting patients older than 14 years of age to an intensive care unit, after 2 to 3 hours in the emergency department, include the following:

1. Need for intubation
2. Seizures

TABLE 4 Agents with Central Nervous System (CNS) Effects

AGENTS	GENERAL MANIFESTATIONS	AGENTS	GENERAL MANIFESTATIONS
CNS Depressants		Hallucinogens	
Alcohols and glycols (S-H)	Bradycardia	Amphetamines [†]	Tachycardia and dysrhythmias
Anticonvulsants (S-H)	Bradypnea	Anticholinergics	Tachypnea
Antidysrhythmics (S-H)	Shallow respirations	Cardiac glycosides	Hypertension
Antihypertensives (S-H)	Hypotension	Cocaine	Hallucinations, usually visual
Barbiturates (S-H)	Hypothermia	Ethanol withdrawal	Disorientation
Benzodiazepines (S-H)	Flaccid coma	Hydrocarbon inhalation (abuse)	Panic reaction
Butyrophenones (Syly)	Miosis	Mescaline (peyote)	Toxic psychosis
β-Adrenergic blockers (Syly)	Hypoactive bowel sounds	Mushrooms (psilocybin)	Moist skin
Calcium channel blockers (Syly)		Phencyclidine	Mydriasis (reactive)
Digitalis (Syly)			Hyperthermia
Opioids			Flashbacks
Lithium (mixed)			
Muscle relaxants			
Phenothiazines (Syly)		Anticholinergics	
Nonbarbiturate/benzodiazepine glutethimide, methaqualone, methyprylon, sedative-hypnotics (chloral hydrate, ethchlorvynol, bromide)		Antihistamines	Tachycardia, dysrhythmias (rare)
		Antispasmodic gastrointestinal preparations	Tachypnea
		Antiparkinsonian preparations	Hypertension (mild)
		Atropine	Hyperthermia
Tricyclic antidepressants (late Syly)		Cyclobenzaprine (Flexeril)	Hallucinations (“mad as a hatter”)
		Mydriatic ophthalmologic agents	Mydriasis (unreactive) (“blind as a bat”)
CNS Stimulants		Over-the-counter sleep agents	
Amphetamines (Sy)	Tachycardia	Plants (<i>Datura</i> spp.)/mushrooms	Flushed skin (“red as a beet”)
Anticholinergics*	Tachypnea and dysrhythmias		Dry skin and mouth (“dry as a bone”)
Cocaine (Sy)	Hypertension	Phenothiazines (early)	Hypoactive bowel sounds
Camphor (mixed)	Convulsions	Scopolamine	Urinary retention
Ergot alkaloids (Sy)	Toxic psychosis	Tricyclic/cyclic antidepressants (early)	Lilliputian hallucinations (“little people”)
		Cholinergics	
Isoniazid (mixed)	Mydriasis (reactive)	Bethanechol (Urecholine)	Bradycardia (muscarinic)
Lithium (mixed)	Agitation and restlessness	Carbamate insecticides (Carbaryl)	Tachycardia (nicotinic effect)
Lysergic acid diethylamide (H)	Moist skin	Edrophonium	Miosis (muscarinic)
Hallucinogens (H)	Tremors	Organophosphate insecticides (Malathion, parathion)	Diarrhea (muscarinic)
Mescaline and synthetic analogues		Parasympathetic agents (physostigmine, pyridostigmine)	Hypertension (variable)
Metals (arsenic, lead, mercury)		Toxic mushrooms (<i>Clitocybe</i> spp.)	Hyperactive bowel sounds
Methylphenidate (Ritalin) (Sy)			Excess urination (muscarinic)
Monoamine oxidase inhibitors (Sy)			Excess salivation (muscarinic)
Pemoline (Cylert) (Sy)			Lacrimation (muscarinic)
Phencyclidine (H) [†]			Bronchospasm (muscarinic)
Salicylates (mixed)			Muscle fasciculations (nicotinic)
Strychnine (mixed)			Paralysis (nicotinic)
Sympathomimetics (Sy) (phenylpropanolamine, theophylline, caffeine, thyroid)			
Withdrawal from ethanol, β-adrenergic blockers, clonidine, opioids, sedative-hypnotics (W)			

*Anticholinergics produce dry skin and mucosa and decreased bowel sounds.

[†]Phencyclidine may produce miosis.[‡]The amphetamine hybrids are methylene dioxymethamphetamine (MDMA, ecstasy, “Adam”) and methylene dioxymphetamine (MDA, “Eve”), which are associated with deaths.

Abbreviations: H = hallucinogen; S-H = sedative-hypnotic; Sy = sympathomimetic; Syly = sympatholytic; W = withdrawal.

3. Unresponsiveness to verbal stimuli
4. Arterial carbon dioxide pressure greater than 45 mm Hg
5. Cardiac conduction or rhythm disturbances (any rhythm except sinus arrhythmia)
6. Close monitoring of vital signs during antidotal therapy or elimination procedures
7. The need for continuous monitoring
8. QRS interval greater than 0.10 second, in cases of tricyclic antidepressant poisoning
9. Systolic blood pressure less than 80 mm Hg
10. Hypoxia, hypercarbia, acid-base imbalance, or metabolic abnormalities
11. Extremes of temperature
12. Progressive deterioration or significant underlying medical disorders

Use of Antidotes

Antidotes are available for only a relatively small number of poisons. An antidote is not a substitute for good supportive care. Table 5 summarizes the commonly used antidotes, their indications, and their methods of administration. The Regional Poison Control Center can give further information on these antidotes.

Enhancement of Elimination

The acceptable methods for elimination of absorbed toxic substances are dialysis, hemoperfusion, exchange transfusion, plasmapheresis, enzyme induction, and inhibition. Methods of increasing urinary excretion of toxic chemicals and drugs have been studied extensively, but the other modalities have not been well evaluated.

In general, these methods are needed in only a minority of cases and should be reserved for life-threatening circumstances when a definite benefit is anticipated.

Dialysis

Dialysis is the extrarenal means of removing certain substances from the body, and it can substitute for the kidney when renal failure occurs. Dialysis is not the first measure instituted; however, it may be lifesaving later in the course of a severe intoxication. It is needed in only a minority of intoxicated patients.

Peritoneal dialysis uses the peritoneum as the membrane for dialysis. It is only 1/20 as effective as hemodialysis. It is easier to use and less hazardous to the patient but also less effective in removing the toxin; thus it is rarely used except in small infants.

Hemodialysis is the most effective dialysis method but requires experience with sophisticated equipment. Blood is circulated past a semipermeable extracorporeal membrane. Substances are removed by diffusion down a concentration gradient. Anticoagulation with heparin is necessary. Flow rates of 300 to 500 mL/min can be achieved, and clearance rates may reach 200 or 300 mL/min.

Dialyzable substances easily diffuse across the dialysis membrane and have the following characteristics: (a) a molecular weight less than 500 daltons and preferably less than 350; (b) a volume of distribution less than 1 L/kg; (c) protein binding less than 50%; (d) high water solubility (low lipid solubility); and (e) high plasma concentration and a toxicity that correlates reasonably with the plasma concentration. Considerations for hemodialysis and hemoperfusion are cases of serious ingestions (the nephrologist should be notified immediately), and cases involving a compound that is ingested in a potentially lethal dose and the rapid removal of which may improve the prognosis. Examples of the latter are ethylene glycol 1.4 mL/kg 100% solution or equivalent and methanol 6 mL/kg 100% solution or equivalent. Common dialyzable substances include alcohol, bromides, lithium, and salicylates.

The patient-related criteria for dialysis are (a) anticipated prolonged coma and the likelihood of complications; (b) renal compromise (toxin excreted or metabolized by kidneys and dialyzable chelating agents in heavy metal poisoning); (c) laboratory confirmation of lethal blood concentration; (d) lethal dose poisoning with an agent with delayed toxicity or known to be metabolized into a more toxic metabolite (e.g., ethylene glycol, methanol); and (e) hepatic impairment when the agent is

metabolized by the liver, and clinical deterioration despite optimal supportive medical management. Table 6 gives plasma concentrations above which removal by extracorporeal measures should be considered.

The contraindications to hemodialysis include the following: (a) substances are not dialyzable; (b) effective antidotes are available; (c) patient is hemodynamically unstable (e.g., shock); and (d) presence of coagulopathy because heparinization is required.

Hemodialysis also has a role in correcting disturbances that are not amenable to appropriate medical management. These are easily remembered by the "vowel" mnemonic:

A—refractory acid-base disturbances

E—refractory electrolyte disturbances

I—intoxication with dialyzable substances (e.g., ethanol, ethylene glycol, isopropyl alcohol, methanol, lithium, and salicylates)

O—overhydration

U—uremia

Complications of dialysis include hemorrhage, thrombosis, air embolism, hypotension, infections, electrolyte imbalance, thrombocytopenia, and removal of therapeutic medications.

Hemoperfusion

Hemoperfusion is the parenteral form of oral activated charcoal. Heparinization is necessary. The patient's blood is routed extracorporeally through an outflow arterial catheter with a filter-adsorbing cartridge (charcoal or resin) and returned through a venous catheter. Cartridges must be changed every 4 hours. The blood glucose, electrolytes, calcium, and albumin levels; complete blood cell count; platelets; and serum and urine osmolality must be carefully monitored. This procedure has extended extracorporeal removal to a large range of substances that were formerly either poorly dialyzable or nondialyzable. It is not limited by molecular weight, water solubility, or protein binding, but it is limited by a volume distribution greater than 400 L, plasma concentration, and rate of flow through the filter. Activated charcoal cartridges are the primary type of hemoperfusion currently available in the United States.

The patient-related criteria for hemoperfusion are (a) anticipated prolonged coma and the likelihood of complications; (b) laboratory confirmation of lethal blood concentrations; (c) hepatic impairment when an agent is metabolized by the liver; and (d) clinical deterioration despite optimally supportive medical management.

The contraindications are similar to those for hemodialysis.

Limited data are available as to which toxins are best treated with hemoperfusion. Hemoperfusion has proved useful in treating glutethimide intoxication, phenobarbital overdose, and carbamazepine, phenytoin, and theophylline intoxication.

Complications include hemorrhage, thrombocytopenia, hypotension, infection, leukopenia, depressed phagocytic activity of granulocytes, decreased immunoglobulin levels, hypoglycemia, hypothermia, hypocalcemia, pulmonary edema, and air and charcoal embolism.

Hemofiltration

Continuous arteriovenous or venovenous hemodiafiltration (CAVHD or CVVHD, respectively) has been suggested as an alternative to conventional hemodialysis when the need for rapid removal of the drug is less urgent. These procedures, like peritoneal dialysis, are minimally invasive, have no significant impact on hemodynamics, and can be carried out continuously for many hours. Their role in the management of acute poisoning remains uncertain, however.

Plasmapheresis

Plasmapheresis consists of removal of a volume of blood. All the extracted components are returned to the blood except the plasma, which is replaced with a colloid protein solution. There are limited clinical data on guidelines and efficacy in toxicology. Centrifugal and membrane separators of cellular elements are used. It can be as effective as hemodialysis or hemoperfusion for removing toxins

TABLE 5 Initial Doses of Antidotes for Common Poisonings

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
N-Acetyl Cysteine (NAC, Mucomyst): Stock level to treat 70 kg adult for 24 h: 25 vials, 20%, 30 mL	Acetaminophen, carbon tetrachloride (experimental)	140 mg/kg loading, followed by 70 mg/kg q4h for 17 doses 150 mg/kg in 200 mL of D ₅ W over 1 h, then 50 mg/kg in 1 liter D ₅ W over 16 h	PO IV	Nausea, vomiting. Dilute to 5% with sweet juice or flat cola. Useful for those who cannot tolerate oral route.
Atropine: Stock level to treat 70 kg adult for 24 h: 1 g (1 mg/mL in 1, 10 mL)	Organophosphate and carbamate pesticides: bradycardiacs, β -adrenergics, calcium channel blockers/nerve agents	<i>Child:</i> 0.02–0.05 mg/kg repeated q5–10 min to max of 2 mg as necessary until cessation of secretions <i>Adult:</i> 1–2 mg q5–10 min as necessary. Dilute in 1–2 mL of 0.9% saline for ET instillation. <i>IV infusion dose:</i> Place 8 mg of atropine in 100 mL D ₅ W or saline. Conc. = 0.08 mg/mL; dose range = 0.02–0.08 mg/kg/h or 0.25–1 mL/kg/h. Severe poisoning may require supplemental doses of IV atropine intermittently in doses of 1–5 mg until drying of secretions occurs.	IV/ET	Tachycardia, dry mouth, blurred vision, and urinary retention. Ensure adequate ventilation before administration.
Calcium Chloride (10%): Stock level to treat 70 kg adult for 24 h: 10 vials 1 g (1.35 mEq/mL)	Hypocalcemia, fluoride, calcium channel blockers, β -blockers, oxalates, ethylene glycol, hypermagnesemia	0.1–0.2 mL/kg (10–20 mg/kg) slow push q10 min up to max 10 mL (1 g). Since calcium response lasts 15 min, some may require continuous infusion 0.2 mL/kg/h up to maximum of 10 mL/h while monitoring for dysrhythmias and hypotension.	IV	Administer slowly with BP and ECG monitoring and have magnesium available to reverse calcium effects. Tissue irritation, hypotension, dysrhythmias from rapid injection. Contraindications: digitalis glycoside intoxication.
Calcium Gluconate (10%): Stock level to treat 70 kg adult for 24 h: 20 vials 1 g (0.45 mEq/mL)	Hypocalcemia, fluoride, calcium channel blockers, hydrofluoric acid; black widow envenomation	0.3–0.4 mL/kg (30–40 mg/kg) slow push; repeat as needed up to max dose 10–20 mL (1–2 g).	IV	Same comments as calcium chloride.
Infiltration of Calcium Gluconate	Hydrofluoric acid skin exposure	Dose: Infiltrate each square cm of affected dermis/subcutaneous tissue with about 0.5 mL of 10% calcium gluconate using a 30-gauge needle. Repeat as needed to control pain.	Infiltrate	
Intra-arterial Calcium Gluconate	Hydrofluoric acid skin exposure	Infuse 20 mL of 10% calcium gluconate (not chloride) diluted in 250 mL D ₅ W via the radial or brachial artery proximal to the injury over 3–4 h.		Alternatively, dilute 10 mL of 10% calcium gluconate with 40–50 mL of D ₅ W.
Calcium Gluconate Gel: Stock level: 3.5 g	Hydrofluoric acid skin exposure	2.5 g USP powder added to 100 mL water-soluble lubricating jelly, e.g., K-Y jelly or Lubifax (or 3.5 mg into 150 mL). Some use 6 g of calcium carbonate in 100 g of lubricant. Place injured hand in surgical glove filled with gel. Apply q4h. If pain persists, calcium gluconate injection may be needed (above).	Dermal	Powder is available from Spectrum Pharmaceutical Co. in California: 800-772-8786. Commercial preparation of Ca gluconate gel is available from Pharmascience in Montreal, Quebec: 514-340-1114.
Cyanide Antidote Kit: Stock level to treat 70 kg adult for 24 h: 2 Lilly Cyanide Antidote kits	Cyanide Hydrogen sulfide (nitrites are given only) Do not use sodium thiosulfate for hydrogen sulfide Individual portions of the kit can be used in certain circumstances (consult PCC)	Amyl nitrite: 1 crushable ampule for 30 sec of every min. Use new amp q3 min. May omit step if venous access is established.	Inhalation	If methemoglobinemia occurs, do not use methylene blue to correct this because it releases cyanide.

Continued

TABLE 5 Initial Doses of Antidotes for Common Poisonings—cont'd

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
	Cyanide Hydrogen sulfide (nitrites are given only) Do not use sodium thiosulfate for hydrogen sulfide Individual portions of the kit can be used in certain circumstances (consult PCC) Do not use sodium thiosulfate for hydrogen sulfide Individual portions of the kit can be used in certain circumstances (consult PCC)	Sodium nitrite: <i>Child</i> : 0.33 mL/kg of 3% solution if hemoglobin level is not known, otherwise based on tables with product. <i>Adult</i> : up to 300 mg (10 mL). Dilute nitrite in 100 mL 0.9% saline, administer slowly at 5 mL/min. Slow infusion if fall in BP. Sodium thiosulfate: <i>Child</i> : 1.6 mL/kg of 25% solution, may be repeated q30–60 min to a maximum of 12.5 g or 50 mL in adult. Administer over 20 min.	IV IV	If methemoglobinemia occurs, do not use methylene blue to correct this because it releases cyanide. Nausea, dizziness, headache. Tachycardia, muscle rigidity, and bronchospasm (rapid administration).
Dantrolene Sodium (Dantrium): Stock level to treat 70 kg adult for 24 h: 700 mg, 35 vials (20 mg/vial)	Malignant hyperthermia	2–3 mg/kg IV rapidly. Repeat loading dose every 10 min. If necessary up to a maximum total dose of 10 mg/kg. When temperature and heart rate decrease, slow the infusion 1–2 mg/kg q6h for 24–28 h until all evidence of malignant hyperthermia syndrome has subsided. Follow with oral doses 1–2 mg/kg four times a day for 24 h as necessary.	IV/PO	Hepatotoxicity occurs with cumulative dose of 10 mg/kg. Thrombophlebitis (best given in central line). Available as 20 mg lyophilized dantrolene powder for reconstruction, which contains 3 g mannitol and sodium hydroxide in 70-mL vial. Mix with 60 mL sterile distilled water without a bacteriostatic agent and protect from light. Use within 6 hours after reconstituting.
Deferoxamine (Desferal): Stock level to treat 70 kg adult for 24 h: 17 vials (500 mg/amp)	Iron	IV infusion of 15 mg/kg/h (3 mL/kg/h: 500 mg in 100 mL D ₅ W) max 6 g/d Rates of >45 µg/kg/h if cone >1000 µg/dL.	Preferred IV: avoid therapy >24 h	Hypotension (minimized by avoiding rapid infusion rates) DFO challenge test 50 mg/kg is unreliable if negative.
Diazepam (Valium): Stock level to treat 70 kg adult for 24 h: 200 mg, 5 mg/mL; 2, 10 mL	Any intoxication that provokes seizures when specific therapy is not available (e.g., amphetamines, PCP, barbiturate and alcohol withdrawal) Chloroquine poisoning	<i>Adult</i> , 5–10 mg IV (max 20 mg) at a rate of 5 mg/min until seizure is controlled. May be repeated 2 or 3 times. <i>Child</i> , 0.1–0.3 mg/kg up to 10 mg IV slowly over 2 min.	IV	Confusion, somnolence, coma, hypotension. Intramuscular absorption is erratic. Establish airway and administer 100% oxygen and glucose.
Digoxin-Specific Fab Antibodies (Digibind): Stock level to treat 70 kg adult for 24 h: 20 vials	Digoxin, digitoxin, oleander tea with the following: (1) Imminent cardiac arrest or shock (2) Hyperkalemia >5.0 mEq/L (3) Serum digoxin >5 ng/mL (child) at 8–12 h post ingestion in adults (4) Digitalis delirium (5) Ingestion over 10 mg in adults or 4 mg in child (6) Bradycardia or second- or third-degree heart block unresponsive to atropine (7) Life-threatening digitoxin or oleander poisoning	(1) If amount ingested is known total dose × bioavailability (0.8) = body burden. The body burden + 0.6 (0.5 mg of digoxin is bound by 1 vial of 38 mg of Fab) = # vials needed. (2) If amount is unknown but the steady state serum concentration is known in ng/mL: Digoxin: ng/mL: (5.6 L/kg Vd) × (wt kg) = µg body burden. Body burden + 100 = mg body burden/0.5 = # vials needed. Digitoxin body burden = ng/mL × (0.56 L/kg Vd) × (wt kg) Body burden + 1000 = mg body burden/0.5 = # vials needed. (3) If the amount is not known, it is administered in life-threatening situations as 10 vials (400 mg) IV in saline over 30 min in adults. If cardiac arrest is imminent, administer 20 vials (adult) as a bolus.	IV	Allergic reactions (rare), return of condition being treated with digitalis glycoside. Administer by infusion over 30 min through a 0.22-µ filter. If cardiac arrest imminent, may administer by bolus. Consult PCC for more details.

Dimercaprol (BAL in Peanut Oil): Stock level to treat 70 kg adult for 24 h: 1200 mg (4 amps—100 mg/mL 10% in oil in 3 mL amp)	Chelating agent for arsenic, mercury, and lead	3–5 mg/kg q4h usually for 5–10 d	Deep IM	Local infection site pain and sterile abscess, nausea, vomiting, fever, salivation, hypertension, and nephrotoxicity (alkalinize urine).
2,3 Dimercaptosuccinic Acid (DMSA Succimer): 100 mg/capsule:20 capsules	Used as a chelating agent for lead, especially blood lead levels >45 µg/dL. May also be used for symptomatic mercury exposure	10 mg/kg 3 × daily for 5 days followed by 10 mg/kg 2 × daily for 14 days	PO	Precautions: monitor AST/ALT; use with caution in G6PD-deficient patients. Avoid concurrent iron therapy. Relatively safe antidote, rarely severe, uncommon minor skin rashes may occur.
Diphenhydramine (Benadryl): Antiparkinsonian action. Stock level to treat a 70 kg adult for 24 h: 5 vials (10 mg/mL, 10 mL each)	Used to treat extrapyramidal symptoms and dystonia induced by phenothiazines, phencyclidine, and related drugs	<i>Children:</i> 1–2 mg/kg IV slowly over 5 min up to maximum 50 mg followed by 5 mg/kg/24 h orally divided every 6 h up to 300 mg/24 h <i>Adults:</i> 50 mg IV followed by 50 mg orally four times daily for 5–7 d. <i>Note:</i> Symptoms abate within 2–5 min after IV.	IV	Fatal dose: 20–40 mg/kg. Dry mouth, drowsiness.
Ethanol (Ethyl Alcohol): Stock level to treat 70 kg adult for 24 h: 3 bottles 10% (1 L each)	Methanol, ethylene glycol	10 mL/kg loading dose concurrently with 1.4 mL/kg (average) infusion of 10% ethanol (consult PCC for more details)	IV	Nausea, vomiting, sedation. Use 0.22-µ filter if preparing from bulk 100% ethanol.
Flumazenil (Romazicon): Stock level to treat 70 kg adult for 24 h: 4 vials (0.1 mg/mL, 10 mL)	Benzodiazepines (may also be beneficial in the treatment of hepatic encephalopathy)	Administer 0.2 mg (2 mL) IV over 30 sec (pediatric dose not established, 0.01 mg/kg), then wait 3 min for a response, then if desired consciousness is not achieved, administer 0.3 mg (3 mL) over 30 sec, then wait 3 min for response, then if desired consciousness is not achieved, administer 0.5 mg (5 mL) over 30 sec at 60-sec intervals up to a maximum cumulative dose of 3 mg (30 mL) (1 mg in children). Because effects last only 1–5 h, if patient responds, monitor carefully over next 6 h for resedation. If multiple repeated doses, consider a continuous infusion of 0.2–1 mg/h.	IV	Nausea, vomiting, facial flushing, agitation, headache, dizziness, seizures, and death. It is not recommended to improve ventilation. Its role in CNS depression needs to be clarified. It should not be used routinely in comatose patients. It is contraindicated in cyclic antidepressant intoxications, stimulant overdose, long-term benzodiazepine use (may precipitate life-threatening withdrawal), if benzodiazepines are used to control seizures, in head trauma.
Folic Acid (Folvite): Stock level to treat 70 kg adult for 24 h: 4 100-mg vials	Methanol/ethylene glycol (investigational)	1 mg/kg up to 50 mg q4h for 6 doses	IV	Uncommon
Fomepizole (4-MP, Antizol): Stock level to treat 70 kg adult: 4 1.5-mL vials (1 g/mL)	Ethylene glycol Methanol	Loading dose: 15 mg/kg (0.015 mL/kg) IV followed by maintenance dose of 10 mg/kg (0.01 mL/kg) q12h for 4 doses, then 15 mg/kg q12h until ethylene glycol levels are <20 mg/dL. Fomepizole can be given to patients undergoing hemodialysis (dose q4h).	IV	Suggested: co-administer folate 50 mg IV (child 1 mg/kg), thiamine 100 mg/d (child 50 mg), and pyridoxine 50 mg IV/IM q6h until intoxication is resolved. Monitor for urinary oxalate crystals. Adverse reactions include headache, nausea, and dizziness. Antizole should be diluted in 100 mL 0.9% saline or D ₅ W and mixed well. Antizole should not be given undiluted.

Continued

TABLE 5 Initial Doses of Antidotes for Common Poisonings—cont'd

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
Glucagon: Stock level to treat 70 kg adult for 24 h: 10 vials, 10 units	β -Blocker, calcium channel blocker	3–10 mg in adult, then infuse 2–5 mg/h (0.05–0.1 mg/kg in child, then infuse 0.07 mg/kg/h) Large doses up to 100 mg/24 h used	IV	Use D ₅ W, not 0.9% saline, to reconstitute the glucagon (rather than diluent of Eli Lilly, which contains phenol). Vomiting precautions.
Magnesium Sulfate: Stock level to treat 70 kg adult for 24 h: approx 25 g (50 mL of 50% or 200 mL of 12.5%)	Torsades de pointes	<i>Adult:</i> 2 g (20 mL or 20%) over 20 min. If no response in 10 min, repeat and follow by continuous infusion 1 g/h. <i>Children:</i> 25–50 mg/kg initially and maintenance is 30–60 mg/kg/24 h (0.25–0.5 mEq/kg/24 h) up to 1000 mg/24 h. (Dose not studied in controlled fashion.)	IV	Use with caution if renal impairment is present.
Methylene Blue: Stock level to treat 70 kg adult for 24 h: 5 amps (10 mg/10 mL)	Methemoglobinemia	0.1–0.2 mL/kg of 1% solution, slow infusion, may be repeated q30–60 min	IV	Nausea, vomiting, headache, dizziness.
Naloxone (Narcan): Stock level to treat 70 kg adult for 24 h: 3 vials (1 mg/mL, 10 mL)	Comatose patient; decreased respirations <12; opioids	In postoperative opioid depression reversal, IV 0.1–0.5 μ g/kg q2 min as needed and may repeat up to a total dose of 1 μ g/kg In suspected overdose, administer IV 0.1 mg/kg in a child younger than 5 years of age up to 2 mg; in older children and adults administer 2 mg every 2 min up to a total of 10–20 mg. Can also be administered into the endotracheal tube. If no response by 10 mg, a pure opioid intoxication is unlikely. If opioid abuse is suspected, restraints should be in place before administration; initial dose 0.1 mg to avoid withdrawal and violent behavior. The initial dose is then doubled every minute progressively to a total of 10 mg. A continuous infusion has been advocated because many opioids outlast the short half-life of naloxone (30–60 min). The naloxone infusion hourly rate to produce a response is equal to the effective dose required (improvement in ventilation and arousal). An additional dose may be required in 15–30 min as a bolus.	IV, ET	Larger doses of naloxone may be required for more poorly antagonized synthetic opioid drugs: buprenorphine (Buprenex), codeine, dextromethorphan, fentanyl, pentazocine (Talwin), propoxyphene (Darvon), diphenoxylate, nalbuphine (Nubain), new potent “designer” drugs, or long-acting opioids such as methadone (Dolophine). Complications. Although naloxone is safe and effective, there are rare reports of complications (<1%) of pulmonary edema, seizures, hypertension, cardiac arrest, and sudden death. The infusions are titrated to avoid respiratory depression and opioid withdrawal manifestations. Tapering of infusions can be attempted after 12 h and when the patient is stable.
Physostigmine (Antilirium): Stock level to treat 70 kg adult for 24 h: 2–4 mg (2 mL each)	Anticholinergic agents (not routinely used, only indicated if life-threatening complications)	<i>Child:</i> 0.02 mg/kg slow push to max 2 mg q30–60 min <i>Adult:</i> 1–2 mg q5 min to max 6 mg.	IV	Bradycardia, asystole, seizures, bronchospasm, vomiting, headaches. Do not use for cyclic antidepressants.
Pralidoxime (2PAM, Protopan): Stock level to treat 70 kg adult for 24 h: 12 vials (1 g per 20 mL)	Organophosphates/nerve agents	Child \leq 12 y, 25–50 mg/kg max (4 mg/min); >12 y, 1–2 g/dose in 250 mL of 0.9% saline over 5–10 min. Max 200 mg/min. Repeat q6–12h for 24–48h. Max adult 6 g/d. Alternative: Maintenance infusion 1 g in 100 mL, of 0.9% saline at 5–20 mg/kg/h (0.5–12 mL/kg/h) up to max 500 mg/h or 50 mL/h. Titrate to desired response. End point is absence of fasciculations and return of muscle strength.	IV	Nausea, dizziness, headache; tachycardia, muscle rigidity, bronchospasm (rapid administration).

Pyridoxine (Vitamin B₆): Stock level to treat 70 kg adult for 24 h: 100 mg/mL 10% solution. For a 70 kg patient, 10 g = 10 vials	Seizures from isoniazid or <i>Gyromitra</i> mushrooms, ethylene glycol	Isoniazid: <i>Unknown amount ingested:</i> 5 g (70 mg/kg) in 50 mL D ₅ W over 5 min + diazepam 0.3 mg/kg IV at rate of 1 mg/min in child or 10 mg dose at rate up to 5 mg/min in adults. Use different site (synergism). May repeat q5–20 min until seizure controlled. Up to 375 mg/kg have been given (52 g). <i>Known amount:</i> 1 g for each gram isoniazid ingested over 5 min with diazepam (dose above) Gyromitra mushroom: Child 25 mg/kg or 2–5 g, adults IV over 15–30 min to max 20 g	IV	After seizure is controlled, administer remainder of pyridoxine 1 g/1 g isoniazid total 5 g as infusion over 60 min. Adverse reactions uncommon; do not administer in same bottle as sodium bicarbonate. For <i>Gyromitra</i> mushrooms, some use PO 25 mg/kg/d early when mushroom ingestion is suspected.
Sodium Bicarbonate (NaHCO₃): Stock level to treat 70 kg adult for 24 h: 10 ampules or syringes (500 mEq)	Tricyclic antidepressant cardiotoxicity (QRS >0.12 sec; ventricular tachycardia, severe conduction disturbances); metabolic acidosis: phenothiazine toxicity <i>Salicylate:</i> to keep blood pH 7.5–7.55 (not >7.55) and urine pH 7.5–8.0. Alkalinization recommended if salicylate conc. >40 mg/dL in acute poisoning and at lower levels if symptomatic in chronic intoxication, 2 mEq/kg will raise blood pH 0.1 unit	<i>Ethylene glycol:</i> 100 mg IV daily. 1–2 mEq/kg undiluted as a bolus. If no effect on cardiotoxicity, repeat twice a few minutes apart <i>Adult</i> with clear physical signs and laboratory findings of acute moderate or severe salicylism: Bolus 1–2 mEq/kg followed by infusion of 100–150 mEq NaHCO ₃ added to 1 L of 5% dextrose at rate of 200–300 mL/h <i>Child:</i> Bolus same as adult followed by 1–2 mEq/kg in infusion of 20 mL/kg/h 5% dextrose in 0.45% saline Add potassium when patient voids Rate and amount of the initial infusion, if patient is volume depleted: 1 h to achieve urine output of 2 mL/kg/h and urine pH 7–8 In mild cases without acidosis and urine pH >6, administer 5% dextrose in 0.9% saline with 50 mEq/L or 1 mEq/kg NaHCO ₃ as maintenance to replace ongoing renal losses. If acidemia is present and pH <7.2, add 2 mEq/kg as loading dose followed by 2 mEq/kg q3–4h to keep pH at 7.5–7.55. If acidemia is present, recommend isotonic NaHCO ₃ , 3 ampules to 1 L of D ₅ W at 10–15 mL/kg/h or sufficient to produce normal urine flow and a urine pH of 7.5 or higher	IV	Monitor sodium, potassium, and blood pH because fatal alkalemia and hyponatremia have been reported. Monitor both urine and blood pH. Do not use the urine pH alone to assess the need for alkalization because of the paradoxical aciduria that may occur. Adjust the urine pH to 7.5–8 by NaHCO ₃ infusion. After urine output established, add potassium 40 mEq/L.
	<i>Long-acting barbiturates:</i> Phenobarbital and primidone (Mysoline). <i>Note:</i> Alkalinization is ineffective for the short- or intermediate-acting barbiturates	NaHCO ₃ : 2 mEq/kg during the first hour or 100 mEq in 1 L of D ₅ W with 40 mEq/L potassium at a rate of 100 mL/h in adults Adequate potassium is necessary to accomplish alkalization	IV	Additional sodium bicarbonate and potassium chloride may be needed. Adjust the urine pH to 7.5–8 by NaHCO ₃ infusion.
Thiamine: 100 mg/mL, 2 vials	Thiamine deficiency, ethylene glycol poisoning, alcoholism	100 mg IV followed with 100 mg V/IM for 5–7 days in an alcoholic and followed by 100 mg/d orally	IV/IM	
Vitamin K₁ (Aqua Mephyton): 10 mg/1–5 mL; 5-mg tablets	Warfarin anticoagulant or rodenticide toxicity	Oral 0.4 mg/kg/dose child, 10–25 mg adults. If evidence of bleeding, administer vitamin K ₁ SC, IV 0.6 mg/kg/dose child and up to 25–50 mg adults for 6 hours depending on severity	PO/SC, IV	Give vitamin K daily until PT/INR are normal. Examine stools and urine for evidence of bleeding.

TABLE 6 Plasma Concentrations Above Which Removal by Extracorporeal Measures Should Be Considered

DRUG	PLASMA CONCENTRATION	PROTEIN BINDING (%)	VOLUME DISTRIBUTION (L/kg)	METHOD OF CHOICE
Amanitin	NA	25	1.0	HP
Ethanol	500–700 mg/dL	0	0.3	HD
Ethchlorvynol	150 µg/mL	35–50	3–4	HP
Ethylene glycol	25–50 µg/mL	0	0.6	HD
Glutethimide	100 µg/mL	50	2.7	HP
Isopropyl alcohol	400 mg/dL	0	0.7	HD
Lithium	4 mEq/L	0	0.7	HD
Meprobamate (Equanil)	100 µg/mL	0	NA	HP
Methanol	50 mg/dL	0	0.7	HD
Methaqualone	40 µg/dL	20–60	6.0	HP
Other barbiturates	50 µg/dL	50	0–1	HP
Paraquat	0.1 mg/dL	poor	2.8	HP > HD
Phenobarbital	100 µg/dL	50	0.9	HP > HD
Salicylates	80–100 mg/dL	90	0.2	HD > HP
Theophylline		0	0.5	
Chronic	40–60 µg/mL			HP
Acute	80–100 µg/mL			HP
Trichlorethanol	250 µg/mL	70	0.6	HP

Abbreviations: HD = hemodialysis; HP = hemoperfusion; HP > HD = hemoperfusion preferred over hemodialysis.

Data from Winchester JF: Active methods for detoxification. In Haddad LM, Winchester JF (eds). *Clinical Management of Poisoning and Drug Overdose*, 2nd ed. Philadelphia, WB Saunders, 1990; Balsam L, Cortisidis GN, Fienfeld DA: Role of hemodialysis and hemoperfusion in the treatment of intoxications. *Contemp Manage Crit Care* 1:61, 1991.

Note: Cartridges for charcoal hemoperfusion are not readily available anymore in most locations. So hemodialysis may be substituted in these situations. In mixed or chronic drug overdoses, extracorporeal measures may be considered at lower drug concentrations.

that have high protein binding, and it may be useful for toxins not filtered by hemodialysis and hemoperfusion.

Plasmapheresis has been anecdotally used in treating intoxications with the following agents: paraquat (removed 10%), propranolol (removed 30%), quinine (removed 10%), L-thyroxine (removed 30%), and salicylate (removed 10%). It has been shown to remove less than 10% of digoxin, phenobarbital, prednisolone, and tobramycin. Complications include infection; allergic reactions including anaphylaxis; hemorrhagic disorders; thrombocytopenia; embolus and thrombus; hypervolemia and hypovolemia; dysrhythmias; syncope; tetany; paresthesia; pneumothorax; acute respiratory distress syndrome; and seizures.

Supportive Care, Observation, and Therapy for Complications

Altered Mental Status

If airway protective reflexes are absent, endotracheal intubation is indicated for a comatose patient or a patient with altered mental status. If respirations are ineffective, ventilation should be instituted, and if hypoxemia persists, supplemental oxygen is indicated. If a cyanotic patient fails to respond to oxygen, the practitioner should consider methemoglobinemia.

Hypoglycemia

Hypoglycemia accompanies many poisonings, including with ethanol (especially in children), clonidine (Catapres), insulin, organophosphates, salicylates, sulfonyleureas, and the unripe fruit or seed of a Jamaican plant called ackee. If hypoglycemia is present or suspected, glucose should be administered immediately as an intravenous bolus. Doses are as follows: in a neonate, 10% glucose (5 mL/kg); in a child, 25% glucose 0.25 g/kg (2 mL/kg); and in an adult, 50% glucose 0.5 g/kg (1 mL/kg).

A bedside capillary test for blood glucose is performed to detect hypoglycemia, and the sample is sent to the laboratory for confirmation. If the glucose reagent strip visually reads less than 150 mg/dL, one administers glucose. Venous blood should be used rather than capillary blood for the bedside test if the patient is in shock or is hypotensive. Large amounts of glucose given rapidly to non-diabetic patients may cause a transient reactive hypoglycemia and hyperkalemia and may accentuate damage in ischemic cerebrovascular and cardiac tissue. If focal neurologic signs are present, it may be prudent to withhold glucose, because hypoglycemia causes focal signs in less than 10% of cases.

Thiamine Deficiency Encephalopathy

Thiamine is administered to avoid precipitating thiamine deficiency encephalopathy (Wernicke-Korsakoff syndrome) in alcohol abusers and in malnourished patients. The overall incidence of thiamine deficiency in ethanol abusers is 12%. Thiamine 100 mg intravenously should be administered around the time of the glucose administration but not necessarily before the glucose. The clinician should be prepared to manage the anaphylaxis that sometimes is caused by thiamine, although it is extremely rare.

Opioid Reactions

Naloxone (Narcan) reverses CNS and respiratory depression, miosis, bradycardia, and decreased gastrointestinal peristalsis caused by opioids acting through μ , κ , and δ receptors. It also affects endogenous opioid peptides (endorphins and enkephalins), which accounts for the variable responses reported in patients with intoxications from ethanol, benzodiazepines, clonidine (Catapres), captopril (Capoten), and valproic acid (Depakote) and in patients with spinal cord injuries. There is a high sensitivity for predicting a

response if pinpoint pupils and circumstantial evidence of opioid abuse (e.g., track marks) are present.

In cases of suspected overdose, naloxone 0.1 mg/kg is administered intravenously initially in a child younger than 5 years of age. The dose can be repeated in 2 minutes, if necessary up to a total dose of 2 mg. In older children and adults, the dose is 2 mg every 2 minutes for five doses up to a total of 10 mg. Naloxone can also be administered into an endotracheal tube if intravenous access is unavailable. If there is no response after 10 mg, a pure opioid intoxication is unlikely. If opioid abuse is suspected, restraints should be in place before the administration of naloxone, and it is recommended that the initial dose be 0.1 to 0.2 mg to avoid withdrawal and violent behavior. The initial dose is then doubled every minute progressively to a total of 10 mg. Naloxone may unmask concomitant sympatho-mimetic intoxication as well as withdrawal.

Larger doses of naloxone may be required for more poorly antagonized synthetic opioid drugs: buprenorphine (Buprenex), codeine, dextromethorphan, fentanyl and its derivatives, pentazocine (Talwin), propoxyphene (Darvon), diphenoxylate, nalbuphine (Nubain), and long-acting opioids such as methadone (Dolophine).

Indications for a continuous infusion include a second dose for recurrent respiratory depression, exposure to poorly antagonized opioids, a large overdose, and decreased opioid metabolism, as with impaired liver function. A continuous infusion has been advocated because many opioids outlast the short half-life of naloxone (30 to 60 minutes). The hourly rate of naloxone infusion is equal to the effective dose required to produce a response (improvement in ventilation and arousal). An additional dose may be required in 15 to 30 minutes as a bolus. The infusions are titrated to avoid respiratory depression and opioid withdrawal manifestations. Tapering of infusions can be attempted after 12 hours and when the patient's condition has been stabilized.

Although naloxone is safe and effective, there are rare reports of complications (less than 1%) of pulmonary edema, seizures, hypertension, cardiac arrest, and sudden death.

Agents Whose Roles Are Not Clarified

Nalmefene (Revex), a long-acting parenteral opioid antagonist that the FDA has approved, is undergoing investigation, but its role in the treatment of comatose patients and patients with opioid overdose is not clear. It is 16 times more potent than naloxone, and its duration of action is up to 8 hours (half-life 10.8 hours, versus naloxone 1 hour).

Flumazenil (Romazicon) is a pure competitive benzodiazepine antagonist. It has been demonstrated to be safe and effective for reversing benzodiazepine-induced sedation. It is not recommended to improve ventilation. Its role in cases of CNS depression needs to be clarified. It should not be used routinely in comatose patients and is not an essential ingredient of the coma therapeutic regimen. It is contraindicated in cases of co-ingestion of cyclic antidepressant intoxication, stimulant overdose, and long-term benzodiazepine use (may precipitate life-threatening withdrawal) if benzodiazepines are used to control seizures. There is a concern about the potential for seizures and cardiac dysrhythmias that may occur in these settings.

Laboratory and Radiographic Studies

An electrocardiogram (ECG) should be obtained to identify dysrhythmias or conduction delays from cardiotoxic medications. If aspiration pneumonia (history of loss of consciousness, unarousable state, vomiting) or noncardiac pulmonary edema is suspected, a chest radiograph is needed. Electrolyte and glucose concentrations in the blood, the anion gap, acid-base balance, the arterial blood gas (ABG) profile (if patient has respiratory distress or altered mental status), and serum osmolality should be measured if a toxic alcohol ingestion is suspected. Table 7 lists appropriate testing on the basis of clinical toxicologic presentation. All laboratory specimens should be carefully labeled, including time and date. For potential legal cases, a "chain of custody" must be established. Assessment of the laboratory studies may provide a clue to the etiologic agent.

TABLE 7 Patient Condition/Systemic Toxin and Appropriate Tests

CONDITION	TESTS
Comatose	Toxicologic tests (acetaminophen, sedative-hypnotic, ethanol, opioids, benzodiazepine), glucose.
Respiratory toxicity	Spirometry, FEV ₁ , arterial blood gases, chest radiograph, monitor O ₂ saturation
Cardiac toxicity	ECG 12-lead and monitoring, echocardiogram, serial cardiac enzymes (if evidence or suspicion of a myocardial infarction), hemodynamic monitoring
Hepatic toxicity	Enzymes (AST, ALT, GGT), ammonia, albumin, bilirubin, glucose, PT, PTT, amylase
Nephrotoxicity	BUN, creatinine, electrolytes (Na, F, Mg, Ca, PO ₄), serum and urine osmolality, 24-hour urine for heavy metals if suspected, creatine kinase, serum and urine myoglobin, urinalysis and urinary sodium
Bleeding	Platelets, PT, PTT, bleeding time, fibrin split products, fibrinogen, type and match

Abbreviations: ALT = alanine transaminase; AST = aspartate transaminase; BUN = blood urea nitrogen; ECG = electrocardiogram; FEV₁ = forced expiratory volume in 1 second; GGT = γ -glutamyltransferase; PT = prothrombin time; PTT = partial thromboplastin time.

Electrolyte, Acid-Base, and Osmolality Disturbances

Electrolyte and acid-base disturbances should be evaluated and corrected. Metabolic acidosis (usually low or normal pH with a low or normal/high PaCO₂ and low HCO₃) with an increased anion gap (AG) is seen with many agents in cases of overdose.

The AG is an estimate of those anions other than chloride and HCO₃ necessary to counterbalance the positive charge of sodium. It serves as a clue to causes, compensations, and complications. The AG is calculated from the standard serum electrolytes by subtracting the total CO₂ (which reflects the actual measured bicarbonate) and chloride from the sodium: $(Na - [Cl + HCO_3]) = AG$. The potassium is usually not used in the calculation because it may be hemolyzed and is an intracellular cation. The lack of anion gap does not exclude a toxic etiology.

The normal gap is usually 7 to 11 mEq/L by flame photometer. However, there has been a "lowering" of the normal AG to 7 ± 4 mEq/L by the newer techniques (e.g., ion selective electrodes or colorimetric titration). Some studies have found AGs to be relatively insensitive for determining the presence of toxins.

It is important to recognize anion gap toxins, such as salicylates, methanol, and ethylene glycol, because they have specific antidotes, and hemodialysis is effective in management of cases of overdose with these agents.

Table 8 lists the reasons for increased AG, decreased anion gap, or no gap. The most common cause of a decreased AG is laboratory error. Lactic acidosis produces the largest AG and can result from any poisoning that results in hypoxia, hypoglycemia, or convulsions.

Table 9 lists other blood chemistry derangements that suggest certain intoxications.

Serum osmolality is a measure of the number of molecules of solute per kilogram of solvent, or mOsm/kg water. The osmolality is molecules of solute per liter of solution, or mOsm/L water at a specified temperature. Osmolality is usually the calculated value and osmolality is usually a measured value. They are considered interchangeable where 1 L equals 1 kg. The normal serum osmolality is 280 to 290 mOsm/kg. The freezing point serum osmolality measurement specimen and the serum electrolyte specimens for calculation should be drawn simultaneously.

The serum osmolal gap is defined as the difference between the measured osmolality determined by the freezing point method and

TABLE 8 Etiologies of Metabolic Acidosis

NORMAL ANION GAP HYPERCHLOREMIC	INCREASED ANION GAP NORMOCHLOREMIC	DECREASED ANION GAP
Acidifying agents	Methanol	Laboratory error [†]
Adrenal insufficiency	Uremia*	Intoxication—bromine, lithium
Anhydrase inhibitors	Diabetic ketoacidosis*	Protein abnormal
Fistula	Paraldehyde,* phenformin	Sodium low
Osteotomies	Isoniazid	
Obstructive uropathies	Iron	
Renal tubular acidosis	Lactic acidosis [†]	
Diarrhea, uncomplicated*	Ethanol,* ethylene glycol*	
Dilutional	Salicylates, starvation solvents	
Sulfamylon		

*Indicates hyperosmolar situation. Studies have found that the anion gap may be relatively insensitive for determining the presence of toxins.

[†]Lactic acidosis can be produced by intoxications of the following: carbon monoxide, cyanide, hydrogen sulfide, hypoxia, ibuprofen, iron, isoniazid, phenformin, salicylates, seizures, theophylline.

TABLE 9 Blood Chemistry Derangements in Toxicology

DERANGEMENT	TOXIN
Acetonemia without acidosis	Acetone or isopropyl alcohol
Hypomagnesemia	Ethanol, digitalis
Hypocalcemia	Ethylene glycol, oxalate, fluoride
Hyperkalemia	β-Blockers, acute digitalis, renal failure
Hypokalemia	Diuretics, salicylism, sympathomimetics, theophylline, corticosteroids, chronic digitalis
Hyperglycemia	Diazoxide, glucagon, iron, isoniazid, organophosphate insecticides, phenylurea insecticides, phenytoin (Dilantin), salicylates, sympathomimetic agents, thyroid vasopressors
Hypoglycemia	β-Blockers, ethanol, insulin, isoniazid, oral hypoglycemic agents, salicylates
Rhabdomyolysis	Amphetamines, ethanol, cocaine, or phencyclidine, elevated creatine phosphokinase

TABLE 10 Conversion Factors for Alcohols and Glycols

ALCOHOLS/ GLYCOLS	1 mg/dL IN BLOOD RAISES OSMOLALITY mOsm/L	MOLECULAR WEIGHT	CONVERSION FACTOR
Ethanol	0.228	40	4.6
Methanol	0.327	32	3.2
Ethylene glycol	0.190	62	6.2
Isopropanol	0.176	60	6.0
Acetone	0.182	58	5.8
Propylene glycol	NA	72	7.2

Example: Methanol osmolality. Subtract the calculated osmolality from the measured serum osmolality (freezing point method) = osmolar gap × 3.2 (one-tenth molecular weight) = estimated serum methanol concentration.

Note: This equation is often not considered very reliable in predicting the actual measured blood concentration of these alcohols or glycols.

the calculated osmolality. It is determined by the following formula (BUN is blood urea nitrogen):

$$(\text{Sodium} \times 2) + (\text{BUN}/3) + (\text{Glucose}/20)$$

This gap estimate is normally within 10 mOsm of the simultaneously measured serum osmolality. Ethanol, if present, may be included in the equation to eliminate its influence on the osmolal gap (the ethanol concentration divided by 4.6; Table 10).

The osmolal gap is not valid in cases of shock and postmortem state. Metabolic disorders such as hyperglycemia, uremia, and dehydration increase the osmolality but usually do not cause gaps greater than 10 mOsm/kg. A gap greater than 10 mOsm/mL suggests that unidentified osmolal-acting substances are present: acetone, ethanol, ethylene glycol, glycerin, isopropyl alcohol, isoniazid, ethanol, mannitol, methanol, and trichloroethane. Alcohols and glycols should be sought when the degree of obtundation exceeds that expected from the blood ethanol concentration or when other clinical conditions exist: visual loss (methanol), metabolic acidosis (methanol and ethylene glycol), or renal failure (ethylene glycol).

A falsely elevated osmolar gap can be produced by other low molecular weight un-ionized substances (dextran, diuretics, sorbitol, ketones), hyperlipidemia, and unmeasured electrolytes (e.g., magnesium).

Note: A normal osmolal gap may be reported in the presence of toxic alcohol or glycol poisoning, if the parent compound is already metabolized. This situation can occur when the osmolar gap is measured after a significant time has elapsed since the ingestion. In cases of alcohol and glycol intoxication, an early osmolar gap is a result of the relatively nontoxic parent drug and delayed metabolic acidosis, and an anion gap is a result of the more toxic metabolites. The serum concentration is calculated as

$$\text{mg/dL} = \text{mOsm gap} \times \text{MW of substance divided by 10.}$$

Radiographic Studies

Chest and neck radiographs are useful for suspected pathologic conditions such as aspiration pneumonia, pulmonary edema, and foreign bodies and to determine the location of the endotracheal tube. Abdominal radiographs can be used to detect radiopaque substances.

The mnemonic for radiopaque substances seen on abdominal radiographs is CHIPES:

C—chlorides and chloral hydrate

H—heavy metals (arsenic, barium, iron, lead, mercury, zinc)

I—iodides

P—PlayDoh, Pepto-Bismol, phenothiazine (inconsistent)

E—enteric-coated tablets

S—sodium, potassium, and other elements in tablet form (bismuth, calcium, potassium) and solvents containing chlorides (e.g., carbon tetrachloride)

Toxicologic Studies

Routine blood and urine screening is of little practical value in the initial care of the poisoned patient. Specific toxicologic analyses and quantitative levels of certain drugs may be extremely helpful. One should always ask oneself the following questions: (a) How will the result of the test alter the management? and (b) Can the result of the test be returned in time to have a positive effect on therapy?

Owing to long turnaround time, lack of availability, factors contributing to unreliability, and the risk of serious morbidity without supportive clinical management, toxicology screening is estimated to affect management in less than 15% of cases of drug overdoses or poisonings. Toxicology screening may look specifically for only 40 to 50 drugs out of more than 10,000 possible drugs or toxins and more than several million chemicals. To detect many different drugs, toxic screens usually include methods with broad specificity, and sensitivity may be poor for some drugs, resulting in false-negative or false-positive findings. On the other hand, some drugs present in therapeutic amounts may be detected on the screen, even though they are causing no clinical symptoms. Because many agents are not sought or detected during a toxicologic screening, a negative result does not always rule out poisonings. The specificity of toxicologic tests is dependent on the method and the laboratory. The presence of other drugs, drug metabolites, disease states, or incorrect sampling may cause erroneous results.

For the average toxicologic laboratory, false-negative results occur at a rate of 10% to 30% and false-positives at a rate of 0% to 10%. The positive screen predictive value is approximately 90%. A negative toxicology screen does not exclude a poisoning. The negative predictive value of toxicologic screening is approximately 70%. For example, the following benzodiazepines may not be detected by some routine immunoassay benzodiazepine screening tests: alprazolam (Xanax), clonazepam (Klonopin), temazepam (Restoril), and triazolam (Halcion).

The "toxic urine screen" is generally a qualitative urine test for several common drugs, usually substances of abuse (cocaine and metabolites, opioids, amphetamines, benzodiazepines, barbiturates, and phencyclidine). Results of these tests are usually available within 2 to 6 hours. Because these tests may vary with each hospital and community, the physician should determine exactly which substances are included in the toxic urine screen of his or her laboratory. Tests for ethylene glycol, red blood cell cholinesterase, and serum cyanide are not readily available.

For cases of ingestion of certain substances, quantitative blood levels should be obtained at specific times after the ingestion to avoid spurious low values in the distribution phase, which result from incomplete absorption. The detection time for drugs is influenced by many variables, such as type of substance, formulation, amount, time since ingestion, duration of exposure, and half-life. For many drugs, the detection time is measured in days after the exposure.

Common Poisons

Acetaminophen (Paracetamol, *N*-Acetyl-Paraaminophenol)

Toxic Mechanism

At therapeutic doses of acetaminophen, less than 5% is metabolized by P450-2E1 to a toxic reactive oxidizing metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). In a case of overdose, there is insufficient glutathione available to reduce the excess NAPQI into nontoxic conjugate, so it forms covalent bonds with hepatic intracellular proteins to produce centrilobular necrosis. Renal damage is caused by a similar mechanism.

Toxic Dose

The therapeutic dose of acetaminophen is 10 to 15 mg/kg, with a maximum of five doses in 24 hours for a maximum total daily dose of 4 g. An acute single toxic dose is greater than 140 mg/kg, possibly greater than 200 mg/kg in a child younger than age 5 years.

Factors affecting the P450 enzymes include enzyme inducers such as barbiturates and phenytoin (Dilantin), ingestion of isoniazid, and alcoholism. Factors that decrease glutathione stores (alcoholism, malnutrition, and HIV infection) contribute to the toxicity of acetaminophen. Alcoholics ingesting 3 to 4 g/d of acetaminophen for a few days can have depleted glutathione stores and require *N*-acetylcysteine therapy at 50% below hepatotoxic blood acetaminophen levels on the nomogram.

Kinetics

Peak plasma concentration is usually reached 2 to 4 hours after an overdose. Volume distribution is 0.9 L/kg, and protein binding is less than 50% (albumin).

Route of elimination is by hepatic metabolism to an inactive nontoxic glucuronide conjugate and inactive nontoxic sulfate metabolite by two saturable pathways; less than 5% is metabolized into reactive metabolite NAPQI. In patients younger than 6 years of age, metabolic elimination occurs to a greater degree by conjugation via the sulfate pathway.

The half-life of acetaminophen is 1 to 3 hours.

Manifestations

The four phases of the intoxication's clinical course may overlap, and the absence of a phase does not exclude toxicity.

- Phase I occurs within 0.5 to 24 hours after ingestion and may consist of a few hours of malaise, diaphoresis, nausea, and vomiting or produce no symptoms. CNS depression or coma is not a feature.
- Phase II occurs 24 to 48 hours after ingestion and is a period of diminished symptoms. The liver enzymes, serum aspartate aminotransferase (AST) (earliest), and serum alanine aminotransferase (ALT) may increase as early as 4 hours or as late as 36 hours after ingestion.
- Phase III occurs at 48 to 96 hours, with peak liver function abnormalities at 72 to 96 hours. The degree of elevation of the hepatic enzymes generally correlates with outcome, but not always. Recovery starts at about 4 days unless hepatic failure develops. Less than 1% of patients with a history of overdose develop fulminant hepatotoxicity.
- Phase IV occurs at 4 to 14 days, with hepatic enzyme abnormalities resolving. If extensive liver damage has occurred, sepsis and disseminated intravascular coagulation may ensue.

Transient renal failure may develop at 5 to 7 days with or without evidence of hepatic damage. Rare cases of myocarditis and pancreatitis have been reported. Death can occur at 7 to 14 days.

Laboratory Investigations

The therapeutic reference range is 10 to 20 µg/mL. For toxic levels, see the nomogram presented in [Figure 1](#).

Appropriate and reliable methods for analysis are radioimmunoassay, high-pressure liquid chromatography, and gas chromatography. Spectroscopic assays often give falsely elevated values: bilirubin, salicylate, salicylamide, diflunisal (Dolobid), phenols, and methyldopa (Aldomet) increase the acetaminophen level. Each 1 mg/dL increase in creatinine increases the acetaminophen plasma level 30 µg/mL.

If a toxic acetaminophen level is reached, liver profile (including AST, ALT, bilirubin, and prothrombin time), serum amylase, and blood glucose must be monitored. A complete blood cell count (CBC); platelet count; phosphate, electrolytes, and bicarbonate level measurements; ECG; and urinalysis are indicated.

Management

Gastrointestinal Decontamination. Although ipecac-induced emesis may be useful within 30 minutes of ingestion of the toxic substance, we do not advise it because it could result in vomiting of the activated charcoal. Gastric lavage is not necessary. Studies have indicated that activated charcoal is useful within 1 hour after ingestion. Activated charcoal does adsorb *N*-acetylcysteine (NAC) if given together, but this is not clinically important. However, if activated charcoal needs to be given along with NAC, separate

Figure 1 Nomogram for acetaminophen intoxication. *N*-acetylcysteine therapy is started if levels and time coordinates are above the lower line on the nomogram. Continue and complete therapy even if subsequent values fall below the toxic zone. The nomogram is useful only in cases of acute single ingestion. Levels in serum drawn before 4 hours may not represent peak levels. (From Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 55:871, 1975.)

the administration of activated charcoal from the administration of NAC by 1 to 2 hours to avoid vomiting.

