Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Renal Calculi

Lawrence Chan, MD

Director of NIH Diabetes and Endocrinology Research Center;
Betty Rutherford Chair for Diabetes Research; Chief of
Diabetes, Endocrinology, and Metabolism Section; Professor
of Medicine, Molecular and Cellular Biology, and
Biochemistry, Baylor College of Medicine, Houston, Texas
Hyperaldosteronism; Hyperlipidemia; Hyperprolactinemia

Miriam Chan, PharmD

Director of Pharmacy Education, Family Medicine Residency
Program, Riverside Methodist Hospital, Columbus, Ohio
*Drug Hypersensitivity Reactions; Popular Herbs and
Nutritional Supplements*

Lin Yee Chen, MD, MS

Associate Professor, Cardiovascular Division, Department of
Medicine, University of Minnesota Medical School,
Minneapolis, Minnesota
Atrial Fibrillation

Shingo Chihara, MD

Section of Infectious Diseases, Virginia Mason Medical Center,
Seattle, Washington
Anthrax

Meera Chitlur, MD

Barnhart-Lusher Hemostasis Research Endowed Chair and
Professor of Pediatrics, Wayne State University; Director,
Hemophilia Treatment Center and Hemostasis Program;
Director, Special Coagulation Laboratory, Children's Hospital
of Michigan, Detroit, Michigan
Hemophilia and Related Conditions

Saima Chohan, MD

Clinical Assistant Professor, Division of Clinical Education,
Arizona College of Osteopathic Medicine, Glendale, Arizona
Gout and Hyperuricemia

Kuang-Yuh Chyu, MD, PhD

Associate Professor of Medicine, University of California–Los
Angeles, Los Angeles, California
*Acute Myocardial Infarction: Focus on ST-Elevation Myocardial
Infarction*

Joaquin E. Cigarroa, MD

Professor of Medicine, Clinical Chief, Knight Cardiovascular
Institute; Division Head, Cardiology, Oregon and Health
Sciences University, Portland, Oregon
Congenital Heart Disease

Peter E. Clark, MD

Associate Professor, Urologic Surgery, Vanderbilt University
Medical Center, Nashville, Tennessee
Malignant Tumors of the Urogenital Tract

Paul Cleland, MD

Clinical Assistant Professor, Department of Family and Community
Medicine, University of Kansas School of Medicine – Wichita;
Associate Director, University of Kansas School of Medicine –
Wichita Sports Medicine Fellowship, Wichita, Kansas
Heat-Related Illness

Matthew Cline, MD

AHEC Professor of Family Medicine, Medical University of South
Carolina, Charleston, South Carolina
Antepartum Care

Kari R. Clouse, MD

Clinical Assistant Professor, Department of Family and
Community Medicine, University of Kansas School of
Medicine – Wichita, Wichita, Kansas; Andover Medical
Clinic, Andover, Kansas
Delirium

August Colenbrander, MD

Affiliate Senior Scientist, Smith-Kettlewell Eye Research Institute,
San Francisco, California
Vision Rehabilitation

Ryan M. Commins, MD

Internal Medicine, Georgetown University Medical Center,
Washington, DC
High Altitude Illness

Christine Conageski, MD

Assistant Professor, Obstetrics and Gynecology, University of
Colorado, Aurora, Colorado
Vulvar Neoplasia

John M. Conly, MD

Medical Officer, Infection Prevention and Control, Foothills
Medical Centre, Calgary, Alberta, Canada
Methicillin-Resistant Staphylococcus Aureus (MRSA)

Carlo Contini, MD

Full Professor of Infectious Diseases, Director of Infectious Diseases Unit, Department of Medical Sciences, University of Ferrara, Ferrara, Italy
Toxoplasmosis

Allison K. Cormier, MD

Departments of Medicine and Population Health Sciences, University of Wisconsin–Madison, Madison, Wisconsin
Treatment and Prevention of HIV Infection

Michael L. Corriveau, MD

Assistant Clinical Professor of Internal Medicine, The Ohio State University School of Medicine; Pulmonologist, Chalmers P. Wylie VA Ambulatory Care Center, Columbus, Ohio
Chronic Obstructive Pulmonary Disease

Bart L. Cox, MD

Associate Professor of Medicine, Department of Cardiology, University of New Mexico, Albuquerque, New Mexico
Congestive Heart Failure

Dustin A. Creech, MD

Assistant Professor, Belleville Family Medicine Residency, St. Louis University/Scott Air Force Base, Belleville, Illinois
Malaria

Ana L. Creo, MD

Fellow, Pediatric Endocrinology Fellowship, Mayo Clinic, Rochester, Minnesota
Obesity