***N*-Acetylcysteine (Mucomyst).** NAC (Table 11), a derivative of the amino acid cysteine, acts as a sulfhydryl donor for glutathione synthesis, as surrogate glutathione, and may increase the nontoxic sulfation pathway resulting in conjugation of NAPQI. Oral NAC should be administered within the first 8 hours after a toxic amount of acetaminophen has been ingested. NAC can be started while one awaits the results of the blood test for acetaminophen plasma concentration, but there is no advantage to giving it before 8 hours. If

the acetaminophen concentration result after 4 hours following ingestion is above the upper line on the modified Rumack-Matthew nomogram (see Figure 1), one should continue with a maintenance course. Repeat blood specimens should be obtained 4 hours after the initial level is measured if it is greater than 20 mg/mL, which is below the therapy line, because of unexpected delays in the peak by food and co-ingestants. Intravenous NAC (see Table 11) is approved in the United States.

There have been a few cases of anaphylactoid reaction and death by the intravenous route.

TABLE 11 Protocol for *N*-Acetylcysteine Administration

ROUTE	LOADING DOSE	MAINTENANCE DOSE	COURSE	FDA APPROVAL
Oral	140 mg/kg	70 mg/kg every 4 h	72 h	Yes
Intravenous	150 mg/kg over 15 min	50 mg/kg over 4 h followed by 100 mg/kg over 16 h	20 h	Yes

Variations in Therapy

In patients with chronic alcoholism, it is recommended that NAC treatment be administered at 50% below the upper toxic line on the nomogram.

If emesis occurs within 1 hour after NAC administration, the dose should be repeated. To avoid emesis, the proper dilution from 20% to 5% NAC must be used, and it should be served in a palatable vehicle, in a covered container through a straw. If this administration is unsuccessful, a slow drip over 30 to 60 minutes through a nasogastric tube or a fluoroscopically placed nasoduodenal tube can be used. Antiemetics can be used if necessary: metoclopramide (Reglan) 10 mg per dose intravenously 30 minutes before administration of NAC (in children, 0.1 mg/kg; maximum, 0.5 mg/kg/d) or ondansetron (Zofran) 32 mg (0.15 mg/kg) by infusion over 15 minutes and repeated for three doses if necessary. The side effects of these antiemetics include anaphylaxis and increases in liver enzymes.

Some investigators recommend variable durations of NAC therapy, stopping the therapy if serial acetaminophen blood concentrations become nondetectable and the liver enzyme levels (ALT and AST) remain normal after 24 to 36 hours.

There is a loss of efficacy if NAC is initiated 8 or 10 hours postingestion, but the loss is not complete, and NAC may be initiated 36 hours or more after ingestion. Late treatment (after 24 hours) decreases the rates of morbidity and mortality in patients with fulminant liver failure caused by acetaminophen and other agents.

Extended relief formulations (ER embossed on caplet) contain 325 mg of acetaminophen for immediate release and 325 mg for delayed release. A single 4-hour postingestion serum acetaminophen concentration can underestimate the level because ER formulations can have secondary delayed peaks. In cases of overdose of the ER formulation, it is recommended that additional acetaminophen levels be obtained at 4-hour intervals after the initial level is measured. If any level is in the toxic zone, therapy should be initiated.

It is recommended that pregnant patients with toxic plasma concentrations of acetaminophen be treated with NAC to prevent hepatotoxicity in both fetus and mother. The available data suggest no teratogenicity to NAC or acetaminophen.

Indications for NAC therapy in cases of chronic intoxication are a history of ingestion of 3 to 4 g for several days with elevated liver enzyme levels (AST and ALT). The acetaminophen blood concentration is often low in these cases because of the extended time lapse since ingestion and should not be plotted on the Rumack-Matthew nomogram. Patients with a history of chronic alcoholism or those on chronic enzyme inducers may also present with elevated liver enzyme levels and should be considered for NAC therapy if they have a history of taking acetaminophen on a chronic basis, because they are considered to be at a greater risk for hepatotoxicity despite a low acetaminophen blood concentration.

Specific support care may be needed to treat liver failure, pancreatitis, transient renal failure, and myocarditis.

Liver transplantation has a definite but limited role in patients with acute acetaminophen overdose. A retrospective analysis determined that a continuing rise in the prothrombin time (4-day peak, 180 seconds), a pH of less than 7.3 2 days after the overdose, a serum creatinine level of greater than 3.3 mg/dL, severe hepatic encephalopathy, and disturbed coagulation factor VII/V ratio greater than 30 suggest a poor prognosis and may be indicators for hepatology consultation for consideration of liver transplantation.

Extracorporeal measures are not expected to be of benefit.

Disposition

Adults who have ingested more than 140 mg/kg and children younger than 6 years of age who have ingested more than 200 mg/kg should receive therapy within 8 hours postingestion or until the results of the 4-hour postingestion acetaminophen plasma concentration are known.

Amphetamines

The amphetamines include illicit methamphetamine ("Ice"), diet pills, and formulations under various trade names. Analogues include MDMA (3,4-methylenedioxyamphetamine, known as "ecstasy," "XTC," or "Adam") and MDA (3,4-methylenedioxyamphetamine, known as "Eve"). MDA is a common hallucinogen and euphoriant "club drug" used at "raves," which are all-night dances. Use of methamphetamine and designer analogues is on the rise, especially among young people between the ages of 12 and 25 years. Other similar stimulants are phenylpropanolamine and cocaine.

Toxic Mechanism

Amphetamines have a direct CNS stimulant effect and a sympathetic nervous system effect by releasing catecholamines from α - and β -adrenergic nerve terminals but inhibiting their reuptake.

Hallucinogenic MDMA has an additional hazard of serotonin effect (refer to serotonin syndrome in the SSRI section). MDMA also affects the dopamine system in the brain. Because of its effects on 5-hydroxytryptamine, dopamine, and norepinephrine, MDMA can lead to serotonin syndrome associated with malignant hyperthermia and rhabdomyolysis, which contributes to the potentially life-threatening hyperthermia observed in several patients who have used MDMA.

Phenylpropanolamine stimulates only the β -adrenergic receptors.

Toxic Dose

In children, the toxic dose of dextroamphetamine is 1 mg/kg; in adults, the toxic dose is 5 mg/kg. The potentially fatal dose of dextroamphetamine is 12 mg/kg.

Kinetics

Amphetamine is a weak base with pKa of 8 to 10. Onset of action is 30 to 60 minutes, and peak effects are 2 to 4 hours. The volume distribution is 2 to 3 L/kg.

Through hepatic metabolism, 60% of the substance is metabolized into a hydroxylated metabolite that may be responsible for psychotic effects.

The half-life of amphetamines is pH dependent—8 to 10 hours in acid urine (pH <6.0) and 16 to 31 hours in alkaline urine (pH >7.5). Excretion is by the kidney—30% to 40% at alkaline urine pH and 50% to 70% at acid urine pH.

Manifestations

Effects are seen within 30 to 60 minutes following ingestion.

Neurologic manifestations include restlessness, irritation and agitation, tremors and hyperreflexia, and auditory and visual hallucinations. Hyperpyrexia may precede seizures, convulsions, paranoia, violence, intracranial hemorrhage, psychosis, and self-destructive behavior. Paranoid psychosis and cerebral vasculitis occur with chronic abuse.

MDMA is often adulterated with cocaine, heroin, or ketamine, or a combination of these, to create a variety of mood alterations. This possibility must be taken into consideration when one manages patients with MDMA ingestions, as the symptom complex may reflect both CNS stimulation and CNS depression.

Other manifestations include dilated but reactive pupils, cardiac dysrhythmias (supraventricular and ventricular), tachycardia, hypertension, rhabdomyolysis, and myoglobinuria.

Laboratory Investigations

The clinician should monitor ECG and cardiac readings, ABG and oxygen saturation, electrolytes, blood glucose, BUN, creatinine, creatine kinase, cardiac fraction if there is chest pain, and liver profile. Also, one should evaluate for rhabdomyolysis and check urine for myoglobin, cocaine and metabolites, and other substances of abuse. The peak plasma concentration of amphetamines is 10 to 50 ng/mL 1 to 2 hours after ingestion of 10 to 25 mg. The toxic plasma concentration is 200 ng/mL. When the rapid immunoassays are used, cross-reactions can occur with amphetamine

derivatives (e.g., MDA, “ecstasy”), brompheniramine (Dimetane), chlorpromazine (Thorazine), ephedrine, phenylpropanolamine, phentermine (Adipex-P), phenmetrazine, ranitidine (Zantac), and Vicks Inhaler (1-desoxyephedrine). False-positive results may occur.

Management

Management is similar to management for cocaine intoxication. Supportive care includes blood pressure and temperature control, cardiac monitoring, and seizure precautions. Diazepam (Valium) can be administered. Gastrointestinal decontamination can be undertaken with activated charcoal administered up to 1 hour after ingestion.

Anxiety, agitation, and convulsions are treated with diazepam. If diazepam fails to control seizures, neuromuscular blockers can be used and the electroencephalogram (EEG) monitored for nonmotor seizures. One should avoid neuroleptic phenothiazines and butyrophenone, which can lower the seizure threshold.

Hypertension and tachycardia are usually transient and can be managed by titration of diazepam. Nitroprusside can be used for hypertensive crisis at a maximum infusion rate of 10 µg/kg/min for 10 minutes followed with a lower infusion rate of 0.3 to 2 mg/kg/min. Myocardial ischemia is managed by oxygen, vascular access, benzodiazepines, and nitroglycerin. Aspirin and thrombolytics are not routinely recommended because of the danger of intracranial hemorrhage. It is important to distinguish between angina and true ischemia. Delayed hypotension can be treated with fluids and vasopressors if needed. Life-threatening tachydysrhythmias may respond to an α-blocker such as phentolamine (Regitine) 5 mg IV for adults or 0.1 mg/kg IV for children and a short-acting β-blocker such as esmolol (Brevibloc) 500 µg/kg IV over 1 minute for adults, or 300 to 500 µg/kg over 1 minute for children. Ventricular dysrhythmias may respond to lidocaine or, in a severely hemodynamically compromised patient, immediate synchronized electrical cardioversion.

Rhabdomyolysis and myoglobinuria are treated with fluids, alkaline diuresis, and diuretics. Hyperthermia is treated with external cooling and cool 100% humidified oxygen. More extensive therapy may be needed in severe cases. If focal neurologic symptoms are present, the possibility of a cerebrovascular accident should be considered and a CT scan of the head should be obtained.

Paranoid ideation and threatening behavior should be treated with rapid tranquilization using a benzodiazepine. One should observe for suicidal depression that may follow intoxication and may require suicide precautions.

Extracorporeal measures are of no benefit.

Disposition

Symptomatic patients should be observed on a monitored unit until the symptoms resolve and then observed for a short time after resolution for relapse.

Anticholinergic Agents

Drugs with anticholinergic properties include antihistamines (H₁ blockers), neuroleptics (phenothiazines), tricyclic antidepressants, antiparkinsonism drugs (trihexyphenidyl [Artane], benztropine [Cogentin]), ophthalmic products (atropine), and a number of common plants.

The antihistamines are divided into the sedating anticholinergic types and the nonsedating single daily dose types. The sedating types include ethanolamines (e.g., diphenhydramine [Benadryl], dimenhydrinate [Dramamine], and clemastine [Tavist]), ethylenediamines (e.g., tripeleminamine [Pyribenzamine]), alkyl amines (e.g., chlorpheniramine [Chlor-Trimeton], brompheniramine [Dimetane]), piperazines (e.g., cyclizine [Marezine], hydroxyzine [Atarax], and meclizine [Antivert]), and phenothiazine (e.g., Phenergan). The nonsedating types include astemizole (Hismanal), terfenadine (Seldane), loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec).

The anticholinergic plants include jimsonweed (*Datura stramonium*), deadly nightshade (*Atropa belladonna*), henbane

(*Hyoscyamus niger*), and antispasmodic agents for the bowel (atropine derivatives).

Toxic Mechanism

By competitive inhibition, anticholinergics block the action of acetylcholine on postsynaptic cholinergic receptor sites. The toxic mechanism primarily involves the peripheral and CNS muscarinic receptors. H₁ sedating-type agents also depress or stimulate the CNS, and in large overdoses some have cardiac membrane-depressant effects (e.g., diphenhydramine [Benadryl]) and α-adrenergic receptor blockade effects (e.g., promethazine [Phenergan]). Nonsedating agents produce peripheral H₁ blockade but do not possess anticholinergic or sedating actions. The original agents terfenadine (Seldane) and astemizole (Hismanal) were recently removed from the market because of the severe cardiac dysrhythmias associated with their use, especially when used in combination with macrolide antibiotics and certain antifungal agents such as ketoconazole (Nizoral), which inhibit hepatic metabolism or excretion. The newer nonsedating agents, including loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec), have not been reported to cause the severe drug interactions associated with terfenadine and astemizole.

Toxic Dose

The estimated toxic oral dose of atropine is 0.05 mg/kg in children and more than 2 mg in adults. The minimal estimated lethal dose of atropine is more than 10 mg in adults and more than 2 mg in children. Other synthetic anticholinergic agents are less toxic, and the fatal dose varies from 10 to 100 mg.

The estimated toxic oral dose of diphenhydramine (Benadryl) in a child is 15 mg/kg, and the potential lethal amount is 25 mg/kg. In an adult, the potential lethal amount is 2.8 g. Ingestion of five times the single dose of an antihistamine is toxic.

For the nonsedating agents, an overdose of 3360 mg of terfenadine was reported in an adult who developed ventricular tachycardia and fibrillation that responded to lidocaine and defibrillation. A 1500-mg overdose produced hypotension. Cases of delayed serious dysrhythmias (torsades de pointes) have been reported with doses of more than 200 mg of astemizole. The toxic doses of fexofenadine (Allegra), cetirizine, and loratadine (Claritin) need to be established.

Kinetics

The onset of absorption of intravenous atropine is in 2 to 4 minutes. Peak effects on salivation after intravenous or intramuscular administration are at 30 to 60 minutes.

Onset of absorption after oral ingestion is 30 to 60 minutes, peak action is 1 to 3 hours, and duration of action is 4 to 6 hours, but symptoms are prolonged in cases of overdose or with sustained-release preparations.

The onset of absorption of diphenhydramine is in 15 minutes to 1 hour, with a peak of action in 1 to 4 hours. Volume distribution is 3.3 to 6.8 L/kg, and protein binding is 75% to 80%. Ninety-eight percent of diphenhydramine is metabolized via the liver by N-demethylation. Interactions with erythromycin, ketoconazole (Nizoral), and derivatives produce excessive blood levels of the antihistamine and ventricular dysrhythmias.

The half-life of diphenhydramine is 3 to 10 hours.

The chemical structure of nonsedating agents prevents their entry into the CNS. Absorption begins in 1 hour, with peak effects in 4 to 6 hours. The duration of action is greater than 24 hours.

These agents are metabolized in the gastrointestinal tract and liver. Protein binding is greater than 90%. The plasma half-life is 3.5 hours. Only 1% is excreted unchanged; 60% of that is excreted in the feces and 40% in the urine.

Manifestations

Anticholinergic signs are hyperpyrexia (“hot as a hare”), mydriasis (“blind as a bat”), flushing of skin (“red as a beet”), dry mucosa and skin (“dry as a bone”), “Lilliputian type” hallucinations and delirium (“mad as a hatter”), coma, dysphagia, tachycardia,

moderate hypertension, and rarely convulsions and urinary retention. Other effects include jaundice (cyproheptadine [Periactin]), dystonia (diphenhydramine [Benadryl]), rhabdomyolysis (doxylamine), and, in large doses, cardiotoxic effects (diphenhydramine).

Overdose with nonsedating agents produces headache and confusion, nausea, and dysrhythmias (e.g., torsades de pointes).

Laboratory Investigations

Monitoring of ABG (in cases of respiratory depression), electrolytes, glucose, and the ECG should be undertaken. Anticholinergic drugs and plants are not routinely included on screens for substances of abuse.

Management

For patients in respiratory failure, intubation and assisted ventilation should be instituted. Gastrointestinal decontamination can be instituted. Caution must be taken with emesis in cases of diphenhydramine (Benadryl) overdose because of the drug's rapid onset of action and risk of seizures. If bowel sounds are present for up to 1 hour after ingestion, activated charcoal can be given. Seizures can be controlled with benzodiazepines (diazepam [Valium] or lorazepam [Ativan]).

The administration of physostigmine (Antilirium) is not routine and is reserved for life-threatening anticholinergic effects that are refractory to conventional treatments. It should be administered with adequate monitoring and resuscitative equipment available. The use of physostigmine should be avoided if a tricyclic antidepressant is present because of increased toxicity. Urinary retention should be relieved by catheterization to avoid reabsorption of the drug and additional toxicity.

Supraventricular tachycardia should be treated only if the patient is hemodynamically unstable. Ventricular dysrhythmias can be controlled with lidocaine or cardioversion. Sodium bicarbonate 1 to 2 mEq/kg IV may be useful for myocardial depression and QRS prolongation. Torsades de pointes, especially when associated with terfenadine and astemizole ingestion, has been treated with magnesium sulfate 4 g or 40 mL 10% solution intravenously over 10 to 20 minutes and countershock if the patient fails to respond.

Hyperpyrexia is controlled by external cooling. Hemodialysis and hemoperfusion are not effective.

Disposition

Antihistamine H₁ Antagonists. Symptomatic patients should be observed on a monitored unit until the symptoms resolve, then observed for a short time (3 to 4 hours) after resolution for relapse.

Nonsedating Agents. All asymptomatic children who acutely ingest more than the maximum adult dose and all symptomatic children should be referred to a health care facility for a minimum of 6 hours' observation as well as cardiac monitoring. Asymptomatic adults who acutely ingest more than twice the maximum adult daily dose should be monitored for a minimum of 6 hours. All symptomatic patients should be monitored for as long as there are symptoms present.

Barbiturates

Barbiturates have been used as sedatives, anesthetic agents, and anticonvulsants, but their use is declining as safer, more effective drugs become available.

Toxic Mechanism

Barbiturates are γ -aminobutyric acid (GABA) agonists (increasing the chloride flow and inhibiting depolarization). They enhance the CNS depressant effect of GABA and depress the cardiovascular system.

Toxic Dose

The shorter-acting barbiturates (including the intermediate-acting agents) and their hypnotic doses are as follows: amobarbital (Amytal), 100 to 200 mg; aprobarbital (Alurate), 50 to 100 mg; butabarbital (Butisol), 50 to 100 mg; butalbital, 100 to 200 mg;

pentobarbital (Nembutal), 100 to 200 mg; secobarbital (Seconal), 100 to 200 mg. They cause toxicity at lower doses than long-acting barbiturates and have a minimum toxic dose of 6 mg/kg; the fatal adult dose is 3 to 6 g.

The long-acting barbiturates and their doses include mephobarbital (Mebaral), 50 to 100 mg, and phenobarbital, 100 to 200 mg. Their minimum toxic dose is greater than 10 mg/kg, and the fatal adult dose is 6 to 10 g. A general rule is that an amount five times the hypnotic dose is toxic and an amount 10 times the hypnotic dose is potentially fatal. Methohexital and thiopental are ultrashort-acting parenteral preparations and are not discussed.

Kinetics

The barbiturates are enzyme inducers. Short-acting barbiturates are highly lipid-soluble, penetrate the brain readily, and have shorter elimination times. Onset of action is in 10 to 30 minutes, with a peak at 1 to 2 hours. Duration of action is 3 to 8 hours. The volume distribution of short-acting barbiturate is 0.8 to 1.5 L/kg; pKa is about 8. Mean half-life varies from 8 to 48 hours.

Long-acting agents have longer elimination times and can be used as anticonvulsants. Onset of action is in 20 to 60 minutes, with a peak at 1 to 6 hours. In cases of overdose, the peak can be at 10 hours. Usual duration of action is 8 to 12 hours. Volume distribution is 0.8 L/kg, and half-life is 11 to 120 hours. The pKa of phenobarbital is 7.2. Alkalinization of urine promotes its excretion.

Manifestations

Mild intoxication resembles alcohol intoxication and includes ataxia, slurred speech, and depressed cognition. Severe intoxication causes slow respirations, coma, and loss of reflexes (except pupillary light reflex).

Other manifestations include hypotension (vasodilation), hypothermia, hypoglycemia, and death by respiratory arrest.

Laboratory Investigations

Most barbiturates are detected on routine drug screens and can be measured in most hospital laboratories. Investigation should include barbiturate level; ABG; toxicology screen, including acetaminophen; glucose, electrolyte, BUN, creatinine, and creatine kinase levels; and urine pH. The minimum toxic plasma levels are greater than 10 μ g/mL for short-acting barbiturates and greater than 40 μ g/dL for long-acting agents. Fatal levels are 30 μ g/mL for short-acting barbiturates and 80 to 150 μ g/mL for long-acting agents. Both short-acting and long-acting agents can be detected in urine 24 to 72 hours after ingestion, and long-acting agents can be detected up to 7 days.

Management

Vital functions must be established and maintained. Intensive supportive care including intubation and assisted ventilation should dominate the management. All stuporous and comatose patients should have glucose (for hypoglycemia), thiamine (if chronically alcoholic), and naloxone (Narcan) (in case of an opioid ingestion) intravenously and should be admitted to the intensive care unit. Emesis should be avoided especially in cases of ingestion of the shorter-acting barbiturates. Activated charcoal followed by MDAC (0.5 g/kg) every 2 to 4 hours has been shown to reduce the serum half-life of phenobarbital by 50%, but its effect on clinical course is undetermined.

Fluids should be administered to correct dehydration and hypotension. Vasopressors may be necessary to correct severe hypotension, and hemodynamic monitoring may be needed. The patient must be observed carefully for fluid overload. Alkalinization (ion trapping) is used only for phenobarbital (pKa 7.2) but not for short-acting barbiturates. Sodium bicarbonate, 1 to 2 mEq/kg IV in 500 mL of 5% dextrose in adults or 10 to 15 mL/kg in children during the first hour, followed by sufficient bicarbonate to keep the urinary pH at 7.5 to 8.0, enhances excretion of phenobarbital and shortens the half-life by 50%. Diuresis is not advocated because of the danger of cerebral or pulmonary edema.

Hemodialysis shortens the half-life to 8 to 14 hours, and charcoal hemoperfusion shortens the half-life to 6 to 8 hours for long-acting barbiturates such as phenobarbital. Both procedures may be effective in patients with both long-acting and short-acting barbiturate ingestion. If the patient does not respond to supportive measures or if the phenobarbital plasma concentration is greater than 150 µg/mL, both procedures may be tried to shorten the half-life.

Bullae are treated as a local second-degree skin burn. Hypothermia should be treated.

Disposition

All comatose patients should be admitted to the intensive care unit. Awake and oriented patients with an overdose of short-acting agents should be observed for at least 6 asymptomatic hours; overdose of long-acting agents warrants observation for at least 12 asymptomatic hours because of the potential for delayed absorption. In the case of an intentional overdose, psychiatric clearance is needed before the patient can be discharged. Chronic use can lead to tolerance, physical dependency, and withdrawal and necessitates follow-up.

Benzodiazepines

Benzodiazepines are used as anxiolytics, sedatives, and relaxants.

Toxic Mechanism

The GABA agonists produce CNS depression and increase chloride flow, inhibiting depolarization.

Flunitrazepam (Rohypnol; street name “roofies”) is a long-acting benzodiazepine agonist sold by prescription in more than 60 countries worldwide, but it is not legally available in the United States.

Toxic Dose

The long-acting benzodiazepines (half-life >24 hours) and their maximum therapeutic doses are as follows: chlorthalidopoxide (Librium), 50 mg; clorazepate (Tranxene), 30 mg; clonazepam (Klonopin), 20 mg; diazepam (Valium), 10 mg in adults or 0.2 mg/kg in children; flurazepam (Dalmane), 30 mg; and prazepam, 20 mg.

The short-acting benzodiazepines (half-life 10 to 24 hours) and their doses include the following: alprazolam (Xanax), 0.5 mg, and lorazepam (Ativan), 4 mg in adults or 0.05 mg/kg in children, which act similar to the long-acting benzodiazepines.

The ultrashort-acting benzodiazepines (half-life <10 hours) are more toxic and include temazepam (Restoril), 30 mg; triazolam (Halcion), 0.5 mg; midazolam (Versed), 0.2 mg/kg; and oxazepam (Serax), 30 mg.

In cases of overdose of short- and long-acting agents, 10 to 20 times the therapeutic dose (>1500 mg diazepam or 2000 mg chlorthalidopoxide) have been ingested with resulting mild coma but without respiratory depression. Fatalities are rare, and most patients recover within 24 to 36 hours after overdose. Asymptomatic unintentional overdoses of less than five times the therapeutic dose can be seen. Ultrashort-acting agents have produced respiratory arrest and coma within 1 hour after ingestion of 5 mg of triazolam (Halcion) and death with ingestion of as little as 10 mg. Midazolam (Versed) and diazepam (Valium) by rapid intravenous injection have produced respiratory arrest.

Kinetics

Onset of CNS depression is usually in 30 to 120 minutes; peak action usually occurs within 1 to 3 hours when ingestion is by the oral route. The volume distribution varies from 0.26 to 6 L/kg (LA, 1.1 L/kg); protein binding is 70% to 99%. For flunitrazepam, the onset of action is in 0.5 to 2 hours, oral peak is in 2 hours, and duration 8 hours or more. The half-life of flunitrazepam is 20 to 30 hours, volume distribution is 3.3 to 5.5 L/kg, and 80% is protein bound. Flunitrazepam can be identified in urine 4 to 30 days after ingestion.

Manifestations

Neurologic manifestations include ataxia, slurred speech, and CNS depression. Deep coma leading to respiratory depression suggests the presence of short-acting benzodiazepines or other CNS depressants. In elderly persons, the therapeutic doses can produce toxicity and can have an additive effect with other CNS depressants. Chronic use can lead to tolerance, physical dependency, and withdrawal.

Laboratory Investigations

Most benzodiazepines can be detected in urine drug screens. Quantitative blood levels are not useful. Some of the immunoassay urinary screens cannot detect all of the new benzodiazepines currently available. A consultation with the laboratory analyst is warranted if a specific case occurs in which the test result is negative but benzodiazepine use is suspected by the patient's history. Situations in which benzodiazepines may not be detected include ingestion of a low dose (e.g., <10 mg), rapid elimination, and a different or no metabolite. Some immunoassay methods can produce a false-positive finding for the benzodiazepines when nonsteroidal antiinflammatory drugs (tolmetin [Tolectin], naproxen [Aleve], etodolac [Lodine], and fenoprofen [Nalfon]) are used. If this is a concern, the laboratory analyst should be consulted.

In cases in which “date rape” drugs such as flunitrazepam are suspected, a police crime or reference laboratory should be consulted for testing.

Management

Emesis and gastric lavage should be avoided. Activated charcoal can be useful only if given early before the peak time of absorption occurs. Supportive treatment should be instituted but rarely requires intubation or assisted ventilation.

Flumazenil (Romazicon) is a specific benzodiazepine receptor antagonist that blocks the chloride flow and inhibitor of GABA neurotransmitters. It reverses the sedative effects of benzodiazepines, zolpidem (Ambien), and endogenous benzodiazepines associated with hepatic encephalopathy. It is not recommended to reverse benzodiazepine-induced hypoventilation. The manufacturer advises that flumazenil be used with caution in cases of overdose with possible benzodiazepine dependency (because it can precipitate life-threatening withdrawal), if cyclic antidepressant use is suspected, or if a patient has a known seizure disorder.

Disposition

If the patient is comatose, he or she must be admitted to the intensive care unit. If the overdose was intentional, psychiatric clearance is needed before the patient can be discharged.

β-Adrenergic Blockers (β-Blockers)

β-Blockers are used in the treatment of hypertension and of a number of systemic and ophthalmologic disorders. Properties of β-blockers include the factors listed in Table 12.

Lipid-soluble drugs have CNS effects, active metabolites, longer duration of action, and interactions (e.g., propranolol). Cardiosensitivity is lost in overdose. Intrinsic partial agonist agents (e.g., pindolol) may initially produce tachycardia and hypertension. Cardiac membrane depressive effect (quinidine-like) occurs in cases of overdose but not at therapeutic doses (e.g., with metoprolol or sotalol). α-Blocking effect is weak (e.g., with labetalol or acebutolol).

Toxic Mechanism

β-Blockers compete with the catecholamines for receptor sites and block receptor action in the bronchi, the vascular smooth muscle, and the myocardium.

Toxic Dose

Ingestions of greater than twice the maximum recommended daily therapeutic dose are considered toxic (see Table 12). Ingestion of 1 mg/kg propranolol in a child may produce hypoglycemia.

TABLE 12 Pharmacologic and Toxic Properties of β -Blockers

β-BLOCKER	MAXIMUM SOLUBILITY	THERAPEUTIC PLASMA LEVEL	LIPID SOLUBILITY	INTRINSIC SYMPATHOMIMETIC ACTIVITY (PARTIAL AGONIST)	MEMBRANE STABILIZING EFFECT		CARDIAC SELECTIVITY
					β-SELECTIVE		α-SELECTIVE
					β ₁	β ₂	
Acebutolol (Sectral)	800 mg	200–2000 ng/mL	Moderate	+	+	+	+
Alprenolol ²	800 mg	50–200 ng/mL	Moderate	2+	+	–	–
Atenolol (Tenormin)	100 mg	200–500 ng/mL	Low	–	–	2+	–
Betaxolol (Kerlone)	20 mg	NA	Low	+	–	+	–
Carteolol (Cartrol)	10 mg	NA	No	+	–	–	–
Esmolol (Brevibloc) (Class II antidysrhythmic, IV only)			Low	–	–	+	–
Labetalol (Trandate)	800 mg	50–500 ng/mL	Low	+	+/–	–	+
Levobunolol (AKBeta eyedrop) (Eye drops 0.25% and 0.5%)	20 mg	NA	No	–	–	–	–

Nadolol (Corgard)	320 mg	20–40 ng/mL	Low	–	–	–	–
Oxyprenolol ²	480 mg	80–100 ng/mL	Moderate	2+	+	–	–
Pindolol (Visken)	60 mg	50–150 ng/mL	Moderate	3+	+/–	–	–
Propranolol (Inderal) (Class II antidysrhythmic)	360 mg	50–100 ng/mL	High	–	2+	–	–
Sotalol (Betapace) (Class II antidysrhythmic)	480 mg	500–4000 ng/mL	Low	–	–	–	–
Timolol (Blocadren)	60 mg	5–10 ng/mL	Low	–	+/–	–	–

²Not available in the United States.

Fatalities have been reported in adults with 7.5 g of metoprolol. The most toxic agent is sotalol, and the least toxic is atenolol.

Kinetics

Regular-release formulations usually cause symptoms within 2 hours. Propranolol's onset of action is 20 to 30 minutes and peak is at 1 to 4 hours, but it may be delayed by co-ingestants. The onset of action with sustained-release preparations may be delayed to 6 hours and the peak to 12 to 16 hours. Volume distribution is 1 to 5.6 L/kg. Protein binding is variable, from 5% to 93%.

Metabolism

Atenolol (Tenormin), nadolol (Corgard), and sotalol (Betapace) have enterohepatic recirculation. The duration of action for regular-acting agents is 4 to 6 hours, but in cases of overdose it may be 24 to 48 hours. The duration of action for sustained-release agents is 24 to 48 hours.

The regular preparation with the longest half-life is nadolol, at 12 to 24 hours, and the one with the shortest half-life is esmolol, at 5 to 10 minutes.

Manifestations

See "Toxic Properties" and Table 12.

Highly lipid soluble agents produce coma and seizures. Bradycardia and hypotension are the major cardiac symptoms and may lead to cardiogenic shock. Intrinsic partial agonists initially may cause tachycardia and hypertension. ECG changes include atrioventricular conduction delay or asystole. Membrane-depressant effects produce prolonged QRS and QT interval, which may result in torsades de

pointes. Sotalol produces a very prolonged QT interval. Bronchospasm may occur in patients with reactive airway disease with any β -blocker because the selectivity is lost in overdose. Other manifestations include hypoglycemia (because β -blockers block catecholamine counter-regulatory mechanisms) and hyperkalemia.

Laboratory Investigations

Measurements of blood levels are not readily available or useful. ECG and cardiac monitoring should be maintained, and blood glucose and electrolytes, BUN, and creatinine levels should be monitored, as well as ABG if there are respiratory symptoms.

Management

Vital functions must be established and maintained. Vascular access, baseline ECG, and continuous cardiac and blood pressure monitoring should be established. A pacemaker must be available. Gastrointestinal decontamination can be undertaken initially with activated charcoal up to 1 hour after ingestion. MDAC is no longer recommended, based on the latest guidelines. Whole-bowel irrigation can be considered in cases of large overdoses with sustained-release preparations, but there are no studies evaluating the efficacy of intervention.

If there are cardiovascular disturbances, a cardiac consultation should be obtained. Class IA antidysrhythmic agents (procainamide, quinidine) and III (bretium) are not recommended. Hypotension is treated with fluids initially, although it usually does not respond. Frequently, glucagon and cardiac pacing are needed. Bradycardia in asymptomatic, hemodynamically stable patients

requires no therapy. It is not predictive of the future course of the disease. If the patient is unstable (has hypotension or a high-degree atrioventricular block), atropine 0.02 mg/kg (up to 2 mg) in adults, glucagon, and a pacemaker can be used. In case of ventricular tachycardia, overdrive pacing can be used. A wide QRS interval may respond to sodium bicarbonate. Torsades de pointes (associated with sotalol) may respond to magnesium sulfate and overdrive pacing. Prophylactic magnesium for prolonged QT interval has been suggested, but there are no data. Epinephrine must not be used because an unopposed α effect may occur.

Hypotension and myocardial depression are managed by correction of dysrhythmias, Trendelenburg position, fluids, glucagon, or amrinone (Inocor), or a combination of these. Hemodynamic monitoring with a Swan-Ganz catheter or arterial line may be necessary to manage fluid therapy.

Glucagon is the initial drug of choice. It works through adenyl cyclase and bypasses catecholamine receptors; therefore, it is not affected by β -blockers. Glucagon increases cardiac contractility and heart rate. It is given as an intravenous bolus of 5 to 10 mg³ over 1 minute and followed by a continuous infusion of 1 to 5 mg/h (in children, 0.15 mg/kg followed by 0.05 to 0.1 mg/kg/h). In large doses and in infusion therapy D₅W, sterile water, or saline should be used as a dilutant to reconstitute glucagon in place of the 0.2% phenol diluent provided with some drugs. Effects are seen within minutes. It can be used with other agents such as amrinone.

Amrinone (Inocor) inhibits phosphodiesterase enzyme, which metabolizes cyclic AMP. It is administered as a bolus of 0.15 to 2 mg/kg (0.15 to 0.4 mL/kg) intravenously, followed by infusion of 5 to 10 μ g/kg/min.

Hypoglycemia should be treated with intravenous glucose. Life-threatening hyperkalemia is treated with calcium (avoid if digoxin is present), bicarbonate, and glucose or insulin. Convulsions can be controlled with diazepam or phenobarbital. If bronchospasm is present, β_2 nebulized bronchodilators are given.

Extraordinary measures such as intra-aortic balloon pump support can be instituted. Extracorporeal measures can be undertaken. Hemodialysis for cases of atenolol, acebutolol, nadolol, and sotalol (low volume distribution, low protein binding) ingestion may be helpful, particularly when there is evidence of renal failure. Hemodialysis is not effective for propranolol, metoprolol, and timolol.

Prenalator² has successfully reversed both bradycardia and hypotension but is not currently available in the United States.

Disposition

Asymptomatic patients with history of overdose require baseline ECG and continuous cardiac monitoring for at least 6 hours with regular-release preparations and for 24 hours with sustained-release preparations. Symptomatic patients should be observed with cardiac monitoring for 24 hours. If seizures or abnormal rhythm or vital signs are present, the patient should be admitted to the intensive care unit.

Calcium Channel Blockers

Calcium channel blockers are used in the treatment of effort angina, supraventricular tachycardia, and hypertension.

Toxic Mechanism

Calcium channel blockers reduce influx of calcium through the slow channels in membranes of the myocardium, the atrioventricular nodes, and the vascular smooth muscles and result in peripheral, systemic, and coronary vasodilation, impaired cardiac conduction, and depression of cardiac contractility. All calcium channel blockers have vasodilatory action, but only bepridil, diltiazem, and verapamil depress myocardial contractility and cause atrioventricular block.

Toxic Dose

Any ingested amount greater than the maximum daily dose has the potential of severe toxicity. The maximum oral daily doses in adults and toxic doses in children of each are as follows: amlodipine (Norvasc), 10 mg for adults and more than 0.25 mg/kg for children; bepridil (Vascor), 400 mg for adults and more than 5.7 mg/kg for children; diltiazem (Cardizem), 360 mg for adults (toxic dose >2 g) and more than 6 mg/kg for children; felodipine (Plendil), 40 mg for adults and more than 0.56 mg/kg for children; isradipine (DynaCirc), 40 mg for adults and more than 0.4 mg/kg for children; nicardipine (Cardene), 120 mg for adults and more than 0.85 mg/kg for children; nifedipine (Procardia), 120 mg for adults and more than 2 mg/kg for children; nimodipine (Nimotop), 360 mg for adults and more than 0.85 mg/kg for children; nitrendipine (Baypress),¹ 80 mg for adults and more than 1.14 mg/kg for children; and verapamil (Calan), 480 mg for adults and 15 mg/kg for children.

Kinetics

Onset of action of regular-release preparations varies: for verapamil it is 60 to 120 minutes, for nifedipine 20 minutes, and for diltiazem 15 minutes after ingestion. Peak effect for verapamil is 2 to 4 hours, for nifedipine 60 to 90 minutes, and for diltiazem 30 to 60 minutes, but the peak action may be delayed for 6 to 8 hours. Duration of action is up to 36 hours. The onset of action for sustained-release preparations is usually 4 hours but may be delayed, and peak effect is at 12 to 24 hours. In cases of massive overdose, concretions and prolonged toxicity can develop.

Volume distribution varies from 3 to 7 L/kg. Hepatic elimination half-life varies from 3 to 7 hours. Patients receiving digitalis and calcium channel blockers run the risk of digitalis toxicity, because calcium channel blockers increase digitalis levels.

Manifestations

Cardiac manifestations include hypotension, bradycardia, and conduction disturbances occurring 30 minutes to 5 hours after ingestion. A prolonged PR interval is an early finding and may occur at therapeutic doses. Torsades de pointes has been reported. All degrees of blocks may occur and may be delayed up to 16 hours. Lactic acidosis may be present. Calcium channel blockers do not affect intraventricular conduction, so the QRS interval is usually not affected.

Hypocalcemia is rarely present. Hyperglycemia may be present because of interference in calcium-dependent insulin release. Mental status changes, headaches, seizures, hemiparesis, and CNS depression may occur.

Laboratory Investigations

Specific drug levels are not readily available and are not useful. Monitor blood sugar, electrolytes, calcium, ABG, pulse oximetry, creatinine, and BUN, and also use hemodynamic monitoring, ECG, and cardiac monitoring.

Management

Vital functions must be established and maintained. Baseline ECG readings should be obtained and continuous cardiac and blood pressure monitoring maintained. A pacemaker should be available. Cardiology consultation should be sought.

Gastrointestinal decontamination with activated charcoal is recommended. If a large dose of a sustained-release preparation was ingested, whole-bowel irrigation can be considered, but its effectiveness has not been investigated.

If the patient is symptomatic, immediate cardiology consult must be obtained, because a pacemaker and hemodynamic monitoring may be needed. In the case of heart block, atropine is rarely effective and isoproterenol (Isuprel) may produce vasodilation. The use of a pacemaker should be considered early.

Hypotension and bradycardia can be treated with positioning, fluids, and calcium gluconate or chloride, glucagon, amrinone

²Not available in the United States.

³Exceeds dosage recommended by the manufacturer.

¹Not FDA approved for this indication.

(Inocor), and ventricular pacing. Calcium salts must be avoided if digoxin is present. Calcium usually reverses depressed myocardial contractility but may not reverse nodal depression or peripheral vasodilation. Calcium chloride can be given in a 10% solution, 0.1 to 0.2 mL/kg up to 10 mL in an adult, or calcium gluconate in a 10% solution 0.3 to 0.4 mL/kg up to 20 mL in an adult. Administration is intravenous, over 5 to 10 minutes. One should monitor for dysrhythmias, hypotension, and the serum ionized calcium. The aim is to increase calcium 4 mg/dL to a maximum of 13 mg/dL. The calcium response lasts 15 minutes and may require repeated doses or a continuous calcium gluconate infusion 0.2 mL/kg/h up to maximum of 10 mL/h.

If calcium fails, glucagon can be tried for its positive inotropic and chronotropic effect, or both. Amrinone (Inocor), an inotropic agent, may reverse the effects of calcium channel blockers. An effective dose is 0.15 mg to 2 mg/kg (0.15–0.4 mL/kg) by intravenous bolus followed by infusion of 5 to 10 µg/kg/min.

In case of hypotension, fluids, norepinephrine (Levophed), and epinephrine may be required. Amrinone and glucagon have been tried alone and in combination. Dobutamine and dopamine are often ineffective.

Extracorporeal measures (e.g., hemodialysis and charcoal hemoperfusion) are not useful, but extraordinary measures such as intra-aortic balloon pump and cardiopulmonary bypass have been used successfully.

For cases of calcium channel blocker toxicity that fail to respond to aggressive management, recent studies demonstrate that insulin and glucose have therapeutic value. The suggested dose range for insulin is to infuse regular insulin at 0.5 IU/kg/h with a simultaneous infusion of glucose 1 g/kg/h, with glucose monitoring every 30 minutes for at least the first 4 hours of administration and subsequent glucose adjustment to maintain euglycemia (70 to 100 mg/dL). Potassium levels should be monitored regularly, as they may shift in response to the insulin.

Disposition

Patients who have ingested regular-release preparations should be monitored for at least 6 hours and those who have ingested sustained-release preparations should be monitored for 24 hours after the ingestion. Intentional overdose necessitates psychiatric clearance. Symptomatic patients should be admitted to the intensive care unit.

Carbon Monoxide

Carbon monoxide is an odorless, colorless gas produced from incomplete combustion; it is also an in vivo metabolic breakdown product of methylene chloride used in paint removers.

Toxic Mechanism

Carbon monoxide's affinity for hemoglobin is 240 times greater than that of oxygen. It shifts the oxygen dissociation curve to the left, which impairs hemoglobin release of oxygen to tissues and inhibits the cytochrome oxidase enzymes.

Toxic Dose and Manifestations

Table 13 describes the manifestations of carbon monoxide toxicity. Exposure to 0.5% for a few minutes is lethal. Sequelae correlate with the patient's level of consciousness at presentation. ECG abnormalities may be noted. Creatine kinase is often elevated, and rhabdomyolysis and myoglobinuria may occur.

The carboxyhemoglobin (CoHB) expresses in percentage the extent to which carbon monoxide has bound with the total hemoglobin. This may be misleadingly low in the anemic patient with less hemoglobin than normal. The patient's presentation is a more reliable indicator of severity than the CoHB level. The manifestations listed in Table 13 for each level are in addition to those listed at the level above. The CoHB may not correlate reliably with the severity of the intoxication, and linking symptoms to specific levels of CoHB frequently leads to inaccurate conclusions. A level of carbon monoxide greater than 40% is usually associated with obvious intoxication.

TABLE 13 Carbon Monoxide Exposure and Possible Manifestations

CoHB SATURATION (%)	MANIFESTATIONS
3.5	None
5	Slight headache, decreased exercise tolerance
10	Slight headache, dyspnea on vigorous exertion, may impair driving skills
10–20	Moderate dyspnea on exertion, throbbing, temporal headache
20–30	Severe headache, syncope, dizziness, visual changes, weakness, nausea, vomiting, altered judgment
30–40	Vertigo, ataxia, blurred vision, confusion, loss of consciousness
40–50	Confusion, tachycardia, tachypnea, coma, convulsions
50–60	Cheyne-Stokes, coma, convulsions, shock, apnea
60–70	Coma, convulsions, respiratory and heart failure, death

Kinetics

The natural metabolism of the body produces small amounts of CoHB, less than 2% for nonsmokers and 5% to 9% for smokers.

Carbon monoxide is rapidly absorbed through the lungs. The rate of absorption is directly related to alveolar ventilation. Elimination also occurs through the lungs. The half-life of CoHB in room air (21% oxygen) is 5 to 6 hours; in 100% oxygen, it is 90 minutes; in hyperbaric pressure at 3 atmospheres oxygen, it is 20 to 30 minutes.

Laboratory Investigations

An ABG reading may show metabolic acidosis and normal oxygen tension. In cases of significant poisoning, the ABG, electrolytes, blood glucose, serum creatine kinase and cardiac enzymes, renal function tests, and liver function tests should be monitored. A urinalysis and test for myoglobinuria should be obtained. Chest radiograph can be useful in cases of smoke inhalation or if the patient is being considered for hyperbaric chamber. ECG monitoring should be maintained, especially if the patient is older than 40 years, has a history of cardiac disease, or has moderate to severe symptoms. Which toxicology studies are used is based on symptoms and circumstances. CoHB should be monitored during and at the end of therapy. The pulse oximeter has two wavelengths and overestimates oxyhemoglobin saturation in carbon monoxide poisoning. The true oxygen saturation is determined by blood gas analysis, which measures the oxygen bound to hemoglobin. The co-oximeter measures four wavelengths and separates out CoHB and the other hemoglobin binding agents from oxyhemoglobin. Fetal hemoglobin has a greater affinity for carbon monoxide than adult hemoglobin and may falsely elevate the CoHB as much as 4% in young infants.

Management

The first step is to adequately protect the rescuer. The patient must be removed from the contaminated area, and his or her vital functions must be established.

The mainstay of treatment is 100% oxygen via a non-rebreathing mask with an oxygen reservoir or endotracheal tube. All patients receive 100% oxygen until the CoHB level is 5% or less. Assisted ventilation may be necessary. ABG and CoHB should be monitored and the present CoHB level determined. *Note:* A near-normal CoHB level does not exclude significant carbon

monoxide poisoning, especially if the measurement is taken several hours after termination of exposure or if oxygen has been administered prior to obtaining the sample.

The exposed pregnant woman should be kept on 100% oxygen for several hours after the CoHB level is almost 0, because carbon monoxide concentrates in the fetus and oxygen is needed longer to ensure elimination of the carbon monoxide from fetal circulation. The fetus must be monitored, because carbon monoxide and hypoxia are potentially teratogenic.

Metabolic acidosis should be treated with sodium bicarbonate only if the pH is below 7.2 after correction of hypoxia and adequate ventilation. Acidosis shifts the oxygen dissociation curve to the right and facilitates oxygen delivery to the tissues.

The decision to use the hyperbaric oxygen chamber must be made on the basis of the ability to handle other acute emergencies that may coexist in the patient and of the severity of the poisoning. The standard of care for persons exposed to carbon monoxide has yet to be determined, but most authorities recommend using the hyperbaric oxygen chamber under any of the following conditions:

- If the patient is in a coma or has a history of loss of consciousness or seizures
- If there is cardiovascular dysfunction (clinical ischemic chest pain or ECG evidence of ischemia)
- If the patient has metabolic acidosis
- If symptoms persist despite 100% oxygen therapy
- In a child, if the initial CoHB is greater than 15%
- In symptomatic patients with preexisting ischemia
- If there are signs of maternal or fetal distress regardless of CoHB level (infants and fetus are a special problem because fetal hemoglobin has greater affinity for carbon monoxide)

Although controversial, a neurologic-cognitive examination has been used to help determine which patients with low carbon monoxide levels should receive more aggressive therapy. Testing should include the following: general orientation memory testing involving address, phone number, date of birth, and present date; and cognitive testing, involving counting by 7s, digit span, and forward and backward spelling of three-letter and four-letter words. Patients with delayed neurologic sequelae or recurrent symptoms up to 3 weeks may benefit from hyperbaric oxygen chamber treatment.

Seizures and cerebral edema must be treated.

Disposition

Patients with no or mild symptoms who become asymptomatic after a few hours of oxygen therapy, have a carbon monoxide level less than 10%, and have normal physical and neurologic-cognitive examination findings can be discharged, but they should be instructed to return if any signs of neurologic dysfunction appear. Patients with carbon monoxide poisoning requiring treatment need follow-up neuropsychiatric examinations.

Caustics and Corrosives

The terms *caustic* and *corrosive* are used interchangeably and can be divided into acids and alkalis. The U.S. Consumer Product Safety Commission Labeling Recommendations on containers for acids and alkalis indicate the potential for producing serious damage, as follows:

- Caution—weak irritant
- Warning—strong irritant
- Danger—corrosive

Some common acids with corrosive potential include acetic acid, formic acid, glycolic acid, hydrochloric acid, mercuric chloride, nitric acid, oxalic acid, phosphoric acid, sulfuric acid (battery acid), zinc chloride, and zinc sulfate. Some common alkalis with corrosive potential include ammonia, calcium carbide, calcium hydroxide (dry), calcium oxide, potassium hydroxide (lye), and sodium hydroxide (lye).

Toxic Mechanism

Acids produce mucosal coagulation necrosis and may be absorbed systemically; they do not penetrate deeply. Injury to the gastric

mucosa is more likely, although specific sites of injury for acids and alkalis are not clearly defined.

Alkalis produce liquefaction necrosis and saponification and penetrate deeply. The esophageal mucosa is likely to be damaged. Oropharyngeal and esophageal damage is more frequently caused by solids than by liquids. Liquids produce superficial circumferential burns and gastric damage.

Toxic Dose

The toxicity is determined by concentration, contact time, and pH. Significant injury is more likely with a substance that has a pH of less than 2 or greater than 12, with a prolonged contact time, and with large volumes.

Manifestations

The absence of oral burns does not exclude the possibility of esophageal or gastric damage. General clinical findings are stridor; dysphagia; drooling; oropharyngeal, retrosternal, and epigastric pain; and ocular and oral burns. Alkali burns are yellow, soapy, frothy lesions. Acid burns are gray-white and later form an eschar. Abdominal tenderness and guarding may be present if perforation has happened.

Laboratory Investigations

If acid ingestion has taken place, the patient's acid-base balance and electrolyte status should be determined. If pulmonary symptoms are present, a chest radiograph, ABG measurement, and pulse oximetry are called for.

Management

It is recommended that the container be brought to the examination, as the substance must be identified and the pH of the substance, vomitus, tears, or saliva tested.

If the acid or alkali has been ingested, all gastrointestinal decontamination procedures are contraindicated except for immediate rinse, removal of substance from the mouth, and dilution with small amounts (sips) of milk or water. The examiner should check for ocular and dermal involvement. Contraindications to oral dilution are dysphagias, respiratory distress, obtundation, or shock. If there is ocular involvement one should immediately irrigate the eye with tepid water for at least 30 minutes, perform fluorescein stain of eye, and consult an ophthalmologist. If there is dermal involvement, one should immediately remove contaminated clothes and irrigate the skin with tepid water for at least 15 minutes. Consultation with a burn specialist is called for.

In cases of acid ingestion, some authorities advocate a small flexible nasogastric tube and aspiration within 30 minutes after ingestion.

Patients should receive only intravenous fluids following dilution until endoscopic consultation is obtained. Endoscopy is valuable to predict damage and risk of stricture. The indications are controversial, with some authorities recommending it in all cases of caustic ingestions regardless of symptoms, and others selectively using clinical features such as vomiting, stridor, drooling, and oral or facial lesions as criteria. We recommend endoscopy for all symptomatic patients or patients with intentional ingestions. Endoscopy may be performed immediately if the patient is symptomatic, but it is usually done 12 to 48 hours postingestion.

The use of corticosteroids is considered controversial. Some feel they may be useful for patients with second-degree circumferential burns. They recommend starting with hydrocortisone sodium succinate (Solu-Cortef) intravenously 10 to 20 mg/kg/d within 48 hours and changing to oral prednisolone 2 mg/kg/d for 3 weeks before tapering the dose. We do not usually recommend using corticosteroids because they have not been shown to be effective.

Tetanus prophylaxis should be provided if the patient requires it for wound care. Antibiotics are not useful prophylactically. Contrast studies are not useful in the first few days and may interfere with endoscopic evaluation; later, they can be used to assess the severity of damage.

Emergency medical therapy includes agents to inhibit collagen formation and intraluminal stents. Esophageal and gastric outlet dilation may be needed if there is evidence of stricture. Bougienage of the esophagus, however, has been associated with brain abscess. Interposition of the colon may be necessary if dilation fails to provide an adequate-sized passage.

Management of inhalation cases requires immediate removal from the environment, administration of humid supplemental oxygen, and observation for airway obstruction and noncardiac pulmonary edema. Radiographic and ABG evaluation should be obtained when appropriate. Intubation and respiratory support may be required.

Certain caustics produce systemic disturbances. Formaldehyde causes metabolic acidosis, hydrofluoric acid causes hypocalcemia and renal damage, oxalic acid causes hypocalcemia, phenol causes hepatic and renal damage, and picric acid causes renal injury.

Disposition

Infants and small children should be medically evaluated and observed. All symptomatic patients should be admitted. If they have severe symptoms or danger of airway compromise, they should be admitted to the intensive care unit. After endoscopy, if no damage is detected, the patient may be discharged when he or she can tolerate oral feedings. Intentional exposures require psychiatric evaluation before the patient can be discharged.

Cocaine (Benzoylmethylecgonine)

Cocaine is derived from the leaves of *Erythroxylum coca* and *Truxillo coca*. "Body packing" refers to the placement of many small packages of contraband cocaine for concealment in the gastrointestinal tract or other areas for illicit transport. "Body stuffing" refers to spontaneous ingestion of substances for the purpose of hiding evidence.

Toxic Mechanism

Cocaine directly stimulates the CNS presynaptic sympathetic neurons to release catecholamines and acetylcholine, while it blocks the presynaptic reuptake of the catecholamines; it blocks the sodium channels along neuronal membranes; and it increases platelet aggregation. Long-term use depletes the CNS of dopamine.

Toxic Dose

The maximum mucosal local anesthetic therapeutic dose of cocaine is 200 mg or 2 mL of a 10% solution. Although CNS effects can occur at relatively low local anesthetic doses (50 to 95 mg), they are more common with doses greater than 1 mg/kg; cardiac effects can occur with doses greater than 1 mg/kg. The potential fatal dose is 1200 mg intranasally, but death has occurred with 20 mg parenterally.

Kinetics

Cocaine is well absorbed by all routes, including nasal insufflation, and oral, dermal, and inhalation routes (Table 14). Protein binding is 8.7%, and volume distribution is 1.5 L/kg.

Cocaine is metabolized by plasma and liver cholinesterase to the inactive metabolites ecgonine methyl ester and benzoylecgonine.

Plasma pseudocholinesterase is congenitally deficient in 3% of the population and decreased in fetuses, young infants, the elderly, pregnant people, and people with liver disease. These enzyme-deficient individuals are at increased risk for life-threatening cocaine toxicity.

Ten percent of cocaine is excreted unchanged. Cocaine and ethanol undergo liver synthesis to form cocaethylene, a metabolite with a half-life three times longer than that of cocaine. It may account for some of cocaine's cardiotoxicity and appears to be more lethal than cocaine or ethanol alone.

Manifestations

The CNS manifestations of cocaine ingestion are euphoria, hyperactivity, agitation, convulsions, and intracranial hemorrhage. Mydriasis and septal perforation can occur, as well as cardiac dysrhythmias, hypertension, and hypotension (with severe overdose). Chest pain is frequent, but only 5.8% of patients have true myocardial ischemia and infarction. Other manifestations include vasoconstriction, hyperthermia (because of increased metabolic rate), ischemic bowel perforation if the substance is ingested, rhabdomyolysis, myoglobinuria, and renal failure. In pregnant users, premature labor and abruptio placentae can occur.

Body cavity packing should be suspected in cases of prolonged toxicity.

Mortality can result from cerebrovascular accidents, coronary artery spasm, myocardial injury, or lethal dysrhythmias.

Laboratory Investigations

Monitoring of the ECG and cardiac rhythms, ABG, oxygen saturation, electrolytes, blood glucose, BUN, creatinine, and creatine kinase levels should be maintained. One should monitor cardiac fraction if the patient has chest pain, as well as the liver profile, and the urine for myoglobin. Intravenous drug users should have HIV and hepatitis virus testing.

Urine should be tested for cocaine and metabolites and other substances of abuse, and abdominal radiographs or ultrasonogram should be ordered for body packers. If the urine sample was collected more than 12 hours after cocaine intake, it will contain little or no cocaine. If cocaine is present, cocaine has been used within the past 12 hours. Cocaine's metabolite benzoylecgonine may be detected within 4 hours after a single nasal insufflation and for up to 114 hours. Cross-reactions with some herbal teas, lidocaine, and droperidol (Inapsine) may give false-positive results by some immunoassay methods.

Management

Supportive care includes blood pressure, cardiac, and thermal monitoring and seizure precautions. Diazepam (Valium) is the drug of choice for treatment of cocaine toxicity agitation, seizures, and dysrhythmias; doses are 10 to 30 mg intravenously at 2.5 mg per minute for adults and 0.2 to 0.5 mg/kg at 1 mg per minute up to 10 mg for a child.

Gastrointestinal decontamination should be instituted, if the cocaine was ingested, by administration of activated charcoal. MDAC may adsorb cocaine leakage in body stuffers or body packers. Whole-bowel irrigation with polyethylene glycol solution

TABLE 14 Routes and Kinetics of Cocaine

TYPE	ROUTE	ONSET	PEAK (min)	HALF-LIFE (min)	DURATION (min)
Cocaine leaf	Oral, chewing	20–30 min	45–90	—	240–360
Hydrochloride	Insufflation	1–3 min	5–10	78	60–90
	Ingestion	20–30 min	50–90	54	Sustained
	Intravenous	30–120 sec	5–11	36	60–90
Freebase/crack	Smoking	5–10 sec	5–11	—	Up to 20
Coca paste	Smoking	Unknown	—	—	—

(PEG) has been used in body packers and stuffers if the contraband is in a firm container. If the packages are not visible on plain radiographs of the abdomen, a contrast study or CT scan can help to confirm successful passage. Cocaine in the nasal passage can be removed with an applicator dipped in a non-water-soluble product (lubricating jelly) if this is done within a few minutes after application.

In body packers and stuffers, venous access must be secured, and drugs must be readily available for treating life-threatening manifestations until the contraband is passed in the stool. Surgical removal may be indicated if the packet does not pass the pylorus, in an asymptomatic body packer, or in the case of intestinal obstruction.

Hypertension and tachycardia are usually transient and can be managed by careful titration of diazepam. Nitroprusside may be used for severe hypertension. Myocardial ischemia is managed by oxygen, vascular access, benzodiazepines, and nitroglycerin. Aspirin and thrombolysis are not routinely recommended because of the danger of intracranial hemorrhage.

Dysrhythmias are usually supraventricular (SVT) and do not require specific management. Adenosine is ineffective. Life-threatening tachydysrhythmias may respond to phenolamine (Regitine) 5 mg IV bolus in adults or 0.1 mg/kg in children at 5- to 10-minute intervals. Phenolamine also relieves coronary artery spasm and myocardial ischemia. Electrical synchronized cardioversion should be considered for patients with hemodynamically unstable dysrhythmias. Lidocaine is not recommended initially but may be used after 3 hours for ventricular tachycardia. Wide complex QRS ventricular tachycardia may be treated with sodium bicarbonate 2 mEq/kg as a bolus. β -Adrenergic blockers are not recommended.

Anxiety, agitation, and convulsions can be treated with diazepam. If diazepam fails to control seizures, neuromuscular blockers can be used. The EEG should be monitored for nonmotor seizure activity. For hyperthermia, external cooling and cool humidified 100% oxygen should be administered. Neuromuscular paralysis to control seizures will reduce temperature. Dantrolene and antipyretics are not recommended. Rhabdomyolysis and myoglobinuria are treated with fluids, alkaline diuresis, and diuretics.

If the patient is pregnant, the fetus must be monitored and the patient observed for spontaneous abortion.

Paranoid ideation and threatening behavior should be treated with rapid tranquilization. The patient should be observed for suicidal depression that may follow intoxication and may require suicide precautions. If focal neurologic manifestations are present, one should consider the possibility of a cerebrovascular accident and obtain a CT scan.

Extracorporeal clearance techniques are of no benefit.

Disposition

Patients with mild intoxication or a brief seizure that does not require treatment who become asymptomatic may be discharged after 6 hours with appropriate psychosocial follow-up. If cardiac or cerebral ischemic manifestations are present, the patient should be monitored in the intensive care unit. Body packers and stuffers require care in the intensive care unit until passage of the contraband.

Cyanide

Hydrogen cyanide is a byproduct of burning plastic and wools in residential fires. Hydrocyanic acid is the liquefied form of hydrogen cyanide. Cyanide salts can be found in ore extraction. Nitriles, such as acetonitrile (artificial nail removers), are metabolized in the body to produce cyanide. Cyanogenic glycosides are present in some fruit seeds (such as amygdalin in apricots, peaches, and apples). Sodium nitroprusside, the antihypertensive vasodilator, contains five cyanide groups.

Toxic Mechanism

Cyanide blocks the cellular electron transport mechanism and cellular respiration by inhibiting the mitochondrial ferricytochrome

oxidase system and other enzymes. This results in cellular hypoxia and lactic acidosis. *Note:* Citrus fruit seeds form cyanide in the presence of intestinal β -glucosidase (the seeds are harmful only if the capsule is broken).

Toxic Dose

The ingestion of 1 mg/kg or 50 mg of hydrogen cyanide can produce death within 15 minutes. The lethal dose of potassium cyanide is 200 mg. Five to 10 mL of 84% acetonitrile is lethal. Infusions of sodium nitroprusside in rates above 2 μ g/kg per minute may cause cyanide to accumulate to toxic concentrations in critically ill patients.

Kinetics

Cyanide is rapidly absorbed by all routes. In the stomach, it forms hydrocyanic acid. Volume distribution is 1.5 L/kg. Protein binding is 60%. Cyanide is detoxified by metabolism in the liver via the mitochondrial thiosulfate-rhodanase pathway, which catalyzes the transfer of sulfur donor to cyanide, forming the less toxic irreversible thiocyanate that is excreted in the urine. Cyanide is also detoxified by reacting with hydroxocobalamin (vitamin B_{12a}) to form cyanocobalamin (vitamin B₁₂).

The cyanide elimination half-life from the blood is 1.2 hours. The elimination route is through the lungs.

Manifestations

Hydrogen cyanide has the distinctive odor of bitter almonds or silver polish. Manifestations of cyanide intoxication include hypertension, cardiac dysrhythmias, various ECG abnormalities, headache, hyperpnea, seizures, stupor, pulmonary edema, and flushing. Cyanosis is absent or appears late.

Laboratory Investigations

The examiner should obtain and monitor ABGs, oxygen saturation, blood lactate, hemoglobin, blood glucose, and electrolytes. Lactic acidemia, a decrease in the arterial-venous oxygen difference, and bright red venous blood occurs. If smoke inhalation is the possible source of cyanide exposure, CoHB and methemoglobin (MetHb) concentrations should be measured.

Cyanide levels in whole blood, red blood cells, or serum are not useful in the acute management because the determinations are not readily available. Specific cyanide blood levels are as follows: smokers have less than 0.5 μ g/mL; a patient with flushing and tachycardia has 0.5 to 1.0 μ g/mL, one with obtundation has 1.0 to 2.5 μ g/mL, and one in coma or who has died has more than 2.5 μ g/mL.

Management

If the cyanide was inhaled, the patient must be removed from the contaminated atmosphere. Attendants should not administer mouth-to-mouth resuscitation. Rescuers and attendants must be protected. Immediate administration of 100% oxygen is called for and oxygen should be continued during and after the administration of the antidote. The clinician must decide whether to use any or all components of the cyanide antidote kit.

The mechanism of action of the antidote kit is twofold: to produce methemoglobinemia and to provide a sulfur substrate for the detoxification of cyanide. The nitrites make methemoglobin, which has a greater affinity for cyanide than does the cytochrome oxidase enzymes. The combination of methemoglobin and cyanide forms cyanomethemoglobin. Sodium thiosulfate provides a sulfur substrate for the rhodanase enzyme, which converts cyanide into the relatively nontoxic sodium thiocyanate, which is excreted by the kidney.

The procedure for using the antidote kit is as follows:

- Step 1: Amyl nitrite inhalant perles is only a temporizing measure (forms only 2% to 5% methemoglobin) and it can be omitted if venous access is established. Alternate 100% oxygen and the inhalant for 30 seconds each minute. Use a new perle every 3 minutes.
- Step 2: Sodium nitrite ampule is indicated for cyanide exposures, except for cases of residential fires, smoke inhalation, and

nitroprusside or acetonitrile poisonings. It is administered intravenously to produce methemoglobin of 20% to 30% at 35 to 70 minutes after administration. A dose of 10 mL of 3% solution of sodium nitrite for adults and 0.33 mL/kg of 3% solution for children is diluted to 100 mL 0.9% saline and administered slowly intravenously at 5 mL/min. If hypotension develops, the infusion should be slowed.

Step 3: Sodium thiosulfate is useful alone in cases of smoke inhalation, nitroprusside toxicity, and acetonitrile toxicity and should not be used at all in cases of hydrogen sulfide poisoning. The administration dose is 12.5 g of sodium thiosulfate or 50 mL of 25% solution for adults and 1.65 mL/kg of 25% solution for children intravenously over 10 to 20 minutes.

If cyanide symptoms recur, further treatment with nitrites or the perles is controversial. Some authorities suggest repeating the antidotes in 30 minutes at half of the initial dose, but others do not advise this for lack of efficacy. The child dosage regimen on the package insert must be carefully followed.

One hour after antidotes are administered, the methemoglobin level should be obtained and should not exceed 20%. Methylene blue should not be used to reverse excessive methemoglobin.

Gastrointestinal decontamination of oral ingestion by activated charcoal is recommended but is not very effective because of the rapidity of absorption. Seizures are treated with intravenous diazepam. Acidosis should be treated with sodium bicarbonate if it does not rapidly resolve with therapy. There is no role for hyperbaric oxygen or hemodialysis or hemoperfusion.

Other antidotes include hydroxocobalamin (vitamin B_{12a}) (Cyanokit), which has proven effective when given immediately after exposure in large doses of 4 g (50 mg/kg) or 50 times the amount of cyanide exposure with 8 g of sodium thiosulfate. Hydroxocobalamin has FDA orphan drug approval.

Disposition

Asymptomatic patients should be observed for a minimum of 3 hours. Patients who ingest nitrile compounds must be observed for 24 hours. Patients requiring antidote administration should be admitted to the intensive care unit.

Digitalis

Cardiac glycosides are found in cardiac medications, common plants, and the skin of the Bufo toad.

Toxic Mechanism

Cardiac glycosides inhibit the enzyme sodium/potassium-adenosine triphosphatase (Na⁺,K⁺,ATPase), leading to intracellular potassium loss and increased intracellular sodium, and producing phase 4 depolarization, increased automaticity, and ectopy. There is increased intracellular calcium and potentiation of contractility. Pacemaker cells are inhibited, and the refractory period is prolonged, leading to atrioventricular blocks. There is increased vagal tone.

Toxic Dose

Digoxin total digitalizing dose, the dose required to achieve therapeutic blood levels of 0.6 to 2.0 ng/mL, is 0.75 to 1.25 mg or 10 to 15 µg/kg for patients older than 10 years of age; 40 to 50 µg/kg for patients younger than 2 years of age; and 30 to 40 µg/kg for patients 2 to 10 years of age.

The acute single toxic dose is greater than 0.07 mg/kg or greater than 2 or 3 mg in an adult, but 2 mg in a child or 4 mg in an adult usually produces only mild toxicity. One to 3 mg or more may be found in a few leaves of oleander or foxglove. Serious and fatal overdoses are more than 4 mg in a child and more than 10 mg in an adult.

Acute digitoxin ingestion of 10 to 35 mg has produced severe toxicity and death. Digitoxin therapeutic steady state is 15 to 25 ng/mL. In cases of chronic or acute-on-chronic ingestions in patients with cardiac disease, more than 2 mg may produce toxicity; however, toxicity can develop within therapeutic range on chronic therapy.

Patients at greatest risk of overdose include those with cardiac disease, those with electrolyte abnormalities (low potassium, low magnesium, low T₄, high calcium), those with renal impairment, and those on amiodarone (Cordarone), quinidine, erythromycin, tetracycline, calcium channel blockers, and β-blockers.

Kinetics

Digoxin is a metabolite of digitoxin. In cases of oral overdose, the typical onset is 30 minutes, with peak effects in 3 to 12 hours. Duration is 3 to 4 days. Intravenous onset is in 5 to 30 minutes; peak level is immediate, and peak effect is at 1.5 to 3 hours.

Volume distribution is 5 to 6 L/kg. The cardiac-to-plasma ratio is 30:1. After an acute ingestion overdose, the serum concentration is not reflective of tissue concentration for at least 6 hours or more, and steady state is 12 to 16 hours after last dose.

Sixty percent to 80% of the parent compound is excreted unchanged in the urine. The elimination half-life is 30 to 50 hours.

Manifestations

Onset of manifestations is usually within 2 hours but may be delayed up to 12 hours.

Gastrointestinal effects of nausea and vomiting are frequently present in cases of acute ingestion but may also occur in cases of chronic ingestion. The “digitalis effect” on ECG is scooped ST segments and PR prolongation; in cases of overdose, any dysrhythmia or block is possible but none are characteristic. Bradycardia occurs in patients with acute overdose with healthy hearts; supraventricular tachycardia occurs in patients with existing heart disease or chronic overdose. Ventricular tachycardia is seen only in cases of severe poisoning.

The CNS effects include headaches, visual disturbances, and colored halo vision. Hyperkalemia occurs following acute overdose and correlates with digoxin level and outcome. Among patients with serum potassium levels of less than 5.0 mEq/L, all survive. If the level is 5 to 5.5, 50% survive, and if the level is greater than 5.5, all die. Hypokalemia is commonly seen with chronic intoxication. Patients with normal digitalis levels may have toxicity in the presence of hypokalemia.

Chronic intoxications are more likely to produce scotoma, color perception disturbances, yellow vision, halos, delirium, hallucinations or psychosis, tachycardia, and hypokalemia.

Laboratory Investigations

Continuous monitoring of ECG, pulse, and blood pressure is called for. Blood glucose, electrolytes, calcium, magnesium, BUN, and creatinine levels should also be monitored. An initial digoxin level should be measured on patient presentation and repeated thereafter. Levels should be measured more than 6 hours postingestion because earlier values do not reflect tissue distribution. Digoxin clinical toxicity is usually associated with serum digoxin levels of greater than 3.5 ng/mL in adults.

An endogenous digoxin-like substance cross-reacts in most common immunoassays (not with high-pressure liquid chromatography) and values as high as 4.1 ng/mL have been reported in newborns, patients with chronic renal failure, patients with abnormal immunoglobulins, and women in the third trimester of pregnancy.

Management

A cardiology consult should be obtained and a pacemaker should be readily available.

In undertaking gastrointestinal decontamination, excessive vagal stimulation should be avoided (e.g., emesis and gastric lavage). Activated charcoal should be administered, and if a nasogastric tube is required for the activated charcoal, pretreatment with atropine (0.02 mg/kg in children and 0.5 mg in adults) should be considered.

Digoxin-specific antibody fragments (Fab, Digibind) 38 mg binds 0.5 mg digoxin and then is excreted through the kidneys. The onset of action is within 30 minutes. Problems associated with Fab therapy are mainly from withdrawal of digoxin and worsening

heart failure, hypokalemia, decrease in glucose (if the patient has low glycogen stores), and allergic reactions (very rare). Digitalis administered after Fab therapy is bound and may be inactivated for 5 to 7 days.

Absolute indications for Fab therapy include the following:

- Life-threatening malignant (hemodynamically unstable) dysrhythmias
- Ventricular dysrhythmias, unstable severe bradycardia, or second- or third-degree blocks unresponsive to atropine or rapid deterioration in clinical status
- Life-threatening digitoxin and oleander poisonings

Relative indications for Fab therapy include the following:

- Ingestions greater than 4 mg in a child and 10 mg in an adult
- Serum potassium level greater than 5.0 mEq/L
- Serum digoxin level greater than 10 ng/mL in adults or greater than 5 ng/mL in children 6 hours after an acute ingestion
- Digitalis delirium and thrombocytopenia response

Digoxin-specific Fab fragments therapy can be administered as a bolus through a 22- μ m filter if the case is a critical emergency. If the case is less urgent, then it can be administered over 30 minutes. An empiric dose is 10 vials in adults and 5 vials in a child for an unknown amount ingested in a symptomatic patient with history of a digoxin overdose.

To calculate the dose in the case of a known ingestion, the following equation is used:

$$\text{Amount (total mg)} \times (0.8) \text{ body burden}$$

If liquid capsules were taken or the substance was given intravenously the 80% bioavailability figure is not used. Instead, the body burden divided by 0.5 (0.5 mg digoxin is bound by 1 vial of 38 mg of Fab) equals the number of vials needed.

If the amount is unknown but the steady state serum concentration is known, the following equations are used:

For digoxin:

$$\begin{aligned} \text{Digitoxin ng/mL} \times (5.6 \text{ L/kg Vd}) \times (\text{wt kg}) &= \text{mg body burden} \\ \text{Body burden} \div 1000 &= \text{mg body burden} \\ \text{Body burden} / 0.5 &= \text{number of vials needed} \end{aligned}$$

For digitoxin:

$$\begin{aligned} \text{Digitoxin ng/mL} \times (0.56 \text{ L/kg Vd}) \times (\text{wt kg}) &= \text{mg body burden} \\ \text{Body burden} \div 1000 &= \text{mg body burden} \\ \text{Body burden} / 0.5 &= \text{number of vials needed} \end{aligned}$$

Antidysrhythmic agents or a pacemaker should be used only if Fab therapy fails. For ventricular tachydysrhythmias, electrolyte disturbances should be corrected by the administration of lidocaine or phenytoin. For torsades de pointes, magnesium sulfate 20 mL 20% IV can be given slowly over 20 minutes (or 25 to 50 mg/kg in a child), titrated to control the dysrhythmia. Magnesium should be discontinued if hypotension, heart block, or decreased deep tendon reflexes are present. Magnesium is used with caution if the patient has renal impairment.

Unstable bradycardia and second-degree and third-degree atrioventricular block should be treated by Fab first. A pacemaker should be available if necessary. Isoproterenol should be avoided because it causes dysrhythmias. Cardioversion is used with caution, starting at a setting of 5 to 10 joules. The patient should be pretreated with lidocaine, if possible, because cardioversion may precipitate ventricular fibrillation or asystole.

Potassium disturbances are caused by a shift, not a change, in total body potassium. Hyperkalemia (>5.0 mEq/L) is treated with Fab only. Calcium must never be used, and insulin/glucose and sodium bicarbonate should not be used concomitantly with Fab because they may produce severe life-threatening hypokalemia. Sodium polystyrene sulfonate (Kayexalate) should not be used. Hypokalemia must be treated with caution because it may be cardioprotective. Treatment can be administered if the patient has ventricular dysrhythmias or a serum potassium level less than 3.0 mEq/L and atrioventricular block.

Extracorporeal procedures are ineffective. Hemodialysis is used for severe or refractory hyperkalemia.

One must never use antidysrhythmic types Ia (procainamide, quinidine, disopyramide [Norpace], amiodarone [Cordarone]), Ic (propafenone [Rythmol], flecainide [Tambocor]), II (β -blockers), or IV (calcium channel blockers). Class Ib drugs (lidocaine, phenytoin [Dilantin], mexiletine [Mexitil], and tocainide [Tonocard]) can be used.

Disposition

Consultation with a poison control center and a cardiologist experienced with digoxin-specific Fab fragments is warranted. All patients with significant dysrhythmias, symptoms, elevated serum digoxin concentration, or elevated serum potassium level should be admitted to the intensive care unit.

Ethanol

Table 15 lists the features of alcohols and glycols.

Toxic Mechanism

Ethanol has CNS depressant and anesthetic effects. Ethanol stimulates the γ -aminobutyric acid (GABA) system. It promotes cutaneous vasodilation (contributes to hypothermia), stimulates secretion of gastric juice (gastritis), inhibits the secretion of the antidiuretic hormone, inhibits gluconeogenesis (hypoglycemia), and influences fat metabolism (lipidemia).

Toxic Dose

A dose of 1 mL/kg of absolute ethanol (100% ethanol, or 200 proof) gives a blood ethanol concentration of 100 mg/dL. A potentially fatal dose is 3 g/kg for children or 6 g/kg for adults. Children are more prone to developing hypoglycemia than adults.

Kinetics

Onset of action is 30 to 60 minutes after ingestion; peak action is 90 minutes on empty stomach. Volume distribution is 0.6 L/kg. The major route of elimination ($>90\%$) is by hepatic oxidative metabolism. The first step is by the enzyme alcohol dehydrogenase, which converts ethanol to acetaldehyde. Alcohol dehydrogenase metabolizes ethanol at a constant rate of 12 to 20 mg/dL/h (12 to 15 mg/dL/h in nondrinkers, 15 to 30 mg/dL/h in social drinkers, 30 to 50 mg/dL/h in heavy drinkers, and 25 to 30 mg/dL/h in children). At very low blood ethanol concentration (>30 mg/dL), the metabolism is by first-order kinetics. In the second step, acetaldehyde is metabolized by acetaldehyde dehydrogenase to acetic acid, which is metabolized by the Krebs cycle to carbon dioxide and water. The enzyme steps are nicotinamide adenine dinucleotide-dependent, which interferes with gluconeogenesis. Less than 10% of ethanol is excreted unchanged by the kidneys. The relationship between blood ethanol concentration (BEC) and dose (amount ingested) can be calculated as follows:

$$\begin{aligned} \text{BEC (mg/dL)} &= \text{amount ingested (mL)} \times \\ &\% \text{ ethanol product} \times \text{SG (0.79)} / \text{Vd (0.6 L/kg)} \times \text{body wt (kg)} \\ \text{Dose (amount ingested)} &= \text{BEC (mg/dL)} \times \\ &\text{Vd (0.6)} \times \text{body wt (kg)} / \% \text{ ethanol} \times \\ &\text{specific gravity (0.79)} \end{aligned}$$

Manifestations

Table 16 lists the clinical signs of acute ethanol intoxication.

Chronic alcoholic patients tolerate higher blood ethanol concentration, and correlation with manifestations is not valid. Rapid interview for alcoholism is the CAGE questions:

- C—Have you felt the need to Cut down?
- A—Have others Annoyed you by criticism of your drinking?
- G—Have you felt Guilty about your drinking?
- E—Have you ever had a morning Eye-opening drink to steady your nerves or get rid of a hangover?

Two affirmative answers indicate probable alcoholism.

TABLE 15 Summary of Alcohol and Glycol Features

	METHANOL	ISOPROPANOL	ETHANOL	ETHYLENE GLYCOL
Principal uses	Gas line antifreeze, Sterno, windshield de-icer	Solvent jewelry cleaner, rubbing alcohol	Beverage, solvent	Radiator antifreeze, windshield de-icer
Specific gravity	0.719	0.785	0.789	1.12
Fatal dose	1 mL/kg 100%	3 mL/kg 100%	5 mL/kg 100%	1.4 mL/kg
Inebriation	±	2+	2+	1+
Metabolic change		Hyperglycemia	Hypoglycemia	Hypocalcemia
Metabolic acidosis	4+	0	1+	2+
Anion gap	4+	±	2+	4+
Ketosis	Ketobutyric	Acetone	Hydroxybutyric	None
Gastrointestinal tract	Pancreatitis	Hemorrhagic gastritis	Gastritis	
Osmolality*	0.337	0.176	0.228	0.190

*1 mL/dL of substances raises freezing point osmolality of serum. The validity of the correlation of osmolality with blood concentrations has been questioned.

TABLE 16 Clinical Signs in the Nontolerant Ethanol Drinker

ETHANOL BLOOD CONCENTRATION (mg/dL)*	MANIFESTATIONS
>25	Euphoria
>47	Mild incoordination, sensory and motor impairment
>50	Increased risk of motor vehicle accidents
>100	Ataxia (legal toxic level in many localities)
>150	Moderate incoordination, slow reaction time
>200	Drowsiness and confusion
>300	Severe incoordination, stupor, blurred vision
>500	Flaccid coma, respiratory failure, hypotension; may be fatal

*Ethanol concentrations sometimes reported in %.

Note: mg% is not equivalent to mg/dL because ethanol weighs less than water (specific gravity 0.79). A 1% ethanol concentration is 790 mg/dL and 0.1% is 79 mg/dL. There is great variation in individual behavior at different blood ethanol levels. Behavior is dependent on tolerance and other factors.

Laboratory Investigations

The blood ethanol concentration should be specifically requested and followed. Gas chromatography or a breathalyzer test gives rapid reliable results if no belching or vomiting is present. Enzymatic methods do not differentiate between the alcohols. ABG, electrolytes, and glucose should be measured, the anion and osmolar gaps determined (measure by freezing point depression, not vapor pressure), and a check for ketosis made.

Management

The examiner should inquire about trauma and disulfiram use. The patient must be protected from aspiration and hypoxia. Vital functions must be established and maintained. The patient may require intubation and assisted ventilation.

Gastrointestinal decontamination plays no role in the management of ethanol intoxication.

If the patient is comatose, glucose should be administered intravenously, 1 mL/kg 50% glucose in adults and 2 mL/kg 25% glucose in children. Thiamine, 100 mg intravenously, is administered if the patient has a history of chronic alcoholism, malnutrition, or

suspected eating disorders to prevent Wernicke-Korsakoff syndrome. Naloxone (Narcan) has produced a partial inconsistent response but is not recommended for known alcoholics.

General supportive care includes administration of fluids to correct hydration and hypotension and correction of electrolyte abnormalities and acid-base imbalance. Vasopressors and plasma expanders may be necessary to correct severe hypotension. Hypomagnesemia is frequent in chronic alcoholics. In case of hypomagnesemia, a loading dose of 2 g magnesium sulfate 10% is administered by intravenous solution over 5 minutes in the intensive care unit with blood pressure and cardiac monitoring and calcium chloride 10% on hand in case of overdose. This is followed with constant infusion of 6 g of 10% solution over 3 to 4 hours. Caution must be taken with the use of magnesium if renal failure is present.

Hypothermic patients should be warmed. See the section on disturbances caused by cold.

Hemodialysis can be used in severe cases when conventional therapy is ineffective (rarely needed).

Repeated or prolonged seizures should be treated with diazepam (Valium). The brief "rum fits" do not need long-term anticonvulsant therapy. Repeated seizures or focal neurologic findings may warrant skull radiographs, lumbar puncture, and CT scan of the head, depending on the clinical findings. Withdrawal is treated with hydration and large doses of chlordiazepoxide (Librium) 50 to 100 mg or diazepam (Valium) 2 to 10 mg intravenously; these doses may be repeated in 2 to 4 hours. Very large doses of benzodiazepines may be required for delirium tremens. Withdrawal can occur in presence of elevated blood ethanol concentration and can be fatal if left untreated.

Chest radiograph is warranted to determine whether aspiration pneumonia is present. Renal and liver function tests and bilirubin level measurement should be made.

Disposition

Clinical severity (e.g., intubation, assisted ventilation, aspiration pneumonia) should determine the level of hospital care needed. Young children with significant unintentional exposure to ethanol (calculated to reach a blood ethanol concentration of 50 mg/dL) should have blood ethanol concentration obtained and blood glucose levels monitored for hypoglycemia frequently for 4 hours after ingestion. Patients with acute ethanol intoxication seldom require admission unless a complication is present. However, intoxicated patients should not be discharged until they are fully functional (can walk, talk, and think independently), have suicide potential evaluated, have proper disposition environment, and have a sober escort.

Ethylene Glycol

Ethylene glycol is found in solvents, de-icers, radiator antifreeze (95%), and air-conditioning units. Ethylene glycol is a sweet-tasting, colorless, water-soluble liquid with a sweet aromatic fragrance.

Toxic Mechanism

Ethylene glycol is oxidized by alcohol dehydrogenase to glycolaldehyde, which is metabolized to glycolic acid and glyoxylic acid. Glyoxylic acid is metabolized to oxalic acid via a pyridoxine-dependent pathway to glycine and by thiamine and magnesium-dependent pathways to α -hydroxy-ketoadipic acid. The metabolites of ethylene glycol produce a profound metabolic acidosis, increased anion gap, hypocalcemia, and oxalate crystals, which deposit in tissues (particularly the kidney).

Toxic Dose

The ingestion of 0.1 mL/kg 100% ethylene glycol can result in a toxic serum ethylene glycol concentration of 20 mg/dL. Ingestion of 3.0 mL (less than 1 teaspoonful or swallow) of a 100% solution in a 10-kg child or 30 mL of 100% ethylene glycol in an adult produces a serum ethylene glycol concentration of 50 mg/dL, a concentration that requires hemodialysis. The fatal amount is 1.4 mL/kg of 100% solution.

Kinetics

Absorption is via dermal, inhalation, and ingestion routes. Ethylene glycol is rapidly absorbed from the gastrointestinal tract. Onset is usually in 30 minutes but may be delayed by co-ingestion of food and ethanol. The usual peak level is at 2 hours. Volume distribution is 0.65 to 0.8 L/kg.

For metabolism, see *Toxic Mechanism*.

The half-life of ethylene glycol without ethanol is 3 to 8 hours; with ethanol, it is 17 hours, and with hemodialysis it is 2.5 hours. Renal clearance is 3.2 mL/kg/min. About 20% to 50% is excreted unchanged in the urine. The relationship between serum ethylene glycol concentration (SEGC) and dose (amount ingested) can be calculated as follows:

$$0.12 \text{ mL/kg of 100\%} = \text{SEGC } 10 \text{ mg/dL}$$

Manifestations

Phase I. The onset of manifestations is 30 minutes to several hours longer after ingestion with concomitant ethanol ingestion. The patient may be inebriated. Hypocalcemia, tetany, and calcium oxalate and hippuric acid crystals in urine can be seen within 4 to 8 hours but are not always present. Early, before metabolism of ethylene glycol, an osmolal gap may be present (see *Laboratory Investigations*). Later, the metabolites of ethylene glycol produce changes starting 4 to 12 hours following ingestion, including an anion gap, metabolic acidosis, coma, convulsions, cardiac disturbances, and pulmonary and cerebral edema. Because fluorescein is added to some antifreeze, the presence of fluorescence may be a clue to ethylene glycol exposure. However, it has been shown that fluorescent urine is not a reliable indicator of ethylene glycol ingestion and should not be used as a screen.

Phase II. After 12 to 36 hours, cardiopulmonary deterioration occurs, with pulmonary edema and congestive heart failure.

Phase III. Phase III occurs 36 to 72 hours after ingestion, with pulmonary edema and oliguric renal failure from oxalate crystal deposition and tubular necrosis predominating.

Phase IV. Neurologic sequelae may occur rarely, especially in patients who fail to receive early antidotal therapy. The onset ranges from 6 to 10 days after ingestion. Findings include facial diplegia, hearing loss, bilateral visual disturbances, elevated cerebrospinal fluid pressure with or without elevated protein levels and pleocytosis, vomiting, hyperreflexia, dysphagia, and ataxia.

Laboratory Investigations

Blood glucose and electrolytes should be monitored. Urinalysis should look for oxalate ("envelope") and monohydrate ("hemp

seed") crystals. Urine fluorescence is not reliable as a screen. ABG, ethylene glycol, and ethanol levels, plasma osmolality (using freezing point depression method), calcium, BUN, and creatinine should be measured. A serum ethylene glycol concentration of 20 mg/dL is toxic (ethylene glycol levels are very difficult to obtain). If possible, a glycolate level should be obtained. Cross-reactions with propylene glycol, a vehicle in many liquids and intravenous medications (phenytoin [Dilantin], diazepam [Valium]), other glycols, and triglycerides, may produce spurious ethylene glycol levels. False-positive ethylene glycol values may occur with colorimetric or gas chromatography using an OV-17 column in the presence of propylene glycol.

The following equations can be used to calculate the osmolality, osmolal gap, and ethylene glycol level:

$$2(\text{Na} + \text{mEq/L}) + (\text{Blood glucose mg/dL})/20 + (\text{BUN mg/dL})/3 = \text{Total calculated osmolality (mOsm/L)}$$

$$\text{Osmolar Gap} = \text{measured osmolality (by freezing point depression method)} - \text{calculated osmolality}$$

A gap greater than 10 is abnormal. *Note:* if ethanol is involved, add ethanol level/4.6 to the calculated equation.

An increased osmolal gap is produced by the following common substances: acetone, dextran, dimethyl sulfoxide, diuretics, ethanol, ethyl ether, ethylene glycol, isopropanol, paraldehyde, mannitol, methanol, sorbitol, and trichloroethane. Table 10 gives the conversion factors for these substances.

Although a specific blood level of ethylene glycol in milligrams per deciliter can be estimated using the equation below, this is not considered to be a reliable method and should not take the place of obtaining a measured ethylene glycol blood concentration.

$$\text{Osmolar gap} \times \text{conversion factor} = \text{serum concentration}$$

Caution: The accuracy of the ethylene glycol estimated decreases as the ethylene glycol levels decrease. The toxic metabolites are not osmotically active, and patients presenting late may show signs of severe toxicity without an elevated osmolar gap.

The anion gap can be calculated using the following equation:

$$\text{Na} - (\text{Cl} + \text{HCO}_3) = \text{anion gap}$$

The normal gap is 8 to 12. Potassium is not used because it is a small amount and may be hemolyzed. Table 8 lists factors that may account for an increased or a decreased anion gap.

Management

Vital functions should be established and maintained. The airway must be protected, and assisted ventilation can be used, if necessary. Gastrointestinal decontamination has a limited role. Only gastric aspiration can be used within 60 minutes after ingestion. Activated charcoal is not effective.

Baseline measurements of serum electrolytes and calcium, glucose, ABGs, ethanol, serum ethylene glycol concentration (may be difficult to obtain readily in some institutions), and methanol concentrations should be obtained. In the first few hours, the measured serum osmolality should be determined and compared to calculated osmolality (see osmolality equation, earlier). If seizures occur, one should measure serum calcium (preferably ionized calcium) and treat with intravenous diazepam. If the patient has hypocalcemic seizures, he or she should also be treated with 10 to 20 mL 10% calcium gluconate (0.2 to 0.3 mL/kg in children) slowly intravenously, with the dose repeated as needed. Metabolic acidosis should be corrected with intravenous sodium bicarbonate.

Ethanol therapy should be initiated immediately if fomepizole (Antizol) is unavailable (see next paragraph). Alcohol dehydrogenase has a greater affinity for ethanol than ethylene glycol. Therefore, ethanol blocks the metabolism of ethylene glycol. Ethanol therapy is called for if there is a history of ingestion of 0.1 mL/kg of 100% ethylene glycol, serum ethylene glycol concentration is greater than 20 mg/dL, there is an osmolar gap not accounted for by other alcohols or factors (e.g., hyperlipidemia), metabolic

acidosis is present with an increased anion gap, or there are oxalate crystals in the urine. Ethanol should be administered intravenously (the oral route is less reliable) to produce a blood ethanol concentration of 100 to 150 mg/dL. The loading dose is 10 mL/kg of 10% ethanol intravenously, administered concomitantly with a maintenance dose of 10% ethanol of 1.0 mL/kg/h. This dose may need to be increased to 2 mL/kg/h in patients who are heavy drinkers. The blood ethanol concentration should be measured hourly and the infusion rate should be adjusted to maintain a blood ethanol concentration of 100 to 150 mg/dL.

Fomepizole (Antizol, 4-methylpyrazole) inhibits alcohol dehydrogenase more reliably than ethanol and it does not require constant monitoring of ethanol levels and adjustment of infusion rates. Fomepizole is available in 1 g/mL vials of 1.5 mL. The loading dose is 15 mg/kg (0.015 mL/kg) IV; maintenance dose is 10 mg/kg (0.01 mL/kg) every 12 hours for four doses, then 15 mg/kg every 12 hours until the ethylene glycol levels are less than 20 mg/dL. The solution is prepared by being mixed with 100 mL of 0.9% saline or D₅W (5% dextrose in water). Fomepizole can be given to patients requiring hemodialysis but should be dosed as follows:

- Dose at the beginning of hemodialysis:
 - If <6 hours since last Antizol dose, do not administer dose
 - If >6 hours since last dose, administer next scheduled dose
- Dosing during hemodialysis:
 - Dose every 4 hours
- Dosing at the time hemodialysis is completed:
 - If <1 hour between last dose and end of dialysis, do not administer dose at end of dialysis
 - If 1 to 3 hours between last dose and end of dialysis, administer one half of next scheduled dose
 - If >3 hours between last dose and end of dialysis, administer next scheduled dose
- Maintenance dosing off hemodialysis:
 - Give the next scheduled dose 12 hours from the last dose administered

Hemodialysis is indicated if the ingestion was potentially fatal; if the serum ethylene glycol concentration is greater than 50 mg/dL (some recommend at levels of >25 mg/dL); if severe acidosis or electrolyte abnormalities occur despite conventional therapy; or if congestive heart failure or renal failure is present. Hemodialysis reduces the ethylene glycol half-life from 17 hours on ethanol therapy to 3 hours. Therapy (fomepizole and hemodialysis) should be continued until the serum ethylene glycol concentration is less than 10 mg/dL, the glycolate level is nondetectable (not readily available), the acidosis has cleared, there are no mental disturbances, the creatinine level is normal, and the urinary output is adequate. This may require 2 to 5 days.

Adjunct therapy involving thiamine, 100 mg/d (in children, 50 mg), slowly over 5 minutes intravenously or intramuscularly and repeated every 6 hours and pyridoxine, 50 mg IV or IM every 6 hours, has been recommended until intoxication is resolved, but these agents have not been extensively studied. Folate, 50 mg IV (child 1 mg/kg), can be given every 4 hours for 6 doses.

Disposition

All patients who have ingested significant amounts of ethylene glycol (calculated level above 20 mg/dL), have a history of a toxic dose, or are symptomatic should be referred to the emergency department and admitted. If the serum ethylene glycol concentration cannot be obtained, the patient should be followed for 12 hours, with monitoring of the osmolal gap, acid-base parameters, and electrolytes to exclude development of metabolic acidosis with an anion gap. Transfer should be considered for fomepizole therapy or hemodialysis.

Hydrocarbons

The lower the viscosity and surface tension of hydrocarbons or the greater the volatility, the greater the risk of aspiration. Volatile substance abuse has produced the "Sudden Sniffing's Death Syndrome," most likely caused by dysrhythmias.

Toxicologic Classification and Toxic Mechanism

All systemically absorbed hydrocarbons can lower the threshold of the myocardium to dysrhythmias produced by endogenous and exogenous catecholamines.

Aliphatic hydrocarbons are branched straight chain hydrocarbons. A few aspirated drops are poorly absorbed from the gastrointestinal tract and produce no systemic toxicity by this route. However, aspiration of very small amounts can produce chemical pneumonitis. Examples of aliphatic hydrocarbons are gasoline, kerosene, charcoal lighter fluid, mineral spirits (Stoddard's solvent), and petroleum naphtha. Mineral seal oil (signal oil), found in furniture polishes, is a low-viscosity and low-volatility oil with minimum absorption that never warrants gastric decontamination. It can produce severe pneumonia if aspirated.

Aromatic hydrocarbons are six carbon ring structures that are absorbed through the gastrointestinal tract. Systemic toxicity includes CNS depression and, in cases of chronic abuse, multiple organ effects such as leukemia (benzene) and renal toxicity (toluene). Examples are benzene, toluene, styrene, and xylene. The seriously toxic ingested dose is 20 to 50 mL in adults.

Halogenated hydrocarbons are aliphatic or aromatic hydrocarbons with one or more halogen substitutions (Cl, Br, Fl, or I). They are highly volatile and are abused as inhalants. They are well absorbed from the gastrointestinal tract, produce CNS depression, and have metabolites that can damage the liver and kidneys. Examples include methylene chloride (may be converted into carbon monoxide in the body), dichloroethylene (also causes a disulfiram [Antabuse] reaction known as "degreaser's flush" when associated with consumption of ethanol), and 1,1,1-trichloroethane (Glamorene Spot Remover, Scotchgard, typewriter correction fluid). An acute lethal oral dose is 0.5 to 5 mL/kg.

Dangerous additives to the hydrocarbons can be summed up with the mnemonic CHAMP: C, camphor (demoting agent); H, halogenated hydrocarbons; A, aromatic hydrocarbons; M, metals (heavy); and P, pesticides. Ingestion of these substances may warrant gastric emptying with a small-bore nasogastric tube.

Heavy hydrocarbons have high viscosity, low volatility, and minimal gastrointestinal absorption, so gastric decontamination is not necessary. Examples are asphalt (tar), machine oil, motor oil (lubricating oil, engine oil), home heating oil, and petroleum jelly (mineral oil).

Laboratory Investigations

The ECG, ABG, pulmonary function, serum electrolytes, and serial chest radiographs should be continuously monitored. Liver and renal function should be monitored in cases of inhalation of aromatic hydrocarbons.

Management

Asymptomatic patients who ingested small amounts of aliphatic petroleum distillates can be followed at home by telephone for development of signs of aspiration (cough, wheezing, tachypnea, and dyspnea) for 4 to 6 hours. Inhalation of any hydrocarbon vapors in a closed space can produce intoxication. The victim must be removed from the environment, have oxygen administered, and receive respiratory support.

Gastrointestinal decontamination is not advised in cases of hydrocarbon ingestion that usually do not cause systemic toxicity (aliphatic petroleum distillates, heavy hydrocarbons). In cases of ingestion of hydrocarbons that cause systemic toxicity in small amounts (aromatic hydrocarbons, halogenated hydrocarbons), the clinician should pass a small-bore nasogastric tube and aspirate if the ingestion was within 2 hours and if spontaneous vomiting has not occurred. Some toxicologists advocate ipecac-induced emesis under medical supervision instead of small-bore nasogastric gastric lavage; we do not.

Patients with altered mental status should have their airway protected because of concern about aspiration. The use of activated charcoal has been suggested, but there are no scientific data as to effectiveness and it may produce vomiting. Activated charcoal

may, however, be useful in adsorbing toxic additives such as pesticides or co-ingestants.

The symptomatic patient who is coughing, gagging, choking, or wheezing on arrival has probably aspirated. The clinician should provide supportive respiratory care and supplemental oxygen, while monitoring pulse oximetry, ABG, chest radiograph, and ECG. The patient should be admitted to the intensive care unit. A chest radiograph for aspiration may be positive as early as 30 minutes after ingestion, and almost all are positive within 6 hours. Negative chest radiographs within 4 hours do not rule out aspiration.

Bronchospasm is treated with a nebulized β -adrenergic agonist and intravenous aminophylline if necessary. Epinephrine should be avoided because of susceptibility to dysrhythmias. Cyanosis in the presence of a normal arterial P_{aO_2} may be a result of methemoglobinemia that requires therapy with methylene blue. Corticosteroids and prophylactic antimicrobial agents have not been shown to be beneficial. (Fever or leukocytosis may be produced by the chemical pneumonitis itself.)

Most infiltrations resolve spontaneously in 1 week; lipid pneumonia may last up to 6 weeks. It is not necessary to surgically treat pneumatoceles that develop because they usually resolve. Dysrhythmias may require α - and β -adrenergic antagonists or cardioversion.

There is no role for enhanced elimination procedures.

Methylene chloride is metabolized over several hours to carbon monoxide. See treatment of carbon monoxide poisoning. Halogenated hydrocarbons are hepatorenal toxins; therefore, hepatorenal function should be monitored. *N*-acetylcysteine therapy may be useful if there is evidence of hepatic damage.

Extracorporeal membrane oxygenation (ECMO) has been used successfully for a few patients with life-threatening respiratory failure. Surfactant used for hydrocarbon aspiration was found to be detrimental.

Disposition

Asymptomatic patients with small ingestions of petroleum distillates can be managed at home. Symptomatic patients with abnormal chest radiographic, oxygen saturation, or ABG findings should be admitted. Patients who become asymptomatic and have normal oxygenation and a normal repeat radiograph can be discharged.

Iron

There are more than 100 iron over-the-counter preparations for supplementation and treatment of iron deficiency anemia.

Toxic Mechanism

Toxicity depends on the amount of elemental iron available in various salts (gluconate 12%, sulfate 20%, fumarate 33%, lactate 19%, chloride 21% of elemental iron), not the amount of the salt. Locally, iron is corrosive and may cause fluid loss, hypovolemic shock, and perforation. Excessive free unbound iron in the blood is directly toxic to the vasculature and leads to the release of vasoactive substances, which produces vasodilation. In cases of overdose, iron deposits injure mitochondria in the liver, the kidneys, and the myocardium. The exact mechanism of cellular damage is not clear but is thought to be related to free radical formation.

Toxic Dose

The therapeutic dose is 6 mg/kg/d of elemental iron. An elemental iron dose of 20 to 40 mg/kg may produce mild self-limited gastrointestinal symptoms, 40 to 60 mg/kg produces moderate toxicity, more than 60 mg/kg produces severe toxicity and is potentially lethal, and more than 180 mg/kg is usually fatal without treatment. Children's chewable vitamins with iron have between 12 and 18 mg of elemental iron per tablet or 0.6 mL of liquid drops. These preparations rarely produce toxicity unless very large quantities are ingested and have never caused death.

Kinetics

Absorption occurs chiefly in the upper small intestine. Ferrous (+2) iron is absorbed into the mucosal cells, where it is oxidized to the

ferric (+3) state and bound to ferritin. Iron is slowly released from ferritin into the plasma, where it binds to transferrin and is transported to specific tissues for production of hemoglobin (70%), myoglobin (5%), and cytochrome. About 25% of iron is stored in the liver and spleen. In cases of overdose, larger amounts of iron are absorbed because of direct mucosal corrosion. There is no mechanism for the elimination of iron (elimination is 1 to 2 mg/d) except through bile, sweat, and blood loss.

Manifestations

Serious toxicity is unlikely if the patient remains asymptomatic for 6 hours and has a negative abdominal radiograph. Iron intoxication can produce five phases of toxicity. The phases may not be distinct from one another.

Phase I. Gastrointestinal mucosal injury occurs 30 minutes to 12 hours postingestion. Vomiting starts within 30 minutes to 1 hour of ingestion and is persistent; hematemesis and bloody diarrhea may occur; abdominal cramps, fever, hyperglycemia, and leukocytosis may occur. Enteric-coated tablets may pass through the stomach without causing symptoms. Acidosis and shock can occur within 6 to 12 hours.

Phase II. A latent period of apparent improvement occurs over 8 to 12 hours postingestion.

Phase III. Systemic toxicity phase occurs 12 to 48 hours postingestion with cardiovascular collapse and severe metabolic acidosis.

Phase IV. Two to 4 days postingestion, hepatic injury associated with jaundice, elevated liver enzymes, and prolonged prothrombin time occur. Kidney injury with proteinuria and hematuria occur. Pulmonary edema, disseminated intravascular coagulation, and *Yersinia enterocolitica* sepsis can occur.

Phase V. Four to 8 weeks postingestion, pyloric outlet or intestinal stricture may cause obstruction or anemia secondary to blood loss.

Laboratory Investigations

Iron poisoning produces anion gap metabolic acidosis. Monitoring should include complete blood cell counts, blood glucose level, serum iron, stools and vomitus for occult blood, electrolytes, acid-base balance, urinalysis and urinary output, liver function tests, and BUN and creatinine levels. Blood type and match should be obtained.

Serum iron measurements taken at the proper time correlate with the clinical findings. The lavender top Vacutainer tube contains EDTA, which falsely lowers serum iron. One must obtain the serum iron measurement before administering deferoxamine. Serum iron levels of less than 350 $\mu\text{g/dL}$ at 2 to 6 hours predict an asymptomatic course; levels of 350 to 500 $\mu\text{g/dL}$ are usually associated with mild gastrointestinal symptoms; those greater than 500 $\mu\text{g/dL}$ have a 20% risk of shock and serious iron toxicity. A follow-up serum iron measurement after 6 hours may not be elevated even in cases of severe poisoning, but a serum iron measurement taken at 8 to 12 hours is useful to exclude delayed absorption from a bezoar or sustained-release preparation. The total iron-binding capacity is not necessary.

Adult iron tablet preparations are radiopaque before they dissolve by 4 hours postingestion. A "negative" abdominal radiograph more than 4 hours postingestion does not exclude iron poisoning.

Patients who develop high fevers and signs of sepsis following iron overdose should have blood and stool cultures checked for *Yersinia enterocolitica*.

Management

Gastrointestinal decontamination should involve immediate induction of emesis in cases of ingestions of elemental iron of greater than 40 mg/kg if vomiting has not already occurred. Activated charcoal is ineffective. An abdominal radiograph should be obtained after emesis to determine the success of gastric emptying. Children's chewable vitamins and liquid iron preparations are not radiopaque. If radiopaque iron is still present, whole-bowel irrigation with polyethylene glycol solution should be considered. In extreme

cases, removal by endoscopy or surgery may be necessary because coalesced iron tablets produce hemorrhagic infarction in the bowel and perforation peritonitis.

Deferoxamine (Desferal) in a dose of about 100 mg binds 8.5 to 9.35 mg of free iron in the serum. The deferoxamine infusion should not exceed 15 mg/kg/h or 6 g daily, but faster rates (up to 45 mg/kg) and larger daily amounts have been administered and tolerated in extreme cases of iron poisoning (>1000 mg/dL). The deferoxamine-iron complex is hemodialyzable if renal failure develops.

Indications for chelation therapy are any of the following:

- Very large, symptomatic ingestions
- Serious clinical intoxication (severe vomiting and diarrhea [often bloody], severe abdominal pain, metabolic acidosis, hypotension, or shock)
- Symptoms that persist or progress to more serious toxicity
- Serum iron level greater than 500 mg/dL

Chelation should be performed as early as possible within 12 to 18 hours to be effective. One should start the infusion slowly and gradually increase to avoid hypotension.

Adult respiratory distress syndrome has developed in patients with high doses of deferoxamine for several days; infusions longer than 24 hours should be avoided.

The end point of treatment is when the patient is asymptomatic and the urine clears if it was originally a positive “vin rosö” color.

For supportive therapy, intravenous bicarbonate may be needed to correct the metabolic acidosis. Hypotension and shock treatment may require volume expansion, vasopressors, and blood transfusions. The physician should attempt to keep the urinary output at greater than 2 mL/kg/h. Coagulation abnormalities and overt bleeding require blood products or vitamin K. Pregnant patients are treated in a fashion similar to any other patient with iron poisoning.

Hemodialysis and hemoperfusion are ineffective. Exchange transfusion has been used in single cases of massive poisonings in children.

Disposition

The asymptomatic or minimally symptomatic patient should be observed for persistence and progression of symptoms or development of toxicity signs (gastrointestinal bleeding, acidosis, shock, altered mental state). Patients with mild self-limited gastrointestinal symptoms who become asymptomatic or have no signs of toxicity for 6 hours are unlikely to have a serious intoxication and can be discharged after psychiatric clearance, if needed. Patients with moderate or severe toxicity should be admitted to the intensive care unit.

Isoniazid

Isoniazid is a hydrazide derivative of vitamin B₃ (nicotinamide) and is used as an antituberculosis drug.

Toxic Mechanism

Isoniazid produces pyridoxine deficiency by increasing the excretion of pyridoxine (vitamin B₆) and by inhibiting pyridoxal 5-phosphate (the active form of pyridoxine) from acting with L-glutamic acid decarboxylase to form γ -aminobutyric acid (GABA), the major CNS neurotransmitter inhibitor, resulting in seizures. Isoniazid also blocks the conversion of lactate to pyruvate, resulting in profound and prolonged lactic acidosis.

Toxic Dose

The therapeutic dose is 5 to 10 mg/kg (maximum 300 mg) daily. A single acute dose of 15 mg/kg lowers the seizure threshold; 35 to 40 mg/kg produces spontaneous convulsions; more than 80 mg/kg produces severe toxicity. A fatal dose in adults is 4.5 to 15 g. The malnourished patients, those with a previous seizure disorder, alcoholic patients, and slow acetylators are more susceptible to isoniazid toxicity. In cases of chronic intoxication, 10 mg/kg/d produces hepatitis in 10% to 20% of patients but less than 2% at doses of 3 to 5 mg/kg/d.

Kinetics

Absorption from intestine occurs in 30 to 60 minutes, and onset is in 30 to 120 minutes, with peak levels of 5 to 8 μ g/mL within 1 to 2 hours. Volume distribution is 0.6 L/kg, with minimal protein binding.

Elimination is by liver acetylation to a hepatotoxic metabolite, acetyl-isoniazid, which is then hydrolyzed to isonicotinic acid. In slow acetylators, isoniazid has a half-life of 140 to 460 minutes (mean 5 hours), and 10% to 15% is eliminated unchanged in the urine. Most (45% to 75%) whites and 50% of African blacks are slow acetylators, and, with chronic use (without pyridoxine supplements), they may develop peripheral neuropathy. In fast acetylators, isoniazid has a half-life of 35 to 110 minutes (mean 80 minutes), and 25% to 30% is excreted unchanged in the urine. About 90% of Asians and patients with diabetes mellitus are fast acetylators and may develop hepatitis on chronic use.

In patients with overdose and hepatic disease, the serum half-life may increase. Isoniazid inhibits the metabolism of phenytoin (Dilantin), diazepam, phenobarbital, carbamazepine (Tegretol), and prednisone. These drugs also interfere with the metabolism of isoniazid. Ethanol may decrease the half-life of isoniazid but increase its toxicity.

Manifestations

Within 30 to 60 minutes, nausea, vomiting, slurred speech, dizziness, visual disturbances, and ataxia are present. Within 30 to 120 minutes, the major clinical triad of severe overdose includes refractory convulsions (90% of overdose patients have one or more seizures), coma, and resistant severe lactic acidosis (secondary to convulsions), often with a plasma pH of 6.8.

Laboratory Investigations

Isoniazid produces anion gap metabolic acidosis. Therapeutic levels are 5 to 8 μ g/mL and acute toxic levels are greater than 20 μ g/mL. These levels are not readily available to assist in making decisions in acute overdose situations. One should monitor the blood glucose (often hyperglycemia), electrolytes (often hyperkalemia), bicarbonate, ABGs, liver function tests (elevations occur with chronic exposure), BUN, and creatinine.

Management

Seizures must be controlled. Pyridoxine and diazepam should be administered concomitantly through different IV sites. Pyridoxine (vitamin B₆) is given in a dose of 1 g for each gram of isoniazid ingested. If the dose ingested is unknown, at least 5 g of pyridoxine should be given intravenously. Pyridoxine is administered in 50 mL D₅W or 0.9% saline over 5 minutes intravenously. It must not be administered in the same bottle as sodium bicarbonate. Intravenous pyridoxine is repeated every 5 to 20 minutes until the seizures are controlled. Total doses of pyridoxine up to 52 g have been safely administered; however, patients given 132 and 183 g of pyridoxine have developed a persistent crippling sensory neuropathy.

Diazepam is administered concomitantly with pyridoxine but at a different site. They work synergistically. Diazepam should be administered intravenously slowly, 0.3 mg/kg at a rate of 1 mg/min in children or 10 mg at a rate of 5 mg/min in adults. After the seizures are controlled, the remainder of the pyridoxine is administered (1 g/1 g isoniazid) or a total dose of 5 g.

Phenobarbital or phenytoin is ineffective and should not be used.

In asymptomatic patients or patients without seizures, pyridoxine has been advised by some toxicologists prophylactically in gram-for-gram doses in cases of large overdoses (<80 mg/kg per dose) of isoniazid, although there are no studies to support this recommendation. In comatose patients, pyridoxine administration may result in the patient's rapid regaining of consciousness. Correction of acidosis may occur spontaneously with pyridoxine administration and correction of the seizures. Sodium bicarbonate should be administered if acidosis persists.

Hemodialysis is rarely needed because of antidotal therapy and the short half-life of isoniazid, but it may be used as an adjunct for

cases of uncontrollable acidosis and seizures. Hemoperfusion has not been adequately evaluated. Diuresis is ineffective.

Disposition

Asymptomatic or mildly symptomatic patients who become asymptomatic can be observed in the emergency department for 4 to 6 hours. Larger amounts of isoniazid may warrant pyridoxine administration and longer periods of observation. Intentional ingestions necessitate psychiatric evaluation before the patient is discharged. Patients with convulsions or coma should be admitted to the intensive care unit.

Isopropanol (Isopropyl Alcohol)

Isopropanol can be found in rubbing alcohol, solvents, and lacquer thinner. Coma has occurred in children sponged for fever with isopropanol. See Table 10 for ethanol features of alcohols and glycols.

Toxic Mechanism

Isopropanol is a gastric irritant. It is metabolized to acetone, a CNS and myocardial depressant. It inhibits gluconeogenesis. Normal propyl alcohol is related to isopropyl alcohol but is more toxic.

Toxic Dose

A toxic dose of 0.5 to 1 mg/kg of 70% isopropanol (1 mL/kg of 70%) produces a blood isopropanol plasma concentration of 70 mg/dL. The CNS depressant potency is twice that of ethanol.

Kinetics

Onset of action is within 30 to 60 minutes, and peak is 1 hour post-ingestion. Volume distribution is 0.6 kg/L. Isopropyl alcohol metabolizes to acetone. Its excretion is renal.

Note: The serum isopropyl concentration and amount ingested can be estimated using the same equation as is used in ethanol kinetics and substituting the specific gravity of 0.785 for isopropyl alcohol.

Manifestations

Ethanol-like inebriation occurs, with an acetone odor to the breath, gastritis, occasionally with hematemesis, acetonuria, and acetone-mia without systemic acidosis.

Depression of the CNS occurs: lethargy at blood isopropyl alcohol levels of 50 to 100 mg/dL, coma at levels of 150 to 200 mg/dL, potentially death in adults at levels greater than 240 mg/dL.

Hypoglycemia and seizures may occur.

Laboratory Investigation

Monitoring of blood isopropyl alcohol levels (not readily available in all institutions), acetone, glucose, and ABG should be maintained. The osmolal gap increases 1 mOsm per 5.9 mg/dL of isopropyl alcohol and 1 mOsm per 5.5 mg/dL of acetone. The absence of excess acetone in the blood (normal is 0.3 to 2 mg/dL) within 30 to 60 minutes or excess acetone in the urine within 3 hours excludes the possibility of significant isopropanol exposure.