Burke A. Cunha, MD

Professor, State University of New York School of Medicine, Stony Brook, New York; Chief, Infectious Disease Division, Winthrop–University Hospital, Mineola, New York
Babesiosis; Viral and Mycoplasmal Pneumonias

Cheston B. Cunha, MD

Infectious Disease Division, Alpert School of Medicine, Brown University, Providence, Rhode Island
Babesiosis; Viral and Mycoplasmal Pneumonias

Gabriel P. Currie, MD

Resident Physician, Dermatology, Portland, Oregon
Erythema Multiforme; Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Amy E. Curry, MD

Clinical Associate Professor, Department of Family and Community Medicine, University of Kansas School of Medicine – Wichita; Associate Director, Via Christi Family Medicine Residency, Wichita, Kansas
Pelvic Inflammatory Disease

Beth A. Damitz, MD

Associate Professor, Family and Community Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin
Immunization Practices

Natalie C. Dattilo, PhD

Assistant Professor of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana
Generalized Anxiety Disorder; Posttraumatic Stress Disorder

Raul Davaro, MD

Associate Professor of Clinical Medicine, University of Massachusetts, Worcester, Massachusetts
Smallpox

David de Berker, MRCP

Consultant Dermatologist, Bristol Dermatology, Bristol Royal Infirmary, Bristol, United Kingdom
Diseases of the Nails

André de Leon, MD

Faculty, Family Medicine, Eisenhower Family Medicine Residency, Rancho Mirage, California
Chronic Diarrhea

Tate de Leon, MD

Faculty, Family Medicine, Eisenhower Family Medicine Residency, Rancho Mirage, California
Acute Diarrhea

Alexei DeCastro, MD

Assistant Professor, Department of Family Medicine, Medical University of South Carolina, Charleston, South Carolina
Osteoporosis

Katharine C. DeGeorge, MD, MS

Assistant Professor, Assistant Residency Program Director, Department of Family Medicine, University of Virginia Charlottesville, Virginia
Bacterial Pneumonia; Asthma in Children

Thomas G. DeLoughery, MD, MACP FAWM

Professor of Medicine, Pathology, and Pediatrics, Oregon Health Sciences University, Portland, Oregon
Hemolytic Anemias

Phyllis A. Dennery, MD

Medical Director, Intensive Care Nursery, Neonatology and Newborn Services, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Hemolytic Disease of the Fetus and Newborn

Clio Dessinioti, MD, MSc, PhD

Dermatologist, Andreas Sygros Hospital, Athens, Greece
Parasitic Diseases of the Skin

Michael P. Diamond, MD

Professor and Chair of Obstetrics and Gynecology, William H. Brooks Distinguished Chair of Obstetrics and Gynecology; Associate Dean for Research, Medical College of Georgia; Senior Vice President of Research, Augusta University, Augusta, Georgia
Infertility

Geoffrey A. Donnan, MD

Department of Neurology, University of Melbourne Faculty of Medicine, Dentistry, and Health Sciences; Florey Neuroscience Institutes, Carlton South, Victoria, Australia
Ischemic Cerebrovascular Disease

John N. Dorsch, MD

Professor, Department of Family and Community Medicine, University of Kansas School of Medicine–Wichita, Wichita, Kansas

Professor and Chief, Division of Cardiology, Director of the
Lillehei Heart Institute, Minneapolis, Minnesota
Atrial Fibrillation

Peter R. Duggan, MD

Associate Clinical Professor of Medicine, University of Calgary,
Calgary, Alberta, Canada
Polycythemia Vera

Maurice Duggins, MD

Clinical Associate Professor, Department of Family and
Community Medicine, University of Kansas School of
Medicine – Wichita; Associate Director, Via Christi Family
Medicine Residency, Wichita, Kansas
Erectile Dysfunction

Kim Eagle, MD

Albion Walter Hewlett Professor of Internal Medicine, Chief of
Clinical Cardiology, and Director, Cardiovascular Center,
University of Michigan Health System, Ann Arbor, Michigan
Angina Pectoris

Leigh M. Eck, MD

Associate Professor of Medicine, Department of Internal
Medicine, University of Kansas Medical Center, Kansas City,
Kansas
Thyroiditis

Genevieve L. Egnatios, MD

Affiliated Dermatology, Scottsdale, Arizona
Contact Dermatitis

Dirk M. Elston, MD

Director, Ackerman Academy of Dermatopathology, New York,
New York
Diseases of the Hair