Management

The airway must be protected with intubation, and assisted ventilation administered if necessary. If the patient is hypoglycemic, glucose should be administered. Supportive treatment is similar to that for ethanol ingestions.

Gastrointestinal decontamination has no role in the treatment of isopropanol ingestion. Hemodialysis is warranted in cases of life-threatening overdose but is rarely needed. A nephrologist should be consulted if the blood isopropanol plasma concentration is greater than 250 mg/dL.

Disposition

Symptomatic patients with concentrations greater than 100 mg/dL require at least 24 hours of close observation for resolution and should be admitted. If the patient is hypoglycemic, hypotensive, or comatose, he or she should be admitted to the intensive care unit.

Lead

Acute lead intoxication is rare and usually occurs by inhalation of lead, resulting in severe intoxication and often death. Lead fumes can be produced by burning of lead batteries or use of a heat gun to remove lead paint. Acute lead intoxication also occurs from exposure to high concentrations of organic lead (e.g., tetraethyl lead).

Chronic lead poisoning occurs most often in children 6 months to 6 years of age who are exposed in their environment and in adults in certain occupations (Table 17). In the United States, the prevalence in children aged 1 to 5 years with a venous blood lead greater than 10 µg/dL decreased from 88.2% in a 1976–1980 survey to 8.9% in a 1988–1991 survey as a consequence of measures to reduce lead in the environment, particularly leaded gasoline. However, an estimated 1.7 million children between 1 and 5 years of age and more than 1 million workers in over 100 different occupations still have blood lead levels greater than 10 µg/dL.

Toxic Dose

In cases of chronic lead poisoning, a daily intake of more than 5 µg/kg/d in children or more than 150 µg/d in adults can give a positive lead balance. In 1991, the Centers for Disease Control and Prevention (CDC) recommended routine screening for all children younger than 6 years of age. In children a venous blood level greater than 10 µg/dL was determined to be a threshold of concern. The average venous blood level in the United States is 4 µg/dL. In cases of occupational exposure (see Table 17), a venous blood level greater than 40 µg/dL is indicative of increased lead absorption in adults.

Toxic Mechanism

Lead affects the sulfhydryl enzyme systems, the immature CNS, the enzymes of heme synthesis, vitamin D conversion, the kidneys, the bones, and growth. Lead alters the tertiary structure of cell proteins by denaturing them and causing cell death. Risk factors are mouth-ing behavior of infants and children and excessive oral behavior (pica), living in the inner city, a poorly maintained home, and poor nutrition (e.g., low calcium and iron). The CDC questionnaire given in Table 18 is recommended at every pediatric visit. If any answers to the CDC questionnaire are “positive,” a blood

TABLE 17 Occupations Associated With Lead Exposure

Lead production or smelting	Demolition of ships and bridges
Production of illicit whiskey	Battery manufacturing
Brass, copper, and lead foundries	Machining/grinding lead alloys
Radiator repair	Welding of old painted metals
Scrap handling	Thermal paint stripping of old buildings
Sanding of old paint	Ceramic glaze/pottery mixing
Lead soldering	
Cable stripping	
Worker or janitor at a firing range	

Modified from Rempel D: The lead-exposed worker. *JAMA* 262:533, 1989.

TABLE 18 CDC Questionnaire: Priority Groups for Lead Screening

1. Children age 6–72 months (was 12–36 months) who live in or are frequent visitors to older, deteriorated housing built before 1960.
2. Children age 6–72 months who live in housing built prior to 1960 with recent, ongoing, or planned renovation or remodeling.
3. Children age 6–72 months who are siblings, housemates, or playmates of children with known lead poisoning.
4. Children age 6–72 months whose parents or other household members participate in a lead-related industry or hobby.
5. Children age 6–72 months who live near active lead smelters, battery recycling plants, or other industries likely to result in atmospheric lead release.

TABLE 19 Sources of Lead

PRODUCT	LEAD CONTENT (%) BY DRY WEIGHT
Paint	0.06
Solder	0.6
Plastic additives	2.0
Priming inks	2.0
Plumbing fixtures	2.0
Pesticides	0.1
Stained glass panes	0.1
Wine bottle foils	0.1
Construction material	0.1
Fertilizers	0.1
Glazes, enamels	0.06
Toys/recreational games	0.1
Curtain weights	0.1
Fishing weights	0.1

screening test for lead should be administered. To be more accurate, however, identifying lead exposure studies have suggested that the questionnaire will have to be modified for each individual community because it has had poor sensitivity (40%) and specificity (60%) as it stands.

Table 19 lists sources of lead. The number one source is deteriorating lead-based paint, which forms leaded dust. Lead concentrations in indoor paint were not reduced to safer (0.06%) levels until 1978. Lead can also be produced by improper interior or exterior home renovation (scraping or demolition). It is found in pre-1960 built homes. The use of leaded gasoline (limited in 1973) resulted in residue from leaded motor vehicle emissions. Lead persists in the soil near major highways and in deteriorating homes and buildings. Vegetables grown in contaminated soil may contain lead.

Oil refineries and lead-processing smelters produce lead residue. Food cans produced in Mexico contain lead solder (95% do not in the United States). Lead water pipes (until 1950) and lead solder (until 1986) deliver lead-containing drinking water (calcium deposits, however, may offer some protection). Water at a

consumer's tap should contain less than 15 parts per billion (ppb) of lead (Table 20).

For occupational exposure, see Table 17. The Occupational Safety and Health Administration (OSHA) standards require employers to provide showering and clothes changing facilities for personnel working with lead; however, businesses with fewer than 25 employees are exempt from the regulation. The OSHA lead standard of 1978 set a limit of 60 µg/dL for occupational exposure to lead. At a blood lead level of 60 µg/dL, a worker should be removed from lead exposure and not allowed back until his or her lead level is below 40 µg/dL. Many authorities believe that this level should be lower. The lead residue on the clothes of the workers may represent a hazard to the family. Other occupations that are potential sources of lead exposure include plumbers, pipe fitters, lead miners, auto repairers, ship-builders, printers, steel welders and cutters, construction workers, and rubber product manufacturers.

Leaded pots to make molds for "kusmusha" tea represent lead exposure. Imported pottery lined with ceramic glaze can leach large amounts of lead into acids (e.g., citrus fruit juices).

Hobbies associated with lead exposure are listed in Box 1. Some "traditional" folk remedies or cosmetics that contain lead include the following:

BOX 1 Hobbies Associated With Lead Exposure

Casting of ammunition
 Collecting antique pewter
 Collecting/painting lead toys (e.g., soldiers and figures)
 Ceramics or glazed pottery
 Refinishing furniture
 Making fishing weights
 Home renovation
 Jewelry making, lead solder
 Glass blowing, lead glass
 Bronze casting
 Print making and other fine arts (when lead white, flake white, chrome yellow pigments are involved)
 Liquor distillation
 Hunting and target shooting
 Painting
 Car and boat repair
 Burning/engraving lead-painted wood
 Making stained leaded glass
 Copper enameling

TABLE 20 Agency Regulations and Recommendations Concerning Lead Content

AGENCY	SPECIMEN	LEVEL	COMMENTS
CDC	Blood (child)	10 µg/dL	Investigate community
OSHA	Blood (adult)	60 µg/dL	Medical removal from work
OSHA	Air	50 µg/m ³	PEL*
	Air	0.75 µg/m ³	Tetraethyl or tetramethyl
ACGIH	Air	150 µg/m ³	TWA [†]
EPA	Air	1.5 µg/m ³	Three-month average
EPA	Water	15 µg/L (ppb)	5 ppb circulating
EPA	Food	100 µg/d	Advisory
FDA	Wine	300 ppm	Plan to reduce to 200 ppm
EPA	Soil/dust	50 ppm	
CPSC	Paint	600 ppm (0.06%) by dry weight	

*PEL = permissible exposure limit (highest level over an 8-hour workday).

[†]TWA = time-weighted average (air concentration for 8-hour workday and 40-hour workweek).

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; CDC = Centers for Disease Control and Prevention; CPSC = Consumer Product Safety Commission; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; OSHA = Occupational Safety and Health Administration.

- “Azarcon por empacho” (“Maria Louisa” 90% to 95% lead trioxide): a bright orange powder used in Hispanic culture, especially Mexican, for digestive problems and diarrhea.
- “Greta” (4% to 90% lead): a yellow powder “por empacho” (“empacho” refers to a variety of gastrointestinal symptoms), used in Hispanic cultures, especially Mexican.
- “Pay-loo-ah”: an orange-red powder used for rash and fever in Southeast Asian cultures, especially among Northern Laos Hmong immigrants.
- “Alkohl” (Al-kohl, kohl, suma 5% to 92% lead): a black powder used in Middle Eastern, African, and Asian cultures as a cosmetic and an umbilical stump astringent.
- “Farouk”: an orange granular powder with lead used in Saudi Arabian culture.
- “Bint Al Zahab”: used to treat colic in Saudi Arabian culture.
- “Surma” (23% to 26% lead): a black powder used in India as a cosmetic and to improve eyesight.
- “Bali goli”: a round black bean that is dissolved in “grippe water,” used by Asian and Indian cultures to aid digestion.

Cases of substance abuse involving lead poisoning have been reported, in which the patient sniffs leaded gasoline or uses improperly synthesized amphetamines.

Kinetics

Absorption of lead is 10% to 15% of the ingested dose in adults; in children, up to 40% is absorbed, especially in cases of iron deficiency anemia. With inhalation of fumes, absorption is rapid and complete. Volume distribution in blood (0.9% of total body burden) is 95% in red blood cells. Lead passes through the placenta to the fetus and is present in breast milk.

Organic lead is metabolized in the liver to inorganic lead. Its half-life is 35 to 40 days in blood; in soft tissue, the half-life is 45 days and in bone (99% of the lead), the half-life is 28 years. The major elimination route is the stool, 80% to 90%, and then renal 10% (80 g/d) and hair, nails, sweat, and saliva. Nine percent of organic lead is excreted in the urine per day.

Manifestations

Adverse health effects are given in Table 21 and include the following.

Hematologic. Lead inhibits γ -aminolevulinic acid dehydratase (early in the synthesis of heme) and ferrochelatase (transfers iron to ferritin for incorporation of iron into protoporphyrin to produce heme). Anemia is a late finding. Decreased heme synthesis starts at $>40 \mu\text{g/dL}$. Basophilic stippling occurs in 20% of severe lead poisoning.

Neurologic. Segmental demyelination and peripheral neuropathy, usually of the motor type (wrist and ankle drop), occurs in workers. A venous blood level of lead greater than $70 \mu\text{g/dL}$ (usually $>100 \mu\text{g/dL}$), produces encephalopathy in children (symptom mnemonic “PAINT”: P, persistent forceful vomiting and papilledema; A, ataxia; I, intermittent stupor and lucidity; N, neurologic coma and refractory convulsions; T, tired and lethargic). Decreased cognitive abilities have been reported with a venous blood level of lead greater than $10 \mu\text{g/dL}$, including behavioral problems, decreased attention span, and learning disabilities. IQ scores may begin to decrease at $15 \mu\text{g/dL}$. Encephalopathy is rare in adults.

Renal. Nephropathy as a result of damaged capillaries and glomerulus can occur at a venous blood level of lead greater than $80 \mu\text{g/dL}$, but recent studies show renal damage and hypertension with low venous blood levels. A direct correlation between hypertension and venous blood level over $30 \mu\text{g/dL}$ has been reported. Lead reduces excretion of uric acid, and high-level exposure may be associated with hyperuricemia and “saturnine gout,” Fanconi’s syndrome (aminoaciduria and renal tubular acidosis), and tubular fibrosis.

Reproductive. Spontaneous abortion, transient delay in the child’s development (catch up at age 5 to 6 years), decreased sperm count, and abnormal sperm morphology can occur with lead exposure. Lead crosses the placenta and fetal blood levels reach 75% to 100% of maternal blood levels. Lead is teratogenic.

TABLE 21 Summary of Lead-Induced Health Effects in Adults and Children

BLOOD LEAD LEVEL ($\mu\text{g/dL}$)	AGE GROUP	HEALTH EFFECT
>100	Adult	Encephalopathic signs and symptoms
>80	Adult Child	Anemia Encephalopathy Chronic nephropathy (e.g., aminoaciduria)
>70	Adult Child	Clinically evident peripheral neuropathy Colic and other gastrointestinal symptoms
>60	Adult	Female reproductive effects CNS disturbance symptoms (i.e., sleep disturbances, mood changes, memory and concentration problems, headaches)
>50	Adult Adult Child	Decreased hemoglobin production Decreased performance on neurobehavioral tests Altered testicular function Gastrointestinal symptoms (i.e., abdominal pain, constipation, diarrhea, nausea, anorexia) Peripheral neuropathy*
>40	Adult	Decreased peripheral nerve conduction Hypertension, age 40–59 years Chronic neuropathy*
>25	Adult	Elevated erythrocyte protoporphyrin in males
15–25	Adult	Elevated erythrocyte protoporphyrin in females
>10	Child Fetus	Decreased intelligence and growth Impaired learning Reduced birth weight* Impaired mental ability Preterm delivery

*Controversial.

From Anonymous: Implementation of the Lead Contamination Control Act of 1988. *MMWR Morb Mortal Wkly Rep* 41:288, 1992.

Metabolic. Decreased cytochrome P450 activity alters the metabolism of medication and endogenously produced substances. Decreased activation of cortisol and decreased growth are caused by interference in vitamin conversion (25-hydroxyvitamin D to 1,25-hydroxyvitamin D) at venous blood levels of 20 to $30 \mu\text{g/dL}$.

Other Manifestations. Abnormalities of thyroid, cardiac, and hepatic function occur in adults. Abdominal colic is seen in children at doses greater than $50 \mu\text{g/dL}$. “Lead gum lines” at the dental border of the gingiva can occur in cases of chronic lead poisoning.

Laboratory Investigations

Serial venous blood lead measurements are taken on days 3 and 5 during treatment and 7 days after chelation therapy, then every 1 to 2 weeks for 8 weeks, and then every month for 6 months. Intravenous infusion should be stopped at least 1 hour before blood lead levels are measured. Table 22 gives a classification of blood lead concentrations in children.

One should evaluate CBC, serum ferritin, erythrocyte protoporphyrin ($>35 \mu\text{g/dL}$ indicates lead poisoning as well as iron deficiency and other causes), electrolytes, serum calcium and phosphorus, urinalysis, BUN, and creatinine. Abdominal and long bone radiographs may be useful in certain circumstances to identify radiopaque material in bowel and “lead lines” in proximal tibia

TABLE 22 Classification of Blood Lead Concentrations in Children

BLOOD LEAD (µg/dL)	RECOMMENDED INTERVENTIONS
<9	None
10–14	Community intervention Repeat blood lead in 3 months
15–19	Individual case management Environmental counseling Nutritional counseling Repeat blood lead in 3 months
20–44	Medical referral Environmental inspection/abatement Nutritional counseling Repeat blood lead in 3 months
45–69	Environmental inspection/abatement Nutritional counseling Pharmacologic therapy DMSA succimer oral or CaNa ₂ EDTA parenteral Repeat every 2 weeks for 6–8 weeks, then monthly for 4–6 months
>70	Hospitalization in intensive care unit Environmental inspection/abatement Pharmacologic therapy Dimercaprol (BAL in oil) IM initial alone Dimercaprol IM and CaNa ₂ EDTA together Repeat every week

Abbreviations: BAL = British anti-Lewisite; CaNa₂EDTA = edetate calcium disodium; DMSA = dimercaptosuccinic acid; IM = intramuscular.

(which occur after prolonged exposure in association with venous blood lead levels greater than 50 µg/dL).

Neuropsychological tests are difficult to perform in young children but should be considered at the end of treatment, especially to determine auditory dysfunction.

Management

The basis of treatment is removal of the source of lead. Cases of poisoning in children should be reported to local health department and cases of occupational poisoning should be reported to OSHA. The source must be identified and abated and dust controlled by wet mopping. Cold water should be let to run for 2 minutes before being used for drinking. Planting shrubbery (not vegetables) in contaminated soil will keep children away.

Supportive care should be instituted, including measures to deal with refractory seizures (continued antidotal therapy, diazepam,

and possibly neuromuscular blockers), with the hepatic and renal failure, and intravascular hemolysis in severe cases. Seizures are treated with diazepam followed by neuromuscular blockers if needed.

Lead does not bind to activated charcoal. One must not delay chelation therapy for complete gastrointestinal decontamination in severe cases. Whole-bowel irrigation has been used prior to treatment. Some authorities recommend abdominal radiographs followed by gastrointestinal decontamination if necessary before switching to oral therapy. Chelation therapy can be used for patients in whom venous blood level of lead is greater than 45 µg/dL in children and greater than 80 µg/dL in adults or in adults with lower levels who are symptomatic or who have a “positive” lead mobilization test result (not routinely performed at most centers) (Table 23).

Succimer (dimercaptosuccinic acid, DMSA, Chemet), a derivative of British anti-Lewisite (BAL), is an oral agent for chelation in children with a venous blood level of greater than 45 µg/dL. The recommended dose is 10 mg/kg every 8 hours for 5 days, then every 12 hours for 14 days. DMSA is under investigation to determine its role in children with a venous blood level less than 45 µg/dL. Although not approved for adults, it has been used in the same dosage. Monitoring should be maintained by CBC, liver transaminases, and urinalysis for adverse effects.

D-Penicillamine (Cuprimine) is another oral chelator that is given in doses of 20 to 40 mg/kg/d not to exceed 1 g/d. However, it is not FDA approved and has a 10% adverse reaction rate. Nevertheless, D-penicillamine has been used infrequently in adults and children with elevated venous blood lead levels.

Edetate calcium disodium (ethylene diaminetetra-acetic acid or CaNa₂EDTA Versenate) is a water-soluble chelator given intramuscularly (with 0.5% procaine) or intravenously. The calcium in the compound is displaced by divalent and trivalent heavy metals, forming a soluble complex, which is stable at physiologic pH (but not at acid pH) and enhances lead clearance in the urine. EDTA usually is administered intravenously, especially in severe cases. It must not be administered until adequate urine flow is established. It may redistribute lead to the brain; therefore, BAL may be given first at a venous blood lead level of greater than 55 µg/dL in children and greater than 100 µg/dL in adults. Phlebitis occurs at a concentration greater than 0.5 mg/mL. Alkalinization of the urine may be helpful. CaNa₂EDTA should not be confused with sodium EDTA (disodium edetate), which is used to treat hypercalcemia; inadvertent use may produce severe hypocalcemia.

Dimercaprol (BAL) is a peanut oil-based dithiol (two sulfhydryl molecules) that combines with one atom of lead to form a heterocyclic stable ring complex. It is usually reserved for patients in whom venous blood lead is greater than 70 µg/dL, and it chelates

TABLE 23 Pharmacologic Chelation Therapy of Lead Poisoning

DRUG	ROUTE	DOSE	DURATION	PRECAUTIONS	MONITOR
Dimercaprol (BAL in oil)	IM	3–5 mg/kg q4–6h	3–5 days	G6PD deficiency Concurrent iron therapy	AST/ALT enzymes
CaNa ₂ EDTA (calcium disodium versenate)	IM/IV	50 mg/kg per day	5 days	Inadequate fluid intake Renal impairment Penicillin allergy	Urinalysis, BUN Creatinine Urinalysis, BUN
D-Penicillamine (Cuprimine)	PO	10 mg/kg per day increase 30 mg/kg over 2 weeks	6–20 weeks	Concurrent iron therapy; lead exposure Renal impairment	Creatinine, CBC
2,3-Dimercaptosuccinic acid (DMSA; succimer)	PO	10 mg/kg per dose 3 times daily 10 mg/kg per dose twice daily for 14 days	19 days	AST/ALT Concurrent iron therapy G6PD deficiency lead exposure	AST/ALT

Abbreviations: ALT = alanine aminotransferase; AST = aspartate transaminase; BAL = British anti-Lewisite; bid = twice daily; BUN = blood urea nitrogen; CBC = complete blood count; G6PD = glucose-6-phosphate dehydrogenase; IM = intramuscular; IV = intravenous; PO = oral; tid = three times daily.

red blood cell lead, enhancing its elimination through the urine and bile. It crosses the blood-brain barrier. Approximately 50% of patients have adverse reactions, including bad metallic taste in the mouth, pain at the injection site, sterile abscesses, and fever.

A venous blood lead level greater than 70 $\mu\text{g}/\text{dL}$ or the presence of clinical symptoms suggesting encephalopathy in children is a potentially life-threatening emergency. Management should be accomplished in a medical center with a pediatric intensive care unit by a multidisciplinary team including a critical care specialist, a toxicologist, a neurologist, and a neurosurgeon. Careful monitoring of neurologic status, fluid status, and intracranial pressure should be undertaken if necessary. These patients need close monitoring for hemodynamic instability. Hydration should be maintained to ensure renal excretion of lead. Fluids, renal and hepatic function, and electrolyte levels should be monitored.

While waiting for adequate urine flow, therapy should be initiated with intramuscular dimercaprol (BAL) only (25 mg/kg/d divided into 6 doses). Four hours later, the second dose of BAL should be given intramuscularly, concurrently with CaNa_2EDTA 50 mg/kg/d as a single dose infused over several hours or as a continuous infusion. The double therapy is continued until the venous blood level is less than 40 $\mu\text{g}/\text{dL}$.

As long as the venous blood level is greater than 40 $\mu\text{g}/\text{dL}$, therapy is continued for 72 hours and followed by two alternatives: either parenteral therapy with two drugs (CaNa_2EDTA and BAL) for 5 days or continuation of therapy with CaNa_2EDTA alone if a good response is achieved and the venous blood level of lead is less than 40 $\mu\text{g}/\text{dL}$. If one cannot get the venous blood lead report back, one should continue therapy with both BAL and EDTA for 5 days. In patients with lead encephalopathy, parenteral chelation should be continued with both drugs until the patient is clinically stable before changing therapy. Mannitol and dexamethasone can reduce the cerebral edema, but their role in lead encephalopathy is not clear. Surgical decompression is not recommended to reduce cerebral edema in these cases.

If BAL and CaNa_2EDTA are used together, a minimum of 2 days with no treatment should elapse before another 5-day course of therapy is considered. The 5-day course is repeated with CaNa_2EDTA alone if the blood lead level rebounds to greater than 40 $\mu\text{g}/\text{dL}$ or in combination with BAL if the venous blood level is greater than 70 $\mu\text{g}/\text{dL}$. If a third course is required, unless there are compelling reasons, one should wait at least 5 to 7 days before administering the course.

Following chelation therapy, a period of equilibration of 10 to 14 days should be allowed and a repeat venous blood lead concentration should be obtained. If the patient is stable enough for oral intake, oral succimer 30 mg/kg/d in three divided doses for 5 days followed by 20 mg/kg/d in two divided doses for 14 days has been suggested, but there are limited data to support this recommendation. Therapy should be continued until venous blood lead level is less than 20 $\mu\text{g}/\text{dL}$ in children or less than 40 $\mu\text{g}/\text{dL}$ in adults.

Chelators combined with lead are hemodialyzable in the event of renal failure.

Disposition

All patients with a venous blood lead level of greater than 70 $\mu\text{g}/\text{dL}$ or who are symptomatic should be admitted. If a child is hospitalized, all lead hazards must be removed from the home environment before allowing the child to return. The source must be eliminated by environmental and occupational investigations. The local health department should be involved in dealing with children who are lead poisoned, and OSHA should be involved with cases of occupational lead poisoning. Consultation with a poison control center or experienced toxicologist is necessary when chelating patients. Follow-up venous blood lead concentrations should be obtained within 1 to 2 weeks and followed every 2 weeks for 6 to 8 weeks, then monthly for 4 to 6 months if the patient required chelation therapy. All patients with venous blood level greater than 10 $\mu\text{g}/\text{dL}$ should be followed at least every 3 months until two venous blood lead concentrations are 10 $\mu\text{g}/\text{dL}$ or three are less than 15 $\mu\text{g}/\text{dL}$.

Lithium (Eskalith, Lithane)

Lithium is an alkali metal used primarily in the treatment of bipolar psychiatric disorders. Most intoxications are cases of chronic overdose. One gram of lithium carbonate contains 189 mg (5.1 mEq) of lithium; a regular tablet contains 300 mg (8.12 mEq) and a sustained-release preparation contains 450 mg or 12.18 mEq.

Toxic Mechanism

The brain is the primary target organ of toxicity, but the mechanism is unclear. Lithium may interfere with physiologic functions by acting as a substitute for cellular cations (sodium and potassium), depressing neural excitation and synaptic transmission.

Toxic Dose

A dose of 1 mEq/kg (40 mg/kg) of lithium will give a peak serum lithium concentration about 1.2 mEq/L. The therapeutic serum lithium concentration in cases of acute mania is 0.6 to 1.2 mEq/L, and for maintenance it is 0.5 to 0.8 mEq/L. Serum lithium concentration levels are usually obtained 12 hours after the last dose. The toxic dose is determined by clinical manifestations and serum levels after the distribution phase.

Acute ingestion of twenty 300-mg tablets (300 mg increases the serum lithium concentration by 0.2 to 0.4 mEq/L) in adults may produce serious intoxication. Chronic intoxication can be produced by conditions listed below that can decrease the elimination of lithium or increase lithium reabsorption in the kidney.

The risk factors that predispose to chronic lithium toxicity are febrile illness, impaired renal function, hyponatremia, advanced age, lithium-induced diabetes insipidus, dehydration, vomiting and diarrhea, and concomitant use of other drugs, such as thiazide and spironolactone diuretics, nonsteroidal antiinflammatory drugs, salicylates, angiotensin-converting enzyme inhibitors (e.g., captopril), serotonin reuptake inhibitors (e.g., fluoxetine [Prozac]), and phenothiazines.

Kinetics

Gastrointestinal absorption of regular-release preparations is rapid; serum lithium concentration peaks in 2 to 4 hours and is complete by 6 to 8 hours. The onset of toxicity may occur at 1 to 4 hours after acute overdose but usually is delayed because lithium enters the brain slowly. Absorption of sustained-release preparations and the development of toxicity may be delayed 6 to 12 hours.

Volume distribution is 0.5 to 0.9 L/kg. Lithium is not protein bound. The half-life after a single dose is 9 to 13 hours; at steady state, it may be 30 to 58 hours. The renal handling of lithium is similar to that of sodium: glomerular filtration and reabsorption (80%) by the proximal renal tubule. Adequate sodium must be present to prevent lithium reabsorption. More than 90% of lithium is excreted by the kidney, 30% to 60% within 6 to 12 hours.

Manifestations

The examiner must distinguish between side effects, acute intoxication, acute or chronic toxicity, and chronic intoxications. Chronic is the most common and dangerous type of intoxication.

Side effects include fine tremor, gastrointestinal upset, hypothyroidism, polyuria and frank diabetes insipidus, dermatologic manifestations, and cardiac conduction deficits. Lithium is teratogenic.

Patients with acute poisoning may be asymptomatic, with an early high serum lithium concentration of 9 mEq/L, and deteriorate as the serum lithium concentration falls by 50% and the lithium distributes to the brain and the other tissues. Nausea and vomiting may occur within 1 to 4 hours, but the systemic manifestations are usually delayed several more hours. It may take as long as 3 to 5 days for serious symptoms to develop. Acute toxicity and acute or chronic toxicity are manifested by neurologic findings, including weakness, fasciculations, altered mental state, myoclonus, hyperreflexia, rigidity, coma, and convulsions with limbs in hypertension. Cardiovascular effects are nonspecific and occur at therapeutic doses, flat T or inverted T waves, atrioventricular block, and

prolonged QT interval. Lithium is not a primary cardiotoxin. Cardiogenic shock occurs secondary to CNS toxicity. Chronic intoxication is associated with manifestations at lower serum lithium concentrations. There is some correlation with manifestations, especially at higher serum lithium concentrations. Although the levels do not always correlate with the manifestations, they are more predictive in cases of severe intoxication. A serum lithium concentration greater than 3.0 mEq/L with chronic intoxication and altered mental state indicates severe toxicity. Permanent neurologic sequelae can result from lithium intoxication.

Laboratory Investigations

Monitoring should include CBC (lithium causes significant leukocytosis), renal function, thyroid function (chronic intoxication), ECG, and electrolytes. Serum lithium concentrations should be determined every 2 to 4 hours until levels are close to therapeutic range. Cross-reactions with green-top Vacutainer specimen tubes containing heparin will spuriously elevate serum lithium concentration 6 to 8 mEq/L.

Management

Vital function must be established and maintained. Seizure precautions should be instituted and seizures, hypotension, and dysrhythmias treated. Evaluation should include examination for rigidity and hyperreflexia signs, hydration, renal function (BUN, creatinine), and electrolytes, especially sodium. The examiner should inquire about diuretic and other drug use that increase serum lithium concentration, and the patient must discontinue the drugs. If the patient is on chronic therapy, the lithium should be discontinued. Serial serum lithium concentrations should be obtained every 4 hours until serum lithium concentration peaks and there is a downward trend toward almost therapeutic range, especially in sustained-release preparations. Vital signs should be monitored, including temperature, and ECG and serial neurologic examinations should be undertaken, including mental status and urinary output. Nephrology consultation is warranted in case of a chronic and elevated serum lithium concentration (>2.5 mEq/L), a large ingestion, or altered mental state.

An intravenous line should be established and hydration and electrolyte balance restored. Serum sodium level should be determined before 0.9% saline fluid is administered in patients with chronic overdose because hyponatremia may be present from diabetes insipidus. Although current evidence supports an initial 0.9% saline infusion (200 mL/h) to enhance excretion of lithium, once hydration, urine output, and normonatremia are established, one should administer 0.45% saline and slow the infusion (100 mL/h) for all patients.

Gastric lavage is often not recommended in cases of acute ingestion because of the large size of the tablets, and it is not necessary after chronic intoxication. Activated charcoal is ineffective. For sustained-release preparations, whole-bowel irrigation may be useful but is not proven. Sodium polystyrene sulfonate (Kayexalate), an ion exchange resin, is difficult to administer and has been used only in uncontrolled studies. Its use is not recommended.

Hemodialysis is the most efficient method for removing lithium from the vascular compartment. It is the treatment of choice for patients with severe intoxication with an altered mental state, those with seizures, and anuric patients. Long runs are used until the serum lithium concentration is less than 1 mEq/L because of extensive re-equilibration. Serum lithium concentration should be monitored every 4 hours after dialysis for rebound. Repeated and prolonged hemodialysis may be necessary. A lag in neurologic recovery can be expected.

Disposition

An acute asymptomatic lithium overdose cannot be medically cleared on the basis of single lithium level. Patients should be admitted if they have any neurologic manifestations (altered mental status, hyperreflexia, stiffness, or tremor). Patients should be admitted to the intensive care unit if they are dehydrated, have renal impairment, or have a high or rising lithium level.

Methanol (Wood Alcohol, Methyl Alcohol)

The concentration of methanol in Sterno fuel is 4% and it contains ethanol, in windshield washer fluid it is 30% to 60%, and in gas-line antifreeze it is 100%.

Toxic Mechanism

Methanol is metabolized by alcohol dehydrogenase to formaldehyde, which is metabolized to formate. Formate inhibits cytochrome oxidase, producing tissue hypoxia, lactic acidosis, and optic nerve edema. Formate is converted by folate-dependent enzymes to carbon dioxide.

Toxic Dose

The minimal toxic amount is approximately 100 mg/kg. Serious toxicity in a young child can be produced by the ingestion of 2.5 to 5.0 mL of 100% methanol. Ingestion of 5-mL 100% methanol by a 10-kg child produces estimated peak blood methanol of 80 mg/dL. Ingestion of 15 mL 40% methanol was lethal for a 2-year-old child in one report. A fatal adult oral dose is 30 to 240 mL 100% (20 to 150 g). Ingestion of 6 to 10 mL 100% causes blindness in adults. The toxic blood concentration is greater than 20 mg/dL; very serious toxicity and potential fatality occur at levels greater than 50 mg/dL.

Kinetics

Onset of action can start within 1 hour but may be delayed up to 12 to 18 hours by metabolism to toxic metabolites. It may be delayed longer if ethanol is ingested concomitantly or in infants. Peak blood methanol concentration is 1 hour. Volume distribution is 0.6 L/kg (total body water).

For metabolism, see *Toxic Mechanism*.

Elimination is through metabolism. The half-life of methanol is 8 hours; with ethanol blocking it is 30 to 35 hours; and with hemodialysis 2.5 hours.

Manifestations

Metabolism creates a delay in onset for 12 to 18 hours or longer if ethanol is ingested concomitantly. Initial findings are as follows:

- 0 to 6 hours: Confusion, ataxia, inebriation, formaldehyde odor on breath, and abdominal pain can be present, but the patient may be asymptomatic. *Note:* Methanol produces an osmolar gap (early), and its metabolite formate produces the anion gap metabolic acidosis (see later). Absence of osmolar or anion gap does not always exclude methanol intoxication.
- 6 to 12 hours: Malaise, headache, abdominal pain, vomiting, visual symptoms, including hyperemia of optic disc, "snow vision," and blindness can be seen.
- More than 12 hours: Worsening acidosis, hyperglycemia, shock, and multiorgan failure develop, with death from complications of intractable acidosis and cerebral edema.

Laboratory Investigation

Methanol can be detected on some chromatography drug screens if specified. Methanol and ethanol levels, electrolytes, glucose, BUN, creatinine, amylase, and ABG should be monitored every 4 hours. Formate levels correlate more closely than blood methanol concentration with severity of intoxication and should be obtained if possible.

Management

One should protect the airway by intubation to prevent aspiration and administer assisted ventilation as needed. If needed, 100% oxygen can be administered. A nephrologist should be consulted early regarding the need for hemodialysis.

Gastrointestinal decontamination procedures have no role.

Metabolic acidosis should be treated vigorously with sodium bicarbonate 2 to 3 mEq/kg intravenously. Large amounts may be needed.

Antidote therapy is initiated to inhibit metabolism if the patient has a history of ingesting more than 0.4 mL/kg of 100% with the following conditions:

- Blood methanol level is greater than 20 mg/dL
- The patient has osmolar gap not accounted for by other factors
- The patient is symptomatic or acidotic with increased anion gap and/or hyperemia of the optic disc.

The ethanol or fomepizole therapy outlined below can be used.

Ethanol Therapy. Ethanol should be initiated immediately if fomepizole is unavailable (see *Fomepizole Therapy*). Alcohol dehydrogenase has a greater affinity for ethanol than ethylene glycol. Therefore, ethanol blocks the metabolism of ethylene glycol.

Ethanol should be administered intravenously (oral administration is less reliable) to produce a blood ethanol concentration of 100 to 150 mg/dL. The loading dose is 10 mL/kg of 10% ethanol administered intravenously concomitantly with a maintenance dose of 10% ethanol at 1.0 mL/kg/h. This dose may need to be increased to 2 mL/kg/h in patients who are heavy drinkers. The blood ethanol concentration should be measured hourly and the infusion rate should be adjusted to maintain a concentration of 100 to 150 mg/dL.

Fomepizole Therapy. Fomepizole (Antizol, 4-methylpyrazole) inhibits alcohol dehydrogenase more reliably than ethanol and it does not require constant monitoring of ethanol levels and adjustment of infusion rates. Fomepizole is available in 1 g/mL vials of 1.5 mL. The loading dose is 15 mg/kg (0.015 mL/kg) IV, maintenance dose is 10 mg/kg (0.01 mL/kg) every 12 hours for 4 doses, then 15 mg/kg every 12 hours until the ethylene glycol levels are less than 20 mg/dL. The solution is prepared by being mixed with 100 mL of 0.9% saline or D₅W. Fomepizole can be given to patients requiring hemodialysis but should be dosed as follows:

Dose at the beginning of hemodialysis:

- If less than 6 hours since last Antizol dose, do not administer dose
- If more than 6 hours since last dose, administer next scheduled dose

Dosing during hemodialysis:

- Dose every 4 hours
- Dosing at the time hemodialysis is completed:
- If less than 1 hour between last dose and end dialysis, do not administer dose at end of dialysis
- If 1 to 3 hours between last dose and end dialysis, administer one half of next scheduled dose
- If more than 3 hours between last dose and end dialysis, administer next scheduled dose

Maintenance dosing off hemodialysis:

- Give the next scheduled dose 12 hours from the last dose administered

Hemodialysis increases the clearance of both methanol and formate 10-fold over renal clearance. A blood methanol concentration greater than 50 mg/dL has been used as an indication for hemodialysis, but recently some toxicologists from the New York City Poison Center recommended early hemodialysis in patients with blood methanol concentration greater than 25 mg/dL because it may be able to shorten the course of intoxication if started early. One should continue to monitor methanol levels and/or formate levels every 4 hours after the procedure for rebound. Other indications for early hemodialysis are significant metabolic acidosis and electrolyte abnormalities despite conventional therapy and if visual or neurologic signs or symptoms are present.

A serum formate level greater than 20 mg/dL has also been used as a criterion for hemodialysis, although this is often not readily available through many laboratories. If hemodialysis is used, the infusion rate of 10% ethanol should be increased 2.0 to 3.5 mL/kg/h. The blood ethanol concentration and glucose level should be obtained every 2 hours.

Therapy is continued with both ethanol and hemodialysis until the blood methanol level is undetectable, there is no acidosis, and the patient has no neurologic or visual disturbances. This may require several days.

Hypoglycemia is treated with intravenous glucose. Doses of folic acid (Leucovorin) and folic acid have been used successfully in animal investigations to enhance formate metabolism to carbon

dioxide and water. Leucovorin 1 mg/kg up to 50 mg IV is administered every 4 hours for several days.

An initial ophthalmologic consultation and follow-up are warranted.

Disposition

All patients who have ingested significant amounts of methanol should be referred to the emergency department for evaluation and blood methanol concentration measurement. Ophthalmologic follow-up of all patients with methanol intoxications should be arranged.

Monoamine Oxidase Inhibitors

Nonselective monoamine oxidase inhibitors (MAOIs) include the hydrazines phenelzine (Nardil) and isocarboxazid (Marplan), and the nonhydrazine tranylcypromine (Parnate). Furazolidone (Furoxone) and pargyline (Eutonyl)² are also considered nonselective MAOIs. Moclobemide,² which is available in many countries but not the United States, is a selective MAO-A inhibitor. MAO-B inhibitors include selegiline (Eldepryl), an antiparkinsonism agent, which does not have similar toxicity to MAO-A and is not discussed. Selectivity is lost in an overdose. MAOIs are used to treat severe depression.

Toxic Mechanism

Monoamine oxidase enzymes are responsible for the oxidative deamination of both endogenous and exogenous catecholamines such as norepinephrine. MAO-A in the intestinal wall also metabolizes tyramine in food. MAOIs permanently inhibit MAO enzymes until a new enzyme is synthesized after 14 days or longer. The toxicity results from the accumulation, potentiation, and prolongation of the catecholamine action followed by profound hypotension and cardiovascular collapse.

Toxic Dose

Toxicity begins at 2 to 3 mg/kg and fatalities occur at 4 to 6 mg/kg. Death has occurred after a single dose of 170 mg of tranylcypromine in an adult.

Kinetics

Structurally, MAOIs are related to amphetamines and catecholamines. The hydrazine peak levels are at 1 to 2 hours; metabolism is hepatic acetylation; and inactive metabolites are excreted in the urine. For the nonhydrazines, peak levels occur at 1 to 4 hours, and metabolism is via the liver to active amphetamine-like metabolites.

The onset of symptoms in a case of overdose is delayed 6 to 24 hours after ingestion, peak activity is 8 to 12 hours, and duration is 72 hours or longer. The peak of MAO inhibition is in 5 to 10 days and lasts as long as 5 weeks.

Manifestations

Manifestations of an acute ingestion overdose of MAO-A inhibitors are as follows:

Phase I. An adrenergic crisis occurs, with delayed onset for 6 to 24 hours, and may not reach peak until 24 hours. The crisis starts as hyperthermia, tachycardia, tachypnea, dysarthria, transient hypertension, hyperreflexia, and CNS stimulation.

Phase II. Neuromuscular excitation and sympathetic hyperactivity occur with increased temperature greater than 40°C (104°F), agitation, hyperactivity, confusion, fasciculations, twitching, tremor, masseter spasm, muscle rigidity, acidosis, and electrolyte abnormalities. Seizures and dystonic reactions may occur. The pupils are mydriatic, sometimes nonreactive with “ping-pong gaze.”

Phase III. CNS depression and cardiovascular collapse occur in cases of severe overdose as the catecholamines are depleted. Symptoms usually resolve within 5 days but may last 2 weeks.

Phase IV. Secondary complications occur, including rhabdomyolysis, cardiac dysrhythmias, multiorgan failure, and coagulopathies.

²Not available in the United States.

Biogenic interactions usually occur while the patient is on therapeutic doses of MAOI or shortly after they are discontinued (30 to 60 minutes), before the new MAO enzyme is synthesized. The following substances have been implicated: indirect acting sympathomimetics such as amphetamines, serotonergic drugs, opioids (e.g., meperidine, dextromethorphan), tricyclic antidepressants, specific serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine [Prozac], sertraline [Zoloft], paroxetine [Paxil]), tyramine-containing foods (e.g., wine, beer, avocados, cheese, caviar, chocolate, chicken liver), and L-tryptophan. SSRIs should not be started for at least 5 weeks after MAOIs have been discontinued.

In mild cases, usually caused by foods, headache and hypertension develop and last for several hours. In severe cases, malignant hypertension and severe hyperthermia syndromes consisting of hypertension or hyperthermia, altered mental state, skeletal muscle rigidity, shivering (often beginning in the masseter muscle), and seizures may occur.

The serotonin syndrome, which may be a result of inhibition of serotonin metabolism, has similar clinical findings to those of malignant hyperthermia and may occur with or without hyperthermia or hypertension.

Chronic toxicity clinical findings include tremors, hyperhidrosis, agitation, hallucinations, confusion, and seizures and may be confused with withdrawal syndromes.

Laboratory Investigations

Monitoring of the ECG, cardiac monitoring, CPK, ABG, pulse oximeter, electrolytes, blood glucose, and acid-base balance should be maintained.

Management

In the case of MAOI overdose, ipecac-induced emesis should not be used. Only activated charcoal alone should be used.

If the patient is admitted to the hospital and is well enough to eat, a nontyramine diet should be ordered.

Extreme agitation and seizures can be controlled with benzodiazepines and barbiturates. Phenytoin is ineffective. Nondepolarizing neuromuscular blockers (not depolarizing succinylcholine) may be needed in severe cases of hyperthermia and rigidity. If the patient has severe hypertension (catecholamine mediated), phentolamine (Regitine), a parenteral β -blocking agent, 3 to 5 mg intravenously, or labetalol (Normodyne), a combination of an α -blocking agent and a β -blocker, 20-mg intravenous bolus, should be given. If malignant hypertension with rigidity is present, a short-acting nitroprusside and benzodiazepine can be used. Hypertension is often followed by severe hypotension, which should be managed by fluid and vasopressors. **Caution:** Vasopressor therapy should be administered at lower doses than usual because of exaggerated pharmacologic response. Norepinephrine is preferred to dopamine, which requires release of intracellular amines.

Cardiac dysrhythmias are treated with standard therapy but are often refractory, and cardioversion and pacemakers may be needed.

For malignant hyperthermia, dantrolene (Dantrium), a nonspecific peripheral skeletal relaxing agent, is administered, which inhibits the release of calcium from the sarcoplasm. Dantrolene is reconstituted with 60 mL sterile water without bacteriostatic agents. Glass equipment must not be used, and the drug must be protected from light and used within 6 hours. Loading dose is 2 to 3 mg/kg intravenously as a bolus, and the loading dose is repeated until the signs of malignant hyperthermia (tachycardia, rigidity, increased end-tidal CO_2 , and temperature) are controlled. Maximum total dose is 10 mg/kg to avoid hepatotoxicity.

When malignant hyperthermia has subsided, 1 mg/kg IV is given every 6 hours for 24 to 48 hours, then orally 1 mg/kg every 6 hours for 24 hours to prevent recurrence. There is a danger of thrombophlebitis following peripheral dantrolene, and it should be administered through a central line if possible. In addition one should administer external cooling and correct metabolic acidosis and electrolyte disturbances. Benzodiazepine can be used for sedation. Dantrolene does not reverse central dopamine blockade; therefore,

bromocriptine mesylate (Parlodel) 2.5 to 10 mg should be given orally or through a nasogastric tube three times a day.

Rhabdomyolysis and myoglobinuria are treated with fluids. Urine alkalinization should also be treated.

Hemodialysis and hemoperfusion are of no proven value.

Biogenic amine interactions are managed symptomatically, similar to cases of overdose. For the serotonin syndrome cyproheptadine (Periactin), a serotonin blocker, 4 mg orally every hour for three doses, or methysergide (Sansert), 2 mg orally every 6 hours for three doses, should be considered. The effectiveness of these drugs has not been proven.

Disposition

All patients who have ingested more than 2 mg/kg of an MAOI should be admitted to the hospital for 24 hours of observation and monitoring in the intensive care unit because the life-threatening manifestations may be delayed. Patients with drug or dietary interactions that are mild may not require admission if symptoms subside within 4 to 6 hours and the patients remain asymptomatic. Patients with symptoms that persist or require active intervention should be admitted to the intensive care unit.

Opioids (Narcotic Opiates)

Opioids are used for analgesia, as antitussives, and as antidiarrheal agents and are illicit agents (heroin, opium) used in substance abuse. Tolerance, physical dependency, and withdrawal may develop.

Toxic Mechanism

At least four main opioid receptors have been identified. The μ receptor is considered the most important for central analgesia and CNS depression. The κ and δ receptors predominate in spinal analgesia. The σ receptors may mediate dysphoria. Death is a consequence of dose-dependent CNS respiratory depression or secondary to pulmonary aspiration or noncardiac pulmonary edema. The mechanism of noncardiac pulmonary edema is unknown.

Dextromethorphan can interact with MAOIs, causing severe hyperthermia, and may cause the serotonin syndrome (see *Selective Serotonin Reuptake Inhibitors*). Dextromethorphan inhibits the metabolism of norepinephrine and serotonin and blocks the reuptake of serotonin. It is found as a component of a large number of non-prescription cough and cold remedies.

Toxic Dose

The toxic dose depends on the specific drug, route of administration, and degree of tolerance. For therapeutic and toxic doses, see Table 24. In children, respiratory depression has been produced by 10 mg of morphine or methadone, 75 mg of meperidine, and 12.5 mg of diphenoxylate. Infants younger than 3 months of age are more susceptible to respiratory depression. The dose should be reduced by 50%.

Kinetics

Oral onset of analgesic effect of morphine is 10 to 15 minutes; the action peaks in 1 hour and lasts 4 to 6 hours. With sustained-release preparations, the duration is 8 to 12 hours. Opioids are 90% metabolized in the liver by hepatic conjugation and 90% excreted in the urine as inactive compounds. Volume distribution is 1 to 4 L/kg. Protein binding is 35% to 75%. The typical plasma half-life of opiates is 2 to 5 hours, but that of methadone is 24 to 36 hours. Morphine metabolites include morphine-3-glucuronide (inactive) and morphine-6-glucuronide (active) and normorphine (active). Meperidine (Demerol) is rapidly hydrolyzed by tissue esterases into the active metabolite normeperidine, which has twice the convulsant activity of meperidine. Heroin (diacetylmorphine) is deacetylated within minutes to 6-monacetylmorphine and morphine. Propoxyphene (Darvon) has a rapid onset of action, and death has occurred within 15 to 30 minutes after a massive overdose. Propoxyphene is metabolized to norpropoxyphene, an active metabolite with convulsive, cardiac dysrhythmic, and heart block properties. Symptoms of diphenoxylate overdose appear within 1 to 4 hours. It is metabolized into the active metabolite difenoxin,

TABLE 24 Doses and Onset and Duration of Action of Common Opioids

DRUG	ADULT ORAL DOSE	CHILD ORAL DOSE	ONSET OF ACTION	DURATION OF ACTION	ADULT FATAL DOSE
Camphored tincture of opium	25 mL	0.25–0.50 mL/kg (0.4 mg/mL)	15–30 min	4–5 h	NA
Codeine	30–180 mg >1 mg/kg is toxic in a child, above 200 mg in adult	0.5–1 mg/kg	15–30 min	4–6 h	800 mg
Dextromethorphan	15 mg 10 mg/kg is toxic	0.25 mg/kg	15–30 min	3–6 h	NA
Diacetylmorphine; street heroin is less than 10% pure	60 mg	NA	15–30 min	3–4 h	100 mg
Diphenoxylate atropine (Lomotil)	5–10 mg 7.5 mg is toxic in a child, 300 mg is toxic in adult	NA	120–240 min	14 h	300 mg
Fentanyl (Duragesic)	0.1–0.2 mg	0.001–0.002 mg/kg	7–8 min	Intramuscular: ½–2 h	1.0 mg
Hydrocodone with APAP (Lortab)	5–30 mg	0.15 mg/kg	30 min	3–4 h	100 mg
Hydromorphone (Dilaudid)	4 mg	0.1 mg/kg	15–30 min	3–4 h	100 mg
Meperidine (Demerol)	100 mg	1–1.5 mg/kg	10–45 min	3–4 h	350 mg
Methadone (Dolophine)	10 mg	0.1 mg/kg	30–60 min	4–12 h	120 mg
Morphine	10–60 mg Oral dose is 6 times parenteral dose, MS Contin sustained-release prep	0.1–0.2 mg/kg	<20 min	4–6 h	200 mg
Oxycodone APAP (Percocet)	5 mg	NA	15–30 min	4–5 h	NA
Pentazocine (Talwin)	50–100 mg	NA	15–30 min	3–4 h	NA
Propoxyphene (Darvon)	65–100 mg	NA	30–60 min	2–4 h	700 mg

which is five times more active as a regular respiratory depressant agent. Death has been reported in children after ingestion of a single tablet.

Manifestations

Initially, mild intoxication produces miosis, dull face, drowsiness, partial ptosis, and “nodding” (head drops to chest then bobs up). Larger amounts produce the classic triad of miotic pupils (exceptions below), respiratory depression, and depressed level of consciousness (flaccid coma). The blood pressure, pulse, and bowel activity are decreased.

Dilated pupils do not exclude opioid intoxication. Some exceptions to the miosis effect include dextromethorphan (paralyzes iris), fentanyl, meperidine, and diphenoxylate (rarely). Physiologic disturbances including acidosis, hypoglycemia, hypoxia, and postictal state, or a co-ingestant may also produce mydriasis.

Usually, the muscles are flaccid, but increased muscle tone can be produced by meperidine and fentanyl (chest rigidity). Seizures are rare but can occur with ingestion of codeine, meperidine, propoxyphene, and dextromethorphan. Hallucinations and agitation have been reported.

Pruritus and urticaria are caused by histamine release by some opioids or by sulfite additives.

Noncardiac pulmonary edema may occur after an overdose, especially with intravenous heroin abuse. Cardiac effects include vasodilation and hypotension. A heart murmur in an intravenous addict suggests endocarditis. Propoxyphene can produce delayed cardiac dysrhythmias.

Fentanyl is 100 times more potent than morphine and can cause chest wall muscle rigidity. Some of its derivatives are 2000 times more potent than morphine.

Laboratory Investigations

For patients with overdose, one should obtain and monitor ABG, blood glucose, and electrolyte levels; chest radiographs; and ECG.

For drug abusers, one should consider testing for hepatitis B, syphilis, and HIV antibody (HIV testing usually requires consent). Blood opioid concentrations are not useful. They confirm diagnosis (morphine therapeutic dose, 65 to 80 ng/mL; toxic, <200 ng/mL), but are not useful for making a therapeutic decision. Cross-reactions can occur with Vick’s Formula 44, poppy seeds, and other opioids (codeine and heroin are metabolized to morphine). Naloxone 4 mg IV was not associated with a positive enzyme multiplied immunoassay technique urine screen at 60 minutes, 6 hours, or 48 hours.

Management

Supportive care should be instituted, particularly an endotracheal tube and assisted ventilation. Temporary ventilation can be provided by a bag-valve mask with 100% oxygen. The patient should be placed on a cardiac monitor, have intravenous access established, and have specimens for ABG, glucose, electrolytes, BUN, and creatinine levels, CBC, coagulation profile, liver function, toxicology screen, and urinalysis taken.

For gastrointestinal decontamination, emesis should not be induced, but activated charcoal can be administered if bowel sounds are present.

If it is suspected that the patient is an addict, he or she should be restrained first and then 0.1 mg of naloxone (Narcan) should be administered. The dose should be doubled every 2 minutes until the patient responds or 10 to 20 mg has been given. If the patient is not suspected to be an addict, then 2 mg every 2 to 3 minutes to total of 10 to 20 mg is administered.

It is essential to determine whether there is a complete response to naloxone (mydriasis, improvement in ventilation), because it is a diagnostic therapeutic test. A continuous naloxone infusion may be appropriate, using the “response dose” every hour. Repeat doses of naloxone may be necessary because the effects of many opioids can last much longer than naloxone does (30 to 60 minutes). Methadone ingestions may require a naloxone infusion for 24 to 48 hours.

Half of the response dose may need to be repeated in 15 to 20 minutes, after the infusion has been started.

Acute iatrogenic withdrawal precipitated by the administration of naloxone to a dependent patient should not be treated with morphine or other opioids. Naloxone's effects are limited to 30 to 60 minutes (shorter than most opioids) and withdrawal will subside in a short time.

Nalmefene (Revox), an FDA-approved long-acting (4 to 8 hours) pure opioid antagonist, is being investigated, but its role in cases of acute intoxication is unclear and it could produce prolonged withdrawal. It may have a role in place of naloxone infusion.

Noncardiac pulmonary edema does not respond to naloxone, and the patient needs intubation, assisted ventilation, positive end-expiratory pressure, and hemodynamic monitoring. Fluids should be given cautiously in patients with opioid overdose because opioids stimulate the antidiuretic hormone.

If the patient is comatose, 50% glucose (3% to 4% of comatose opioid overdose patients have hypoglycemia) and thiamine should be given prior to naloxone. If the patient has seizures that are unresponsive to naloxone, one administers diazepam and examines for metabolic (hypoglycemia, electrolyte disturbances) causes and structural disturbances.

Hypotension is rare and should direct a search for another etiology. If the patient is agitated, hypoxia and hypoglycemia must be excluded before opioid withdrawal is considered as a cause. Complications to consider include urinary retention, constipation, rhabdomyolysis, myoglobinuria, hypoglycemia, and withdrawal.

Disposition

If a patient responds to intravenous naloxone, careful observation for relapse and the development of pulmonary edema is required, with cardiac and respiratory monitoring for 6 to 12 hours. Patients requiring repeated doses of naloxone or an infusion, or those who develop pulmonary edema, require intensive care unit admission and cannot be discharged from the intensive care unit until they are symptom free for 12 hours. Intravenous overdose complications are expected to be present within 20 minutes after injection, and discharge after 4 symptom-free hours has been recommended. Adults with oral overdose have delayed onset of toxicity and require 6 hours of observation. Children with oral opioid overdose should be admitted to the hospital for observation because of delayed toxicity. Some toxicologists advise restraining a patient who attempts to sign out against medical advice after treatment with naloxone, at least until the patient receives psychiatric evaluation.

Organophosphates and Carbamates

Cholinergic intoxication sources are insecticides (organophosphates or carbamates), some medications, and some mushrooms. Examples of organophosphate insecticides are malathion (low toxicity, median lethal dose [LD₅₀] 2800 mg/kg), chlorpyrifos, which has been removed from market (moderate toxicity), and parathion (high toxicity, LD₅₀ 2 mg/kg). Carbamate insecticides include carbaryl (low toxicity, LD₅₀ 500 mg/kg), propoxur (moderate toxicity, LD₅₀ 95 mg/kg), and aldicarb (high toxicity, LD₅₀ 0.9 mg/kg). Pharmaceuticals with carbamate properties include neostigmine (Prostigmin) and physostigmine (Antilirium). Cholinergic compounds also include the "G" nerve war weapons tabun (GA), sarin (GB), soman (GB), and venom X (VX).

Toxic Mechanism

Organophosphates phosphorylate the active site on red cell acetylcholinesterase and pseudocholinesterase in the serum, neuromuscular and parasympathetic neuroeffector junctions, and in the major synapses of the autonomic ganglia, causing irreversible inhibition. There are two types of organophosphate intoxication: (a) direct action by the parent compound (e.g., tetraethylpyrophosphate), or (b) indirect action by the toxic metabolite (e.g., parathion or malathion).

Carbamates (esters of carbonic acid) cause reversible carbamylation of the active site of the enzymes. When a critical amount,

greater than 50%, of cholinesterase is inhibited, acetylcholine accumulates and causes transient stimulation at cholinergic synapses and sympathetic terminals (muscarinic effect), the somatic nerves, the autonomic ganglia (nicotinic effect), and CNS synapses. Stimulation of conduction is followed by inhibition of conduction.

The major differences between the carbamates and the organophosphates are as follows: (a) carbamate toxicity is less and the duration is shorter; (b) carbamates rarely produce overt CNS effects (poor CNS penetration); (c) carbamate inhibition of the acetylcholinesterase enzyme is reversible and activity returns to normal rapidly; (d) pralidoxime, the enzyme regenerator, may not be necessary in the management of mild carbamate intoxication (e.g., carbaryl).

Toxic Dose

Parathion's minimum lethal dose is 2 mg in children and 10 to 20 mg in adults. The lethal dose of malathion is greater than 1375 mg/kg and that of chlorpyrifos is 25 g; the latter compound is unlikely to cause death.

Kinetics

Absorption is by all routes. The onset of acute ingestion toxicity occurs as early as 3 hours, usually before 12 hours and always before 24 hours. Lipid-soluble agents absorbed by the dermal route (e.g., fenthion) may have a delayed onset of more than 24 hours. Inhalation toxicity occurs immediately after exposure. Massive ingestion can produce intoxication within minutes.

Metabolism is via the liver. With some pesticides (e.g., parathion, malathion), the effects are delayed because they undergo hepatic microsomal oxidative metabolism to their toxic metabolites, the -oxons (e.g., paroxon, malaaxon).

The half-life of malathion is 2.89 hours and that of parathion is 2.1 days. The metabolites are eliminated in the urine and the presence of *p*-nitrophenol in the urine is a clue up to 48 hours after exposure.

Manifestations

Many organophosphates produce a garlic odor on the breath, in the gastric contents, or in the container. Diaphoresis, excessive salivation, miosis, and muscle twitching are helpful clues to diagnosis.

Early, a cholinergic (muscarinic) crisis develops that consists of parasympathetic nervous system activity. DUMBELS is the mnemonic for defecation, cramps, and increased bowel motility; urinary incontinence; miosis (mydriasis may occur in 20%); bronchospasm and bronchorrhea; excess secretion; lacrimation; and seizures. Bradycardia, pulmonary edema, and hypotension may be present.

Later, sympathetic and nicotinic effects occur, consisting of MATCH: muscle weakness and fasciculation (eyelid twitching is often present), adrenal stimulation and hyperglycemia, tachycardia, cramps in muscles, and hypertension. Finally, paralysis of the skeletal muscles ensues.

The CNS effects are headache, blurred vision, anxiety, ataxia, delirium and toxic psychosis, convulsions, coma, and respiratory depression. Cranial nerve palsies have been noted. Delayed hallucinations may occur.

Delayed respiratory paralysis and neurologic and neurobehavioral disorders have been described following certain organophosphate ingestions or dermal exposure. The "intermediate syndrome" is paralysis of proximal and respiratory muscles developing 24 to 96 hours after the successful treatment of organophosphate poisoning. A delayed distal polyneuropathy has been described with ingestion of certain organophosphates, such as triorthocresyl phosphate, bromoleptophos, and methomidophos.

Complications include aspiration, pulmonary edema, and acute respiratory distress syndrome.

Laboratory Investigations

Monitoring should include chest radiograph, blood glucose (nonketotic hyperglycemia is frequent), ABG, pulse oximetry, ECG, blood coagulation status, liver function, hyperamylasemia

(pancreatitis reported), and urinalysis for the metabolite alkyl phosphate paranitrophenol. Blood should be drawn for red blood cell cholinesterase determination before pralidoxime is given. The red blood cell cholinesterase activity roughly correlates with clinical severity. Mild poisoning is 20% to 50% of normal, moderate poisoning is 10% to 20% of normal, and severe poisoning is 10% of normal (>90% depressed). A postexposure rise of 10% to 15% in the cholinesterase level determined at least 10 to 14 days after the exposure confirms the diagnosis.

Management

Protection of health care personnel with clothing (masks, gloves, gowns, goggles) and respiratory equipment or hazardous material suits, as necessary, is called for. General decontamination consists of isolation, bagging, and disposal of contaminated clothing and other articles. Vital functions should be established and maintained. Cardiac and oxygen saturation monitoring are needed. Intubation and assisted ventilation may be needed. Secretions should be suctioned until atropinization drying is achieved.

Dermal decontamination involves prompt removal of clothing and cleansing of all affected areas of skin, hair, and eyes. Ocular decontamination involves irrigation with copious amounts of tepid water or 0.9% saline for at least 15 minutes. Gastrointestinal decontamination, if the ingestion was recent, involves the administration of activated charcoal.

Atropine sulfate can be given as an antidote. It is both a diagnostic and a therapeutic agent. Atropine counteracts the muscarinic effects but is only partially effective for the CNS effects (seizures and coma). Preservative-free atropine (no benzyl alcohol) should be used. If the patient is symptomatic (bradycardia or bronchorrhea), a test dose should be administered, 0.02 mg/kg in children or 1 mg in adults, intravenously. If no signs of atropinization are present (tachycardia, drying of secretions, and mydriasis), atropine should be administered immediately, 0.05 mg/kg in children or 2 mg in adults, every 5 to 10 minutes as needed to dry the secretions and clear the lungs. Beneficial effects are seen within 1 to 4 minutes and maximum effect in 8 minutes. The average dose in the first 24 hours is 40 mg, but 1000 mg or more has been required in severe cases. Glycopyrrolate (Robinul) can be used if atropine is not available. The maximum dose should be maintained for 12 to 24 hours, then tapered and the patient observed for relapse. Poisoning, especially with lipophilic agents (e.g., fenthion, chlorfenthion), may require weeks of atropine therapy. An alternative is a continuous infusion of atropine 8 mg in 100 mL 0.9% saline at rate of 0.02 to 0.08 mg/kg/h (0.25 to 1.0 mL/kg/h) with additional 1 to 5 mg boluses as needed to dry the secretions.

Pralidoxime chloride (Protopam) has both antinicotinic and antimuscarinic effects and possibly also CNS effects. Successful treatment with pralidoxime chloride may allow a reduction in the dose of atropine. Pralidoxime acts to reactivate the phosphorylated cholinesterases by binding the phosphate moiety on the esteritic site and displacing it. It should be given early before "aging" of phosphate bond produces tighter binding. However, recent reports indicate that pralidoxime chloride is beneficial even several days after the poisoning. Improvement is seen within 10 to 40 minutes. The initial dose of pralidoxime chloride is 1 to 2 g in 250 mL 0.89% saline over 5 to 10 minutes, maximum 200 mg/min, in adults or 25 to 50 mg/kg, maximum 4 mg/kg/min, in children younger than 12 years of age. The dose can be repeated every 6 to 12 hours for several days. An alternative is a continuous infusion of 1 g in 100 mL 0.89% saline at 5 to 20 mg/kg/h (0.5 to 12 mL/g/h) up to 500 mg/h and titrated to desired response. Maximum adult daily dose is 12 g. Cardiac and blood pressure monitoring is advised during and for several hours after the infusion. The end point is absence of fasciculations and return of muscle strength.

Contraindicated drugs include morphine, aminophylline, barbiturates, opioids, phenothiazine, reserpine-like drugs, parasympathomimetics, and succinylcholine.

Noncardiac pulmonary edema may require respiratory support. Seizures may respond to atropine and pralidoxime chloride but

often require anticonvulsants. Cardiac dysrhythmias may require electrical cardioversion or antidysrhythmic therapy if the patient is hemodynamically unstable. Extracorporeal procedures are of no proven value.

Disposition

Asymptomatic patients with normal examination findings after 6 to 8 hours of observation may be discharged. In cases of intentional poisoning, the patients require psychiatric clearance for discharge. Symptomatic patients should be admitted to the intensive care unit. Observation of milder cases of carbamate poisoning, even those requiring atropine, for 6 to 8 hours symptom-free may be sufficient to exclude significant toxicity. In cases of workplace exposure, OSHA should be notified.

Phencyclidine (Angel Dust)

Phencyclidine is an arylcyclohexylamine related to ketamine and chemically related to the phenothiazines. Originally a "dissociative" anesthetic banned in United States since 1979, it is now an illicit substance, with at least 38 analogues. It is inexpensively manufactured by "kitchen chemists" and is mislabeled as other hallucinogens. Improper phencyclidine synthesis may release cyanide when heated or smoked and can cause explosions.

Toxic Mechanism

The mechanism of phencyclidine is complex and not completely understood. It inhibits some neurotransmitters and causes a loss of pain sensation without depressing the CNS respiratory status. It stimulates α -adrenergic receptors and may act as a "false neurotransmitter." The effects are sympathomimetic, cholinergic, and cerebellar.

Toxic Dose

The usual dose of phencyclidine mixed with marijuana joints is 100 to 400 mg of phencyclidine. Joints or leaf mixtures contain 0.24% to 7.9% of PCP, 1 mg of PCP/150 leaves. Tablets contain 5 mg (the usual street dose). CNS effects at doses of 1 to 6 mg include hallucinations and euphoria, 6 to 10 mg produces toxic psychosis and sympathetic stimulation, 10 to 25 mg produces severe toxicity, and more than 100 mg has resulted in fatalities.

Kinetics

Phencyclidine is a lipophilic weak base, with a pKa of 8.5 to 9.5. It is rapidly absorbed when smoked and snorted, poorly absorbed from the acid stomach, and rapidly absorbed from the alkaline middle small intestine. It has an enterogastric secretion and is reabsorbed in the small intestine. The onset of action when smoked is 2 to 5 minutes, with a peak in 15 to 30 minutes. With oral ingestion, the onset is in 30 to 60 minutes and when taken intravenously it is immediate. Most adverse reactions in cases of overdose begin within 1 to 2 hours. Its duration of action at low doses is 4 to 6 hours and normality returns in 24 hours; in large overdoses, fluctuating coma may last 6 to 10 days.

Volume distribution is 6.2 L/kg. Phencyclidine concentrates in brain and adipose tissue. Protein binding is 70%. The route of elimination is by gastric secretion, liver metabolism, and 10% urinary excretion of conjugates and free phencyclidine. Renal excretion may be increased 50% with urinary acidification. The half-life is 1 hour (in cases of overdose, it is 11 to 89 hours).

Manifestations

The classic picture is bursts of horizontal, vertical, and rotary nystagmus, which is a clue to diagnosis (occurs in 50% of cases), miosis, hypertension, and fluctuating altered mental state. There is a wide spectrum of clinical presentations.

Mild intoxication with 1 to 6 mg produces drunken and bizarre behavior, agitation, rotary nystagmus, and blank stare. Violent behavior and sensory anesthesia make these patients insensitive to pain, self-destructive, and dangerous. Most are communicative within 1 to 2 hours, are alert and oriented in 6 to 8 hours, and recover completely in 24 to 48 hours.

Moderate intoxication with 6 to 10 mg produces excess salivation, hypertension, hyperthermia, muscle rigidity, myoclonus, and catatonia. Recovery of consciousness occurs in 24 to 48 hours and complete recovery in 1 week.

Severe intoxication with 10 to 25 mg results in opisthotonus, decerebrate rigidity, convulsions, prolonged fluctuating coma, and respiratory failure. Patients in this category have a high rate of medical complications. Recovery of consciousness occurs in 24 to 48 hours, with complete normality in a month. Medical complications include apnea, aspiration pneumonia, cardiac arrest, hypertensive encephalopathy, hyperthermia, intracerebral hemorrhage, psychosis, rhabdomyolysis and myoglobinuria, and seizures. Loss of memory and “flashbacks” last for months. Phencyclidine-induced depression and suicide have been reported.

Fatalities occur with ingestions of greater than 100 mg and with serum levels greater than 100 to 250 ng/mL.

Laboratory Investigations

Marked elevation of creatine kinase level may occur. Values greater than 20,000 units have been reported. Urinalysis should be monitored and urine tested for myoglobin. One should monitor the blood for creatine kinase, uric acid (an early clue to rhabdomyolysis), BUN, creatinine, electrolytes (hyperkalemia), blood glucose (20% of patients have hypoglycemia), urinary output, liver function tests, ECG, and ABG if the patient has any respiratory manifestations. Measurement of phencyclidine in the gastric juice is called for because concentrations are 10 to 50 times higher than in blood or urine. Phencyclidine blood concentrations are not helpful. Phencyclidine may be detected in the urine of the average user for 10 days to 3 weeks after the last dose. In chronic users, it can be detected for over 1 month. The analogues of phencyclidine may not produce positive test results for phencyclidine in the urine. Cross-reactions with bleach and dextromethorphan may cause false-positive urine test results on immunoassay, and cross-reaction with doxylamine may produce a false-positive finding on gas chromatography.

Management

The patient should be observed for violent, self-destructive, bizarre behavior, and paranoid schizophrenia. Patients should be placed in a low sensory environment and dangerous objects should be removed from the area.

Gastrointestinal decontamination is not effective because phencyclidine is rapidly absorbed from intestines. Overtreating the mild intoxication should be avoided. There is insufficient evidence to support the use of MDAC. In cases of severe toxicity (stupor or coma), continuous gastric suction can be tried (with protection of the airway) because the drug is secreted into the gastric juice. The value of this procedure is controversial because of limited data.

The patient must be protected from harming himself or herself or others. Physical restraints may be necessary, but they should be used sparingly and for the shortest time possible because they increase risk of rhabdomyolysis. Metal restraints such as handcuffs should be avoided. For behavioral disorders and toxic psychosis, diazepam is the agent of choice. Pharmacologic intervention includes diazepam (Valium) 10 to 30 mg orally or 2 to 5 mg intravenously initially and titrated upward to 10 mg; however, up to 30 mg may be required. “Talk down” technique is usually ineffective and dangerous. Phenothiazines and butyrophenones should be avoided in the acute phase because they lower the convulsive threshold; however, they may be needed later for psychosis. Haloperidol (Haldol) administration has been reported to produce catatonia.

Seizures and muscle spasm are managed with diazepam, from 2.5 mg up to 10 mg. Hyperthermia ($>38.5^{\circ}\text{C}$ [101.3°F]) is treated with external cooling measures. Hypertension is usually transient and does not require treatment. In the case of emergent hypertensive crisis (blood pressure $>200/115$ mm Hg) nitroprusside can be used in a dose of 0.3 to 2 $\mu\text{g/kg/min}$. Maximum infusion rate is 10 $\mu\text{g/kg/min}$ for only 10 minutes.

Acid ion trapping diuresis is not recommended because of the danger of myoglobin precipitation in the renal tubules.

Rhabdomyolysis and myoglobinuria are treated by correcting volume depletion and ensuring a urinary output of greater than 2 mL/kg/h. Alkalinization is controversial because of reabsorption of phencyclidine.

Hemodialysis is beneficial if renal failure occurs; otherwise, the extracorporeal procedures are not beneficial.

Disposition

All patients with coma, delirium, catatonia, violent behavior, aspiration pneumonia, sustained hypertension greater than 200/115 mm Hg, and significant rhabdomyolysis should be admitted to the intensive care unit until asymptomatic for at least 24 hours. If patients with mild intoxication are mentally and neurologically stable and become asymptomatic (except for nystagmus) for 4 hours, they may be discharged in the company of a responsible adult. All patients must be assessed for suicide risk before discharge. Drug counseling and psychiatric follow-up should be arranged. Patients should be warned that episodes of disorientation and depression may continue intermittently for 4 weeks or more.

Phenothiazines and Nonphenothiazines (Neuroleptics)

Toxic Mechanism

Neuroleptics have complex mechanisms of toxicity, including (a) block of the postsynaptic dopamine receptors; (b) block of peripheral and central α -adrenergic receptors; (c) block of cholinergic muscarinic receptors; (d) quinidine-like antidysrhythmic and myocardial depressant effect in cases of large overdose; (e) lowering of the convulsive threshold; (f) effect on hypothalamic temperature regulation (Table 25).

Toxic Dose

Extrapyramidal reactions, anticholinergic effects, and orthostatic hypotension may occur at therapeutic doses. The toxic amount is not established, but the maximum daily therapeutic dose may result in significant side effects, and twice this amount may be potentially fatal. Chlorpromazine (Thorazine), the prototype, may produce serious hypotension and CNS depression at doses greater than 200 mg (17 mg/kg) in children and 3 to 5 g in an adult. Fatalities have been reported after 2.5 g of loxapine (Loxitane) and mesoridazine (Serentil) and 1.5 g of thioridazine (Mellaril).

Kinetics

These agents are lipophilic and have unpredictable gastrointestinal absorption. Peak levels occur 2 to 6 hours postingestion and have enterohepatic recirculation.

The mean serum half-life in phase 1 is 1 to 2 hours and the biphasic half-life is 20 to 40 hours. Volume distribution is 10 to 40 L/kg; protein binding is 92% to 98%. Chlorpromazine taken orally has an onset of action in 30 to 60 minutes, peak in 2 to 4 hours, and duration of 4 to 6 hours. With sustained-release preparations, the onset is in 30 to 60 minutes and duration is 6 to 12 hours.

Elimination is by hepatic metabolism, which results in multiple metabolites (some are active). Metabolites can be detected in urine months after chronic therapy. Only 1% to 3% is excreted unchanged in the urine.

Manifestations

In cases of phenothiazine overdose, anticholinergic symptoms may be present early but are not life-threatening. Miosis is usually present (80%) if the phenothiazine has strong α -adrenergic blocking effect (e.g., chlorpromazine), but anticholinergic activity mydriasis may occur. Agitation and delirium rapidly progress into coma. Major problems are cardiac toxicity and hypotension. The cardiotoxic effects are seen more commonly with thioridazine and its metabolite mesoridazine. These agents have produced the largest number of fatalities in patients with phenothiazine overdose. Cardiac conduction disturbances include prolonged PR, QRS, and QTc intervals, U- and T-wave abnormalities, and ventricular dysrhythmias, including torsades de pointes. Seizures occur mainly in patients with convulsive disorders or with administration of loxapine. Sudden death in children and adults has been reported.

TABLE 25 Neuroleptics and Properties

COMPOUND	ANTIPSYCHOTIC	ANTICHOLINERGIC	EXTRAPYRAMIDAL	HYPOTENSIVE AND CARDIOTOXIC	SEDATIVE
Phenothiazine					
Aliphatic Chlorpromazine (Thorazine) Promethazine (Phenergan)	1+	3+	2+	2+	3+
Piperazine Fluphenazine (Prolixin) Perphenazine (Trilafon) Prochlorperazine (Compazine) Trifluoperazine (Stelazine)	3+	1+	3+	1+	1+
Piperidine Mesoridazine (Serentil) Thioridazine (Mellaril)	1+	2+	1+	3+	3+
Nonphenothiazine					
Butyrophenone Haloperidol (Haldol)	3+	1+	3+	1+	1+
Dibenzoxazepine Loxapine (Loxitane)	3+	1+	3+	1+	2+
Dihydroindolone Molindone (Moban)	3+	1+	3+	1+	1+
Thioxanthenes Thiothixene (Navane) Chlorprothixene (Taractan)	3+	1+	3+	3+	1+

1+ = very low activity; 2+ = moderate activity; 3+ = very high activity.

Idiosyncratic dystonic reactions are most common with the piperidine group. Reactions are not dose-dependent and consist of opisthotonos, torticollis, orolingual dyskinesia, or oculogyric crisis (painful upward gaze). These reactions are more frequent in children and women. Neuroleptic malignant syndrome occurs in patients on chronic therapy and is characterized by hyperthermia, muscle rigidity, autonomic dysfunction, and altered mental state. There is one case reported with acute overdose. The loxapine syndrome consists of seizures, rhabdomyolysis, and renal failure.

Laboratory Investigations

Monitoring should include arterial blood gases, renal and hepatic function, electrolytes, blood glucose, and creatine kinase and myoglobinemia in neuroleptic malignant syndrome. Most of these agents are detected on routine screening. Quantitative serum levels are not useful in management. Cross-reactions with enzyme multiplied immunoassay technique tests occur with cyclic antidepressants. Phenothiazines give false-negative results on pregnancy urine tests using human chorionic gonadotropin as an indicator, and give false-positive results for urine porphyrins, indirect Coombs test, urobilinogen, and amylase.

Management

Vital functions must be established and maintained. All overdose patients require venous access, 12-lead ECG (to measure intervals), cardiac and respiratory monitoring, and seizure precautions. One should monitor core temperature to detect poikilothermic effect. If the patient is comatose, intubation and assisted ventilation may be required, as well as 100% oxygen, intravenous glucose, naloxone (Narcan), and thiamine.

Emesis is not recommended. Activated charcoal can be administered if ingestion was within 1 hour. MDAC has not been proven beneficial. A radiograph of the abdomen may be useful, if the phenothiazine is radiopaque. Haloperidol (Haldol) and trifluoperazine (Stelazine) are most likely to be radiopaque. Whole-bowel irrigation may be useful when a large number of pills are visualized on radiograph or if sustained-release preparations were taken,

but whole-bowel irrigation has not been evaluated in patients with phenothiazine overdose.

Convulsions are treated with diazepam or lorazepam (Ativan). Loxapine (Loxitane) overdose may result in status epilepticus. If nondepolarizing neuromuscular blockade is required, pancuronium (Pavulon) or vecuronium (Norcuron) should be used (not succinyl-choline [Anectine], which may cause malignant hyperthermia), and EEG should be monitored during paralysis.

Patients with dysrhythmias should be monitored with serial ECGs. Unstable rhythms can be treated with electrical cardioversion. Class 1a antidysrhythmics (procainamide, quinidine, and disopyramide [Norpace]) must be avoided.

Hypokalemia predisposes to dysrhythmias and should be corrected aggressively. Supraventricular tachycardia with hemodynamic instability is treated with electrical cardioversion. The role of adenosine has not been defined. Calcium channel and β -blockers should be avoided.

Prolongation of the QRS interval is treated with sodium bicarbonate 1 to 2 mEq/kg by intravenous bolus over a few minutes. Torsades de pointes is treated with magnesium sulfate IV 20% solution 2 g over 2 to 3 minutes. If there is no response in 10 minutes, the dose is repeated and followed by a continuous infusion of 5 to 10 mg/min or given as an infusion of 50 mg/min for 2 hours followed by 30 mg/min for 90 minutes twice a day for several days, as needed. The dose in children is 25 to 50 mg/kg initially and maintenance dose is 30 to 60 mg/kg per 24 hours (0.25 to 0.50 mEq/kg per 24 hours) up to 1000 mg per 24 hours. Serum magnesium levels should be monitored.

To treat ventricular tachydysrhythmias in a stable patient, lidocaine is used. If the patient is unstable, electrical cardioversion is used. Patients with heart block with hemodynamic instability should be managed with temporary cardiac pacing.

Hypotension is treated with the Trendelenburg position and 0.9% saline. If the condition is refractory to treatment or there is a danger of fluid overload, vasopressors are administered. The vasopressor of choice is α -adrenergic agonist norepinephrine (Levophed), titrated to response. Epinephrine and dopamine

should not be used because β -receptor stimulation in the presence of α -receptor blockade may provoke dysrhythmias and phenothiazines are antidopaminergic.

Hypothermia and hyperthermia are treated with external warming and cooling measures, respectively. Antipyretic drugs must not be used.

Management of the neuroleptic malignant syndrome includes the following actions:

- Immediately discontinuing the offending agent
- Hyperventilating the patient, using 100% humidified, cooled oxygen at high gas flows (at least 10 L/min) because of rapid breathing
- Administering a benzodiazepine to control convulsions and facilitate cooling measures
- Initiating appropriate mechanical cooling measures, which may include intravenous cold saline (not lactated Ringer's), ice baths, cold lavage of the stomach, bladder, and rectum, and a hypothermic blanket
- Correcting acid-base and electrolyte disturbances and treating significant hyperkalemia with hyperventilation, calcium, sodium bicarbonate, intravenous glucose, and insulin; hemodialysis may be necessary

In addition, dysrhythmias usually respond to correction of the underlying acid-base disturbances and hyperkalemia. If antidysrhythmic agents are required, calcium channel blockers must be avoided because they may precipitate hyperkalemia and cardiovascular collapse. Dantrolene sodium (Dantrium), which is a phenytoin derivative, inhibits calcium release from the sarcoplasmic reticulum and results in decreased muscle contraction. Dantrolene acts peripherally and does not reverse the rigidity or psychomotor disturbances resulting from the central dopamine blockade; it therefore is often used in combination with bromocriptine. Bromocriptine mesylate (Parlodel) acts centrally as a dopamine agonist, as does amantadine hydrochloride (Symmetrel). Bromocriptine and dantrolene have been reported to be successful in combination with cooling and good supportive measures in malignant hyperthermia.

Dosing for these agents is as follows: dantrolene sodium at 2 to 3 mg/kg IV as a bolus, then 1 mg/kg/min to a maximum of 10 mg/kg or until the tachycardia, rigidity, increased end-tidal CO_2 , and temperature elevation are controlled. *Note:* Hepatotoxicity occurs with doses greater than 10 mg/kg. To prevent symptom recurrence, 1 mg/kg should be administered every 6 hours for 24 to 48 hours after the episode. After that time, oral dantrolene can be used at a dose of 1 mg/kg every 6 hours for 24 hours as necessary. The patient should be observed for thrombophlebitis following intravenous dantrolene. It is best administered via a central line. Bromocriptine mesylate at 2.5 to 10 mg orally or via a nasogastric tube, three times a day, should be used in combination with dantrolene.

Idiosyncratic dystonic reaction can be treated with diphenhydramine (Benadryl) 1 to 2 mg/kg/dose intravenously over 5 minutes up to maximum of 50 mg intravenously; a response is noted within 2 to 5 minutes. This can be followed with oral doses for 4 to 6 days to prevent recurrence.

Extracorporeal measures (hemodialysis, hemoperfusion) are not effective in removing these agents.

Disposition

Asymptomatic patients should be observed for at least 6 hours after gastric decontamination. Symptomatic patients with cardiotoxicity, hypotension, and convulsions should be admitted to the intensive care unit and monitored for 48 hours.

Salicylates (Acetylsalicylic Acid, Salicylic Acid)

Toxic Mechanism

The primary toxic mechanisms include (a) direct stimulation of the medullary chemoreceptor trigger zone and respiratory center; (b) uncoupling oxidative phosphorylation; (c) inhibition of the Krebs cycle enzymes; (d) inhibition of vitamin K dependent and independent clotting factors; (e) alteration of platelet function; and (f) inhibition of prostaglandin synthesis.

Toxic Dose

Acute mild intoxication occurs at a dose of 150 to 200 mg/kg, moderate intoxication at 200 to 300 mg/kg, and severe intoxication at 300 to 500 mg/kg. Acute salicylate plasma concentration greater than 30 mg/dL (usually >40 mg/dL) may be associated with clinical toxicity. Chronic intoxication occurs at ingestions greater than 100 mg/kg/d for more than 2 days because of accumulation kinetics. Methyl salicylate (oil of wintergreen) is the most toxic form of salicylate. A dose of 1 mL of 98% contains 1.4 g of salicylate. Fatalities have occurred with ingestion of 1 teaspoonful in children and 1 ounce in adults. It is found in topical ointments and liniments (18% to 30%).

Kinetics

Acetylsalicylic acid and salicylic acid are weak acids with a pK_a of 3.5 and 3.0, respectively. Acetylsalicylic acid is absorbed from the stomach, from the small bowel, and dermally. Onset of action is within 30 minutes. Methyl salicylate and effervescent tablets are absorbed more rapidly. Salicylate plasma concentration is detectable within 15 minutes after ingestion and peaks in 30 to 120 minutes. The peak may be delayed 6 to 12 hours in cases of large overdose, overdose with enteric-coated or sustained-release preparations, and development of concretions. The therapeutic duration of action is 3 to 4 hours but is markedly prolonged in cases of overdose.

Volume distribution is 0.13 L/kg for salicylic acid but increases as the salicylate plasma concentration increases. Protein binding is greater than 90% for salicylic acid at pH 7.4 and a salicylate plasma concentration of 20 to 30 mg/dL, 75% at a salicylate plasma concentration greater than 40 mg/dL, 50% at a salicylate plasma concentration of 70 mg/dL, and 30% at a salicylate plasma concentration of 120 mg/dL.

The half-life for salicylic acid is 3 hours after a 300 mg dose, 6 hours after a 1 g overdose, and greater than 10 hours after a 10 g overdose. Elimination includes Michaelis-Menten hepatic metabolism by three saturable pathways: (a) glycine conjugation to salicyluric acid (75%); (b) glucuronyl transferase to salicyl phenol glucuronide (10%); and (c) salicyl aryl glucuronide (4%). Non-saturable pathways are hydrolysis to gentisic acid (<1%). Ten percent is excreted unchanged.

Acidosis increases the severity of the intoxication by increasing the non-ionized salicylate that can cross membranes and enter the brain cells. In kidneys, the unionized salicylic acid undergoes glomerular filtration, and the ionized portion undergoes tubular secretion in proximal tubules and passive reabsorption in the distal tubules. Renal excretion of salicylate is enhanced by alkaline urine.

Manifestations

The ingestion of concentrated topical salicylic acid preparations (e.g., wart remover) can cause mucosal caustic injury to the gastrointestinal tract. Occult salicylate overdose should be considered in any patient with unexplained acid-base disturbance.

The manifestations of acute overdose of salicylates are as follows:

Minimal Symptoms. Tinnitus, dizziness, and deafness may occur at high therapeutic salicylate plasma concentrations of 20 to 30 mg/dL. Nausea and vomiting may occur immediately because of local gastric irritation.

Phase I. Mild manifestations occur at 1 to 12 hours after ingestion with a 6-hour salicylate plasma concentration of 45 to 70 mg/dL. Nausea and vomiting followed by hyperventilation are usually present within 3 to 8 hours after acute overdose. Hyperventilation, an increase in both rate (tachypnea) and depth (hyperpnea), is present but it may be subtle. It results in a mild respiratory alkalosis with a serum pH greater than 7.4 and urine pH greater than 6.0. Some patients may have lethargy, vertigo, headache, and confusion. Diaphoresis may be noted.

Phase II. Moderate manifestations occur at 12 to 24 hours after ingestion with a 6-hour salicylate plasma concentration of 70 to 90 mg/dL. Serious metabolic disturbances, including a marked respiratory alkalosis with anion gap metabolic acidosis,

dehydration, and urine pH less than 6.0, may occur. Other metabolic disturbances include hypoglycemia or hyperglycemia, hypokalemia, decreased ionized calcium, and increased BUN, creatinine, and lactate. Mental disturbances (confusion, disorientation, hallucinations) may occur. Hypotension and convulsions have been reported.

Phase III. Severe intoxication occurs more than 24 hours after ingestion with a 6-hour salicylate plasma concentration of 90 to 130 mg/dL. In addition to the above clinical findings, coma and seizures develop and indicate severe intoxication. Pulmonary edema may occur. Metabolic disturbances include metabolic acidemia (pH <7.4) and aciduria (pH <6.0). In adults, alkalosis may persist until terminal respiratory failure.

In children younger than 4 years of age, a mixed metabolic acidosis and respiratory alkalosis develop earlier (within 4 to 6 hours) than in adults because children have less respiratory reserve and accumulate lactate and other organic acids. Hypoglycemia is more common in children.

Fatalities occur at 6-hour salicylate plasma concentrations greater than 130 to 150 mg/dL and result from CNS depression, cardiovascular collapse, electrolyte imbalance, and cerebral edema.

Chronic salicylism is more serious than acute intoxication and the 6-hour salicylate plasma concentration does not correlate well with the manifestations in both acute and chronic cases of intoxication. Chronic intoxication usually occurs with therapeutic errors in young children or the elderly with underlying illness, and the diagnosis is delayed because it is not recognized. Noncardiac pulmonary edema is a frequent complication in the elderly. The mortality rate is about 25%. Chronic salicylate poisoning in children may mimic Reye syndrome. It is associated with exaggerated CNS findings (hallucinations, delirium, dementia, memory loss, papilledema, bizarre behavior, agitation, encephalopathy, seizures, and coma). Hemorrhagic manifestations, renal failure, and pulmonary and cerebral edema may occur. The metabolic picture is hypoglycemia and mixed acid-base derangements. A chronic salicylate plasma concentration greater than 60 mg/dL with metabolic acidosis and an altered mental state is very serious.

Laboratory Investigations

All patients with intentional salicylate overdoses should have acetaminophen plasma level measured after 4 hours.

One should continuously monitor ECG, urine output, urine pH, and specific gravity. Every 2 to 4 hours in cases of severe intoxication, salicylate plasma concentration, glucose (in a case of salicylism, CNS hypoglycemia may be present despite normal serum glucose), electrolytes, ionized calcium, magnesium and phosphorus, anion gap, ABGs, and pulse oximeter should be monitored.

Daily monitoring of BUN, creatinine, liver function tests, and prothrombin time should take place.

The therapeutic salicylate plasma concentration is less than 10 mg/dL for analgesia and 15 to 30 mg/dL for antiinflammatory effect. Cross-reaction with diflunisal (Dolobid) will give a falsely high salicylate plasma concentration. The Done nomogram is not considered accurate in evaluating acute or chronic salicylate intoxications.

Management

Treatment is based on clinical and metabolic findings, not on salicylate levels. Continuous monitoring of the urine pH is essential for successful alkalization treatment. One should always obtain an acetaminophen plasma level.

Vital functions must be established and maintained. If the patient is in an altered mental state, glucose, naloxone, and thiamine are administered in standard doses. Depending on the severity, the initial studies include an immediate and a 6-hour postingestion salicylate plasma concentration, ECG and cardiac monitoring, pulse oximeter, urine (analysis, pH, and specific gravity), chest radiograph, ABGs, blood glucose, electrolytes and anion gap calculation, calcium (ionized), magnesium, renal and liver profiles, and prothrombin time. Gastric contents and stool should be tested for occult blood. Bismuth and magnesium salicylate preparations may be radiopaque on radiographs. Consultation with a nephrologist is warranted in cases of moderate, severe, or chronic intoxication.

For gastrointestinal decontamination, activated charcoal is useful (each gram of activated charcoal binds 550 mg of salicylic acid) if a toxic dose was ingested up to 4 hours postingestion. MDAC is not recommended for salicylate intoxication.

Concretions may occur with massive (usually >300 mg/kg) ingestions. If blood levels fail to decline, prompt contrast radiography of the stomach may reveal concretions that have to be removed by repeated lavage, whole-bowel irrigation, endoscopy, or gastrostomy.

Fluids and electrolyte treatment of salicylate poisonings is given in Table 26. For shock, perfusion and vascular volume should be established with 5% dextrose in 0.9% saline, then the treatment can proceed with correction of dehydration and alkalization.

For cases of acute moderate or severe salicylism (see Table 26), adults should receive a bolus of 1 to 2 mEq/kg of sodium bicarbonate (NaHCO_3) followed by an infusion of 100 to 150 mEq NaHCO_3 added to 500 to 1000 mL of 5% dextrose and administered over 60 minutes. Children should receive a bolus of 1 to 2 mEq/kg of NaHCO_3 followed by an infusion of 1 to 2 mEq/kg added to 20 mL/kg of 5% dextrose administered over 60 minutes. Potassium is added after the patient voids. The goal is to achieve a

TABLE 26 Fluid and Electrolyte Treatment of Salicylate Poisoning

TYPE OF SALICYLISM	METABOLIC DISTURBANCE	BLOOD pH	URINE pH	HYDRATING SOLUTION	AMOUNT OF NaHCO_3 (mEq/L)	AMOUNT OF POTASSIUM (mEq/L)
Mild	Respiratory alkalosis	>7.4	>6.0	5% Dextrose, 0.45% saline	50 (adult) 1 mEq/kg (child)	20
Moderate	Respiratory alkalosis	>7.4	<6.0	5% Dextrose in water	100 (adult) 1–2 mEq/kg (child)	40
Chronic Child <4 years	Metabolic acidosis					
Severe	Metabolic acidosis	<7.4	<6.0	5% Dextrose in water	150 (adult) 2 mEq/kg (child)	60
Chronic Child <4 years	Respiratory alkalosis					
CNS Depressant Co-ingestant	Respiratory acidosis	<7.4	<6.0	5% Dextrose in water	100–150*	60

*Correct hypoventilation.

Modified from Linden CH, Rumack BH: The legitimate analgesics, aspirin and acetaminophen. In Hansen Jr W (ed): *Toxic Emergencies*. New York, Churchill Livingstone, 1984.

urine output of greater than 2 mL/kg/h and a urine pH of greater than 8. The initial infusion is followed by subsequent infusions (two to three times normal maintenance) of 200 to 300 mL/h in adults or 10 mL/kg/h in children. If the patient is acidotic and has a serum pH of less than 7.15, an additional 1 to 2 mEq/kg of NaHCO_3 is given over 1 to 2 hours; persistent acidosis may require 1 to 2 mEq/kg of bicarbonate every 2 hours. The infusion rate, the amount of bicarbonate, and the electrolytes should be adjusted to correct serum abnormalities and to maintain the targeted urine output and urinary pH. Diuresis is not as important as the alkalinization. Careful monitoring for fluid overload should take place for patients at risk of pulmonary and cerebral edema (e.g., the elderly) and because of inappropriate secretion of the anti-diuretic hormone.

In patients with mild intoxication who are not acidotic and have a urine pH greater than 6, 5% dextrose in 0.45% saline should be administered as maintenance to replace ongoing fluid loss. Some toxicologists may consider adding sodium bicarbonate 50 mEq/L or 1 mEq/kg in some cases.

To achieve alkalinization, sodium bicarbonate is administered to produce a serum pH 7.4 to 7.5 and a urine pH greater than 8. Carbonic anhydrase inhibitors (acetazolamide [Diamox]) should not be used. If the patient is acidotic, additional bicarbonate may be required. About 2 mEq/kg raises the blood pH 0.1. In children, alkalinization may be a difficult problem because of the organic acid production and hypokalemia. Hypokalemic and fluid-depleted patients cannot be adequately alkalinized. Alkalinization is usually discontinued in asymptomatic patients with a salicylate plasma concentration less than 30 to 40 mg/dL but is continued in symptomatic patients regardless of the salicylate plasma concentration. A decreased serum bicarbonate but normal or high blood pH indicates respiratory alkalosis predominating over metabolic acidosis, and the bicarbonate should be administered cautiously. An alkalemic pH of 7.40 to 7.50 is not a contraindication to bicarbonate therapy because these patients have a significant base deficit in spite of elevated blood pH.

Potassium is added, 20 to 40 mEq/L, to the infusion after the patient voids. In cases of severe, late, and chronic salicylism, 60 mEq/L of potassium may be needed. When the serum potassium is below 4.0 mEq/L, 10 mEq/L should be added over the first hour. If the patient has hypokalemia less than 3 mEq/L and flat T waves and U waves, 0.25 to 0.5 mEq/kg up to 10 mEq/h is administered. Potassium should be administered under ECG monitoring. Serum potassium is rechecked after each rapidly administered dose. A paradoxical urine acidosis (alkaline serum pH and acid urine pH) indicates that potassium is probably needed.

Convulsions are treated with diazepam or lorazepam, but hypoglycemia, low ionized calcium, cerebral edema, and hemorrhage should first be excluded with a CT scan. If tetany develops, the NaHCO_3 therapy is discontinued and calcium gluconate 0.1 to 0.2 mL/kg 10% administered.

Pulmonary edema management consists of fluid restriction, high FiO_2 , mechanical ventilation, and positive end-expiratory pressure.

Cerebral edema management consists of fluid restriction, elevation of the head, hyperventilation, osmotic diuresis, and administration of dexamethasone. Vitamin K_1 is administered parenterally to correct an increased prothrombin time (>20 seconds) and coagulation abnormalities. If the patient has active bleeding, fresh plasma and platelets are administered as needed. Hyperpyrexia is managed by external cooling measures, not antipyretics.

Hemodialysis is the choice for removal of salicylates because it corrects the acid-base, electrolyte, and fluid disturbances as well. The indications for hemodialysis include the following:

- Acute poisoning with salicylate plasma concentration greater than 100 mg/dL without improvement after 6 hours of appropriate therapy
- Chronic poisoning with cardiopulmonary disease and a salicylate plasma concentration as low as 40 mg/dL with refractory acidosis, severe CNS manifestations (coma and seizures), and progressive deterioration, especially in elderly patients

- Impairment of vital organs of elimination
- Clinical deterioration in spite of good supportive care and alkalinization
- Severe refractory acid-base or electrolyte disturbances despite appropriate corrective measures

Disposition

There are limitations of salicylate plasma levels and patients are treated on the basis of clinical and laboratory findings. Patients who are asymptomatic should be monitored for a minimum of 6 hours, and longer if enteric-coated tablets or massive overdose was taken or if there is suspicion of concretions. Those who remain asymptomatic with a salicylate plasma concentration less than 35 mg/dL may be discharged following psychiatric evaluation, if indicated. Chronic salicylate-intoxicated patients with acidosis and an altered mental state should be admitted to the intensive care unit. Patients with acute ingestion and a salicylate plasma concentration less than 60 mg/dL and mild symptoms may be able to be treated in the emergency department. Patients with moderate and severe intoxications should be admitted to the intensive care unit.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are primarily prescribed as antidepressants. SSRIs include fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft).

Toxic Mechanism

The SSRIs interfere with the neuron reuptake of serotonin (5-hydroxytryptamine) at the presynaptic ganglia sites in the brain, increasing the activity of serotonin. SSRIs should not be used within 5 weeks of when a MAOI is given, nor should MAOI therapy be initiated or discontinued within 5 weeks of SSRI therapy.

Toxic Dose

The therapeutic oral dose of fluoxetine is 20 to 80 mg/d. No toxicity is seen in children with up to 3.5 mg/kg/dose orally. A fatal dose for adults is 6 g. The therapeutic dose for paroxetine is 20 to 50 mg/d. In 35 adult patients, none developed serious side effects after the ingestion of 10 to 1000 mg, and a study involving 35 children failed to demonstrate serious adverse effects at doses less than 180 mg. The therapeutic dose for sertraline is 50 mg to 200 mg/d. Patients have ingested up to 2.6 g without serious side effects. Overdose involving children who ingested less than 100 mg failed to cause adverse events.

Kinetics

Fluoxetine is well absorbed from the gastrointestinal tract and has a peak plasma concentration at 6 to 8 hours. Volume distribution is 20 to 42 L/kg; 95% is protein bound. The half-life is 4 days (for the demethylated active metabolite norfluoxetine, the half-life is 7 to 15 days). Elimination is 80% renal. Fluoxetine and other serotonin inhibitors are inhibitors of the cytochrome P450, CYP2D6 enzyme. Therefore interactions may occur with many other medications, such as antidysrhythmic class IC drugs (quinidine), phenytoin (Dilantin), haloperidol, lithium, tricyclic antidepressants (TCAs), β -blockers, codeine, and carbamazepine (Tegretol).

Paroxetine is almost completely absorbed from the gastrointestinal tract, with a peak in 2 to 8 hours. Protein binding is greater than 90%; volume distribution is 13 L/kg. Paroxetine undergoes extensive first-pass liver metabolism by oxidation and methylation to inactive metabolites. It inhibits the P450 system (see fluoxetine metabolism). The average half-life is 21 hours.

Sertraline peaks in 8 to 12 hours. Its volume distribution is 20 L/kg and protein binding is 98%. The average half-life of sertraline is 26 hours. It is metabolized to form a less-active metabolite, N-desmethylsertraline (half-life of 62 to 104 hours).

Manifestations

All SSRIs may cause serotonin syndrome, a potentially life-threatening reaction, if they are administered concurrently with an MAOI. Serotonin syndrome is caused by cerebral serotonergic

stimulation and can cause severe hyperthermia, myoclonus, rhabdomyolysis, confusion, tremors, and a variety of psychological disturbances. In addition, cardiovascular complications and extrapyramidal side effects, including akathisia, dyskinesia, and Parkinson-like syndromes may occur. Also, increased suicidal ideation, seizures, sexual disorders, and hematologic disorders (platelet serotonin activity blockade leading to prolonged bleeding times) may develop. Inappropriate secretion of antidiuretic hormone resulting in hyponatremia may occur when SSRIs are administered to the elderly. This effect is usually seen within the first week of therapy.

Overdose effects are similar to the serotonin syndrome.

Laboratory Investigations

One should obtain a complete blood count (CBC), electrolytes, glucose levels, a coagulation profile, liver function tests, creatine kinase level, and an ECG.

Management

There is no specific antidote to SSRI intoxication.

Initial management consists of stabilizing vital functions, including thermoregulation. Supportive therapy and anticipation of potential life-threatening manifestations (hypotension, hyperthermia, seizures, coma, disseminated intravascular coagulation, ventricular tachycardia, and metabolic acidosis) are essential. Vital signs, EEG, creatine kinase, and blood chemistry should be monitored.

Benzodiazepines are administered to prevent and control muscle hyperactivity (diazepam [Valium] for seizures, clonazepam [Klonopin] for myoclonus). If benzodiazepine therapy fails to control muscle activity or seizures, anesthesia or nondepolarizing neuromuscular blockade may be necessary.

Electrolyte abnormalities and acid-base balance should be corrected. Fluids are used to maintain a urine output of greater than 2 mL/kg/h if there is a risk of myoglobinuria.

There are no data to support the use of gastrointestinal decontamination, although activated charcoal may be used if an ingestion has occurred within 1 hour. Hemodialysis and charcoal hemoperfusion are unlikely to be beneficial. Haloperidol (Haldol), phenothiazines, and other highly protein-bound drugs are to be avoided.

Benzodiazepine and cooling therapy can be used for hyperthermia. Serotonin antagonists, such as cyproheptadine (Periactin), may be useful in treating serotonin syndrome, although there are no controlled data. Dantrolene (Dantrium) and bromocriptine (Parlodel) are not recommended and may actually precipitate serotonin syndrome.

Disposition

Cases of ingestions in children up to 5 years of age of less than 180 mg of paroxetine (Paxil), less than 3.5 mg/kg of fluoxetine (Prozac), or less than 100 mg of sertraline (Zoloft) can be observed at home. Symptomatic patients should be admitted to the intensive care unit until asymptomatic for 24 hours. Asymptomatic patients should be observed for 6 hours. All patients should be assessed for risk of suicide before discharge. When taken chronically, SSRIs may increase cholesterol and triglycerides and decrease uric acid, so these test results should be followed.

Theophylline

Theophylline (Slo-Phyllin) is a methylxanthine alkaloid similar to caffeine and theobromine. Aminophylline is 80% theophylline. Theophylline is used in the acute treatment of asthma, pulmonary edema, chronic obstructive pulmonary disease, and neonatal apnea.

Toxic Mechanism

The proposed mechanisms of action include phosphodiesterase inhibition, adenosine receptor antagonism, inhibition of prostaglandins, and increase in serum catecholamines. Theophylline stimulates the central nervous, respiratory, and emetic centers and reduces the seizure threshold. It has positive cardiac inotropic

and chronotropic effects, acts as a diuretic, relaxes smooth muscle, and causes peripheral vasodilation but cerebral vasoconstriction. Gastric secretions, gastrointestinal motility, lipolysis, glycogenolysis, and gluconeogenesis are all increased.

Toxic Dose

A single dose of 1 mg/kg produces a theophylline plasma concentration of approximately 2 µg/mL. The therapeutic range usually is 10 to 20 µg/mL. An acute, single dose greater than 10 mg/kg causes mild toxicity, a dose greater than 20 mg/kg causes moderate toxicity, and a dose greater than 50 mg/kg causes serious, possibly fatal toxicity. Fatalities occur at lower doses in patients with chronic toxicity, especially those with risk factors (see *Kinetics*).

Kinetics

The pKa is 9.5. Absorption from the stomach and upper small intestine is complete and rapid, with onset in 30 to 60 minutes. Peak theophylline plasma concentration occurs within 1 to 2 hours after ingestion of liquid preparations, 2 to 4 hours after ingestion of regular tablets, and 7 to 24 hours after ingestion of slow-release formulations. Volume distribution is 0.3 to 0.7 L/kg. Protein binding is 40% to 60% in adults, mainly to albumin (low albumin increases free active theophylline).

Elimination is 90% by hepatic metabolism to an active metabolite, 2-methyl xanthine. The half-life is 3.5 hours in a child and 4 to 6 hours in an adult. The half-life is shorter in smokers and patients taking enzyme-inducing drugs. Only 8% to 10% of the drug is excreted unchanged in the urine.

Risk factors that produce a longer half-life include age younger than 6 months or older than 60 years, use of enzyme-inhibitor drugs (calcium channel blockers, oral contraceptives, cimetidine [Tagamet], ciprofloxacin [Cipro], erythromycin, macrolide antibiotics, isoniazid), illness (persistent fever >38.9°C [>102°F]), viral illness, liver impairment, heart failure, chronic obstructive pulmonary disease, and influenza vaccination.

Manifestations

Acute toxicity generally correlates with blood levels; chronic toxicity does not (Table 27).

TABLE 27 Theophylline Blood Concentrations and Acute Toxicity

PLASMA CONCENTRATION (µg/mL)	TOXICITY DEGREE	MANIFESTATIONS
8–10	None	Bronchodilation
10–20	Mild	Therapeutic range: nausea, vomiting, nervousness, respiratory alkalosis, tachycardia
15–25		35% have mild manifestations of toxicity
20–40	Moderate	Gastrointestinal complaints and central nervous system stimulation Transient hypertension, tachypnea, tachycardia; 80% will have some manifestations of toxicity
60–100	Severe	Convulsions, dysrhythmias Hypokalemia, hyperglycemia Ventricular dysrhythmias, protracted convulsions, hypotension, acid-base abnormalities

Reprinted and modified from Linden CH, Rumack BH: In Hansen Jr W (ed): *Toxic Emergencies*. New York, Churchill Livingstone, 1984. With permission from Elsevier.

In the case of an acute, single, regular-release overdose, vomiting and occasionally hematemesis occur at low theophylline plasma concentrations. CNS stimulation includes restlessness, muscle tremors, and protracted tonic-clonic seizures, but coma is rare. Convulsions are a sign of severe toxicity and usually are preceded by gastrointestinal symptoms (except with sustained-release and chronic intoxications). Cardiovascular disturbances include cardiac dysrhythmias (supraventricular tachycardia) and transient hypertension with mild overdoses, but hypotension and ventricular dysrhythmias with severe intoxications. Rhabdomyolysis and renal failure are occasionally seen. Children tolerate higher serum levels, and cardiac dysrhythmias and seizures occur at theophylline plasma concentrations greater than 100 µg/mL. Possible metabolic disturbances include hyperglycemia, pronounced hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, increased serum amylase, and elevation of uric acid.

Chronic intoxication, defined as multiple doses of theophylline over 24 hours, or cases in which interacting drugs or illness interfere with theophylline metabolism are more serious and difficult to treat. Cardiac dysrhythmias and convulsions may occur at theophylline plasma concentrations of 40 to 60 µg/mL and there is no correlation with TPC. The seizures occur without warning and are protracted and repetitive and may produce status epilepticus. Vomiting and typical metabolic disturbances do not occur.

Differences with slow-release preparations are that few or no gastrointestinal symptoms occur, peak concentrations and convulsions may be delayed 12 to 24 hours postingestion, and convulsions occur without warning.

Laboratory Investigations

Monitoring includes vital signs, pulse oximeter, ABG, hemoglobin, hematocrit (for gastrointestinal hemorrhage), ECG and cardiac monitor, renal and hepatic function, electrolytes, blood glucose, acid-base balance, and serum albumin. Gastric contents and stools should be tested for occult blood. Samples for theophylline plasma concentration measurement should be drawn within 1 to 2 hours after ingestion of liquid preparations, 2 to 4 hours after ingestion of regular-release formulations, and 4 hours after ingestion of slow-release formulations. One should check the serum albumin level because a decrease in albumin levels may cause manifestations of toxicity despite normal theophylline plasma concentration. A single theophylline plasma concentration reading may be misleading; therefore, theophylline plasma concentration measurement should be repeated every 2 to 4 hours to determine the trend until a declining trend is reached and then monitored every 4 to 6 hours until it is below 20 µg/mL.

Management

Vital functions must be established and maintained. If the patient is in a coma or has convulsions or vomiting, he or she should be intubated immediately. The theophylline plasma concentration is obtained and repeated every 2 to 4 hours to determine peak absorption, and a theophylline bezoar should be considered if the theophylline plasma concentration fails to decline. Consultation with a nephrologist about charcoal hemoperfusion is recommended.

Gastrointestinal decontamination is warranted in the case of an acute overdose, but emesis must not be induced. Activated charcoal is the choice decontamination procedure in a dose of 1 g/kg to all patients, followed with MDAC 0.5 g/kg every 2 to 4 hours until the theophylline plasma concentration is less than 20 µg/mL. MDAC is effective in treating acute, chronic, and intravenous overdoses. Activated charcoal shortens the half-life of theophylline by about 50% and may be indicated up to 24 hours following ingestion.

Whole-bowel irrigation with polyethylene-electrolyte solution has been recommended for cases of massive overdose, possible concretions, and ingestion of sustained-release preparations. If intractable vomiting occurs, the antiemetic metoclopramide (Reglan) (0.1 mg/kg adult dose), droperidol (Inapsine) (2.5 to 10 mg IV), or ondansetron (Zofran) (8 to 32 mg IV) is administered. Ondansetron, however, inhibits metabolism of theophylline after a few doses.

Convulsions are controlled with lorazepam (Ativan) or diazepam (Valium) and phenobarbital. Phenytoin (Dilantin) is ineffective. The convulsions in patients with chronic intoxication are often refractory and may require, in addition to anticonvulsants, neuromuscular paralyzing agents, sedation, assisted ventilation, and EEG monitoring.

Hypotension is treated with fluids and vasopressors, if necessary. Norepinephrine (Levophed) 0.05 µg/kg/min is preferred as the vasopressor over dopamine.

Supraventricular tachycardia with hemodynamic instability requires cardioversion. Low-dose β-blockers may be used but should not be used in patients with reactive airway disease or hypotension. Adenosine (Adenocard) is ineffective. For ventricular dysrhythmias, electrolyte disturbances should be corrected. Lidocaine is the treatment of choice but has the potential to cause seizures at toxic concentrations. Cardioversion may be needed.

Hematemesis is managed with sucralfate (Carafate) 1 g four times daily and/or Maalox TC 30 mL every 2 hours and blood replacement, if necessary. H₂ antihistamine blockers that are enzyme inhibitors are not used.

Fluid and metabolic disturbances should be corrected. Hyperglycemia does not require insulin therapy. Hypokalemia should be corrected cautiously, as it may be largely an intracellular shift and not total body loss. Usually adding 40 mEq potassium to a liter of fluid will suffice. The serum potassium level must be monitored closely.

Charcoal hemoperfusion is the management of choice for patients with serious intoxications. Hemoperfusion can increase the clearance twofold to threefold over hemodialysis, but hemodialysis can be used if hemoperfusion is not available. Criteria for charcoal hemoperfusion are as follows:

- Life-threatening events such as convulsions or dysrhythmias
- Intractable vomiting refractory to antiemetics
- Acute intoxications with a theophylline plasma concentration greater than 80 µg/mL or greater than 70 µg/mL 4 hours after overdose with a sustained-release formulation and greater than 40 µg/mL in the case of chronic intoxication
- Acute or chronic overdoses with a theophylline plasma concentration greater than 40 µg/mL, especially if the patient has risk factors that lengthen the half-life of the drug (see Kinetics).

Disposition

Patients with mild symptoms and a theophylline plasma concentration less than 20 µg/mL can be treated in emergency department and discharged when asymptomatic for a few hours. Any patient with acute ingestion and a theophylline plasma concentration greater than 35 µg/mL should be admitted to a monitored bed with seizure precautions and suicide precautions, if needed. If neurologic or cardiotoxic effects or a theophylline plasma concentration greater than 50 µg/mL is present, the patient should be admitted to the intensive care unit. A patient with an overdose of a sustained-release preparation, regardless of symptoms or initial theophylline plasma concentration, requires admission, monitoring, activated charcoal, and MDAC. In patients on chronic therapy, toxicity may occur at a lower theophylline plasma concentration, and these patients should not be discharged until they are asymptomatic for several hours.

Tricyclic and Cyclic Antidepressants

Historically, tricyclic antidepressants are an important cause of pharmaceutical overdose fatalities. The mortality rate was reduced from 15% in the 1970s to less than 1% in the 1990s because of a better understanding of the pathophysiology of these agents and improvements in management (Table 28).

Toxic Mechanism

The major mechanisms of toxicity of the tricyclic antidepressants are (a) central and peripheral anticholinergic effects; (b) peripheral α-adrenergic blockade; (c) quinidine-like cardiac membrane stabilizing action blockade of the fast inward sodium channels; and (d) inhibition of synaptic neurotransmitter reuptake in the

TABLE 28 Cyclic Antidepressants: Daily Dose and Their Major Properties

GENERIC NAME (TRADE NAME)	ADULT DAILY DOSE (mg)	THERAPEUTIC RANGE (ng/mL)	HALF-LIFE (HOURS)	TOXICITY		
				ANTICHOL	CNS	CARDIAC
Tertiary Amines						
Amitriptyline (Elavil)	75–300	120–250	31–46	3+	3+	3+
Imipramine (Tofranil)	75–300	125–250	9–24	3+	3+	2+
Doxepin (Sinequan)	75–300	30–150	8–24	3+	3+	2+
Trimipramine (Surmantil)	75–200	10–240	16–18	3+	3+	2+
Secondary Amines						
Nortriptyline (Pamelor)	75–150	50–150	18–93	2+	3+	3+
Desipramine (Norpramin)	75–200	75–160	14–62	1+	3+	3+
Protriptyline (Vivactil)	20–60	70–250	54–198	2+	3+	3+
Newer Cyclic Antidepressants						
Teracyclic	75–300	—	30–60	1+	2+	3+
Maprotiline (Ludiomil)			30–60	1+	2+	3+
Trizolopyridine, a noncyclic, produces less serious cardiac and CNS toxicity						
Trazodone (Desyrel)	50–600	700	4–7	1+	1+	1+
Monocyclic Aminoketones						
Bupropion (Wellbutrin)	200–400	—	8–24	1+	3+	1+
Dibenzazepine	100–250	200–500	21–32	2+	2+	2+
Clomipramine (Anafranil)						
Dibenzoxazepine						
Amoxapine (Ascendin)	150–300	200–500	6–10	1+	3+	2+

Abbreviations: Antichol = anticholinergic effect; CNS = central nervous system effect primarily seizures; cardiac = cardiac effect.

Other drugs with similar structures are cyclobenzaprine, a muscle relaxant (similar to amitriptyline), and carbamazepine, an anticonvulsant (similar to imipramine); however, they cause less cardiac toxicity.

CNS presynaptic neurons. The tetracyclics, monocyclic aminoketones, and dibenzoxazepines possess convulsive activity and less cardiac toxicity in overdose than the older tricyclic antidepressants. Triazolopyridine has less serious cardiac and CNS toxicity.

Toxic Dose

The therapeutic dose of imipramine (Tofranil) is 1.5 to 5 mg/kg; a dose greater than 5 mg/kg may be mildly toxic; 10 to 20 mg/kg may be life threatening, although less than 20 mg/kg has produced few fatalities; greater than 30 mg/kg carries a 30% mortality rate; and at a dose greater than 70 mg/kg, patients rarely survive. In children 375 mg and in adults as little as 500 mg have been fatal. In adults, five times the maximum daily dose is toxic and 10 times is potentially fatal. Although major overdose symptoms are associated with plasma concentrations greater than 1 µg/mL (>1000 ng/mL), plasma tricyclic levels do not correlate well with toxicity; clinical signs and symptoms should guide therapy.

The relative dosage or potency equivalents are as follows: amitriptyline (Elavil) 100 mg = amoxapine (Ascendin) 125 mg = desipramine (Norpramin) 75 mg = doxepin (Sinequan) 100 mg = imipramine (Tofranil) 75 mg = maprotiline (Ludiomil) 75 mg = nortriptyline (Pamelor) 50 mg = trazodone (Desyrel) 200 mg. This allows one to determine an equivalent dosage of an agent compared with another (see Table 28).

Kinetics

The tricyclic and cyclic antidepressants are lipophilic. They are rapidly absorbed from the alkaline small intestine, but absorption may be prolonged and delayed in cases of massive overdose owing to anticholinergic action. Onset varies from less than 1 hour (30 to 40 minutes) to, rarely, 12 hours. The peak serum levels are reached in 2 to 8 hours and the peak effect is in 6 hours but may be delayed 12 hours because of erratic absorption. The clinical effects correlate poorly with plasma levels.

Cyclic antidepressants are highly protein-bound to plasma glycoproteins, 98% at a pH 7.5 and 90% at 7.0. Volume distribution is 10 to 50 L/kg. The elimination route is by hepatic metabolism. The tertiary amines are metabolized into active demethylated secondary amine metabolites. The active secondary amine metabolites undergo a 15% enterohepatic recirculation and are metabolized over a period of days into nonactive metabolites. The intestinal bacterial flora may reconstitute the metabolites, which are active.

The half-life varies from 10 hours for imipramine to 81 hours for amitriptyline and 100 hours for nortriptyline. The active metabolites have longer half-lives.

Only 3% of the ingested dose is excreted in the urine unchanged.

Manifestations

There are reports of asymptomatic patients who, upon arrival to an emergency department, suddenly have a seizure, develop hemodynamically unstable dysrhythmias, and die shortly thereafter from ingestion of a tricyclic antidepressant. Most patients with severe toxicity develop symptoms within 1 to 2 hours, but symptoms may be delayed 6 hours after overdose.

Small overdoses produce early anticholinergic effects, agitation, and transient hypertension, which are not life-threatening. Large overdoses produce depression of the CNS and myocardium, convulsions, and hypotension. Death can occur within the first 2 to 6 hours following ingestion.

Some ECG screening tools for predicting cardiac or neurologic toxicity from ingestion of a tricyclic antidepressant have been developed: (a) a QRS greater than 0.10 second may produce seizures, and if greater than 0.16 second, 50% of patients may develop ventricular dysrhythmias (20% of these may be life-threatening) and seizures; (b) a terminal 40 msec of the QRS axis greater than 120 degrees in the right frontal plane may be associated with toxicity; or (c) a large R wave greater than 3 mm in ECG lead aVR may predispose the patient to toxicity. The quinidine cardiac membrane stabilizing effect produces depression of

myocardium, conduction, and ECG changes. The peripheral α -adrenergic blockade produces hypotension.

The secondary amines are metabolized to inactive metabolites. The tetracyclics produce a high incidence of cardiovascular disturbances and seizures. Monocyclic aminoketones produce seizures in doses greater than 600 mg. Dibenzoxazepines produce a syndrome of convulsions, rhabdomyolysis, and renal failure.

Laboratory Investigations

If the patient has altered mental status or ECG abnormalities, ABG, ECG, chest radiograph, blood glucose, serum electrolytes, calcium, magnesium, blood urea nitrogen, and creatinine levels, liver profile, creatine kinase level, urine output, and, in severe cases, hemodynamic monitoring are indicated. Levels of the tricyclic and cyclic antidepressants less than 300 ng/mL are therapeutic; levels greater than 500 ng/mL indicate toxicity, and levels greater than 1000 ng/mL indicate serious poisoning and are associated with QRS widening.

Management

Vital functions must be established and maintained. Even if the patient is asymptomatic, intravenous access should be established, vital signs and neurologic status monitored, and baseline 12-lead ECG and continuous cardiac monitoring obtained for at least 6 hours from admission or 8 to 12 hours postingestion. QRS interval should be measured on a limb lead ECG every 15 minutes for 6 hours postingestion.

For gastrointestinal decontamination, emesis should not be induced and gastric lavage should not be used. Activated charcoal is preferable. If the patient is in an altered mental state, the airway must be protected. Activated charcoal 1 g/kg is recommended up to 1 hour postingestion. Benefit from MDAC has not been demonstrated.

Alkalinization does not control seizures; diazepam or lorazepam should be used. Status epilepticus may require high-dose barbiturates or neuromuscular blockers with intravenous diazepam. If not successful, the patient can be paralyzed with short-term nondepolarizing neuromuscular blockers such as vecuronium (Norcuron), intubation, and assisted ventilation. A bolus of sodium bicarbonate is recommended as an adjunct to correct the acidosis produced by the seizures.

Sodium bicarbonate is administered in a dose of 1 to 2 mEq/kg undiluted as a bolus and repeated twice a few minutes apart, if needed, for "sodium loading" and alkalinization, which may increase protein binding from 90% to 98%. The sodium loading overcomes the sodium channel blockage and is more important than the alkalinization. Indications include (a) a QRS complex greater than 0.12 second, (b) ventricular tachycardia, (c) severe conduction disturbances, (d) metabolic acidosis, (e) coma, and (f) seizures. A continuous infusion of sodium bicarbonate is of limited usefulness for controlling dysrhythmias. Bolus therapy should be used as needed.

Hyperventilation alone has been recommended, but the pH elevation is not as instantaneous and there is compensatory renal excretion of bicarbonate; therefore, we do not recommend it. The combination of hyperventilation and sodium bicarbonate has produced fatal alkalemia and is not recommended. One should monitor serum potassium level (the sudden increase in blood pH can aggravate or precipitate hypokalemia), serum sodium, and ionized calcium levels (hypocalcemia may occur with alkalinization) and blood pH.

Specific cardiovascular complications should be treated as follows: Hypotension is treated with norepinephrine, a predominantly α -adrenergic drug, which is preferred over dopamine. Hypertension that occurs early rarely requires treatment. Sinus tachycardia usually does not require treatment. Supraventricular tachycardia in a patient who is hemodynamically unstable requires synchronized electrical cardioversion, starting at 0.25 to 1.0 watt-second per kilogram, after sedation. Ventricular tachycardia that persists after alkalinization requires intravenous lidocaine or countershock if the patient is hemodynamically unstable. Ventricular

fibrillation should be treated with defibrillation. Torsades de pointes is treated with magnesium sulfate IV 20% solution, 2 g over 2 to 3 minutes, followed by a continuous infusion of 1.5 mL 10% solution or 5 to 10 mg per minute. For the treatment of bradydysrhythmias, atropine is contraindicated because of the anticholinergic activity. Isoproterenol 0.1 μ g/kg/min, used with caution, may produce hypotension. If the patient is hemodynamically unstable, a pacemaker is used.

Extraordinary measures, such as aortic balloon pump and cardiopulmonary bypass, have been successful.

Investigational treatments include FAB fragments specific for tricyclic antidepressant, which have been successful in animals. Prophylactic NaHCO_3 to prevent dysrhythmias is also being investigated.

Physostigmine has produced asystole, and flumazenil has produced seizures. Both are contraindicated.

Disposition

A patient with an antidepressant overdose who meets any of the following criteria should be admitted to the intensive care unit for 12 to 24 hours: (a) ECG abnormalities except sinus tachycardia, (b) altered mental state, (c) seizures, (d) respiratory depression, and (e) hypotension. Low-risk patients include those in whom the above symptoms are absent at 6 hours postingestion, those who present with minor transient manifestations such as sinus tachycardia who subsequently become and remain asymptomatic for a 6-hour period, and asymptomatic patients who remain asymptomatic for 6 hours. These patients may be discharged if the ECG remains normal, they have normal bowel sounds, and they undergo psychiatric disposition.

Even if the patient is asymptomatic upon presentation to the health care facility, intravenous access should be established, vital signs and neurologic status monitored, a baseline 12-lead ECG obtained, and cardiac monitoring continued for at least 6 hours. **Caution:** In 25% of fatal cases, the patients were initially alert and awake at presentation. However, in most cases of fatality initially deemed as sudden cardiac death, the patient, upon reexamination, actually had symptoms that were missed.

Children younger than 6 years of age with non-intentional (accidental) exposures to amitriptyline (Elavil), desipramine (Norpramin), doxepin (Sinequan), imipramine (Tofranil), or nortriptyline (Aventyl) in a dose less than 5 mg/kg, who are asymptomatic and have what are deemed reliable caregivers, can be observed at home, with close poison control follow-up for 6 hours. Parents or caregivers should be given instructions regarding signs and symptoms to be alert for. Children who are symptomatic, or who ingested greater than 5 mg/kg, should be referred to the emergency department for monitoring, observation, and activated charcoal treatment.

SPIDER BITES AND SCORPION STINGS

Method of

Anne-Michelle Ruha, MD

CURRENT DIAGNOSIS

Black Widow Bite

- Target lesion, not always present
- Generalized pain and muscle cramps
- Hypertension, regional diaphoresis

Brown Recluse Bite

- Unlikely to occur outside of endemic areas
- Cyanotic or blistering wound within area of pallor surrounded by erythema
- Systemic loxoscelism associated with rash, fever, hemolysis, renal failure

myocardium, conduction, and ECG changes. The peripheral α -adrenergic blockade produces hypotension.

The secondary amines are metabolized to inactive metabolites. The tetracyclics produce a high incidence of cardiovascular disturbances and seizures. Monocyclic aminoketones produce seizures in doses greater than 600 mg. Dibenzoxazepines produce a syndrome of convulsions, rhabdomyolysis, and renal failure.

Laboratory Investigations

If the patient has altered mental status or ECG abnormalities, ABG, ECG, chest radiograph, blood glucose, serum electrolytes, calcium, magnesium, blood urea nitrogen, and creatinine levels, liver profile, creatine kinase level, urine output, and, in severe cases, hemodynamic monitoring are indicated. Levels of the tricyclic and cyclic antidepressants less than 300 ng/mL are therapeutic; levels greater than 500 ng/mL indicate toxicity, and levels greater than 1000 ng/mL indicate serious poisoning and are associated with QRS widening.

Management

Vital functions must be established and maintained. Even if the patient is asymptomatic, intravenous access should be established, vital signs and neurologic status monitored, and baseline 12-lead ECG and continuous cardiac monitoring obtained for at least 6 hours from admission or 8 to 12 hours postingestion. QRS interval should be measured on a limb lead ECG every 15 minutes for 6 hours postingestion.

Spider Bites

The majority of spiders native to the United States are incapable of envenomating humans. Important exceptions are *Latrodectus* and *Loxosceles* spiders, which produce clinical envenomations that, on rare occasion, are life-threatening.

Brown Recluse Spider

The most famous and abundant *Loxosceles* spider in the United States is *Loxosceles reclusa*, known as the brown recluse or fiddle-back spider, due to the violin-shaped marking on its cephalothorax. The brown recluse inhabits the midwestern United States, with a range extending from east Texas to west Georgia and reaching north to southern Iowa. Bites from this nonaggressive spider are defensive, and they generally occur when spiders become trapped in clothes or bedsheets. The risk of a bite, even in heavily infested homes, appears to be very small. Most diagnoses of brown recluse bites, including many published in the medical literature, are likely erroneous, occurring in nonendemic areas without identification of the spider. Other *Loxosceles* species found in the United States are even less likely to bite because they avoid human dwellings. Evidence supporting an association between other native spider species and necrotic wounds is weak.

Although the majority of brown recluse bites do not produce significant injury, some result in loxoscelism, which ranges from minor dermonecrosis to, very rarely, life-threatening illness. The venom component thought responsible for loxoscelism is sphingomyelinase D, which affects platelets and cell membranes and activates inflammatory mediators. The first signs of dermonecrosis are often erythema, pruritus, and pain at the bite site. Over hours the site becomes pale and edematous. Erythema can progress and spread gravitationally. A vesicle can develop, form an eschar, and slough over days to weeks. In the first days after the bite, a sunken bluish wound surrounded by a ring of pallor and then erythema is characteristic. Some patients develop a generalized maculopapular rash. Although most necrotic lesions are not serious, some can enlarge to 40 cm and leave a significant scar. Obese persons are at risk for more-severe lesions.

Very rarely, systemic loxoscelism develops within 48 hours of the bite, characterized by fever, myalgias, and hemolysis. Vomiting and diarrhea can occur, and some patients develop a diffuse erythroderma. Renal failure, disseminated intravascular coagulation, and death can result. Death from massive hemolysis is rare and is more likely to occur in children.

Diagnosis of loxoscelism depends on recognition of signs and symptoms in combination with positive identification of the spider when possible. Alternative etiologies for necrotic wounds are much more common than necrotic arachnidism, especially in nonendemic areas. The differential diagnosis of brown recluse bite is large and includes infectious causes, neoplastic disease, and vascular disease.

Treatment is supportive. Most wounds heal without intervention, although a scar might remain. Early surgical excision, dapsone,¹ hyperbaric oxygen, or prophylactic antibiotics cannot be recommended owing to lack of convincing evidence. Patients should receive tetanus prophylaxis (Td) and general wound care. In severe cases, healing can take months and require surgical intervention, which should occur 6 to 8 weeks following the bite after the wound is fully demarcated.

Black Widow Spiders

Latrodectus, or widow, spiders are, medically, the most important group of spiders in the world. Native black widow spiders are shiny black with a red hourglass pattern on their ventral surface. They can reside in or near human structures, leading to contact with humans and subsequent bites.

α-Latrotoxin in venom causes neurotransmitters to be released from synaptic vesicles. This results in a combination of neuromuscular and autonomic effects unique to *Latrodectus* bites, termed *latrodectism*. Bites are inconsistently felt, and they might or might not leave visible puncture marks and a target-like lesion. Pain can progress locally or become generalized within several hours. Severe muscle pain, particularly involving the abdomen and back, is common. Other findings include hypertension, tachycardia, tremor, localized or diffuse diaphoresis, periorbital edema, and urinary retention. Less commonly, vomiting, fever, priapism, paresthesias, and fasciculations occur. Rhabdomyolysis can result from increased muscle activity. Rarely, acute cardiomyopathy, cardiac ischemia, and pulmonary edema occur. Deaths are uncommon but reported.

Diagnosis of latrodectism is based on history of a spider bite and consistent clinical findings. In the absence of a witnessed bite, diagnosis can be difficult. Sudden onset and rapid progression of symptoms should raise suspicion. Infectious and surgical etiologies must be considered in a febrile or vomiting patient. Similar neuromuscular and autonomic findings might also be seen with intoxication by stimulant drugs and scorpion envenomations, and these should be considered in the differential.

Latrodectism typically resolves within 2 to 7 days. Opioid analgesics are often required to treat pain. Severe symptoms require intravenous opioids for adequate pain control and benzodiazepines for muscle spasms and anxiety. If symptoms are life-threatening or not controlled with these therapies, antivenom (Antivenin [*Latrodectus mactans*, equine origin], Merck, Boston, Mass.) should be considered. One vial reverses symptoms of envenomation. This whole-immunoglobulin product can produce acute hypersensitivity and should be administered in a monitored setting. Risks and benefits must be weighed before using this product. If antivenom is not an option or the patient is critically ill, care is supportive, including oxygen and airway support as needed, antihypertensives, antiemetics, and other symptomatic treatment.

Tarantulas

Tarantulas are common pets and are generally harmless. Bites may be painful, but envenomation by native species has not been reported. Most injury to humans resulting from interaction with tarantulas is secondary to trauma and inflammation caused by barbed abdominal hairs that the spiders eject defensively when threatened. If the hairs embed in the skin, a rash and pruritus can result. They can also embed in the cornea or be transferred there by rubbing the eyes after handling a tarantula. Ophthalmia

¹Not FDA approved for this indication.

nodosa, iritis, and keratouveitis have all been reported following exposure to tarantula hairs.

Treatment of embedded corneal hairs entails referral to an ophthalmologist and removal of the hairs if possible. Topical steroids are generally recommended, and some authors also recommend topical antibiotics.

Scorpion Stings

The bark scorpion, *Centruroides sculpturatus*, is the only native scorpion capable of producing a life-threatening envenomation. This small (<3 inches), yellowish-brown scorpion is found throughout Arizona and in bordering areas of surrounding states.

The scorpion seeks cool, dark environments and commonly enters homes. It injects venom by thrusting its stinger, located at the tip of its tail, toward the victim. The neurotoxic venom increases release of neurotransmitters that act at the neuromuscular junction and autonomic nerve endings.

Most stings are minor, producing local pain and paresthesias. Less than 5% of stings result in neurotoxicity, and the majority of these occur in children. Stings typically do not produce a visible skin lesion, although on rare occasion a small red mark is noted. Pain is immediate, and in a grade 1 envenomation remains local and resolves quickly. Grade 2 envenomations involve pain and paresthesias distal from the sting site, which can persist for days to weeks.

Most severe envenomations affect children younger than 5 years. Symptoms develop within 5 to 45 minutes and can progress for 4 hours. Infants and toddlers can exhibit sudden agitation and crying and transient vomiting, and they might rub their face and ears in response to paresthesias. If the child is verbal, complaints of burning pain and sensation of tongue swelling are common. Sinus tachycardia, hypertension, low-grade fever, and hypersalivation are common, and some children develop stridor. Restlessness, agitation, and twisting of the trunk with thrashing of the extremities is typical, as are tongue fasciculations and dysconjugate eye movements, or opsochonus. Patients are conscious but often keep their eyes closed owing to diplopia. Presence of cranial nerve findings or neuromuscular agitation constitute a grade 3 envenomation; both are present in grade 4 envenomation. Severe envenomation may be associated with pulmonary edema, rhabdomyolysis, and aspiration pneumonia. Respiratory failure can occur due to several factors, including loss of tongue and respiratory muscle control, hypersalivation, and use of respiratory depressant medications.

Diagnosis often relies on recognition of symptoms, because children might not report a sting. Characteristic findings in regions inhabited by this scorpion usually make diagnosis straightforward. Differential diagnosis includes seizures or amphetamine toxicity. If a suspected envenomation does not follow the expected clinical course, a urine drug screen should be obtained.

Patients with grade 4 envenomation must be monitored for respiratory compromise in an emergency department or intensive care unit. If available, treatment with the antivenom *Centruroides* (Scorpion) Immune F(ab')₂ (Equine) Injection (Anascorp) should be considered. Anascorp reverses neurotoxicity within hours and often allows discharge home from the emergency department. In clinical trials Anascorp had an excellent safety profile; however, acute hypersensitivity reactions are possible, so antihistamines and epinephrine (Adrenalin) must be accessible. Serum sickness can also develop up to 3 weeks after receiving antivenom.

If antivenom is not an option, longer-acting medications (morphine and lorazepam [Ativan]¹) may be used to control pain and agitation. Intubation and mechanical ventilation is sometimes necessary owing to venom effects and respiratory depression from the medications used to control symptoms. While the patient is intubated, continuous infusion of sedative, analgesic, and muscle relaxing agents may be necessary until signs and symptoms of envenomation resolve. This typically occurs within 24 hours, although residual medication effects can require prolonged observation.

VENOMOUS SNAKEBITE

Method of

Steven A. Seifert, MD

Two families of significantly venomous snakes are native to the United States. The Viperidae family (viperids) is composed of three genera and more than 30 species of rattlesnakes, copperheads, and cottonmouths. The Elapidae family (elapids) is composed of two genera and several species of coral snakes.

Each year, there are over 5,500 venomous snakebites by native species reported to U.S. poison centers, with fewer than 10 deaths. Ninety-eight percent of these bites are from viperids, and a single Crotalidae polyvalent immune FAB (ovine) antivenom (CroFab, Protherics, Brentwood, Tenn.) is effective against all native species in this family. There is also a single antivenom (Antivenin [*Micrurus fulvius*], equine origin, Wyeth Laboratories, Marietta, Pa.) against coral snakes, which are usually easily recognized by their distinctive markings. After a bite, it is not necessary to capture or further identify the snake, because this will only increase the likelihood of additional bites and/or victims.

There are approximately 50 additional bites per year by a wide variety of nonnative venomous species of snakes housed in zoos, academic institutions, serpentariums, and private collections. Identification of the biting species in these cases is usually not an issue.

Diagnostic and Management Overview

Taking Action

Only a few actions can be undertaken in the field to reduce morbidity or mortality from a venomous snakebite. Most “treatments” that have been advocated—cutting, sucking, or applying tourniquets, heat, cold, or electricity—have no proven efficacy and are much more likely to result in additional tissue injury and delay of definitive therapy. Appropriate local injury management—primarily removal of jewelry, splinting of the extremity, and measures to retard venom entry into central circulation until definitive therapy can be undertaken in carefully selected cases—and expeditious transport to a health care facility can produce optimal outcomes.

Definitive management for native venomous snakes in the United States is achieved with appropriate local wound care and antivenom, which is composed of antibodies raised in a host animal (horses or sheep) against snake venom components. Because native viperids inhabit every state except Maine, every hospital should stock or have ready access to this antivenom.

No FDA-approved elapid antivenom is currently being manufactured in the United States. Older stocks of a previously produced antivenom (Antivenin) are still available at many hospitals in endemic areas (e.g., Florida, Georgia, Alabama, Louisiana, Texas),

¹Not FDA approved for this indication.

nodosa, iritis, and keratouveitis have all been reported following exposure to tarantula hairs.

Treatment of embedded corneal hairs entails referral to an ophthalmologist and removal of the hairs if possible. Topical steroids are generally recommended, and some authors also recommend topical antibiotics.

VENOMOUS SNAKEBITE

Method of

Steven A. Seifert, MD

Two families of significantly venomous snakes are native to the United States. The Viperidae family (viperids) is composed of three genera and more than 30 species of rattlesnakes, copperheads, and cottonmouths. The Elapidae family (elapids) is composed of two genera and several species of coral snakes.

Each year, there are over 5,500 venomous snakebites by native species reported to U.S. poison centers, with fewer than 10 deaths. Ninety-eight percent of these bites are from viperids, and a single Crotalidae polyvalent immune FAB (ovine) antivenom (CroFab, Protherics, Brentwood, Tenn.) is effective against all native species in this family. There is also a single antivenom (Antivenin [*Micrurus fulvius*], equine origin, Wyeth Laboratories, Marietta, Pa.) against coral snakes, which are usually easily recognized by their distinctive markings. After a bite, it is not necessary to capture or further identify the snake, because this will only increase the likelihood of additional bites and/or victims.

There are approximately 50 additional bites per year by a wide variety of nonnative venomous species of snakes housed in zoos, academic institutions, serpentariums, and private collections. Identification of the biting species in these cases is usually not an issue.

Diagnostic and Management Overview

Taking Action

Only a few actions can be undertaken in the field to reduce morbidity or mortality from a venomous snakebite. Most “treatments” that have been advocated—cutting, sucking, or applying tourniquets, heat, cold, or electricity—have no proven efficacy and are much more likely to result in additional tissue injury and delay of definitive therapy. Appropriate local injury management—primarily removal of jewelry, splinting of the extremity, and measures to retard venom entry into central circulation until definitive therapy can be undertaken in carefully selected cases—and expeditious transport to a health care facility can produce optimal outcomes.

Definitive management for native venomous snakes in the United States is achieved with appropriate local wound care and antivenom, which is composed of antibodies raised in a host animal (horses or sheep) against snake venom components. Because native viperids inhabit every state except Maine, every hospital should stock or have ready access to this antivenom.

No FDA-approved elapid antivenom is currently being manufactured in the United States. Older stocks of a previously produced antivenom (Antivenin) are still available at many hospitals in endemic areas (e.g., Florida, Georgia, Alabama, Louisiana, Texas),

¹Not FDA approved for this indication.

but they are rapidly being depleted, and existing stocks eventually will be consumed or pass their expiration dates. An experimental antivenom has completed a Phase 3 clinical trial but is not currently available. Foreign-produced antivenoms against related coral snake species may also have efficacy against U.S. snakes but should be used only in the unavailability of an FDA-approved drug and, ideally, with prior FDA approval.

An even more difficult situation results from exotic envenomations, for which the appropriate antivenom (if one exists) is certain to be a non-FDA-approved product and may be located at a zoo or other non-health care source quite distant from the location of the envenomation.

Antivenom, local wound care, and symptomatic and supportive care are the mainstays of envenomation management. A regional poison center should be contacted for information and assistance in managing any venomous snake exposure, including locating an appropriate antivenom. Poison centers have personnel who are experienced at assessing and managing envenomations and have access to a database, the Antivenom Index, which lists sources of antivenoms for non-native species. Poison centers can be contacted from anywhere in the United States by calling 1-800-222-1222.

Snake Identification

Beyond determining whether the victim has been bitten by a coral snake or a viperid, it is relatively immaterial to know the species of the offending snake. A photo taken with a cell phone may be of some value to the treating physician, but it should be obtained only if it can be done safely and without causing a delay in transporting the patient. Viperid snakes are easily differentiated from coral snakes by virtue of the latter's distinctive color pattern of red, yellow, and black bands. It can be difficult to differentiate a coral snake from nonvenomous snakes that have similar markings. The ditty "red on yellow, kills a fellow; red on black, venom lack," which describes the red band being surrounded on either side by yellow or black, is accurate only for North American coral snakes. South American coral snakes may have the opposite pattern.

Because all viperid envenomations are currently treated with a single product and the physical findings or laboratory evaluation is all that is required to determine that the snake is venomous, attempting to kill or capture the snake is unlikely to add additional information to treatment decisions but is likely to result in the individual being bitten a second time or other individuals becoming bite victims. Differences in the appearance of the bite wound (e.g., fang punctures, swelling, ecchymosis) and the observation of signs and symptoms are usually sufficient to determine whether the biting snake was venomous and to guide therapy.

Since approximately half of envenomations are associated with intentional interactions with snakes, remember this advice: "Red on yellow, leave it alone. Red on black, leave it alone. Slithers on the ground, LEAVE IT ALONE."

Factors Affecting Toxicity and the Severity of Envenomation

Many factors govern whether an envenomation occurs after a bite, the signs and symptoms that develop, and the overall severity of effects. Up to 25% of viperid bites and up to 50% of elapid bites do not result in an envenomation. Barriers to fang penetration and other factors may result in no venom being injected. Patients must be watched for a sufficient length of time (i.e., 8 hours in a viperid bite and 24 hours in a coral snakebite) to ensure that this has been the case.

If an envenomation has occurred, the family and species of snake generally determines the spectrum of symptoms and signs. The amount of venom, specific venom components, and the underlying health status of the victim determine severity.

Viperid Envenomations

Epidemiology and Recognition

Viperid snakes are distributed throughout North America, with the apparent exception of Maine. Bites are more common in southern

states and during summer months, but they occur year-round and may occur at any time and in any location with captive collections. The various genera and species of viperids in the United States have relatively stable geographic ranges, with much overlap. Many different species of venomous snakes may inhabit any given area. Nonvenomous or mildly venomous colubrid snakes are also native to the United States. Viperids, also called pit vipers (i.e., rattlesnakes, copperheads, and cottonmouths), may be recognized by a generally triangular-shaped head, the so-called pit (an infrared heat-detection organ) located approximately midway between the nostril and the eye, and pupils shaped like those of a cat (not round).

Pit vipers have large, movable fangs through which venom is injected into the victim. Because fangs are curved, venom is usually injected subcutaneously rather than into deeper muscle compartments. Because of anatomic and other physical factors, bite wounds may appear as scratches or as one or more punctures. Envenomation may occur with any break in the skin.

Viperid venom is complex, consisting of dozens of proteolytic enzymes, small peptides, phospholipases, and other elements responsible for the spectrum of clinical effects seen. There is a great variability in this complex poison between species, within species, and even within a single specimen over the course of a season and life span.

Clinical Effects

The spectrum of clinical effects is based on the specific genus or species of viperid and is unpredictable, ranging in any given event from a non-envenomation (a "dry bite"; up to 25% of bites) to life-threatening reactions. Viperid snake envenomation invariably results in tissue injury, manifested by pain and progressive swelling, and it may include ecchymosis, elevated tissue and compartment pressures, tissue necrosis, and tissue loss. The complete absence of local effects can be used as a reliable marker of non-envenomation in a viperid bite as long as a sufficient period (8–10 hours) of observation has occurred.

Systemic effects may occur, including hematologic, neurologic, cardiovascular, and nonspecific findings. Rattlesnake envenomations are more likely to result in hematologic effects, such as thrombocytopenia, hypofibrinogenemia, or prolongation of the prothrombin time (PT) or activated partial thromboplastin time (aPTT), and are more likely to produce neurologic effects, such as muscle fasciculation or weakness, compared with copperhead or cottonmouth envenomations, but these effects can be seen with any viperid snake. Hypotension from direct myocardial depression or from type 1 hypersensitivity (i.e., anaphylactic or anaphylactoid) reactions may occur with any viperid exposure. Nausea, vomiting, diaphoresis, anxiety, and other nonspecific effects may be seen.

Duration of Clinical Effects

Local effects may develop rapidly or may not be apparent for many hours. Progression may occur for 24 to 36 hours, with resolution of tissue injury occurring over 3 to 6 weeks. Complications of tissue necrosis or infection have their own time frame of resolution. Hematologic effects usually begin within 1 to 2 hours of envenomation. If antivenom is given within this time frame, the detection of those effects may be masked and become apparent only after unbound antivenom has been eliminated from the body, usually 2 to 4 days after treatment. Hematologic effects may persist for 1 to 3 weeks after an envenomation. Neurologic and other systemic effects tend to occur within a few hours of envenomation and resolve over 24 to 36 hours.

Severity of Envenomation

Untreated, local injury worsens over time, with proximal progression of tissue injury. Hematologic effects can be profound, resulting in spontaneous hemorrhage. Hypotension may be profound and can result in death. Neurologic and other systemic effects are rarely life-threatening events. Because of changes in basic medical care and health care systems, it is not directly applicable to compare case-fatality rates before the introduction of antivenom (1950) with what can be expected today. Currently, there are three to five deaths from snakebite per year in the U.S.

Management

Determining Whether Envenomation Has Occurred and Its Severity

Because of the unpredictability of envenomation and the variability of possible clinical effects, each viperid bite must be assessed and responded to individually (Box 1). It is important to determine whether an envenomation has occurred. If there are no signs or symptoms of envenomation, there is no indication for antivenom or other specific treatment. The severity of the envenomation helps determine the amount of antivenom required to counter and neutralize venom effects, but this may not be immediately apparent, because envenomations tend to progress over time, and what may at first appear to be mild venom effects may progress to a severe envenomation.

Initial Hospital Management

On arrival at the hospital, jewelry should be removed and the bitten extremity loosely splinted. The wound should be cleaned, and a radiograph should be obtained to rule out a foreign body (Box 2). Tetanus status should be updated if needed. In the absence of other factors, the extremity should be maintained slightly below heart level until antivenom is started and then should be elevated. If there are immediate life-threatening effects (e.g., anaphylaxis, hypotension), the extremity should be placed in an inferior position and consideration given to impeding venom entry into central circulation by means of a lymphatic constriction band or pressure immobilization bandage, weighing the potential benefit against the possible risk of increased local tissue injury from increasing venom concentration and duration in the tissues. Patients often require opioid-level pain relief.

At least one large intravenous line should be initiated and crystalloid infused as needed. Initial hospital therapy, including a first dose of antivenom, should be provided in an area capable of close monitoring of vital signs and capable of managing life-threatening reactions; this usually is an emergency department. Whether an intensive care unit (ICU) or similar patient care area is used for subsequent management depends on the clinical situation.

Indications for Antivenom

Because of the safety of the current FDA-approved antivenom and its ability to stop proximal progression of local tissue injury, all patients with signs of progressive local envenomation effects as well as those with significant systemic effects are candidates for treatment with antivenom. Aside from the benefit in managing systemic venom effects, a recent study of antivenom in the treatment of copperhead envenomation demonstrated that antivenom improved limb function at 14 days post envenomation.

Depending on the original indication for treatment (local effects, systemic effects, or both), initial control of envenomation effects is the goal of the loading dose of antivenom. Currently, there are two FDA-approved viperid antivenoms for North American pit viper envenomation: Crotalidae Polyvalent Immune Fab (Ovine) Antivenin (CroFab), and Anavip. CroFab is an ovine-based Fab antivenom. The incidence of type 1 hypersensitivity reactions is approximately 6%. There are rare reports of IgE-mediated type 1 hypersensitivity reactions on repeat exposure in individuals who

BOX 2

Hospital Diagnosis and Initial Management for Viperid Envenomation

- Remove jewelry.
- If an arterial or venous tourniquet has been placed, convert to a lymphatic constriction band.
- Obtain intravenous access, and use crystalloid as indicated.
- Obtain CBC with platelet count, PT or INR, aPTT, and fibrinogen level q6–12h for 1 day and then daily if values are abnormal. An initial D-dimer value (or fibrin degradation products) should be obtained to detect fibrinolytic activity that may not yet have produced hypofibrinogenemia. Multiple D-dimer determinations are not required beyond two hours of envenomation and an elevated D-dimer is not an independent indication for antivenom. It is an indication of fibrinolytic activity and indicates the potential for late hypofibrinogenemia.
- Determine whether an envenomation has occurred.
- Determine severity based on the family or species of snake, age and health status of the victim, and development and rate of progression of signs and symptoms (e.g., local injury, hematologic abnormalities, hypotension and other systemic effects).
- Determine the tetanus vaccination status and update if necessary.
- Seek consultation from a poison center: 1-800-222-1222.
- If a pressure immobilization or lymphatic constriction band was placed before arriving at the hospital, determine whether antivenom is indicated, and remove the band after the antivenom infusion is started.
- If there are minimal or no signs of envenomation or if the bands are placed inappropriately, remove them under close observation.
- Determine whether antivenom is indicated, and administer per protocol.
- Provide basic wound care (i.e., cleaning and radiograph), and determine whether local injury requires specific management.
- Determine whether hematologic or other systemic effects require specific management.

Abbreviations: aPTT = activated partial thromboplastin time; CBC = complete blood cell count; INR = international normalized ratio; PT = prothrombin time.

BOX 1

Prehospital Management of Viperid Envenomation

- Remove jewelry.
- Splint the extremity and maintain just below heart level.
- Expeditiously transport to a health care facility.
- Consider use of lymphatic constriction band (blood pressure cuff at 15–25 mm Hg) for life-threatening effects only.
- Obtain intravenous access if possible.
- Do not use cutting, sucking, heat, cold, or other local “therapies.”

were previously treated with CroFab, but most people who have been previously treated do not develop an adverse reaction to subsequent administrations. The incidence of type 3 hypersensitivity reactions (“serum sickness”) is also approximately 6%. Pretreatment sensitivity testing is not required or recommended. The half-life of this antivenom is approximately 18 to 24 hours, which is considerably shorter than IgG or F(ab')₂ antivenoms, and it is responsible for the recurrence of hematologic effects in approximately 70% of patients with an initial coagulopathy. Anavip, is an equine-based F(ab')₂ antivenom that is scheduled to become available in the U. S. in 2018. Phase 3 clinical trial data suggest a similar safety profile to CroFab and a lower risk of subacute coagulopathy.

For confirmed and progressive envenomations, antivenom is administered as an intravenous solution, with 4 to 6 vials diluted into 250 to 500 mL of D₅W or normal saline. Treatment of life-threatening envenomations may be started with 10 to 12 vials. The infusion should be run slowly for the first 5 to 10 minutes, and the patient should be observed closely for a type 1 hypersensitivity reaction. If such a reaction occurs, the infusion should be slowed or stopped, depending on the severity, and appropriate symptomatic treatment should be started with H₁- and H₂-blockers, epinephrine, corticosteroids, and other supportive measures, as needed. It should be determined whether antivenom is still required, and if so, it should be restarted at a slower rate or higher dilution, or both. If a reaction does not occur, the infusion is concluded over 1 hour.

Treatment of Local Tissue Injury

Monitoring of the proximal extent of the active leading edge of edema, usually seen as a raised, tender, and perhaps erythematous margin, is usually sufficient to document progressive local injury and an indication for antivenom. There is little to no value in circumferential measurements of extremities, although comparisons between right and left in large fleshy areas (e.g. the thigh) may be helpful in detecting a deeper envenomation. If the antivenom is given exclusively for local findings, the syndromic response to envenomation is deemed to be controlled if there is cessation of proximal progression of edema at the end of the infusion. There is often some redistribution of existing tissue edema, but uncontrolled proximal progression is usually seen as an active leading edge of edema. If antivenom is being given for hematologic effects, cessation of worsening or reversal should be seen. Often, thrombocytopenia rebounds dramatically. Hypofibrinogenemia may not rebound as quickly or merely stabilize, because the liver must manufacture new fibrinogen. Although an elevated D-dimer value indicates fibrinolytic activity, it is not an independent indicator for antivenom treatment.

Other systemic effects may serve as indicators for antivenom use, and they should show control by the end of the initial infusion. If initial control is not deemed to have occurred, additional doses of antivenom should be administered until initial control is determined to have occurred. Most patients achieve initial control with 4 to 12 vials of antivenom, although more may be required.

Maintenance Doses

Because of the rapid decline of antivenom levels resulting from the larger volume of distribution of Fab antivenoms, after initial control is achieved, maintenance dosing of 2 vials every 6 hours for three doses is commenced. This usually maintains adequate antivenom serum levels to prevent recurrence of local tissue injury progression. If progression of local effects does recur, an additional 2 vials of antivenom usually are sufficient to control local worsening. Phase 3 clinical trials data suggest that maintenance dosing is not required with Anavip. Tissue pressures may be increased, and elevated muscle compartment pressures may be identified when measured directly. My colleagues and I do not routinely measure tissue or compartment pressures. When pressures are measured and demonstrated to be elevated, it should be remembered that the mechanisms of these phenomena are different from other muscle compartment syndromes. For example, extensive edema in the subcutaneous space circumferentially in an extremity may elevate compartment pressures by extrinsic compression. Case reports and series suggest that additional antivenom and extremity elevation result in reduced tissue and compartment pressures. Intracompartmental injection of venom can result in a true compartment syndrome. However, there is no evidence that fasciotomy is beneficial in this setting, and there are animal data to suggest that it may result in worse clinical outcomes.

Bleb formation at the site of a bite is not an important sign in and of itself, although it may suggest significantly elevated tissue pressures resulting in dermal-epidermal separation or the presence of tissue necrosis. Bleb fluid may contain unneutralized venom. It is reasonable to unroof blebs at or near the bite site and to débride obviously necrotic tissue that usually becomes apparent several days after the bite.

Antibiotics

The incidence of culture-proven infection in U.S. viperid bites is low, probably less than 5%. There are no data to support the use of prophylactic antibiotics, and it is best to limit the opportunities for adverse drug effects. It is often difficult to distinguish inflammatory venom effects from infection starting on the second day after an envenomation. If antibiotics are prescribed, a first-generation, broad-spectrum agent should be used.

Long-Term Local Tissue Effects

The edema and tissue injury produced by most North American viperid envenomations usually resolves within 1 to 2 months,

and a return to normal function can be anticipated. However, tissue necrosis or deep tissue injury may result in longer-term or even permanent structural and functional disability. Loss of tissue may occur, including digits and other parts of extremities, although this is rare and may be associated with prehospital application of tourniquets or other imprudent surgical interventions, delayed care, or complications such as infections. Some victims engage in behaviors that result in multiple envenomations, and this may increase the risks of long-term tissue injury.

Hematologic Abnormalities and Bleeding

One or more hematologic abnormalities may occur with native viperid envenomation (Box 3). Significant decreases in platelet count or fibrinogen concentrations are independent indications for antivenom treatment. Isolated, mild prolongations of PT or aPTT may not require antivenom treatment. However, these effects may be progressive or indicate an impending hypofibrinogenemia, and early antivenom treatment may prevent severe abnormalities. Even if platelets, fibrinogen, and intrinsic and extrinsic clotting systems are involved, the end result is not a true disseminated intravascular coagulopathy, because there is no true intravascular coagulation. Sufficient platelets, fibrinogen, and thrombin are usually available for hemostasis, and clinically significant bleeding is rarely seen. However, severe depletion of individual clotting elements or a combination of hematologic abnormalities can result in bleeding.

The management of initial or persistent laboratory abnormalities is achieved with additional antivenom. Administration of blood products (e.g., fresh-frozen plasma [FFP], platelet concentrates, other blood products) should be reserved for clinically significant bleeding and be given in conjunction with additional antivenom, because transfused elements are similarly likely to be consumed by venom activity. Ecchymoses in damaged tissues, expansion of the vascular volume from crystalloid administration, and red blood cell hemolysis from hemolytic venom factors may produce an anemia that may rarely require a red blood cell transfusion.

BOX 3

Management of Hematologic Effects and Recurrence in Viperid Envenomation

- Administer 4 to 6 vials of antivenom (Crotalidae Polyvalent Immune Fab [Ovine, CorFab]) for significant abnormalities of platelet count, PT or INR, aPTT, or fibrinogen. An elevated D-dimer value indicates accelerated fibrinogen breakdown and should prompt close monitoring of the fibrinogen concentrations, but it is not an independent indication to treat with antivenom.
- Administer additional antivenom in 4- to 6-vial increments until there is reversal of hematologic abnormalities. Replacement of platelets, clotting factors, or fibrinogen may be gradual, and a positive trend indicates neutralization of venom or replacement in excess of venom effect.
- Patients with initial hematologic effects or who were treated within 1 to 2 hours of envenomation are at risk for recurrent effects 2 to 4 days after treatment and should be followed closely: every other day until no recurrence at 4 days or daily for declining parameters.
- Consider treating recurrent hematologic abnormalities with additional antivenom. Indications include platelets $<25,000/\text{mm}^3$; fibrinogen $<50 \text{ mg/dL}$; INR >5 ; aPTT >150 seconds; and lesser abnormalities involving more than one parameter.
- Consider readmission for severe abnormalities, other risk factors (e.g., uncontrolled hypertension, advanced age, other bleeding diatheses), or clinically significant bleeding.
- Administer blood products *plus* additional antivenom for significant bleeding.

Abbreviations: aPTT = activated partial thromboplastin time; INR = international normalized ratio; PT = prothrombin time.

Recurrence of Hematologic Effects

Approximately 70% of patients who develop an initial hematologic effect will have a recurrence of those effects 2 to 4 days after initial treatment. The severity of the recurrence is usually similar to the initial effects. A person who presented with a severe thrombocytopenia is likely to return with recurrent severe thrombocytopenia. The mechanism is recurrent unneutralized venomemia after elimination of unbound Fab antivenom. The recurrent effects may be milder, because there is less venom in the body and severity is a function of venom effect and the body's ability to produce factors such as platelets or fibrinogen in excess of their rate of consumption. Recurrent effects may be more severe, however, or even appear to be occurring *de novo* if the patient was treated soon after envenomation, blunting the acute effects of the venom and masking the true severity of the envenomation.

Patients who present with severe early hematologic effects, an elevated D-dimer, an increase in the platelet count of more than 20% within 4 hours of the initial antivenom dose, or who are treated with antivenom within 1 to 2 hours of envenomation are at risk for severe recurrent effects and should be followed closely after discharge. Although the incidence of significant bleeding is low, even with profound laboratory abnormalities, it seems prudent to administer additional antivenom if the platelet count is less than 25,000, the fibrinogen level is less than 50 mg/dL, the PT or aPTT values indicate nonclotting, there is a combination of significant defects in coagulation, or there are underlying medical conditions that make hemorrhage more likely, such as advanced age, hypertension, or a bleeding diathesis. Additional antivenom may be given for severe hematologic effects or abnormalities associated with significant bleeding. In patients who have been discharged and who are not actively bleeding, 2 to 4 vials IV may be given in an outpatient setting and the patient followed daily. Additional such doses may be needed for more than 2 weeks. For patients who remain hospitalized or are readmitted, antivenom has been given by continuous IV infusion in a number of individual cases and small case series. An infusion initiated at 3 vials over 24 hours and titrated to clinical effect (up to 4 vials per 24 hours) was successful in reversing recurrent hematologic effects in all five cases reported in one series. Sterility and stability data for this product during prolonged administration is not currently available, however. If used in this way, sterile reconstitution and infusing 1 vial continuously over no more than 8 hours (3 vials per 24 hours) would be prudent. All patients treated in this way were able to have antivenom discontinued by 14 days and most were able to have it discontinued by 7 to 10 days. In the Phase 3 clinical trial of Anavip, subacute coagulopathy was seen in 5% to 10% of Anavip-treated patients, compared with 30% of CroFab-treated patients.

Disposition

Patients whose local effects are regressing and do not have complications, such as infection or necrosis, and whose hematologic and other systemic effects are controlled may be discharged. Typically, this occurs between 36 and 48 hours after envenomation. Patients with any venom-related hematologic abnormality during hospitalization (thrombocytopenia, hypofibrinogenemia, elevated D-dimer, or prolonged PT/INR or aPTT) should have at least one repeat set of labs within 5 days of treatment, as there is a risk of recurrent effects or late, new onset of hematologic abnormalities. Patients without any of these abnormalities and who also did not have an increase of more than 20% in platelet count within 4 hours of antivenom administration may constitute a group at very low risk of late effects, although confirmatory studies are needed. Ongoing pain relief may be required, with an effort to transition to non-opioid agents during the first week, and the patient should be warned to watch for signs of serum sickness. Occupational or physical therapy should be arranged to maximize return of function, and follow-up for local and systemic effects should be arranged.

Elapid Envenomations

Epidemiology and Recognition

U.S. coral snakes can be recognized by their distinctive band pattern, with a red band seeming to be placed on top of a larger yellow

band. This color pattern applies only to North American coral snakes. Each year, there are approximately 75 to 100 bites by coral snakes in the United States. Two genera and several species inhabit the United States, with the *Micrurus* genus responsible for most bites in Florida, Texas, Georgia, Louisiana, Alabama, and some neighboring states. A smaller genus, *Micruroides*, is found in Arizona and New Mexico, but it is responsible for very few bites, and there have been no reports of serious envenomations in recent years. Bites are more common during the warmer months.

Elapids have relatively short, fixed fangs, which may decrease the rate of envenomation. More than one puncture, deep punctures, and a history of the snake hanging on increases the risk of envenomation.

Clinical Effects

Envenomation by the coral snake produces primarily neurologic toxicity from presynaptic toxins initially producing bulbar muscle weakness, ptosis, diplopia, and dysphagia. These effects can begin within 15 to 30 minutes or may be delayed up to 24 hours after an envenomation. Muscle weakness and paralysis progress to include respiratory muscles, and they can result in respiratory arrest and death. Typical of presynaptic toxins, effect progression can be arrested with the use of antivenom, but the effects are not rapidly reversed. Typically, there is no or little local tissue injury, and the absence of local injury cannot be used to exclude envenomation. Likewise, there is usually no effect on hematologic function, and other systemic effects are rare. Patients cannot be assumed to have eluded envenomation by a coral snake because they lack these symptoms, and patients should be observed for at least 24 hours before concluding that an envenomation has not occurred.

Because of changes in basic medical care and health care systems, it is not directly applicable to compare case-fatality rates before the introduction of antivenom (1967) with what can be expected today. However, at that time, the case-fatality rate was approximately 10%.

Management

Because of the potential for rapid progression of motor paralysis and respiratory compromise, the difficulty of reversing paralysis after it is established, and the lack of local effects, it is reasonable to attempt to retard venom progression into the circulation until a decision regarding antivenom can be made. A pressure immobilization band (i.e., elastic bandage wrapped from an extremity's tip to trunk with the degree of tension used for sprains) is used for this purpose for elapid envenomations elsewhere in the world (Boxes 4 and 5). In Australian studies, a pressure immobilization bandage has been shown to slow venom absorption and in those studies, bandage pressures have been between 40–70 mm Hg in the upper extremity and 55–70 mm Hg in the lower extremity. However, the proper technique requires training, and the infrequency of these bites makes teaching and retention of such skills problematic. A blood pressure cuff inflated to similar pressures may also retard venom entry into circulation, and it can be a more reliable and easily taught technique, although it has not been validated in clinical studies.

BOX 4

Prehospital Management of Elapid Envenomation

- Remove jewelry.
- Splint the extremity and maintain just below heart level.
- Expeditiously transport to a health care facility.
- Apply a pressure immobilization bandage (i.e., 3- to 4-inch crepe bandage at lymphatic pressure from the tip of the extremity to the trunk) or a lymphatic constriction band (i.e., wide rubber band or blood pressure cuff at 15–25 mm Hg) proximal to the bite site.
- Obtain intravenous access if possible.
- Do not use cutting, sucking, heat, cold, or other local "therapies."

BOX 5

Hospital Diagnosis and Initial Management of Elapid Envenomation

- Remove jewelry.
- If an arterial or venous tourniquet has been placed, convert to a lymphatic constriction band.
- Obtain intravenous access, and use crystalloid as indicated.
- Determine whether an envenomation has occurred.
- Determine severity based on the family or species of snake, the age and health status of the victim, and the rate of progression of signs or symptoms (i.e., paralysis and other neurologic effects).
- Determine the tetanus vaccination status and update if necessary.
- Seek consultation from a poison center: 1-800-222-1222.
- If a pressure immobilization band or lymphatic constriction band has been placed before arrival at the hospital, determine whether antivenom is needed, and begin antivenom infusion before removing the band.
- Determine whether antivenom is indicated, and administer per protocol.
- Provide basic wound care (i.e., cleaning and radiograph), and determine whether local injury requires specific management.
- Determine whether other systemic effects require specific management.

Standard wound care should be performed, including cleansing the wound, obtaining a radiograph, and updating the tetanus status, if needed. Wound infection is uncommon, and prophylactic antibiotics are not recommended.

Because the first signs of envenomation can be rapidly progressive neurotoxicity and because of the difficulty of reversing paralysis, some authorities have proposed administering antivenom in cases in which an envenomation is possible, before the appearance of any clinical symptoms. Others have pointed to the infrequency of respiratory muscle paralysis resulting in the need for intubation and respiratory support and to possible geographic differences in snake toxicity, and they have counseled observation and antivenom treatment only after envenomation has been confirmed by progressive symptoms. Recent analysis of the national database has not demonstrated a significant difference in clinical severity between Florida and Texas coral snake envenomations, which supports early treatment. However, shortages of the FDA-approved coral snake antivenom and delays in obtaining the experimental product or a non-U.S. antivenom is likely to result in delays of many hours before antivenom can be administered, if it is available at all. The expiration date for one lot of Wyeth North American Coral Snake Antivenin (*Micrurus fulvius*) (Equine Origin, Lot L67530, has been extended through January 31, 2019 (<https://www.fda.gov/biologicsbloodvaccines/safetyavailability/ucm594352.htm>). Updated information can be obtained from the FDA website on Vaccines, Blood and Biologics (<http://www.fda.gov/BiologicsBloodVaccines/>). The designated poison center (1-800-222-1222) will have information on antivenom availability in the region. Aggressive and meticulous respiratory support, including intubation and ventilation that may be needed for days to weeks, should ultimately result in survival of even severe neurotoxic envenomations. If an FDA-approved coral snake antivenom is not available, there may be a clinical trial of an investigational coral snake antivenom in progress. Clinical trials can be located at: www.clinicaltrials.gov.

Exotic Snakebite

Epidemiology and Clinical Effects

In the United States, most exotic snake envenomations occur in private collections. These are not usually known to authorities or health care providers until an envenomation occurs, and they may involve the collection owner or family members, including children. They may occur in any locale, and victims may present to any health care facility.

Viperid and elapid snakes, which account for the bulk of venomous bites worldwide, have patterns of venom activity similar to those of their North American counterparts, with some variation and with generally greater toxicity for some non-U.S. species. Some nonnative elapids, such as cobras, mambas, black snakes, or taipans, produce much higher rates of respiratory paralysis and may produce much greater local tissue injury than U.S. coral snakes. Similarly, envenomation from some nonnative viperids, such as *Bothrops*, *Echis*, or *Bitis* species, or from an African colubrid, such as the boomslang, results in a greater risk of bleeding. Some of these species may directly activate prothrombin (e.g., *Echis* species, *Bothrops* species) and factor X (e.g., *Vipera* species, *Dispholidus* species), leading to a true disseminated intravascular coagulopathy with intravascular thrombosis, marked organ dysfunction, and potentially death.

Management

The specific management of exotic envenomations is beyond the scope of this chapter. Not all venomous exotic snakes have antivenoms, and even for snakes with antivenoms, none may be available in the United States, but zoos stock antivenoms for snakes in their collections. An updateable online database, the Antivenom Index, lists these antivenoms and is accessible by regional poison centers. For information on exotic antivenoms and assistance in managing an exotic snake envenomation, the regional poison center should be contacted (1-800-222-1222).

IMMUNIZATION PRACTICES

Method of

Beth A. Damitz, MD

CURRENT DIAGNOSIS

- Single-agent and poly-agent variety vaccines are available in the United States.
- Vaccine-preventable diseases are occurring in the United States despite efforts.
- Vaccine registries and office-based strategies can increase vaccination rates.

CURRENT THERAPY

- Vaccination schedules are available through various sources such as the CDC, including catch-up dosing.
- Vaccines can prevent diseases that are still occurring in the United States.
- Vaccination registry participation can increase vaccination rates.
- Each office visit should be used as an opportunity to review and offer vaccines.
- Providers need to be aware of special populations such as breast-feeding and pregnant women, immunosuppressed persons, and health care workers who could need different vaccines.

Definitions and Background

Vaccination is one of the most successful and cost-effective ways to prevent infectious diseases. Immunization is the process of inducing immunity artificially by either active immunization or passive immunization. It also occurs naturally through transplacental transmission of antibodies to a fetus, which provides protection against many infectious diseases for the first few months of life.

Physiology of Vaccines

Vaccines prevent disease in the people who receive them and protect those who come into contact with unvaccinated individuals such as children too young to receive vaccines, those who cannot be immunized for medical reasons, and those who cannot make an adequate response to vaccination. Vaccines are preparations of proteins, polysaccharides, or nucleic acids of pathogens that are delivered to the immune system as single entities, as part of complex particles, or by live, attenuated agents to induce specific responses that inactivate, destroy, or suppress the pathogen.

Immunization Recommendations

The Advisory Committee on Immunization Practices (ACIP) sponsored by the Centers for Disease Control (CDC), the American Academy of Pediatrics (AAP), and the American Academy of Family Practice (AAFP) work together to issue a national schedule

for routinely recommended vaccinations. They recommend routine vaccination to prevent 17 vaccine-preventable diseases that occur in infants, children, adolescents, or adults. These recommendations are reviewed and revised periodically. These immunization schedules give ranges of target ages for vaccines to be given (Figures 1 to 3). They include single and combination vaccine products. Catch-up dosing and special-population schedules are also available (updated immunization schedules are available <https://www.cdc.gov/vaccines/schedules/index.html>).

Disease Prevention

Since the development of vaccines, we have seen a dramatic decrease in both cases and deaths from vaccine-preventable diseases. For example, in 1950, there were 319,124 cases and 468 deaths from measles. This dramatically decreased to 43 cases and zero deaths in 2007. Obviously, decrease in disease and death is paramount, but in addition is the decrease in cost burden to our health care system. For every \$1 spent on measles, mumps, and rubella (MMR) vaccine, \$21 is saved in direct medical costs of treating a case of measles.

Immunization Responsibility

Appropriate vaccination is the responsibility of the health care team and patient (and parents). Education is critical. This can be done through various dissemination techniques such as one-on-one counseling, posters in the office, health fairs, and handouts at school and work. An office-based strategy consists of nursing and physician education of updates and changes in vaccines, the ability to track patient immunization records through registries, sending reminder letters to patients that there are vaccines they are recommended to have, and adopting standing orders to take advantage of appropriate office visits to maximize vaccination opportunities.

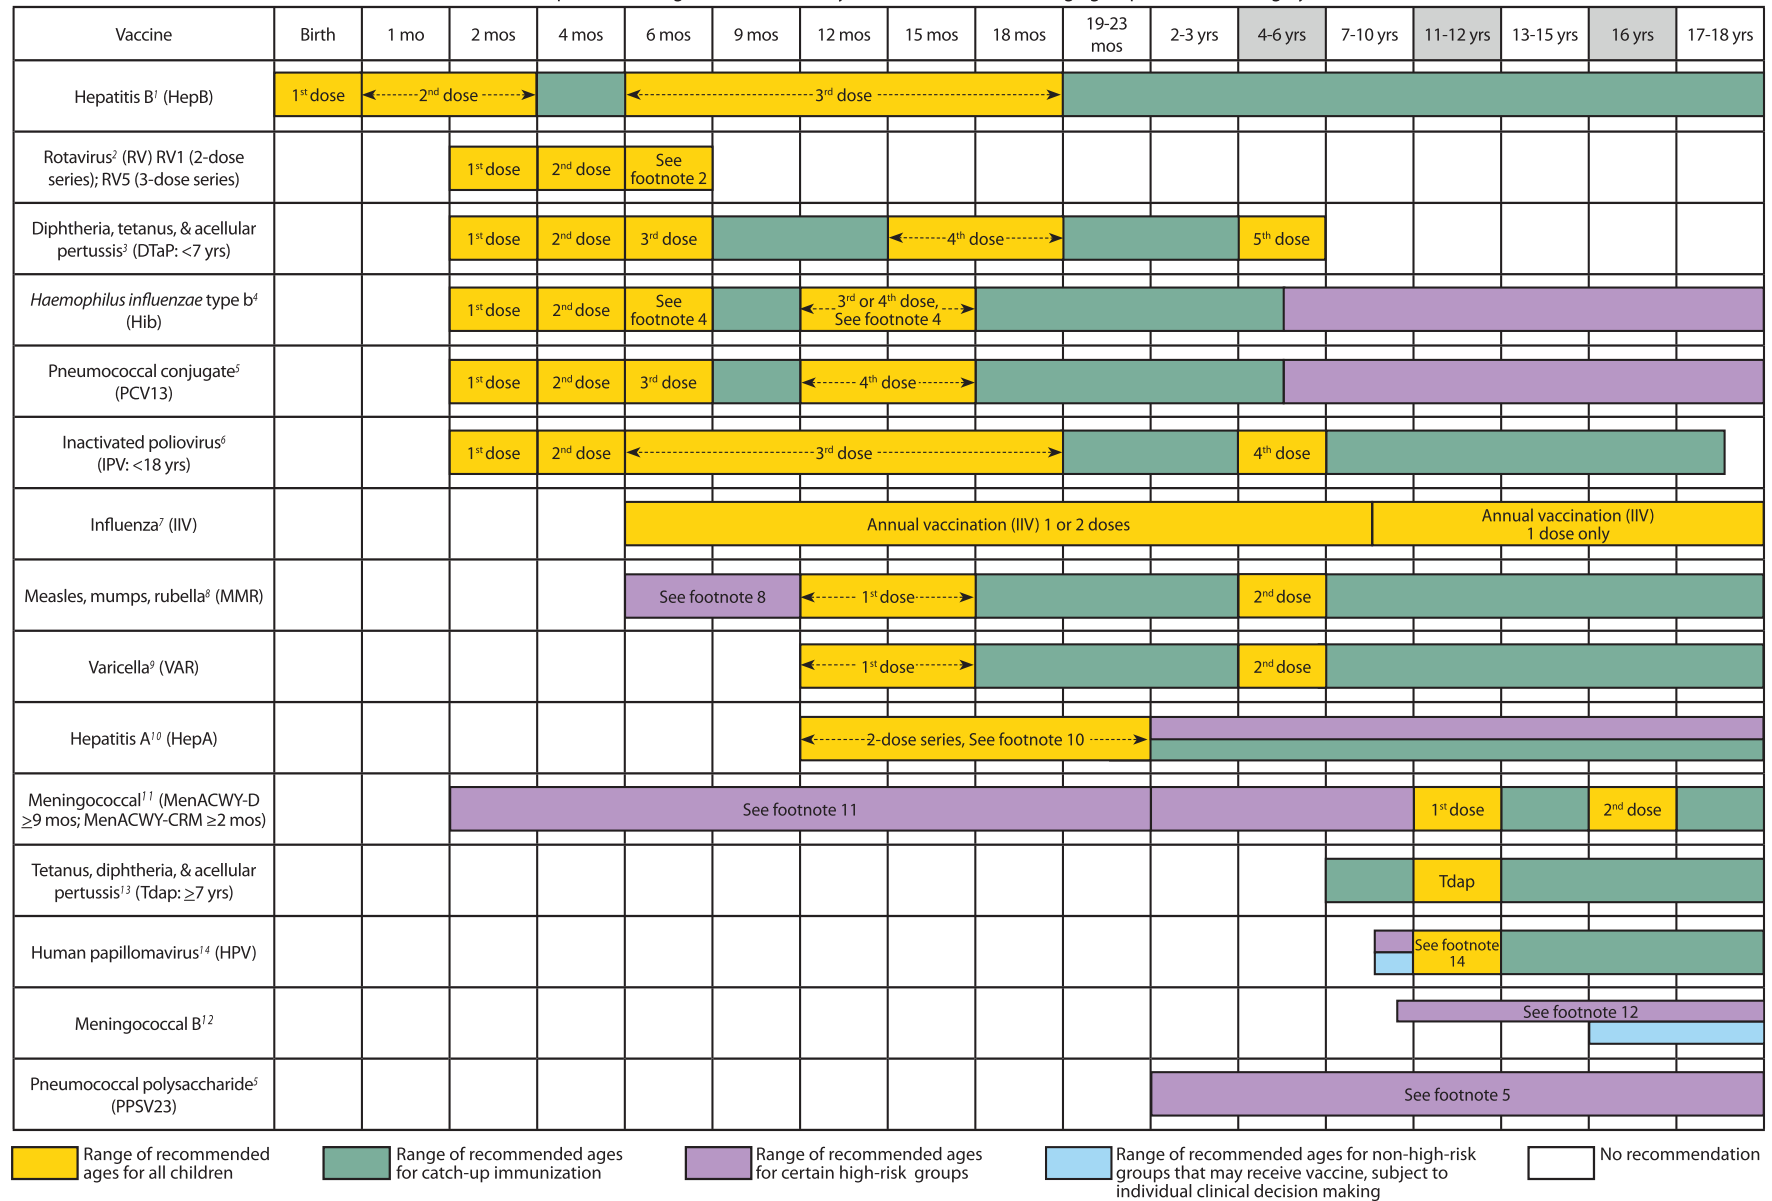

There are many sources for keeping current on immunizations and vaccines including the CDC's *Morbidity and Mortality Weekly Report* (MMWR). For parents and patients, the vaccine information statement (VIS), which is made available by the CDC to inform patients about the risks and benefits of immunizations, is very helpful and by law must be distributed before administering any vaccine. After the patient reads the VIS, the physician can then give any further information or answer questions before administering the vaccine. This discussion should be documented in the patient's medical record, including the refusal to receive certain vaccines (i.e., informed refusal).

General Principles for Vaccine Scheduling

Optimal response to a vaccine depends on several factors, including the type of vaccine, age of the recipient, and immune status of the recipient. Simultaneous administration of vaccines increases the probability that a patient will be vaccinated fully by the appropriate age. Simultaneous administration of all age-appropriate doses of vaccines is recommended by the MMWR for children for whom no specific contraindications exist at the time of the visit. The use of combination vaccine preparations greatly reduces the overall number of injections a child or patient will receive. However, care must be taken to ensure that the individual vaccine entities are not administered too early and are not administered too many at once.

(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE (FIGURE 2)).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded in gray.

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Figure 1 Recommended Immunization Schedule for Children and Adolescents Aged 18 Years or Younger—United States, 2018.

This figure should be reviewed with the accompanying footnotes. This figure and the footnotes describe indications for which vaccines, if not previously administered, should be administered unless noted otherwise.

Vaccine	19–21 years	22–26 years	27–49 years	50–64 years	≥65 years
Influenza ¹	1 dose annually				
Tdap ² or Td ²	1 dose Tdap, then Td booster every 10 yrs				
MMR ³	1 or 2 doses depending on indication (if born in 1957 or later)				
VAR ⁴	2 doses				
RZV ⁵ (preferred) or ZVL ⁵				2 doses RZV (preferred) or 1 dose ZVL	
HPV–Female ⁶	2 or 3 doses depending on age at series initiation				
HPV–Male ⁶	2 or 3 doses depending on age at series initiation				
PCV13 ⁷	1 dose				
PPSV23 ⁷	1 dose				
HepA ⁸	2 or 3 doses depending on vaccine				
HepB ⁹	3 doses				
MenACWY ¹⁰	1 or 2 doses depending on indication, then booster every 5 yrs if risk remains				
MenB ¹⁰	2 or 3 doses depending on vaccine				
Hib ¹¹	1 or 3 doses depending on indication				

Recommended for adults who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended for adults with other indications

No recommendation

Figure 2 Recommended immunization schedule for adults aged 19 years or older by age group, United States, 2018.

This figure should be reviewed with the accompanying footnotes. This figure and the footnotes describe indications for which vaccines, if not previously administered, should be administered unless noted otherwise.

Vaccine	Pregnancy ^{1,6}	Immuno-compromised (excluding HIV infection) ^{3,7,11}	HIV infection CD4+ count (cells/ μ L) ^{3-7,9-10}		Asplenia, complement deficiencies ^{7,10,11}	End-stage renal disease, on hemodialysis ^{7,9}	Heart or lung disease, alcoholism ⁷	Chronic liver disease ⁷⁻⁹	Diabetes ^{7,9}	Health care personnel ^{3,4,9}	Men who have sex with men ^{6,8,9}
			<200	\geq 200							
Influenza ¹	1 dose annually										
Tdap ² or Td ²	1 dose Tdap each pregnancy	1 dose Tdap, then Td booster every 10 yrs									
MMR ³	contraindicated			1 or 2 doses depending on indication							
VAR ⁴	contraindicated			2 doses							
RZV ⁵ (preferred)					2 doses RZV at age \geq 50 yrs (preferred)						
or ZVL ⁵	contraindicated				1 dose ZVL at age \geq 60 yrs						
HPV–Female ⁶		3 doses through age 26 yrs			2 or 3 doses through age 26 yrs						
HPV–Male ⁶		3 doses through age 26 yrs			2 or 3 doses through age 21 yrs					2 or 3 doses through age 26 yrs	
PCV13 ⁷		1 dose									
PPSV23 ⁷		1, 2, or 3 doses depending on indication									
HepA ⁸	2 or 3 doses depending on vaccine										
HepB ⁹						3 doses					
MenACWY ¹⁰			1 or 2 doses depending on indication , then booster every 5 yrs if risk remains								
MenB ¹⁰					2 or 3 doses depending on vaccine

---	--	---	---	---	-----------------	---	-------------------

Figure 3 Recommended immunization schedule for adults aged 19 years or older by medical condition and other indications, United States, 2018.

This can be a challenge when patients switch clinics or in times of vaccine shortages.

More often, dosing intervals longer than recommended are encountered in the office. With the exception of oral live typhoid vaccine (Vivotif Berna), an interruption in the vaccination schedule does not require restarting the entire series of a vaccine or toxoid or addition of extra doses. When an unknown or uncertain vaccination status is encountered, every effort should be made to access records. If this cannot be done in a reasonable amount of time, these persons should be considered susceptible and started on the age-appropriate vaccination schedule. Serologic testing for immunity is an alternative to vaccination; however, commercial serologic testing might not always be sufficiently sensitive or standardized for detection of vaccine-induced immunity, and research laboratory testing might not be readily available.

Route of Administration

There are two orally administered vaccines in the United States: rotavirus (Rotarix, RotaTeg) and typhoid vaccines. Rotavirus is licensed for infants and does not need to be repeated if the vaccine is spit up or vomited. Typhoid vaccine capsules should be taken as directed by the manufacturer. Live, attenuated influenza vaccine (LAIV, FluMist) is the only intranasal vaccine available. It does not need to be repeated if the person coughs or sneezes immediately after administration. With the exception of bacille Calmette-Guérin (BCG) vaccine and smallpox vaccine,¹ injectable vaccines are administered by the intramuscular or subcutaneous route.

Storage

In general, vaccines need to be stored in a refrigerator or freezer. When vaccines are inappropriately stored, they can lose potency. Refrigerator and freezer storage units must be properly monitored and maintained to assure vaccine integrity. Temperature logs should be maintained for 3 years unless state or local authorities require a longer time. Vaccines that have been stored at inappropriate temperatures should not be administered. An office protocol should be established for handling inappropriately stored vaccines, procedures for follow-up when these vaccines are inadvertently given, emergency vaccine retrieval and storage, handling vaccine shipments, maintaining a vaccine inventory log, and rotating vaccine stock to avoid expiration. Care should be taken to store similar vaccine products (sound-alike or lookalike) away from each other (on different shelves) or by color-coding labels. Diphtheria toxoid-, tetanus toxoid-, and acellular pertussis-containing vaccines are easily confused.

Vaccine Safety

Vaccines in the United States undergo extensive safety and efficacy evaluations through the FDA licensing process. Despite this rigorous process, adverse reactions can and do occur. Adverse reactions are reportable to the Vaccine Adverse Event Reporting System (VAERS). VAERS is a national reporting system created in 1990 to unify the collection of all reports of adverse events after vaccination. Its primary purpose is detecting new or rare vaccine adverse events, increases in rates of known side effects, and risk factors for particular types of adverse events.

In 1986, the National Childhood Vaccine Injury Act established the Vaccine Injury Compensation Program (VICP). It is a no-fault program that covers all routinely recommended childhood vaccines. Those claims may be based on a vaccine injury table, which lists the adverse events associated with vaccines and provides a rebuttable presumption of causation, or by proving by preponderant evidence that the vaccine caused an injury not on the table. The table was created to provide swift compensation to those possibly injured by vaccines.

The provider's role to help ensure safety of vaccination includes proper vaccine storage and administration, timing and spacing of vaccine doses, observation of contraindications and precautions, and reporting adverse events to the VAERS.

Contraindications and Adverse Events

A contraindication is a condition in a recipient that increases the chance of a *serious* adverse reaction. A precaution is a condition in a recipient that *might* increase the chance or severity of an adverse reaction or compromise the ability of the vaccine to produce immunity. Situations do arise when the benefits outweigh the risks of a side effect. The only contraindication applicable to all vaccines is a history of a severe allergic reaction (anaphylaxis) after a previous dose of vaccine or to a vaccine component unless the recipient has been desensitized. Children who experienced encephalopathy within 7 days after administration of a previous dose of DTP,² DTaP (Daptacel, Infanrix), or Tdap (Adacel, Boostrix) not attributable to another identifiable cause should not receive additional doses of a vaccine that contains pertussis. The following are *not* contraindications to vaccination:

- Minor illness
- Diarrhea
- Mild or moderate local reaction or fever following a prior dose
- Antimicrobial therapy
- Disease exposure or convalescence
- Pregnant or immunosuppressed person in the household
- Premature birth
- Breast-feeding

Vaccination should be deferred for persons with a moderate or severe acute illness. This precaution avoids causing diagnostic confusion between manifestations of the underlying illness and possible adverse effects of vaccination or superimposing adverse effects of the vaccine on the underlying illness.

Vaccine adverse reactions are classified as local, systemic, or allergic. Allergic reactions might be caused by the vaccine antigen, residual animal protein, antimicrobial agents, preservatives, stabilizers, or other vaccine components. Anaphylaxis is rare and usually begins within minutes of vaccine administration. Children who have had an apparent severe allergic reaction to a vaccine should be evaluated by an allergist to determine the responsible allergen and to make recommendations regarding future vaccination.

Barriers

Barriers to appropriate and timely vaccination include patients' misconceptions, false contraindications, complexity of the immunization schedules, religious or philosophical beliefs, and cost. The Vaccines for Children Program (VCP) is a federally funded program that provides free ACIP-recommended vaccines to adolescents and children younger than 19 years old. This program has reduced the barrier of cost.

Recording Vaccinations

Health care providers who administer vaccines covered by the National Childhood Vaccine Injury Act are required to ensure that the permanent medical record of the recipient indicates the date the vaccine was administered, the vaccine manufacturer, the vaccine lot number, and the name, address, and title of the person administering the vaccine. In addition, the provider is required to record the edition date of the VIS distributed and the date those materials were provided. Patients should also keep a record of the immunizations they receive, when they were received, and at what facility they received them. A permanent vaccination record card should be established for each newborn infant and maintained by the parent or guardian.

Immunization information systems (IIS), formerly referred to as immunization registries, are confidential population-based computerized information systems that collect and consolidate

¹Available in the United States from the Centers for Disease Control and Prevention.

²Not available in the United States.

vaccination data from multiple health care providers within a geographic area. The CDC oversees a network of 64 IIS programs distributed throughout all 50 states, the District of Columbia, and eight U.S. territories. A fully operational IIS can prevent duplicate vaccinations, provide a complete record of immunizations if the patient has received vaccines from multiple sites, and offer catch-up and needed vaccine information. Although participation of a provider is voluntary, it is highly encouraged.

Special Populations

Children

Although infants are born with some level of immunoglobulin (Ig) G that is contributed from the mother via passive immunity, these levels generally decrease by 9 months of age, leaving them vulnerable to many infectious diseases. Infants begin developing IgG shortly after birth and continue to increase these levels throughout the first year of life, but they remain generally susceptible to infection until they achieve adult levels of IgG at 10 years of age. Therefore this age group is especially important to vaccinate.

Breast-feeding

Neither inactivated nor live virus vaccines administered to a lactating woman affect the safety of breast-feeding for women or their infants. Breast-feeding is a contraindication for smallpox vaccination of the mother because of the theoretical risk for contact transmission from mother to infant. Yellow fever vaccine (YF-VAX) should be avoided. Breast-fed infants should be vaccinated according to the recommended schedule.

Pregnancy

No evidence exists of risk to the fetus from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. Live vaccines, such as smallpox, MMR, and varicella (Varivax), pose a theoretical risk to the fetus and therefore are generally contraindicated during pregnancy. New recommendations from ACIP advise to give all pregnant women a Tdap in every pregnancy. New data indicate that maternal antipertussis antibodies are short-lived; therefore Tdap vaccination in one pregnancy will not provide high levels of antibodies to protect newborns during subsequent pregnancies. Alternatively, if Tdap is not administered during pregnancy, the woman should receive a dose of Tdap as soon as possible after delivery to ensure pertussis immunity and reduce the risk for transmission to the newborn regardless of when she last received a tetanus booster. Routine influenza vaccination is recommended for all women who are or will be pregnant (in any trimester) during influenza season, which usually occurs early October through late March.

Altered Immunocompetence

Persons with altered immunocompetence include those with primary and secondary causes of immunodeficiency as well as those with asplenia, chronic kidney disease, treatments with therapeutic monoclonal antibodies, and prolonged administration of high-dose corticosteroids. In general they should receive trivalent inactivated influenza virus (TIV, Fluzone) and age-appropriate polysaccharide-based vaccines (pneumococcal conjugate vaccine [PCV, Prevnar], pneumococcal polyvalent [PPSV, Pneumovax 23], meningococcal conjugate [MCV4, Menactra], meningococcal polysaccharide [MPSV4, Menomune] and haemophilus B conjugate [Hib, ActHib, PedvaxHib]). Persons with most forms of altered immunocompetence should not receive live vaccines (MMR, varicella, MMRV [ProQuad], LAIV, zoster [Zostavax], yellow fever, oral typhoid, BCG, and rotavirus).

Health Care Personnel

Health care personnel are considered to be at substantial risk for acquiring or transmitting hepatitis B, influenza, measles, mumps, rubella, pertussis, and varicella and should be counseled on appropriate vaccinations.

TRAVEL MEDICINE

Method of

Jane Zuckerman, MD; and Yael Paran, MD

International travel is increasing, with the global air passenger market forecast to grow by 3.9% per annum. In 2015, international tourist arrivals in all countries exceeded 1.2 billion persons; it is estimated that the number of flights worldwide will more than double in the next 20 years. Such statistics exemplify the ever-increasing need for the specialty of travel medicine to protect the health of all groups of travelers.

Eight percent of travelers seek health care assistance either while abroad or upon returning home, with 22% to 64% of travelers reporting some type of illness. Most of the latter are mild and self-limiting, with diarrhea, respiratory infections, and skin disorders being the most common¹; however, some illnesses can be severe in returning travelers. Approximately 4% of travelers who seek medical help have an acute potentially life-threatening infectious disease, the most common being *falciparum* malaria. The most common causes of death in travelers are noninfectious, with the leading causes of death being cardiovascular events among older travelers and motor vehicle accidents among younger travelers.

The goal of a travel medicine visit is to maximize health and to prevent illness while traveling through the use of appropriate drugs and immunizations. Knowledge of disease risk, current outbreaks, and local health conditions relevant to each destination is constantly changing; thus the use of current, updated resources is essential. Table 1 lists several recommended information resources.

¹Not U.S. Food and Drug Administration (FDA) approved for this indication.

TABLE 2 Checklist of Items to Address in the Pretravel Consultation*

CATEGORY	ISSUES THAT SHOULD BE ADDRESSED
Patient risk assessment	Obtain history: itinerary, type of travel, personal medical history, age, underlying diseases, allergies, current medication, pregnancy status, previous vaccination status
Immunizations	Update routine immunization Provide routine travel immunization Provide destination-specific immunization
Malaria prophylaxis	If indicated: Provide malaria education and advice; discuss bite avoidance measures Prescribe antimalaria prophylaxis
Travelers' diarrhea	Prescribe self-treatment medication
Prevention against mosquito bites	Give advice regarding mosquito-borne disease Discuss personal protection measures
Rabies prevention	Give advice regarding behavior near animals Discuss measures to be taken if bitten or scratched by an animal—seek urgent medical advice Administer vaccine where indicated
Altitude sickness	Provide education Prescribe acetazolamide (Diamox) as appropriate
Prevention of sexually transmitted diseases	Provide education regarding safe sex
Zika	Discuss potential risk of congenital Zika syndrome for pregnant women or women/men planning to conceive following return from an endemic area
Others	Deep venous thrombosis prevention Accident prevention Motion sickness

*Some of the recommendations are indicated only for specific destinations or specific at-risk groups.

The preferred timing of a pretravel health consultation is usually 6 to 8 weeks before travel for most travelers, but may be longer when travelers are going overseas for long-term employment or several months of travel. The pretravel health consultation should be structured and comprehensive. Table 2 lists items that might require consideration and discussion during consultation. Patients should be asked to arrive with documentation of previous vaccinations. The consultation should begin with details including information regarding the proposed travel itinerary, type of travel, purpose of travel, and planned activities and information regarding the patient's medical history, including age, underlying diseases, allergies, current medications, pregnancy status, and previous vaccination status. A useful "travel history form" is available on the Shoreland Travax website.

Vaccinations

When deciding which vaccination to recommend, several factors must be considered, including any specific potential risks associated with the travel itinerary, length of stay, and activities. For each vaccine-preventable disease (VPD), one should consider the prevalence and impact of the disease in question. Since many people will be traveling multiple times during their lives, the health care provider should not only consider the next scheduled trip but also take into account future travel plans and the benefit of long-term vaccination. For example, a three-dose rabies vaccine preexposure series should confer lifelong protection for the "ordinary" traveler and

will only necessitate a short postexposure course of vaccine in case of an animal bite. Such an approach might be worthwhile for travelers who plan recurrent travel to developing countries.

Routine Vaccinations

The travel health practitioner should confirm that the traveler is up to date with routine vaccinations. Most travelers from developed countries will have received routine childhood vaccinations or experienced the illnesses themselves, and are therefore naturally immune. Nevertheless, some destinations require a booster immunization. In contrast, some travelers born in less developed countries might not have been fully immunized as children. The pretravel health consultation is a good "checkpoint" to verify routine vaccination status, which is important beyond the immediate requirement for travel. For example, measles, one of the most contagious diseases, is more common in developing countries because vaccine coverage is poor, leaving many susceptible to infection.

Measles–Mumps–Rubella Vaccine

Measles remains a serious cause of morbidity and mortality in the non-Western world. Importation of measles from regions that report endemic disease such as Europe, Africa, and parts of Asia remains one of the main reasons for outbreaks in areas where there is interrupted transmission (like the Americas). Indeed, several cases have even been associated with transmission during the course of air travel itself.

The measles–mumps–rubella (MMR) vaccine is routinely recommended for the following;

- All children from the age of 12 months. Younger children traveling to endemic areas might require a first dose of MMR vaccine at age 6 months, but will still need the standard two-dose schedule after the age of 12 months to ensure immunity.
- Nonimmune children and adolescents who did not complete a childhood series.
- Adults born after 1956 in the United States (1970 or later in Canada and the United Kingdom; 1966 or later in Australia) without evidence of immunity, regardless of level of risk.

These groups should receive two doses of the vaccine after the age of 12 months, with at least 4 weeks having elapsed between the doses. The effectiveness of the individual measles, mumps, and rubella components of the MMR vaccine after one dose is 95% to 98%, 94%, and 95%, respectively. After two doses, more than 99% will be protected against measles and rubella (90%–95% against mumps) for more than 20 years.

Poliovirus Vaccine

Owing to successful efforts to eradicate poliomyelitis, most of the world is now polio-free. As of 2016, Afghanistan and Pakistan are the only countries that still have endemic wild-type poliovirus infections, but outbreaks from importation of polio from endemic countries can occur. In 2012 and 2013, outbreaks of imported polio occurred in seven countries in Africa and the Middle East. In addition, a small number of developing countries continue to report cases of circulating vaccine-derived poliovirus (cVDPV). A single adult booster of poliovirus vaccine is recommended for travelers to endemic areas who have received the primary childhood series. A country is considered "endemic" when local disease is due to wild-type infection or to cVDPV. An inactivated, injectable poliovirus vaccine (IPV) (Ipol) is available for adults and children.

Since 2014, in view of the risk of international spread, the World Health Organization (WHO) has issued temporary polio vaccine exit recommendations under the authority of the International Health Regulations (IHR) for long-term travelers (staying >4 weeks) and residents departing from countries with either wild poliovirus (WPV) transmission or cVDPV transmission. As of 2017, countries covered by the WHO vaccine exit recommendation are Afghanistan, Nigeria, Pakistan, Guinea, Laos, and Madagascar. These recommendations are likely to change from time to time. A small number of individual countries also require proof of polio vaccination prior to entering the country.

Tetanus–Diphtheria–Pertussis Vaccine

Unvaccinated or inadequately vaccinated travelers are at risk of contracting diphtheria in developing countries, as well as tetanus and pertussis anywhere in the world. The potential risk of exposure to pertussis is worldwide, with the highest rates of disease being found in developing countries where vaccine coverage is low. In recent decades there has also been a resurgence of pertussis in several developed countries despite adequate vaccine programs, including the United States. One explanation for this phenomenon involves waning of immunity in adulthood following receipt of the currently used acellular pertussis vaccine series given in childhood. Adolescents and adults who completed the childhood series of DTaP (Daptacel, Infanrix) and did not previously receive Tdap (Adacel, Boostrix) should receive a one-time Tdap vaccine before travel, instead of a Td booster, to booster their immunity against pertussis.

If more than 5 years have elapsed since the last booster dose, a tetanus-containing booster should be considered for persons going to remote areas where tetanus boosters may not be readily available, to eliminate the need for in-country vaccination after contaminated trauma. A Tdap booster is recommended every 10 years, and can be given regardless of the interval from the last Td booster.

Varicella Vaccine

Varicella remains prevalent worldwide. The morbidity and mortality associated with varicella increases with age, with pregnant women and their unborn or newborn children being especially prone to severe sequelae. Travelers without either a history of the disease or documented immunity should consider receiving a course of the vaccine, especially if they will be living in close proximity to the local community. In several developed countries including the United States, varicella vaccine (Varivax) is now part of the routine childhood vaccine program, while most adults are immune to the disease because of past infection.

Influenza Vaccine

Influenza is the most common vaccine-preventable disease among travelers. Travelers aged 6 months and older should receive the most up-to-date influenza vaccine available in their countries if traveling to an area where influenza is circulating at the time of their travel (year round in tropical and subtropical areas, and winter months in temperate areas).

Pneumococcal Vaccine

The prevalence of pneumococcal disease is highest in developing countries. Since 2014, the Advisory Committee of Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends administration of pneumococcal conjugate vaccine (PCV13; Prevnar13) to all individuals 65 years or older who did not receive a pneumococcal vaccine in the past, followed by a dose of pneumococcal polysaccharide vaccine (PPSV23; Pneumovax) given 1 or more years later for immune-competent individuals and 8 or more weeks later for immune-compromised patients. This recommendation is not implemented in several developed countries, which continue to administer polysaccharide vaccine (PPSV23; Pneumovax) to otherwise healthy individuals 65 years or older.

Routine Travel Vaccination

Hepatitis A Vaccine

Hepatitis A is the second most common vaccine-preventable disease in travelers after influenza. A vaccine for hepatitis A is recommended to people traveling to any developing country and even some industrialized countries where sanitary conditions are variable. The vaccine is recommended for travel of any duration and for any purpose.

Two hepatitis A vaccine preparations are available (Havrix, Vaqta), which are approved for administration in those aged 12 months or older. A combination of hepatitis A and B vaccines (Twinrix) is also available and is approved for people aged 18 years or older, with accelerated schedules available to provide protection

for those traveling at short notice. A single dose of hepatitis A vaccine given any time before travel will provide complete protection for healthy persons. A booster dose is generally recommended at 6 to 12 months after the second dose to ensure long-term protection, but recent studies have shown that protection after only one dose can last for years. A 2012 position paper of the WHO stated that use of a single-dose schedule¹ for hepatitis A can be considered; however, this does not apply to immune-compromised individuals or at-risk groups, for whom a two-dose schedule is still recommended.

Typhoid Vaccine

Although hepatitis A and typhoid are both transmitted by contaminated food and water, hepatitis A is 100 times more common than typhoid in travelers. The Indian subcontinent seems to be a key focus of typhoid in travelers, accounting for more than 80% of travel-related cases in the United States. The efficacy of typhoid vaccines ranges from 50% to 80% in various published studies.

Typhoid vaccine is protective against *Salmonella enterica* serotype *typhi*, but not against paratyphoid fever, which is caused by strains of *Salmonella enterica* paratyphi A, B, and C. Typhoid vaccine is recommended to long-term travelers to developing countries and short-term travelers to South Asia, as well as for other destinations for high-risk groups such as travelers visiting friends and relatives and food adventurers.

Two vaccines are available: the oral live, attenuated typhoid vaccine (Ty21A, Vivotif Berna) and the injectable typhoid V1 polysaccharide vaccine (Typhim Vi). The oral vaccine, which consists of four capsules (one taken every other day), should be completed at least 1 week before travel, and the injectable vaccine should be given at least 1 week before travel.

Hepatitis B

Hepatitis B is endemic worldwide. In Asia, the Middle East, Eastern and Southern Europe, Sub-Saharan Africa (excluding West Africa), and Russia, disease prevalence is intermediate (2%–7%), while in West Africa, the prevalence is high ($\geq 8\%$). The vaccine (Engerix-B, Recombivax HB) is recommended for long-stay travelers to intermediate- and high-prevalence areas, and for short stays for high-risk groups such as travelers who are likely to have new sexual partners during travel and those with underlying medical conditions that may cause them to seek medical care while abroad. Health care workers should be vaccinated for any destination, regardless of the period of travel. The availability of accelerated schedules of administration of monovalent and combination hepatitis B vaccines enables rapid protection to be given when necessary.

Geographically Targeted Vaccines

Yellow Fever Vaccine

Yellow fever is a mosquito-borne disease endemic in parts of Sub-Saharan Africa and tropical South America. It is reported rarely in travelers, with only 10 cases documented during 1970 to 2013, and two more reported from 2016 to 2017. The risk of a traveler acquiring yellow fever varies with season, location, activities, and duration of travel. For a 2-week stay, the estimated risk for illness attributed to yellow fever for an unvaccinated traveler to West Africa is 50 cases per 100,000 population; for South America, the risk for illness is 5 cases per 100,000 population. The vaccine is recommended for personal protection of travelers to endemic areas. In addition, under WHO rules, any given country may routinely require vaccination for entry into its territory. Valid yellow fever vaccinations must be administered at an authorized site, recorded on a WHO standardized yellow card, and completed at least 10 days before entry. The aim of the regulation is to protect countries that have the mosquito vector, which can potentially introduce the virus by virtue of a viremic traveler.

Yellow fever vaccine (YF-VAX) is a live attenuated preparation that has been rarely associated with severe and even fatal adverse reactions—generally following a first dose to the individual. The overall rate of serious adverse reaction is 1 event per 250,000

doses. The likelihood of serious adverse events increases with age, with patients older than age 60 years having a much higher risk for severe adverse reaction than younger people, and in particular those with a history of thymus dysfunction or myasthenia gravis, which is associated significantly with a disease affecting the thymus gland (thymic hyperplasia or thymoma). The incidence of yellow fever–associated neurotropic disease (YEL-AND) is 17 per million doses in those older than 60 years of age and 4 per million in those younger than 60 years of age. The incidence of yellow fever–associated viscerotropic disease is 20.5 per million in those older than 60 years of age and 3 per million in those younger than 60 years of age. The decision on the need for administering yellow fever vaccine should consider the benefit from the vaccine versus the potential risk.

A change in the IHR since July 2016 now considers a valid yellow fever vaccination as effective for life, with no need for boosters at 10-year intervals. This also applies retrospectively to yellow fever vaccines given any time before 2016. The new policy also extends to the validity of the vaccine for personal protection, with no need for booster doses among healthy, immune-competent individuals. A booster vaccine after 10 years is still recommended for specific high-risk individuals: long-term travelers, travelers to West Africa, and travelers to an area where there is a current outbreak.

Japanese Encephalitis

Japanese encephalitis (JE) is a mosquito-borne arbovirus disease found primarily in China, Korea, the Indian subcontinent, Southeast Asia, and the Western Pacific. Japanese encephalitis has a mortality rate of up to 30% and is rarely reported in travelers. The risk varies according to destination, duration, season, and activities being undertaken. The risk is highest for travelers to rural areas, travel in the active transmission period, and travelers who plan nighttime outdoor activities. The overall incidence of JE among persons from nonendemic countries traveling to Asia is estimated to be less than 1 case per 1 million. Only 55 cases of travel-associated JE were reported between 1973 and 2008, with most cases reported from Thailand and Bali.

A killed-cell vaccine, IXIARO, is licensed in the United States for use in persons aged 2 months or older. Children 2 months to 2 years old are given half the dose used for adults. The vaccine is given as a two-dose series, at 0 and 28 days. Recent studies on accelerated vaccine schedules for travelers who are unable to receive the vaccine 28 days before departure have shown that a two-dose schedule of the vaccine given at an interval of 1 week³ provides good immunogenicity for up to 2 months postvaccination. Results for longer duration of protection using this accelerated schedule are currently unknown.

Rabies

Rabies exists worldwide, with only small pockets of the world being rabies-free. Disease rates are highest in Asia, Africa, and South and Central America. Dogs remain the primary vector, but bats are increasingly important sources. From 1990 to 2013, 66 cases of rabies were documented in travelers—40% from Asia, and 85% following canine exposure.² Bites from animals during travel are common. Approximately 2700 travelers received care for animal-related exposures and required rabies postexposure prophylaxis at GeoSentinel clinics during a 15-year period (1997–2012). Of note, the median duration of stay for these travelers was less than 1 month. In another study, 1.6% of Israeli travelers traveling for more than a month had experienced an injury from a potentially rabid animal.

A three-dose preexposure course of rabies vaccine (Imovax Rabies, RabAvert) can be administered before travel. In the event of an exposure, persons vaccinated before exposure do not require human rabies immune globulin (HRIG [HyperRab, Imogam Rabies]), which may be expensive, unavailable, or unreliable in

the traveler's locale. Following an exposure and despite having received the three-dose preexposure course of vaccine, a traveler will still require two additional doses following an animal bite, administered as soon as possible. Children may be at higher risk for exposure to rabies because of more frequent contact with dogs and their failure to inform parents of incidental bites or scratches. Rabies vaccine is recommended for travelers based on age, destination, duration of stay, likelihood of activities that may lead to potential exposure to rabid animals, visiting remote areas, and the likely need for rabies vaccine and rabies immune globulin for postexposure care. In light of the devastating consequences of rabies, the fact that animal bites, scratches, or licks over mucous membranes are common among travelers even during short trips; the difficulties in receiving rabies immune globulin in the developing world; and the fact that a one-time preexposure course of vaccine is “for life” suggest that the threshold for recommending rabies vaccine to travelers to the developing world should be low.

Meningococcal Vaccine

Meningococcal disease is endemic worldwide. The “meningitis belt” in Sub-Saharan Africa is a hyperendemic area for meningococcal disease, with seasonal epidemics occurring during the dry season (December–June). The serogroups prevalent in the meningitis belt are A, C, W, and, to a smaller extent, X.

Meningococcal disease is rare in travelers (1:100,000 to <1:1,000,000 per month of travel). The vaccines recommended for travelers include quadrivalent conjugated preparations (Menactra, Menveo, and Nimenrix²), which are recommended for travelers to the meningitis belt, travelers to areas with current outbreaks of meningococcal disease, and those who anticipate close contact with crowds or the local population in developing countries (e.g., aid workers in refugee camps).

Meningococcal vaccine is required for entry for pilgrims going to Saudi Arabia (Hajj or Umrah). The risk of meningococcal serogroup B may be underestimated as a potential public health hazard during the Hajj and Umrah, and with the availability of an effective vaccine against men B, vaccination of pilgrims against men B in addition to vaccination with meningococcal ACWY should be considered.³ Since serogroup B is common in industrialized countries but not in developing countries, the newly approved meningococcal vaccine for serogroup B (Bexsero, Trumenba) is not recommended for travelers in general, unless they fall into a high-risk group (e.g., asplenia). Attendance at a travel clinic, however, can present an opportunity to vaccinate against men B.

Tick-Borne Encephalitis

Tick-borne encephalitis (TBE), an arboviral zoonosis transmitted primarily through the bite of *Ixodes* species ticks, is endemic in many popular tourist destinations in Europe, Eastern Europe, and parts of Asia including China, Japan, Russia, and Siberia. In Europe, the highest rates occur in Austria, Estonia, Lithuania, and Slovenia. TBE is an emerging infection, and since 1973 there has been an increase in TBE of nearly 400% in all endemic regions of Europe. Most cases of tick-borne encephalitis occur between June and October, with a peak in July. The risk for travelers is difficult to quantitate, but recently published data suggests there is a higher risk than previously thought. A TBE vaccine² is available and considered immunogenic and safe. In some countries in Europe, the vaccine is included in the routine immunization program, and it is highly effective in reducing TBE in disease-endemic areas. Vaccination is recommended even for short stays for travelers to disease-endemic areas in the transmission period and for those planning high-risk activities such as hiking and camping.

Cholera

Cholera is endemic in several countries in Asia, Sub-Saharan Africa, and the Caribbean. Vaxchora, an oral live attenuated cholera vaccine, was approved for use by the FDA in 2016. The vaccine

²Not available in the United States.

³Exceeds dosage recommended by the manufacturer.

²Not available in the United States.

is recommended for aid and refugee workers and health care workers who are traveling to affected countries to support displaced populations.

Malaria Prophylaxis

Malaria continues to kill millions of people worldwide. Malaria is transmitted by the *Anopheles* mosquito and involves five species of the parasite *Plasmodium*, with *Plasmodium falciparum* and *Plasmodium vivax* being the most common species. The mosquitoes that spread malaria are most active from dusk to dawn. Transmission of malaria occurs both in urban and in rural areas in the African continent and the Indian subcontinent. In South America, Central America, and the Caribbean, transmission of malaria occurs in rural areas. There is no transmission of malaria in areas above altitudes of 2500 meters.

Malaria is the most common cause of fever in the returning traveler. Malaria is also by far the most common acute potentially life-threatening disease in travelers, constituting 76% of this group of diseases in an analysis of the GeoSentinel registry. In the United States, the overall trend of malaria cases has been increasing since 1973, with approximately 1,700 cases each year. In a 2013 malaria surveillance report of the CDC, 82% of the cases were from the African continent (mostly from West Africa); 11% from Asia (mostly India); 6% from Central America, South America, and the Caribbean; and 1% from Oceania. Travelers visiting friends and relatives (e.g., people who emigrated from a malaria-endemic area and return to visit their homeland) are a major source of imported malaria because they often do not use prophylaxis when returning to the endemic country.

There is no vaccine available against malaria for travelers. Protection against malaria includes:

1. Using chemoprophylaxis where needed
2. Using personal protection/bite avoidance measures
3. Advising travelers to seek medical care if they have a febrile illness during or after travel

Chemoprophylaxis

Among patients diagnosed with malaria in the United States, only about a third report having taken chemoprophylaxis. Among those who do take chemoprophylaxis, adherence is poor. Distribution of malaria in a country is focal and can change greatly from one area to another. Malaria maps by country are available on the CDC website, and they are updated regularly and should be consulted before deciding whether chemoprophylaxis is recommended. In almost all areas with malaria, atovaquone-proguanil (Malarone), doxycycline, and mefloquine (Lariam) are equally effective against chloroquine-resistant *P. falciparum*. Although resistance to mefloquine limits its use in Southeast Asia, *P. falciparum* is resistant to chloroquine in most areas where this species occurs. Areas where the parasite is still chloroquine sensitive are Central America west of the Panama Canal, Haiti, the Dominican Republic, and most of the Middle East. As such, chloroquine is the drug of choice in these areas.

The traveler should be briefed on the side effects of any of the types of chemoprophylaxis, as well as when to start the medication before travel and how long to continue it once outside the endemic malarial zone. Travelers should be instructed if the drug is to be taken once daily (e.g., doxycycline [Vibramycin], atovaquone-proguanil [Malarone]) or once a week (e.g., mefloquine [Lariam], chloroquine), because serious instances of toxicity and drug failures have occurred when these drugs are taken improperly.

In 2013, the FDA added a “black box” warning to the mefloquine drug label because of the potential risk of serious psychiatric and neurologic side effects that can persist for long periods, or even for life, after the discontinuation of mefloquine.

Owing to its good safety profile, atovaquone-proguanil [Malarone] may be the drug of choice for malaria prophylaxis in most situations. Malarone is taken 1 day before entering and until 1 week after leaving the endemic area. Some experts believe that taking atovaquone-proguanil only until 1 day after leaving the endemic

area³ is safe and can improve traveler compliance. This recommendation is based on several small studies and the fact that both atovaquone and proguanil kill early stages of *P. falciparum* in the liver and have a half-life elimination period of nearly 6 days.

It is important to remember that the aforementioned medications are not protective against dormant hepatic forms of two species of the malaria parasite (*P. vivax* or *P. ovale*), which can cause relapses of malaria months and even years after returning from travel.

Personal Protection/Bite Avoidance Measures

Travelers should be informed about the principles of malaria transmission and prevention, including avoiding outdoor exposure from dusk to dawn, wearing long-sleeved clothing to provide maximum cover of exposed areas of the body, using of repellents, and sleeping in an air-conditioned room. If the traveler is unable to sleep in a sealed, air-conditioned room, permethrin-coated mosquito bed nets have been demonstrated to significantly reduce malaria incidence. Travelers can protect themselves by sleeping under well-made, treated bed nets and by employing a knock-down aerosol repellent to treat the room. Repellents containing DEET (30%–35%) or picaridin (20% or above) are recommended. The concentration of DEET determines the length of protection; 35% DEET is effective from 6 to 8 hours, and concentrations of DEET of up to 30% are safe for children and infants older than 2 months when the eyes, hands, and mouth and mucous membranes are avoided.

Seeking Medical Care

Travelers should be advised to seek medical attention if they experience any symptoms that could be compatible with malaria (mainly fever and rigors) and about the need to tell their health care practitioner about where they have traveled. They should be aware of the fatal potential of this disease, the detrimental effect of delay in diagnosis and treatment, and the possibility of the disease appearing again, even months or years after leaving their destination (*P. vivax*, *P. malariae*, or *P. ovale*).

Travelers' Diarrhea

Travelers' diarrhea (TD) is the most common health problem encountered by travelers. Travelers' diarrhea is defined as passing three or more unformed stools in 24 hours, in addition to at least one additional symptom such as abdominal cramps, tenesmus, nausea, vomiting, fever, or fecal urgency. The condition usually has an abrupt onset. Most cases of travelers' diarrhea are self-limited, lasting a median duration of 3 to 4 days. The risk of acquiring diarrhea ranges from 20% to 83% in travelers to the developing world and varies by location, individual, and length of stay. Of these factors destination is most important, with South Asia and West/Central Africa being the destinations with the highest risk.

Most cases of TD are caused by bacterial pathogens, with *Escherichia coli* (mostly enterotoxigenic) being most common, followed by *Shigella*, *Campylobacter*, and *Salmonella*. Causative viral pathogens include noroviruses and rotavirus. Protozoa are uncommon causes of TD and are generally associated with a more gradual onset of diarrhea. Postinfectious irritable bowel syndrome (PI-IBS) following travelers' diarrhea may occur in 3% to 17% of patients.

Prevention

Travelers' diarrhea is associated with the consumption of contaminated food and beverages and coming into contact with contaminated hands. Foods more often linked to diarrhea include reheated foods (such as quiche, rice, or casseroles), raw vegetables, raw meats (especially shellfish), unpasteurized milk products (also a source of brucellosis), buffet services, and raw berries. The key to food safety is keeping hot foods hot and following standard recommendations with regard to food preparation; evidence that food restrictions reduce the likelihood of acquiring travelers' diarrhea is weak. The importance of frequent handwashing should be stressed in addition to drinking clean, bottled water. Ice prepared from

³Exceeds dosage recommended by the manufacturer.

contaminated water can contaminate any drink. Water may be made safer at any altitude by bringing it to a boil and allowing it to cool while covered (boiling for 1 minute, or 3 minutes at altitudes above 2000 m). Halogenation with iodine or chlorine is also an acceptable means to treat water.

Treatment

TD is a self-limited disease. Mild to moderate cases can be treated with rehydration, antimotility agents such as loperamide (Imodium), or antisecretory agents such as bismuth subsalicylate (Pepto-Bismol). Since adult travelers with travelers' diarrhea rarely lose significant quantities of electrolytes, specific replacement is rarely indicated. Children may experience more severe fluid and electrolyte losses, and oral rehydration remains paramount to any pediatric drug therapy, as does seeking immediate medical advice. Packets of oral rehydration salts (ORSs) are available in most pharmacies in the developing world. ORSs are rapidly absorbed from the intestine and can be useful even in the presence of vomiting.

Antibiotic therapy should be reserved only for severe cases. A recent study showed that the use of antibiotic therapy for TD increases the likelihood of gut colonization with extended-spectrum beta-lactamase-producing Enterobacteriaceae (ESBL-PE) among returning travelers. Rates of colonization with ESBL-PE for travelers treated with antibiotics for TD have reached 80% among those returning from Southeast Asia. Concomitant use of loperamide and antibiotics for TD has also been shown to increase the rate of colonization of ESBL-PE. Patients should be advised to restrict the use of antibiotics for self-treatment of TD only to severe cases, or for episodes associated with high fever or bloody stools.

Antibiotics can shorten the duration of illness. A quinolone is recommended as first-line treatment for most destinations. Azithromycin (Zithromax)¹ is preferred for Southeast Asia in view of an increased incidence of quinolone-resistant *Campylobacter* strains. Azithromycin is also the drug of choice for children and pregnant women. Most patients will improve after 24 hours of treatment with antibiotics, and if diarrhea persists beyond 24 hours, a 3-day course is recommended (Table 3).

Altitude Sickness

Altitude sickness can be fatal and, importantly, is preventable. For example, Nepal registers 2 to 3 deaths in travelers due to altitude sickness per week, with an estimated mortality rate of 7.7 per 100,000 trekkers. Travelers should be aware of the illness and must be educated to recognize and acknowledge the presence of symptoms when they first appear. Air travel to an elevated environment allows for sudden exposure, with little time for acclimatization. Rapid ascent (<24 hours) to altitudes over 2400 meters is associated with altitude sickness. Common destinations at high altitudes include Cusco, Peru (3400 m); La-Paz, Bolivia (2650 m); Lhasa, Tibet (3700 m); and Quito, Ecuador (2800 m).

Ideally, ascent rates below 300 meters per day to altitudes over 2400 meters may reduce the risk of altitude sickness. Acute mountain sickness is characterized by headache, dyspnea, nausea, vomiting, insomnia, and changes in mental status. The condition may be reduced or prevented in adults by taking acetazolamide (Diamox), 125 mg orally twice a day, for 1 day before ascent, continuing for 2 to 3 days on arrival at maximum altitude. The risks for infants and children at high altitude remains controversial because acute mountain sickness can be more difficult to diagnose, with only non-specific symptoms being present such as irritability, poor feeding, and sleeplessness. Increasing hydration, resting, and limiting exertion in the first few days following arrival help acclimatization. The definitive treatment of all forms of altitude sickness is descent to a lower altitude. All travelers experiencing difficulty at altitude should be prepared to abandon their trip if symptoms persist or worsen.

¹Not FDA approved for this indication.

TABLE 3 Drugs for Treatment of Travelers' Diarrhea

DRUG	ADULT DOSAGE	COMMENTS
Symptomatic medication		
Bismuth subsalicylate (Pepto-Bismol)	Two tablets or 2 tablespoonfuls (1 dose cup, 30 mL), repeated half hourly, as needed. Do not exceed a total dose of 16 tablets, or 8 oz. of the liquid, in any 24-hour period.	The maximum recommended dose is 240 mL/d (16 tabs)
Loperamide (Imodium)	2 caplets (2 mg each) for first dose, then 1 after each loose stool. Do not exceed 8 caplets (16 mg) in 24 h	Antiperistaltic drug Do not use if dysentery is diagnosed Sold "over the counter"
Antibiotics		
Ciprofloxacin (Cipro)	500 mg tab q12h × 3 d or 750 mg tab once at start of diarrhea symptoms	Do not use in pregnant women Do not use in children <18 y
Azithromycin* (Zithromax)	1 g as a single oral dose or 500 mg once daily × 3 d	Drug of choice for quinolone-resistant <i>Campylobacter</i> strains Use for travelers' diarrhea in persons unable to use fluoroquinolones
Rifaximin (Xifaxan)	200 mg tab tid × 3 d	Nonabsorbable antibiotic Do not use for diarrhea complicated by fever or blood For patients 12 y of age or older Safety for adults ≥65 y has not been studied

*Not US Food and Drug Administration approved for this indication.

Conclusion

With the ease of travel and the ever-increasing numbers of travelers exploring the world, the need for meeting the health needs of this diverse group of travelers continues to grow. Travel medicine specialist practitioners are ideally placed to identify and treat travel-related health problems, both before and after travel.

BIOLOGIC AGENTS REFERENCE CHART

Method of

James J. James, MD, DrPH; and James M. Lyznicki, MS, MPH

Biological weapons are devices used intentionally to cause disease or death through dissemination of microorganisms or toxins in food and water, by insect vectors, or by aerosols. Potential targets include human beings, food crops, livestock, and other resources essential for national security, economy, and defense. Unlike nuclear, chemical, and conventional weapons, the onset of a biological attack will probably be insidious. For some infectious agents, secondary and tertiary transmission could continue for weeks or months after the initial attack.

Initial detection of an unannounced biological attack will likely occur when an astute health professional notices an unusual case or disease cluster and reports his or her concerns to local public health authorities. Physicians and other health professionals should be alert to the following:

- Unusual temporal or geographic clustering of illnesses
- Sudden increase of illness in previously healthy persons
- Sudden increase in nonspecific illnesses such as pneumonia; flu-like illness; bleeding disorders; unexplained rashes, particularly in adults; neuromuscular illnesses; and diarrhea

To enhance detection and treatment capabilities, physicians and other health professionals in acute care settings should be familiar with the clinical manifestations, diagnostic techniques, isolation precautions, treatment, and prophylaxis for likely causative agents (e.g., smallpox, pneumonic plague, anthrax, viral hemorrhagic fevers). [Table 1](#) provides a quick summary of diagnostic and treatment considerations for various infectious and toxic biological agents. For some of these agents, delay in medical response could

result in a potentially devastating number of casualties. To mitigate such consequences, early identification and intervention are imperative. Frontline physicians must have an increased level of suspicion regarding the possible intentional use of biological agents as well as an increased sensitivity to reporting those suspicious to public health authorities, who, in turn, must be willing to evaluate a predictable increase in false-positive reports.

Medical response efforts require coordination and planning with emergency management agencies, law enforcement, health care facilities, and social services agencies. Health care agencies should ensure that physicians know whom to call with reports of suspicious cases and clusters of infectious diseases, and they should work to build a good relationship with the local medical community. Resource integration is absolutely necessary to

- Establish adequate capacity to initiate rapid investigation of an outbreak
- Educate the public
- Begin mass distribution of antibiotics and vaccines
- Ensure mass medical care
- Control public anger and fear

In an epidemic, overwhelming numbers of critically ill patients will require acute and follow-up medical care. Both infected persons and the worried well will seek medical attention, with a corresponding need for medical supplies, diagnostic tests, and hospital beds. The impact—or even the threat—of an attack can elicit widespread panic and civil disorder, overwhelm hospital resources, and disrupt social services.

Any suspicious or confirmed exposure to a biological weapons agent should be reported immediately to the local health department, local Federal Bureau of Investigation office, and the Centers of Disease Control and Prevention (770-488-7100).

TABLE 1 Quick Reference Chart on Biological Weapon Agents

DISEASE AND AGENT	DIAGNOSTIC CONSIDERATIONS	INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS				TREATMENT	PROPHYLAXIS	COMMENTS
Bacteria							
Anthrax <i>Bacillus anthracis</i> (all forms)		1–5 d (perhaps ≤60 d) [†]	Gram stain and culture of blood, pleural fluid, cerebrospinal fluid, ascitic fluid, vesicular fluid, or lesion exudate Confirmatory serologic and PCR tests are available through public health laboratory network		Steroids may be considered for severe edema and for meningitis Penicillin ¹ should be considered if strain is susceptible and does not possess inducible β-lactamases	Ciprofloxacin or doxycycline with or without vaccination If strain is susceptible, penicillin ¹ or amoxicillin ¹ (Amoxil) should be considered Inactivated vaccine (licensed but not readily available): six injections and annual booster	If meningitis is suspected, doxycycline may be less optimal because of poor CNS penetration
Cutaneous	Evolving skin lesion (face, neck, arms), progresses to vesicle, depressed ulcer, and black necrotic lesions			20% if untreated, otherwise rarely fatal			
Gastrointestinal	Nausea, vomiting, abdominal pain, bloody diarrhea, sepsis Widened mediastinum on chest radiograph is occasionally seen [‡]			Approaches 100% if untreated, but data are limited Rapid, aggressive treatment can reduce mortality			
Inhalational	Abrupt onset of flulike symptoms, fever with or without chills, sweats, fatigue or malaise, non- or minimally productive cough, nausea, vomiting, dyspnea, headache, chest pain, followed in 2–5 d by severe respiratory distress, mediastinitis, hemorrhagic meningitis, sepsis, shock [§] Widened mediastinum on chest radiograph is characteristic [‡]		Sputum is rarely positive	Once respiratory distress develops, mortality rates approach 90% Begin treatment when inhalational anthrax is suspected; do not wait for confirmatory testing	Combination therapy of ciprofloxacin or doxycycline plus one or two other antimicrobials should be considered [¶]		

Brucellosis <i>Brucella abortus</i> , <i>B. canis</i> , <i>B. mellitensis</i> , <i>B. suis</i>	Nonspecific flulike symptoms, fever, headache, profound weakness and fatigue GI symptoms such as anorexia, nausea, vomiting, diarrhea, or constipation	5–60 d, usually 1–2 mo	Blood and bone marrow culture (can require 6 wk to grow <i>Brucella</i>) Confirmatory culture and serologic testing available through public health laboratory network	Less than 5% even if untreated Tends to incapacitate rather than kill	Doxycycline plus streptomycin or rifampin ¹ <i>Alternative therapies:</i> Ofloxacin ¹ plus rifampin ¹ Doxycycline plus gentamicin (Garamycin) TMP-SMX ¹ plus gentamicin	Doxycycline plus streptomycin or rifampin No approved human vaccine	Osteoarticular complications are common
Inhalational (pneumonic) tularemia <i>Francisella tularensis</i>	Sudden onset of acute febrile illness, weakness, chills, headache, generalized body aches, elevated WBCs Pulmonary symptoms such as dry cough, chest pain or tightness with or without objective signs of pneumonia Progressive weakness, malaise, anorexia, and weight loss, potentially leading to sepsis and organ failure	3–5 d Range, 1–21 d	Largely clinical Culture of blood, sputum, biopsies, pleural fluid, bronchial washings (culture is difficult and potentially dangerous); confirmatory testing available through public health laboratory network	~30%–60% Fatal if untreated	Streptomycin or gentamicin (Garamycin) <i>Alternative therapies:</i> Ciprofloxacin ¹ Doxycycline Chloramphenicol ¹ (Chloromycetin)	Tetracycline Doxycycline Ciprofloxacin ¹ Live, attenuated vaccine (USAMRIID, IND) given by scarification; currently under FDA review, limited availability	
Pneumonic plague <i>Yersinia pestis</i>	Acute onset of flulike prodrome: fever, myalgia, weakness, headache; within 24 h of prodrome, chest discomfort, cough with bloody sputum, and dyspnea By day 2 to 4 of illness, symptoms progressing to cyanosis, respiratory distress, and hemodynamic instability	1–10 d, typically 2–3 d	Gram stain and culture of blood, CSF, sputum, lymph node aspirates, bronchial washings Confirmatory serologic and bacteriologic tests available through public health laboratory network	Almost 100% if untreated 20%–60% if appropriately treated within 18–24 h of symptoms	Streptomycin, gentamicin (Garamycin) <i>Alternative therapies:</i> Doxycycline Tetracycline Ciprofloxacin ¹ Chloramphenicol ¹ (Chloromycetin) is first choice for meningitis except for pregnant women	Tetracycline Doxycycline Ciprofloxacin ¹ Inactivated whole-cell vaccine licensed but not readily available; injection with boosters Vaccine not effective against aerosol exposure	Begin treatment when diagnosis of plague is suspected; do not wait for confirmatory testing

DISEASE AND AGENT	DIAGNOSTIC CONSIDERATIONS	INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS				TREATMENT	PROPHYLAXIS	COMMENTS
Rickettsia Q-fever <i>Coxiella burnetii</i>	Nonspecific febrile disease, chills, cough, weakness and fatigue, pleuritic chest pain Pneumonia is possible	2–14 d May be ≤40 d	Isolation of organism may be difficult; confirmatory testing via serology or PCR available through public health laboratory network	1%–3% Fatalities are uncommon even if untreated Relapsing symptoms can occur	Tetracycline Doxycycline	Tetracycline Doxycycline Inactivated whole-cell ² vaccine (IND)	Skin test to determine prior exposure to <i>C. burnetii</i> is recommended before vaccination
DISEASE AND AGENT	SIGNS AND SYMPTOMS	INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
Viruses							
Smallpox Variola major virus	Prodrome of high fever, malaise, prostration, headache, vomiting, delirium followed in 2–3 d by maculopapular rash uniformly progressing to pustules and scabs, mostly on extremities and face	7–17 d	Pharyngeal swab, vesicular fluid, biopsies, scab material for electron microscopy and PCR testing through public health laboratory network	30% in unvaccinated persons	Supportive care Cidofovir (Vistide) shown to be effective in vitro and in experimental animals infected with surrogate orthopox virus	Live, attenuated vaccinia vaccine derived from calf lymph; given by scarification (licensed, restricted supply) New vaccine being developed from tissue culture Vaccination given within 3–4 d following exposure can prevent or decrease the severity of disease	Requires astute clinical evaluation; may be confused with chickenpox, erythema multiforme with bullae, or allergic contact dermatitis Notify CDC Poxvirus Section at 404–639–2184
Viral Encephalitis							
All forms	Systemic febrile illness, with encephalitis developing in some populations Generalized malaise, spiking fevers, headache, myalgia		Clinical and epidemiologic diagnosis WBC count can show striking leukopenia and lymphopenia Confirmatory test and viral isolation available through public health laboratory network		Supportive care Analgesics, anticonvulsants as needed	Several IND vaccines, poorly immunogenic, highly reactogenic	Incidence of seizures and/or focal neurologic deficits may be higher after biological attack
Eastern equine encephalitis		7–14 d		50%–75%			
Western equine encephalitis		7–14 d		10%			
Venezuelan equine encephalitis		2–6 d		<10%			

Viral Hemorrhagic Fevers

Arenaviruses (Lassa, Junin, and related viruses)	Fever with mucous membrane bleeding, petechiae, thrombocytopenia, and hypotension in patients without underlying malignancies	4–21 d	Confirmatory testing and viral isolation available through public health laboratory network	Variable depending on viral strain; 15%–25% with Lassa fever to ≤90% with Ebola	Supportive therapy Ribavirin (Virazole) A may be effective for Lassa fever, Rift Valley fever, Argentine hemorrhagic fever, and Congo–Crimean hemorrhagic fever	Ribavirin (Virazole) ¹ is suggested for Congo–Crimean hemorrhagic fever and Lassa fever Yellow fever vaccine is the only licensed vaccine available Vaccines for some of the other VHF exist but are for investigational use only	Call CDC Special Pathogens Office at 404–639–1115
Bunyaviruses (Hanta, Congo–Crimean, Rift Valley)	Malaise, myalgias, headache, vomiting, diarrhea possible						
Filoviruses (Ebola, Marburg)							
Flaviviruses (yellow fever, dengue, various tick-borne disease viruses)							

DISEASE AND AGENT	SIGNS AND SYMPTOMS	SYMPTOM ONSET	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
Biological Toxins							
Botulism <i>Clostridium botulinum</i> toxin	Blurred vision, diplopia, dry mouth, ptosis, fatigue As disease progresses, acute bilateral descending flaccid paralysis, respiratory paralysis resulting in death	1–5 d, typically 12–36 h	Clinical Serum and stool should be assayed for toxin by mouse neutralization bioassay, which can take several days	60% without ventilatory support	Intensive and prolonged supportive care; ventilation may be necessary Trivalent equine antitoxin (serotypes A, B, E, – licensed, available from the CDC) should be administered immediately after clinical diagnosis	Pentavalent toxoid (A–E), yearly booster (IND, CDC) Not available to the public Antitoxin may be sufficient to prevent illness following exposure but is not recommended until patient is showing symptoms	Anaphylaxis and serum sickness are potential complications of antitoxin Aminoglycosides and clindamycin (Cleocin) A must not be used
Enterotoxin B <i>Staphylococcus aureus</i>	Acute onset of fever, chills headache, nonproductive cough	3–12 h	Clinical Normal chest radiograph Serology on acute and convalescent serum can confirm diagnosis	Probably low (few data available for respiratory exposure)	Supportive care	No vaccine available	
Ricin toxin <i>Ricinus communis</i>	Weakness, nausea, chest tightness, fever, cough, pulmonary edema, respiratory failure, circulatory collapse, hypoxemia resulting in death (usually within 36–72 h)	≤6–24 h	Clinical and epidemiologic Confirmatory serological testing available through public health laboratory network	Mortality data are not available, but likely to be high with extensive exposure	Supportive care Treatment for pulmonary edema Gastric decontamination if toxin is ingested	No vaccine available

TABLE 1 Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	SYMPTOM ONSET	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
T-2 Mycotoxins <i>Fusarium</i> <i>Myrothecium</i> <i>Trichoderma</i> <i>Stachybotrys</i>	Abrupt onset of mucocutaneous and airway irritation and pain Can include skin, eyes, and GI tract; systemic toxicity can follow	Minutes to hours			Clinical support	No vaccine available	Soap and water washing within 4–6 h reduces dermal toxicity; washing within 1 h can eliminate toxicity entirely
Other filamentous fungi			Confirmation requires testing blood, tissue, and environmental samples	Severe exposure can cause death in hours to days			Consult with local health department regarding specimen collection and diagnostic testing procedures

Adapted from Lyznicki JL: AMA quick reference guide: Biological emergencies. In American Medical Association: Management of Public Health Emergencies. A Resource Guide for Physicians and Other Community Responders. Chicago, American Medical Association, 2005.

¹Not FDA approved for this indication.

²Not available in the United States.

*Different situations can require different dosage and treatment regimens. Please consult other references and an infectious disease specialist for definitive dosage information, especially dosages for pregnant women and children.

[†]Data from 22 patients infected with anthrax in October and November 2001 indicate a median incubation period of 4 days (range, 4–7 days) for inhalational anthrax and a mean incubation of 5 days (range, 1–10 days) for cutaneous anthrax.

[‡]Chest radiograph abnormalities include paratracheal and hilar fullness and may be subtle. Consider chest computed tomography if diagnosis is uncertain.

[§]Limited data from the October and November 2001 anthrax infections indicate hemorrhagic pleural effusions to be strongly associated with inhalational anthrax; rhinorrhea was present in only 1/10 patients.

^{||}Limited data from the 2001 terrorist-related anthrax infections indicate that early treatment significantly decreased the mortality rate.

[¶]Other agents with in vitro activity suggested for use in conjunction with ciprofloxacin or doxycycline for treatment of inhalational anthrax include rifampin, vancomycin (Vancocin), imipenem (Primaxin), chloramphenicol (Chloromycetin), penicillin and ampicillin, clindamycin (Cleocin), and clarithromycin (Biaxin).

Popular Herbs and Nutritional Supplements

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Aloe vera	Commonly found in skin products as a moisturizer Used topically to treat burns, wounds, skin infections, and inflammation Approved in Germany to use orally as a laxative Used orally for a variety of conditions, including diabetes, asthma, epilepsy, and osteoarthritis	For external use, apply aloe gel on the skin tid to qid For constipation, 40–170 mg of dried aloe juice or latex (corresponds to 10–30 mg hydroxyanthracene derivatives) taken in the evening For other conditions, no established dosage documented	Aloe gel is generally well tolerated and safe when used topically Aloe gel taken orally can cause hypoglycemia in patients who are concomitantly taking antidiabetic drugs Aloe juice or latex contains anthraquinone, a cathartic laxative and should not be taken by people with intestinal obstruction, acute intestinal inflammation, and ulcers Pregnant women should not take aloe latex because it may cause uterine contractions Oral use of aloe latex can cause abdominal cramps and diarrhea. Long-term use or abuse can cause electrolyte imbalances, albuminuria, hematuria, and pseudomelanosis coli. Prolonged use of high doses (≥ 1 g/d) can cause nephritis, acute renal failure, and death In 2002, the FDA banned the sale of aloe-containing laxative products in the United States because of the lack of safety data Aloe can decrease platelet aggregation and should be avoided at least 2 wk before surgery
Astragalus	Used in combination with other herbs to support and enhance the immune system Used to prevent and treat common colds and upper respiratory infections Used for heart disease Widely used in China for chronic hepatitis and as an adjunctive therapy in cancer	Extract: 250–500 mg tid to qid standardized to 0.4% 4-hydroxy-3-methoxyisoflavone 7-sug Powdered root: 500–1000 mg tid Tincture (1:5) in 30% ethanol: 3–5 mL tid Decoction: 3–6 g of dried root per 12 oz water tid	Avoid using astragalus in organ transplant patients and those with autoimmune disorders Side effects include mild stomach upset and allergic reactions Astragalus can decrease the effects of cyclophosphamide and other immunosuppressants
Bilberry fruit	Often used orally to improve visual acuity and to treat degenerative retinal conditions Used orally to treat chronic venous insufficiency, varicose veins, and hemorrhoids Approved in Germany to use orally for acute diarrhea and topically for mild inflammation of the mucous membranes of mouth and throat	For eye conditions and circulation, 80–160 mg tid of the extract standardized to at least 25% anthocyanosides For diarrhea, 20–60 g/d of the dried, ripe berries or as a tea preparation (5–10 g of crushed dried berries in 150 mL water, brought to a boil for 10 min, then strained) For external use, 10% decoction	No known side effects reported with bilberry fruit and extract However, bilberry leaf taken in large quantities or used long term has been shown to cause wasting, anemia, jaundice, acute excitation, disturbances of tonus, and death in animals The anthocyanidin extracts from bilberry can increase the risk of bleeding in those taking warfarin or other blood thinners
Black cohosh root	Commonly used to relieve hot flashes and other menopausal symptoms Used to treat premenstrual discomfort and dysmenorrhea	20 mg bid of the rhizome extract standardized to triterpene glycosides Remifemin is the proprietary brand used in a number of clinical trials The German guidelines do not recommend its use for > 6 mo	Black cohosh may have an estrogen-like effect and should be avoided in women with breast cancer Large doses may induce miscarriage and it is contraindicated during pregnancy It may cause GI disturbances, headache, and hypotension International case reports of liver dysfunction suspected to be associated with its use

Continued

Popular Herbs and Nutritional Supplements—cont'd

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Black haw	To relieve uterine cramps and painful periods To prevent miscarriage and ease pain that followed childbirth	For menstrual pain, 5 mL of tincture in water, taken 3–5 times daily For prevention of miscarriage, 1–2 cups of tea per day (1 tsp of dried herb in 1 cup of boiling water, steeped for 10 min)	Black haw should not be used in pregnancy because of its uterine relaxant effects The salicylate constituent in black haw could trigger allergic reactions in individuals with aspirin allergies or asthma Black haw may aggravate tinnitus Large doses of black haw can prolong bleeding time The oxalic acid component of black haw can increase kidney stone formation in susceptible individuals Black haw can interact with warfarin and increase risk of bleeding
Cat's claw	Used primarily to reduce pain in osteoarthritis and rheumatoid arthritis Used for a variety of health conditions, including viral infections (e.g., herpes, HIV), Alzheimer's disease, and cancer Used to support the immune system and promote kidney health Used to prevent and abort pregnancy	For osteoarthritis, 100 mg/d of the dry encapsulated extract For rheumatoid arthritis, 20 mg tid of the dry extract standardized to 1.3% pentacyclic oxindole alkaloids free of tetracyclic oxindole alkaloids For general uses, 1–3 cups of tea per day (1 g root bark boiled for 15 min in 250 mL of water) or 1 mL of tincture 2–3 ×/d	Avoid using cat's claw during pregnancy or breastfeeding People with autoimmune diseases and transplant recipients should avoid cat's claw because of its immune stimulating effects Side effects include headaches, dizziness, and vomiting Cat's claw can lower blood pressure and cause hypotension when use with antihypertensive drugs Cat's claw can inhibit CYP3A4 enzyme and increase levels of drugs metabolized by this enzyme
Chamomile flower	Used orally to calm nerves and treat GI spasms and inflammatory diseases of the GI tract Used topically to treat wounds, skin infections, and skin or mucous membrane inflammation	1 cup of freshly made tea 3–4 times daily (1 tbsp or 3 g of dried flower in 150 mL boiling water for 5–10 min)	Chamomile can cause an allergic reaction, especially in people with severe allergies to ragweed or other members of the daisy family (e.g., echinacea, feverfew, and milk thistle) It should not be taken concurrently with other sedatives, such as alcohol or benzodiazepines
Chaste tree berry (Chasteberry, Vitex)	For normalizing irregular menstrual periods and relieving premenstrual complaints For relieving menopausal symptoms For restoring fertility in women For treating acne associated with menstrual cycles For increasing breast milk production in lactating women	For menstrual irregularities and premenstrual complaints, 30–40 mg/d of the dried berries or an equivalent amount of aqueous-alcoholic extracts (50%–70% v/v) Dried fruit extract, standardized to 0.6% agnusides, is used in doses of 175–225 mg/d For other conditions, no established dosage documented	Chaste tree berry can have uterine stimulant properties and should be avoided in pregnancy Women with hormone-dependent conditions (e.g., breast, uterine, and ovarian cancers, and endometriosis and uterine fibroids) and men with prostate cancer should avoid chaste tree berry because it contains progestins Side effects include intramenstrual bleeding, dry mouth, headache, nausea, rash, alopecia, and tachycardia High doses (≥ 480 mg/d extract) can paradoxically decrease lactation Chaste tree berry is thought to have dopaminergic effects and can interact with dopamine antagonists, such as antipsychotics and metoclopramide Chaste tree berry can decrease the effects of oral contraceptives and hormone therapy
Chondroitin	Orally, used frequently in combination with glucosamine for osteoarthritis Topically, in combination with sodium hyaluronate, as a viscoelastic agent in cataract surgery	Oral: 200–400 mg tid	Occasional mild side effects include nausea, indigestion, and allergic reactions Chondroitin derived from bovine cartilage carries a potential risk of contamination with diseased animals

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Chromium	For diabetes For hypercholesterolemia Commonly found in weight-loss products Also promoted for body building	For diabetes, 100 mcg bid for ≤ 4 mo or 500 mcg bid for 2 mo For hypercholesterolemia, 200 mcg tid or 500 mcg bid for 2–4 mo For body building, 200–400 mcg/d Chromium picolinate has been used in most studies, even though the chloride form is also available	Adverse effects are rare, but they include headaches, insomnia, sleep disturbances, irritability and mood changes; some patients may also experience cognitive, perceptual, and motor dysfunction Long-term use of high doses (600–2400 mcg/d) can cause anemia, thrombocytopenia, hemolysis, hepatic dysfunction, and renal failure Interstitial nephritis has been reported A few studies suggest that chromium can cause DNA damage Chromium competes with iron for binding to transferrin and can cause iron deficiency Antacids, H_2 blockers, and proton pump inhibitors can decrease the absorption of chromium
Coenzyme Q10	As adjunctive treatment for congestive heart failure, angina, hypertension, and diabetes Used for reducing cardiotoxicity associated with doxorubicin Used to treat statin-induced myopathy	For heart failure, 100 mg/d in 2 or 3 divided doses For angina, 50 mg tid For hypertension, 60 mg bid For diabetes, 100–200 mg/d	Mild adverse events include gastric distress, nausea, vomiting, and hypotension Doses > 300 mg/d can cause elevated liver enzyme levels Coenzyme Q10 can reduce the anticoagulation effects of warfarin Oral hypoglycemic agents and HMG-CoA reductase inhibitors can reduce serum coenzyme Q10 levels
Cranberry	To prevent and treat UTIs or <i>Helicobacter pylori</i> infections that can lead to stomach ulcers To prevent dental plaque As an antioxidant to prevent cardiovascular disease and cancer	For UTIs, 150–600 mL of cranberry juice daily or 300–400 mg of standardized extract bid For other conditions, no dosage determined	Drinking excessive amounts of juice could cause GI upset or diarrhea Prolonged use of cranberry juice in large doses increases the risk of kidney stones formation because of its high oxalate content Cranberry can interact with warfarin and cause an increase in INR The effectiveness of proton pump inhibitors can be reduced by cranberry because of its acidity
Creatine	To enhance muscle performance, especially during short-duration, high-intensity exercise	Loading dose of 20 g/d for 5–7 d followed by a maintenance dose of ≥ 2 g/d An alternative dosing of 3 g/d for 28 d has been suggested	Creatine can cause gastroenteritis, diarrhea, heat intolerance, muscle cramps, and elevated serum creatinine levels Creatine is contraindicated in patients taking diuretics Concurrent use with cimetidine, probenecid, or nonsteroidal antiinflammatory drugs increases the risk of adverse renal effects Caffeine can decrease creatine's ergogenic effects
Dehydroepiandrosterone (DHEA)	Replace low serum DHEA levels in adrenal insufficiency Treat SLE Reverse aging Used in many other conditions, including Alzheimer's disease, depression, diabetes, menopause, osteoporosis, impotence, and AIDS Used to promote weight loss Used by bodybuilders to increase muscle mass	For replacement therapy, 25–50 mg/d For SLE, 200 mg/d For antiaging and osteoporosis, 50 mg/d For other conditions, no established dosage documented	Most common side effects are androgenic in nature and include acne, hair loss, hirsutism, and deepening of the voice Cases of hepatitis have been reported When used in high doses, DHEA can cause insomnia, manic symptoms, and palpitations DHEA at physiologic doses increases circulating androgens in women, but not in men; it also increases circulating estrogens in both men and women Avoid use of DHEA in individuals with a history of sex hormone-dependent malignancy Safety of DHEA in individuals aged < 30 y is unknown DHEA inhibits CYP3A4 enzyme and could increase serum concentrations of drugs metabolized by this enzyme (e.g., lovastatin, ketoconazole, itraconazole, and triazolam)

Continued

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Dong quai root	Commonly used for the relief of premenstrual and menopausal symptoms Used as a “blood tonic” and a strengthening treatment for the heart, spleen, liver, and kidneys	For premenstrual and menopausal symptoms, 3–4 g/d in 3 divided doses For other conditions, no established dosage documented	Dong quai should not be used in pregnant women because of its uterine stimulant and relaxant effects Women with hormone sensitive conditions (e.g., breast, uterine, and ovarian cancers, and endometriosis and uterine fibroids) should avoid dong quai because of its estrogenic effects Drinking the essential oil of dong quai is not recommended because it contains a small amount of carcinogenic constituents Dong quai contains psoralens that can cause photosensitivity and photodermatitis Dong quai contains natural coumarin derivatives that can increase the risk of bleeding in those who are taking anticoagulant or antiplatelet drugs
Echinacea	As an immune stimulant, particularly for the prevention and treatment of the common cold and influenza Supportive therapy for lower urinary tract infections Used topically to treat skin disorders and promote wound healing	300 mg tid of <i>Echinacea pallida</i> root or 2–3 mL tid of expressed juice of <i>Echinacea purpurea</i> herb Do not use for > 8 wk because echinacea may suppress immunity if used long term	Echinacea should not be used in transplant patients and those with autoimmune disease or liver dysfunction Allergic reactions have been reported Adverse events are rare and include mild GI effects It should be discontinued as far in advance of surgery as possible Echinacea can decrease effectiveness of the immunosuppressants
Ephedra (ma huang)	For diseases of the respiratory tract with mild bronchospasm Promoted for weight loss and performance enhancement	1 tsp or 2 g of dried herb (15–30 mg of ephedrine) in 240 mL boiling water for 10 min In Canada, the maximum allowable dosage of ephedrine is 8 mg per dose or 32 mg/d	Ephedra contains ephedrine, which has sympathomimetic activities; consequently, it should not be used in patients who have cardiovascular disease, diabetes, glaucoma, hypertension, hyperthyroidism, prostate enlargement, psychiatric disorders, or seizures Serious adverse effects, including seizures, arrhythmias, heart attack, stroke, and death, have been associated with the use of ephedra; as a result, the FDA banned the sale of ephedra-containing products in the United States. The ban does not apply to traditional Chinese herbal remedies Because of the cardiovascular effects of ephedrine, patients taking ephedra should discontinue use at least 24 h before surgery Concurrent use of ephedra and digitalis, guanethidine, monoamine oxidase inhibitors, or other stimulants, including caffeine, is not recommended
Evening primrose oil	For PMS, especially if mastalgia is present For treatment of atopic eczema Used for other medical conditions, including rheumatoid arthritis, menopausal symptoms, Raynaud's phenomenon, Sjögren's syndrome, and diabetic neuropathy	For PMS, 2–4 g/d For atopic eczema, 6–8 g/d For rheumatoid arthritis, 2.8 g/d These doses are based on products standardized to 9% γ -linolenic acid Daily dose can be given in divided doses	Evening primrose oil can increase the risk of pregnancy complications Side effects include indigestion, nausea, soft stools, and headache Seizures have been reported in patients with schizophrenia who were taking phenothiazines and evening primrose oil concomitantly Evening primrose oil can interact with anesthesia and cause seizures Concomitant use of evening primrose oil with anticoagulant and antiplatelet drugs can increase the risk of bleeding

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Fenugreek seed	For diabetes and hypercholesterolemia For constipation, dyspepsia, gastritis, and kidney ailments Approved in Germany for use orally for loss of appetite and topically as a poultice for local inflammation	For loss of appetite, 1–2 g of the seed tid or 1 cup of tea (500 mg seed in 150 mL cold water for 3 h) several times a day Maximum 6 g/d For other conditions, no established dosage documented For topical use, 50 g powdered seed in 0.25 L of hot water to form a paste	Fenugreek can cause uterine contractions and should be avoided in pregnancy Individuals who have allergies to peanuts or soybeans might also be allergic to fenugreek Fenugreek can cause diarrhea and flatulence; it can also make urine smell like maple syrup Hypoglycemia can occur if fenugreek is taken in large amounts Repeated external applications can result in undesirable skin reactions Fenugreek contains small amounts of coumarins and can interact with anticoagulants and antiplatelet drugs High mucilage content of fenugreek can affect the absorption of oral drugs; therefore, fenugreek should not be taken within 2 h of other drugs
Feverfew	For migraine headache prophylaxis For treatment of fever, menstrual problems, and arthritis	Migraine prevention: 25–75 mg bid of the encapsulated dried leaf extract standardized to 0.2% parthenolide, for up to 4 mos 2.08–18.75 mg tid for MIG-99 preparation (a carbon dioxide extract enriched with parthenolide) for 3–4 mos For other conditions, no established dosage documented	Feverfew can induce menstrual bleeding and is contraindicated in pregnancy Fresh leaves can cause oral ulcers and GI irritation Sudden discontinuation of feverfew can precipitate rebound headache Feverfew can interact with anticoagulants and potentiate the antiplatelet effect of aspirin
Fish oils (omega-3 fatty acids)	Commonly used in the treatment of hypertriglyceridemia Used to prevent CHD and stroke Used in many noncardiac conditions, including depression, diabetes, dysmenorrhea, rheumatoid arthritis, and IgA nephropathy Used to reduce the risk of developing age-related maculopathy, Alzheimer's disease, and cancer Promotes visual and mental development in children	For hypertriglyceridemia, 3–5 g/d For cardioprotection, 1 g/d for patients with CHD; oily fish at least twice a week, or about 0.5 g/d for people with no known heart disease For other conditions, no established dosage documented Fish oils are composed of EPA and DHA; fish oil capsules vary widely in amounts and ratios of EPA and DHA; the most common fish oil capsules in the United States provide 180 mg of EPA and 120 mg DHA per capsule, and three capsules will provide about 1 g/d of omega-3 fatty acids	Common side effects include fishy aftertaste, GI disturbances, belching, halitosis, and heartburn High doses can cause nausea and loose stools Doses > 3 g/d can inhibit platelet aggregation, suppress immune function, worsen glycemic control, and raise LDL cholesterol levels Long-term use may be associated with weight gain Less well-controlled preparations can contain appreciable amount of organochloride contaminants Fish oil can increase the risk of bleeding in patients taking warfarin, an antiplatelet agent, or herbs that have antiplatelet constituents (e.g., garlic, ginkgo, and red clover) Fish oils can lower blood pressure and can have additive effects with antihypertensive agents Oral contraceptives can interfere with the triglyceride lowering effects of fish oils
Flaxseed	Orally, approved in Germany for chronic constipation, irritable bowel and other colon disorders Often used orally for hypercholesterolemia and atherosclerosis Topically, approved in Germany for painful skin inflammation	For constipation, 1 tbsp (5 g) of whole or “bruised” seeds (not ground) in 150 mL of liquid 2–3 times daily For bowel inflammation, soak 2–3 tbsp of milled flaxseed soaked in 200–300 mL water and strain after 30 min For hypercholesterolemia, 1–2 tbsp flaxseed oil daily Topical: 30–50 g flaxseed flour as poultice or compress for a moist-heat direct application directly to the skin	Flaxseed should be taken with plenty of water to prevent possible intestinal blockage Patients with ileus should not take flaxseed High mucilage content of flaxseed can delay absorption of other drugs taken at the same time

Continued

Popular Herbs and Nutritional Supplements—cont'd

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Garlic	To lower blood pressure and serum cholesterol To prevent atherosclerosis	Fresh clove: one 4 g clove per day Tablet: 300 mg bid to tid standardized to 0.6%–1.3% allicin	Intake of large quantities can lead to stomach complaints Garlic has antiplatelet effects, so patients should discontinue use of garlic at least 7 d before surgery Concomitant use of garlic and anticoagulants can increase the risk of bleeding
Ginger root	As an antiemetic For prevention of motion sickness	Fresh rhizome: 2–4 g/d Powdered ginger: 250 mg 3–4 times daily Tea: 1 cup of tea tid (0.5–1 g dried root in 150 mL boiling water for 5–10 min)	Ginger should not be used by patients with gallstones because of its cholagogic effect It can inhibit platelet aggregation; cases of postoperative bleeding have been reported Large doses of ginger can increase bleeding time in patients taking antiplatelet agents
<i>Ginkgo biloba</i> leaf	To slow cognitive deterioration in dementia To increase peripheral blood flow in claudication To treat sexual dysfunction associated with the use of SSRIs	60–120 mg bid of extract Egb761 standardized to 24% flavonoids and 6% terpenoids	Adverse effects are rare and can include mild stomach or intestinal upset, headache, or allergic skin reaction Ginkgo can inhibit platelet aggregation; reports of spontaneous bleeding have been published Patients should discontinue ginkgo at least 36 h before surgery Concurrent use of ginkgo and anticoagulants, antiplatelet agents, vitamin E, or garlic can increase the risk of bleeding
Ginseng root	As a tonic during times of stress, fatigue, disability, and convalescence To improve physical performance and stamina	Root: 1–2 g/d Tablet: 100 mg bid of extract standardized to 4%–7% ginsenosides A 2- to 3-wk period of using ginseng followed by a 1- to 2-wk “rest” period is generally recommended Ginseng is commonly adulterated, especially Siberian ginseng (eleuthero) products	Ginseng has a mild stimulant effect and should be avoided in patients with cardiovascular disease Tachycardia and hypertension can occur Overdosages can lead to ginseng abuse syndrome, characterized by insomnia, hypotonia, and edema Ginseng has estrogenic effects and can cause vaginal bleeding and breast tenderness Ginseng has been shown to inhibit platelets, so patients should discontinue ginseng use at least 7 d before surgery Ginseng should not be used with other stimulants Patients taking antidiabetic agents and ginseng should be monitored to avoid the hypoglycemic effects of ginseng Ginseng can interact with warfarin and cause a decreased INR Siberian ginseng can increase digoxin levels Ginseng can interact with phenelzine (a MAOI) resulting in insomnia, headache, tremulousness, and manic-like symptoms
Glucosamine	For osteoarthritis	500 mg tid with meals Glucosamine is available in the form of sulfate, hydrochloride, or N-acetyl salt; glucosamine sulfate is the form that has been used in most clinical studies	Side effects are generally limited to mild GI symptoms, including stomach upset, heartburn, diarrhea, nausea, and indigestion Glucosamine derived from marine exoskeletons may cause reactions in people allergic to shellfish Glucosamine may raise blood glucose level in patients with diabetes

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Goldenseal	Often combined with echinacea to treat colds and other upper respiratory infections Used for diarrhea, dyspepsia, and gastritis Used topically as an eyewash, mouthwash, feminine cleansing product, and skin remedy	Oral: 0.5–1 g of the dried rhizome/root or 2–4 mL tincture (1:10, 60% ethanol) or 0.3–1 mL fluid extract (1:1, 60% ethanol) tid Eyewash: For trachoma infections, 2 drops of a 0.2% aqueous berberine solution tid × 3 wk	Avoid using goldenseal during pregnancy and breast feeding; berberine, the principle constituent in goldenseal, can cause uterine contractions and neonatal jaundice Avoid using goldenseal in kidney failure because of inadequate urinary excretion of its alkaloids High dosages or long-term usage can lead to nausea, vomiting, headache, hypotension, bradycardia, leucopenia, and mucosal irritation Berberine can increase the risk of bleeding in patients taking warfarin or an antiplatelet agent Be aware that other herbs containing berberine, including Chinese goldthread and Oregon grape, are sometimes substituted for goldenseal
Grape seed	For conditions related to the heart and blood vessels, such as atherosclerosis, high blood pressure, high cholesterol, and poor circulation For vision problems, diabetic neuropathy or retinopathy, and swelling after an injury or surgery For cancer prevention and wound healing	For general health purposes, 100–300 mg daily of a standardized extract (95% oligomeric proanthocyanidin complexes)	Side effects include headache, dizziness, nausea, and dry, itchy scalp Concomitant use with warfarin or antiplatelet agents can increase risk of bleeding because of the tocopherol content of grape seed oil
Hawthorn leaf with flower	Commonly used in Germany to increase cardiac output in patients with New York Heart Association stage I and II heart failure	160–900 mg water-ethanol extract (30–169 mg procyanidins or 3.5–19.8 mg flavonoids) divided into 2–3 doses	Side effects include GI upset, palpitations, hypotension, headache, dizziness, and insomnia Concomitant use with CNS depressants can have additive CNS effects Hawthorn can potentiate effects of digoxin and vasodilators
Hops	For mood disturbances such as restlessness and anxiety For sleep disturbances Commonly found in combination products with other herbal sedatives	0.5 g of cut or powdered strobile in a single dose; can be taken as tea (0.5 g in 150 mL water), fluid extract 1:1 (0.5 mL), tincture 1:5 (2.5 mL), or dry extract 6–8:1 (60–80 mg) The preparation contains at least 0.35% (v/w) essential oil	Side effects are rare but include drowsiness and allergic reactions Hops is not recommended for use during pregnancy and lactation It can potentiate the sedative effect of CNS depressants (e.g., benzodiazepines, alcohol) and other herbal tranquilizers
Horse chestnut seed	To relieve symptoms of chronic venous insufficiency	250 mg bid of extract standardized to 50 mg aescin in delayed-release form Unsafe to ingest the raw seed, which contains significant amounts of the most toxic constituent, esculin	Mild GI symptoms, headache, dizziness, and pruritis have been reported Ingestion of high doses can cause renal, hepatic, and hematologic toxicity Concomitant use with anticoagulants can increase the risk of bleeding Horse chestnut can potentiate the effects of hypoglycemic drugs
Kava kava	As an anxiolytic for nervous anxiety, stress, and restlessness As a sedative to induce sleep	Herb and preparations equivalent to 60–120 mg/d of kava pyrones Most clinical trials have used 100 mg tid of extract standardized to 70% kava pyrones for anxiety disorders	Kava should not be used by patients with depression Kava should be avoided in pregnant or nursing women Kava can affect motor reflexes and judgment, so it should not be taken while driving and/or operating heavy machinery Accommodative disturbances have been reported; kava can exacerbate Parkinson's disease Extended use can cause a temporary yellow discoloration of skin, hair, and nails Reports have linked kava use to at least 25 cases of severe liver toxicity; sale of products containing kava has been banned in Canada and several European countries

Continued

Popular Herbs and Nutritional Supplements—cont'd

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Kava kava, cont'd			Kava has been shown to have additive CNS depressant effects with benzodiazepines, alcohol, and herbal tranquilizers Kava can potentiate the sedative effects of anesthetics, so kava should be discontinued at least 24 h before surgery
Lutein	Commonly used to prevent AMD and cataracts Used to prevent skin cancer, breast cancer, and colon cancer Used to protect against cardiovascular disease	For AMD and cataracts, 6–20 mg/d of lutein from diet For other uses, no established dosage documented Foods containing high concentrations of lutein include kale, spinach, broccoli, and romaine lettuce Not known if supplemental lutein is as effective as natural lutein Supplemental lutein in the form of esters might require a higher fat intake for effective absorption than purified lutein	No major adverse effects and drug interactions have been reported
Lycopene	Commonly used to prevent and treat prostate cancer Used for cancer prevention, atherosclerosis prevention, and reduction of asthma symptoms	For decreasing the growth of prostate cancer, 15 mg supplement bid For prostate cancer prevention, at least 6 mg/d from tomato products (or ≥ 10 servings/wk) For other uses, no established dosage documented Heat processing converts lycopene in fresh tomatoes from the <i>trans</i> to the <i>cis</i> -configuration. The <i>cis</i> isomer has better bioavailability Lycopene supplements usually do not specify the type and amount of isomers in their product labeling	Lycopene, when consumed in amounts found in foods, is generally considered to be safe Concomitant ingestion of beta-carotene can increase lycopene absorption Lycopene may reduce cholesterol levels and potentiate the effects of statins
Melatonin	For jet lag, insomnia, shift-work disorder, and circadian rhythm disorders For other medical conditions, including depression, multiple sclerosis, tinnitus, headache, and cancer	For jet lag, 5 mg at bedtime for 2–5 d beginning the day of return For sleep disorders, 0.3–5 mg taken 2 h before bedtime Avoid melatonin from animal pineal gland because of the possibility of contamination.	Avoid use in pregnancy because melatonin decreases serum luteinizing hormone concentrations and increases serum prolactin levels The common adverse reactions include headache, transient depressive symptoms, daytime fatigue and drowsiness, dizziness, abdominal cramps, irritability, and reduced alertness Concomitant use of melatonin with alcohol, benzodiazepines, or other CNS depressants can cause additive sedation Melatonin can affect immune function and may interfere with immunosuppressive therapy Concomitant use with other herbs that have sedative properties (e.g., chamomile, goldenseal, hop, kava, valerian) can produce additive CNS-impairing effects
Milk thistle fruit	As a hepatoprotectant and antioxidant, particularly for treatment of hepatitis, cirrhosis, and toxic liver damage Used in Europe for the treatment of hepatotoxic mushroom poisoning from <i>Amanita phalloides</i>	Average daily dose is 12–15 g of crude drug or formulations equivalent to 200–400 mg of silymarin	Adverse effects are rare but include diarrhea and allergic reactions Milk thistle can potentiate the hypoglycemic effect of antidiabetic agents

Popular Herbs and Nutritional Supplements—cont'd

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Peppermint	Commonly used for indigestion and irritable bowel syndrome (IBS) Used externally for myalgia and neuralgia	Indigestion: 1 tsp dried leaves in 1 cup of boiling water, steeped for 10 min; drink 4–5 ×/d between meals IBS: 1–2 enteric coated cap (0.2 mL of peppermint oil/cap) 2–3 ×/d. Take peppermint ≥ 2 h before or after an acid-reducing drug to ensure adequate absorption	Peppermint, in amounts normally found in food, is likely to be safe Larger supplemental amounts can cause side effects including heartburn, flushing, headache, and mouth sores Hypersensitivity reactions, contact dermatitis, and exacerbations of asthma may occur Peppermint can exacerbate symptoms in patients with GERD because it can relax the lower esophageal sphincter Peppermint tea has been shown to reduce free testosterone levels in men Peppermint can decrease the blood levels of cyclosporine and drugs that metabolized by the CYP3A4 isoenzyme
Probiotics	Prevent and treat antibiotic-associated diarrhea and acute infectious diarrhea Relieve symptoms of irritable bowel syndrome Treat atopic dermatitis for at-risk infants	Dosage varies based on preparations <i>Lactobacillus</i> sp., <i>Bifidobacterium</i> sp., <i>Saccharomyces boulardii</i> are the most widely used organisms For <i>Lactobacillus</i> sp., 10 billion CFUs/d For <i>Lactobacillus</i> sp./ <i>Bifidobacterium</i> sp., 100 million to 35 billion CFUs/d For <i>Saccharomyces boulardii</i> , 250–500 mg/d Quality of products varies among brands Refrigeration is required to maintain potency	Avoid use in short-gut syndrome and severe immunocompromised condition Common adverse effects include flatulence, mild abdominal discomfort, and, rarely, septicemia
Red clover flower	Commonly used for conditions associated with menopause, such as hot flashes, cardiovascular health, and osteoporosis Used for PMS, benign prostate hyperplasia, and cancer prevention Used topically to treat psoriasis, eczema, and other rashes	For hot flashes, 40 mg/d of the isoflavones extract (Promensil™) For other conditions, no established dosage documented	Red clover has estrogenic activity and should be avoided during pregnancy and lactation Women with hormone-dependent conditions (e.g., breast, uterine, and ovarian cancer, and endometriosis and uterine fibroids) and men with prostate cancer should also avoid taking red clover Side effects include headache, myalgia, nausea, and rash Red clover contains coumarin derivatives and can increase the risk of bleeding in those who are taking anticoagulants or antiplatelet drugs Preliminary report suggests that red clover might antagonize the effects of tamoxifen Some evidence suggests that red clover can increase the levels of drugs that metabolized by the cytochrome P450 3A4 isoenzyme (e.g., lovastatin, ketoconazole, itraconazole, fexofenadine, and triazolam)
SAMe (S-adenosyl-L-methionine)	For treatment of osteoarthritis, depression, fibromyalgia, and liver disease	For osteoarthritis, 200 mg tid For depression and fibromyalgia, 800 mg bid For liver disease, 600–800 mg bid	Common side effects include flatulence, nausea, vomiting, and diarrhea SAMe can cause anxiety in people with depression and hypomania in people with bipolar disorder Concurrent use of SAMe and other antidepressants can cause serotonin syndrome
Saw palmetto berry	To treat symptomatic benign prostatic hyperplasia and irritable bladder	160 mg bid of extract standardized to 85%–95% fatty acids and sterols	Adverse effects are rare but include headache, nausea, and upset stomach High doses can cause diarrhea

Popular Herbs and Nutritional Supplements—cont'd

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE	PRECAUTIONS AND DRUG INTERACTIONS
Soy	Commonly used for cholesterol reduction in combination with a low fat diet Used for menopausal symptoms and for prevention of osteoporosis and cardiovascular disease in postmenopausal women	For lowering cholesterol, 25–50 g/d of soy protein For hot flashes, 20–60 g/d of soy protein For osteoporosis, 40 g/d of soy protein containing 90 mg isoflavones	Soy, when consumed as whole foods (e.g., tofu or soy milk), has minimal adverse effects Consumption of large amounts of soy can cause gastric complaints such as constipation, bloating, and nausea Long-term use of soy tablets containing isoflavones (150 mg/d for 5 y) has been shown to cause endometrial hyperplasia
St. John's wort	Used for treatment of mild to moderate depression May have anti-inflammatory and antiinfective activities	300 mg tid of hypericum extract standardized to 0.3% hypericin	St. John's wort should not be used in pregnancy Side effects include dry mouth, GI upset, dizziness, fatigue, and constipation St. John's wort can induce photosensitivity, especially in fair-skinned individuals It can cause serotonin syndrome if used with other antidepressants, including SSRIs, or other serotonergic drugs It has been shown to induce CYP3A4 and decrease blood levels of many drugs such as indinavir, nevirapine, cyclosporine, digoxin, theophylline, simvastatin, oral contraceptive pills, and warfarin St. John's wort should be discontinued at least 5 d before surgery to avoid any potential drug interactions
Stinging nettle root	Approved in Germany for difficulty in urination in BPH stage 1 and 2	4–6 g per day of cut root; can be taken as tea (1.5 g in 150 mL boiling water for 10–20 min, tid), fluid extract 1:1 (1.5 mL tid), tincture 1:5 (5–7.5 mL tid), or dry extract 5.4–6.6:1 (0.22–0.33 g tid)	Occasionally, mild GI upsets may occur No known interactions with drugs
Valerian root	Used as a mild sedative for insomnia and anxiety	2–3 g of dried root or 1–3 mL of tincture, qd to several times per day Two clinical trials found 400–450 mg of the root extract effective for insomnia	Valerian has a bad odor and can cause morning drowsiness Long-term administration can lead to paradoxical stimulation, including restlessness and palpitations Because of the risk of benzodiazepine-like withdrawal, valerian should be tapered over a period of several weeks before surgery It can potentiate the sedative effect of CNS depressants (e.g., benzodiazepines, alcohol) and other herbal tranquilizers

Abbreviations: AMD = age-related macular degeneration; BPH = benign prostatic hyperplasia; CFU = colony-forming unit; CHD = coronary heart disease; CNS = central nervous system; CYP3A4 = cytochrome P450 3A4; DHE = docosahexaenoic acid; EPA = eicosapentaenoic acid; FDA = Food and Drug Administration; GI = gastrointestinal; HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; INR = international normalized ratio; LDL = low-density lipoprotein; MAOI = monoamine oxidase inhibitor; PMS = premenstrual syndrome; SLE = systemic lupus erythematosus; SSRIs = selective serotonin reuptake inhibitors; UTIs = urinary tract infections.

*Doses presented in the table are adapted from the German Commission E Monographs and/or data from clinical trials. Products from different manufacturers vary considerably. A reliable product should have a label clearly stating the botanical name of the herb and milligram amount contained in the product. Standardized extracts should be used whenever possible and are often disclosed on the label of quality products.

TOXIC CHEMICAL AGENTS REFERENCE CHART: SYMPTOMS AND TREATMENT

Method of

James J. James, MD, DrPH; and James M. Lyznicki, MS, MPH

Toxic chemical agents are poisonous vapors, aerosols, gases, liquids, or solids that have toxic effects on people, animals, or plants. Most of these agents are liquid at room temperature and are disseminated as vapors and aerosols. They may be released as bombs, sprayed from aircraft and boats, or disseminated by other means to intentionally create a hazard to people and the environment. Some of these agents are highly toxic and persistent, features that can render a site uninhabitable and require costly and potentially hazardous decontamination and remediation. Health effects range from irritation and burning of skin and mucous membranes to rapid cardiopulmonary collapse and death.

Efficient deployment of hazardous materials (HazMat) teams is critical to control a chemical agent attack. Although all major cities and emergency medical systems have plans and equipment in place to address this situation, physicians and other health professionals must be aware of principles involved in managing a patient or multiple patients exposed to these agents. Chemical-weapon agents have a high potential for secondary contamination from victims to responders. This requires that medical treatment facilities have clearly defined procedures for handling contaminated casualties, many of whom will transport themselves to the facility. Precautions must be used until thorough decontamination has been performed

or the specific chemical agent is identified. Health care professionals must first protect themselves (e.g., by using protective suits, respiratory protection, and chemical-resistant gloves) because secondary contamination with even small amounts of these substances (particularly nerve agents such as VX) may be lethal.

Primary detection of exposure to chemical agents is based on the signs and symptoms of the potential victim (Table 1). Confirmation of a chemical agent, using detection equipment or laboratory analyses, takes considerable time and will not likely contribute to the early management of mass casualty victims. Several patients presenting with the same symptoms should alert physicians and hospital staff to the possibility of a chemical attack. If a chemical attack occurs, most victims will likely arrive within a short time. This situation differentiates a chemical attack from a biological attack involving infectious microorganisms. Additional diagnostic clues include the following:

- Unusual temporal or geographic clustering of illness
- Any sudden increase in illness in previously healthy persons
- Sudden increase in nonspecific syndromes (e.g., sudden unexplained weakness in previously healthy persons; dimmed or blurred vision; hypersecretion, inhalation, or burnlike syndrome)

A coordinated communication network is critical for transmitting reliable information from the incident scene to treatment facilities. Any suspicious or confirmed exposure to a chemical weapons agent should be reported to the local health department, local Federal Bureau of Investigation office, and the Centers for Disease Control and Prevention (770-488-7100).

TABLE 1 Quick Reference Chart on Chemical Weapon Agents

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
Cyanides								
Cyanogen chloride (CK) Hydrogen cyanide (AC)	Nonspecific hypoxic and hypoxemic symptoms Resp: SOB, chest tightness, hyperventilation, resp arrest GI: nausea, vomiting CV: ventricular arrhythmias, hypotension, cardiac arrest, shock CNS: anxiety, headache, drowsiness, weakness, apnea, convulsions, seizure, coma Metabolic acidosis and increased concentration of venous oxygen (possibly also cyanosis)	Rapid, seconds to minutes	Bitter almond, musty, or chlorine-like	Binds cellular cytochrome oxidase, causing chemical asphyxia	Cyanide, thiocyanate, serum lactate levels Venous and arterial partial oxygen pressure	Immediate treatment of symptomatic patients is critical Hydroxycobalamin (vitamin B _{12a}) administered with thiosulfate ^{5,†} Activated charcoal ¹ for oral exposure Mechanical ventilation as needed Circulatory support with crystalloids and vasopressors Metabolic acidosis corrected with IV sodium bicarbonate Seizures controlled with benzodiazepines	Sodium nitrite and sodium thiosulfate; repeat one-half initial doses of both agents in 30 min if inadequate clinical response; amyl nitrate capsules are available for first aid until intravenous access is achieved Hydroxycobalamin (vitamin B _{12a} , Cyanokit)	Cyanide antidote kits are commercially available CNS effects may be confused with carbon monoxide and hydrogen sulfide poisoning
Incapacitating Agents								
Agent 15 3-quinuclidinyl benzilate (BZ)	Mydriasis, blurred vision, dry mouth, dry skin, possible atropine-like flush, initial rise in heart rate, decreased level of consciousness, confusion, disorientation, visual hallucinations, impaired memory	Hours 0–4 h: parasympathetic blockade and mild CNS effects 4–20 h: stupor with ataxia and hyperthermia 20–96 h: full-blown delirium Resolution phase: paranoia, deep sleep, reawakening, crawling, climbing automatisms, eventual reorientation	Odorless	Competitive inhibitor of acetylcholine muscarinic receptor		Support, intravenous fluids	Physostigmine salicylate (Antilirium) ¹	
Nerve Agents								
Cyclohexyl sarin (GF) Sarin (GB) Soman (GD) Tabun (GA) VX	Most toxic of known chemical agents May be confused with organophosphate and carbamate pesticide poisoning	Vapor: seconds Liquid: minutes or hours Symptom onset may be delayed up to 18 h,	GB, VX: none GA: fruity GD: camphor-like	Irreversible acetylcholinesterase inhibitors	Erythrocyte or serum cholinesterase activity to confirm exposure	Rapid establishment of patent airway Early administration of 2-PAM is critical to minimize permanent agent inactivation of	Atropine ¹ and 2-PAM ¹ Additional doses until bronchial secretions are cleared and ventilation improved	Atropine, ¹ 2-PAM, ¹ and diazepam ¹ are available in autoinjector kits through

<p>Eyes: excessive lacrimation, miosis may be present</p> <p>Resp: rhinorrhea, bronchospasm, resp failure</p> <p>GI: hypersalivation, nausea, vomiting, diarrhea</p> <p>Skin: localized sweating</p> <p>Cardiac: sinus bradycardia</p> <p>Skeletal muscles: fasciculations followed by weakness, flaccid paralysis</p> <p>CNS: loss of consciousness, convulsions, apnea, seizures</p>	<p>particularly for localized exposures</p>	<p>acetylcholinesterase (i.e., “aging”)</p> <p>Benzodiazepines to control nerve agent–induced seizures</p> <p>Airway and ventilatory support as needed</p>	<p>the U.S. military</p>
--	---	--	--------------------------

Pulmonary or Choking Agents

<p>Acrolein</p> <p>Ammonia (NH₃)</p> <p>Chlorine (Cl)</p> <p>Chloropicrin (PS)</p> <p>Diphosgene (DP)</p> <p>Nitrogen oxides (NO_x)</p> <p>Perfluoroisobutylene (PFIB)</p> <p>Phosgene (CG)</p> <p>Sulfur dioxide (SO₂)</p>	<p>Degree of water solubility of the agent influences onset and severity of respiratory injury</p> <p>Eye and airway irritation, dyspnea, chest tightness, rhinorrhea, hypersalivation, cough, wheezing</p> <p>High-dose inhalation can cause laryngospasm, pneumonitis, and acute lung injury with delayed onset (≤ 48 h) of acute resp distress syndrome</p> <p>Chest radiograph: hyperinflation, noncardiogenic pulmonary edema</p>	<p>Rapid or delayed 1–24 h; rarely up to 72 h</p>	<p>CG: freshly mown hay or grass</p>	<p>Supportive measures</p> <p>Specific treatment depends on the agent</p> <p>IV fluids for hypotension; no diuretics</p> <p>Ventilation with or without positive airway pressure</p> <p>Bronchodilators for bronchospasm</p> <p>Methylprednisolone¹ may be effective in preventing noncardiogenic pulmonary edema</p>	<p>No specific antidote</p>	<p>Easily absorbed via mucous membranes of eyes, nose, oropharynx</p> <p>May be confused with inhalation exposure to industrial chemicals (e.g., HCl, Cl₂, NH₃)</p>
---	--	---	--------------------------------------	--	-----------------------------	---

Riot Control Agents

<p>Mace (CN)</p> <p>Tear gas (CS)</p>	<p>Metallic taste</p> <p>Burning and pain on mucosal membranes and skin</p> <p>Eyes: irritation, pain, tearing, blepharospasm</p> <p>Airways: burning in nose and mouth, respiratory discomfort, bronchospasm (may be delayed 36 h)</p> <p>Skin: tingling, erythema</p>	<p>Immediate</p>	<p>CN: apple blossom</p> <p>CS: pepper</p>	<p>SN2 alkylating agents</p>	<p>No specific laboratory tests</p>	<p>Supportive care</p> <p>Irrigation as necessary</p> <p>Persons with asthma, emphysema might need oxygen, inhaled bronchodilators, steroids, assisted ventilation</p> <p>Lotions, such as calamine¹ for persistent erythema</p>
---------------------------------------	---	------------------	--	------------------------------	-------------------------------------	---

TABLE 1 Quick Reference Chart on Chemical Weapon Agents—cont'd

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		COMMENTS
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	
	Nausea and vomiting are common CN can cause corneal opacification							
Vesicant or Blister Agents								
General	Clinical effects depend on extent and route of exposure	Effects may be delayed, appearing hours after exposure		Intracellular enzyme and DNA alkylating agents		Immediate decontamination Supportive care Thermal burn-type treatment Symptomatic management of lesions		Primary liquid hazard May be confused with skin exposure to caustic irritants (e.g., NaOH, NH ₃)
Sulfur mustard (H) Distilled mustard (HD)	Skin: erythema and blisters (may be delayed ≤ 8 h), pruritus Eye: irritation, conjunctivitis, corneal damage, lacrimation, pain, blepharospasm Resp: mild to marked acute airway damage, pneumonitis within 1–3 d, respiratory failure GI effects (nausea, vomiting diarrhea) may be present Bone marrow stem cell suppression leading to pancytopenia and increased susceptibility to infection Fever, sputum production	Delayed 2–48 h	Garlic, horseradish, or mustard			Skin: silver sulfadiazine ¹ Eye: homatropine ¹ ophthalmic ointment Pulmonary: antibiotics, bronchodilators, steroids Colony-stimulating factor may be helpful for leukopenia Systemic analgesic and antipruritics Early use of PEEP or CPAP Maintain fluid and electrolyte balance (do not excessively fluid resuscitate as in thermal burns)	No specific antidote	Combination with lewisite (called mustard-Lewisite or HL) results in rapid effects of lewisite and delayed effects of mustard agents
Lewisite (L)	Skin: gray area of dead skin within 5 min, erythema within 30 min, blistering 2–3 h, immediate irritation or burning pain on contact, severe tissue necrosis Eye: pain, blepharospasm, conjunctival and lid edema Airway: pseudomembrane formation, nasal irritation Intravascular fluid loss, hypovolemia, shock, organ congestion, leukocytosis	Immediate	Fruity or geranium				British anti-lewisite (BAL or dimercaprol)	More volatile than mustard Damages eyes, skin, and airways by direct contact

Phosgene oxime (CX)	Burning, irritation, wheal-like skin lesions, eye and airway damage, conjunctivitis, lacrimation, lid edema, blepharospasm	Immediate	Freshly mown hay	Urticant, nonvesicant agent	No distinctive laboratory findings	Parenteral methylprednisolone ¹ may be effective in preventing noncardiogenic pulmonary edema Experimental: aerosolized dexamethasone ¹ and theophylline ¹ for pulmonary involvement	No antidote	Vapor extremely irritating; vapor and liquid cause tissue damage upon contact
---------------------	--	-----------	------------------	-----------------------------	------------------------------------	--	-------------	---

Vomiting (Arsine-Based) Agents

Adamsite (DM) Diphenylchlorarsine (DA) Diphenylcyanoarsine (DC)	Eyes: conjunctival irritation, tearing, and blepharospasm Airways: sneezing, mucosal lung irritation, edema, progressive cough, wheezing Cardiac: tachypnea, tachycardia GI: intestinal cramps, emesis, diarrhea Skin: erythema, edema at the site of dermal contact CNS: depression, syncope	All rapidly acting within minutes	DA: none DC: garlic DM: burning fireworks	Arsine gas depletes erythrocyte glutathione and causes hemolysis	Chest radiograph to rule out chemical pneumonitis	Supportive care Monitor for hemolysis Wheezing or dyspnea: may need albuterol inhalation Eye irrigation (water, normal saline, lactated Ringer's) in patients with ocular exposure Treat repetitive emesis with IV hydration and antiemetics Blood transfusion may be required Exchange transfusion may be required Hemodialysis may be useful in decreasing arsenic level and treating renal failure	Primary route of absorption is through respiratory system
---	--	-----------------------------------	---	--	---	--	---

Adapted from Lyznicki JL: AMA quick reference guide: Exposure to toxic chemical agents. In American Medical Association: Management of Public Health Emergencies. A Resource Guide for Physicians and Other Community Responders. Chicago, American Medical Association, 2005.

¹Not FDA approved for this indication.

³Investigational drug in the United States.

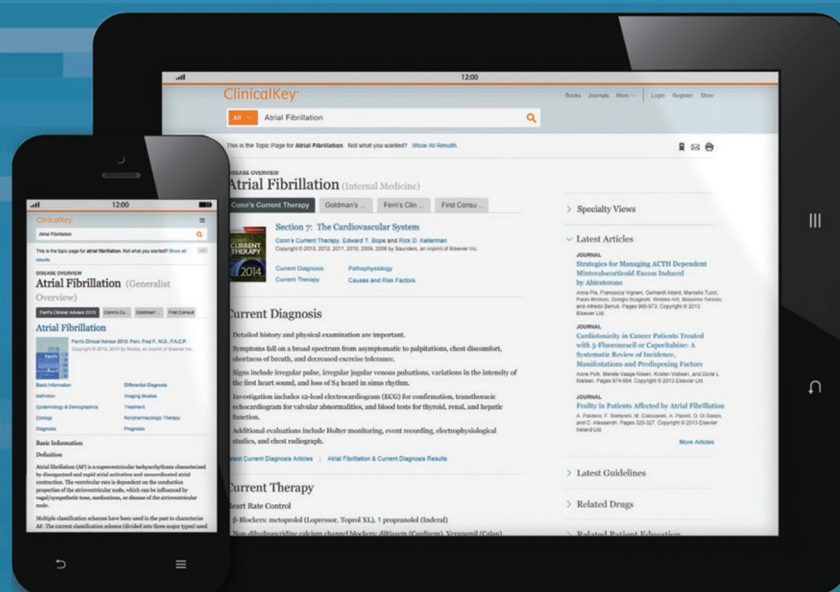

*Different situations can require different treatment and dosage regimens. Please consult other references as well as a regional poison control center (800-222-1222), medical toxicologist, clinical pharmacologist, or other drug information specialist for definitive dosage information, especially dosages for pregnant women and children.

[†]Available in Europe.

Abbreviations: CNS=central nervous system; CPAP=continuous positive airway pressure; CV=cardiovascular; GI=gastrointestinal; 2-PAM=pralidoxime (2-pyridine aldoxime methyl chloride); PEEP=positive end-expiratory pressure; resp=respiratory; SOB=shortness of breath.