John M. Embil, MD

Professor, Departments of Internal Medicine (Section of Infectious
Diseases) and Medical Microbiology, University of Manitoba,
Infection Prevention and Control Unit, Health Sciences Centre;
Consultant, Infectious Diseases, Director, BSc(Med) Program,
University of Manitoba; Medical Director, Infection Prevention
and Control Unit, Health Sciences Centre, and Winnipeg Regional
Health Authority, Winnipeg, Manitoba, Canada
Blastomycosis

Scott K. Epstein, MD

Dean for Educational Affairs and Professor of Medicine, Tufts
University School of Medicine, Boston, Massachusetts
Acute Respiratory Failure

Patricia Evans, MD

Program Director, Family Medicine Residency, Georgetown
University-Providence Hospital, Washington, DC
Uterine Leiomyomas

Andrew M. Evens, DO, MSc

Professor of Medicine, Chief of Division of Hematology/
Oncology, Tufts Medical Center; Director of Tufts Cancer
Center, Boston, Massachusetts
Non-Hodgkin Lymphoma

J. Barry Fagan, MD

Service Chief, Medical Specialties, Chalmers P. Wiley VA
Ambulatory Care Center; Pulmonary and Critical Care
Physician, Mount Carmel Health System, Columbus, Ohio
Chronic Obstructive Pulmonary Disease

Kinder Fayssoux, MD

Center for Family Medicine, Eisenhower Medical Associates, La
Quinta, California
Bacterial Infections of the Urinary Tract in Women

Dorianne Feldman, MD

Assistant Professor of Physical Medicine and Rehabilitation, The
Johns Hopkins University School of Medicine, Baltimore,
Maryland
Rehabilitation of the Stroke Patient

Terry D. Fife, MD

Director, Otonerology and Balance Disorders, Barrow
Neurological Institute, Phoenix, Arizona
Ménière's Disease

David J. Finley, MD

Co-Director, Complex Airway Program; Surgeon, Thoracic Service,
Memorial Sloan Kettering Cancer Center, New York, New York
Pleural Effusion and Empyema Thoracis

William E. Fisher, MD

Professor, Michael E. DeBakey Department of Surgery, Baylor
College of Medicine, Houston, Texas
Acute and Chronic Pancreatitis

Maria Fleseriu, MD

Professor of Medicine and Neurological Surgery, Director of
Pituitary Center, Oregon Health and Science University,
Portland, Oregon
Adrenocortical Insufficiency

Donald C. Fletcher, MD

Adjunct Associate Professor, Department of Ophthalmology,
University of Kansas School of Medicine, Kansas City, Kansas
Vision Rehabilitation

Raja Flores, MD

Ames Professor of Cardiothoracic Surgery, Chief of Division of
Thoracic Surgery, Mount Sinai School of Medicine, New York,
New York
Pleural Effusion and Empyema Thoracis

Sarah Forsberg, PsyD

Psychiatry and Behavioral Sciences, Stanford University, Stanford,
California
Eating Disorders

Daniel P. Fox, MD

Otolaryngology – Head and Neck Surgery, Baylor College of
Medicine, Houston, Texas
Obstructive Sleep Apnea

Jennifer Frank, MD

Theda Care Physicians, Neenah, Wisconsin
Syphilis; Vaginal Bleeding Late in Pregnancy

Robert S. Freelove, MD

Associate Professor, Department of Family and Community
Medicine, University of Kansas School of Medicine – Wichita,
Wichita, Kansas; Smoky Hill Family Medicine Residency,
Salina, Kansas
Pancreatic Cancer; Nongonococcal Urethritis

Ellen W. Freeman, PhD

Research Professor, Obstetrics/Gynecology, Perelman School of
Medicine, University of Pennsylvania, Philadelphia, Pennsylvania
Premenstrual Syndrome

Theodore M. Freeman, MD

Owner, San Antonio Asthma and Allergy Clinic, San Antonio, Texas

Allergic Reaction to Insect Stings

Aaron Friedman, MD

Ruben Bentson Professor and Chair, Pediatrics, University of Minnesota, Minneapolis, Minnesota

Parenteral Fluid Therapy for Infants and Children

Melissa Gaines, MD

Cox Senior Health, Geriatrics Division, Springfield, Missouri

Constipation

R. Michael Gallagher, DO

Headache Consultant, Headache Center of Central Florida, Melbourne, Florida

Headache

Marc G. Ghany, MD, MHSc

Clinical Research Section, Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland

Hepatitis A, B, D, and E

Muhammad Ahmad Ghazi, MD

Clinical Instructor, Department of Family Medicine, University at Buffalo, Buffalo, New York

Pruritus Ani and Vulvae

Lawrence M. Gibbs, MD, MSEd

Assistant Professor, Belleville Family Medicine Residency, St. Louis University/Scott Air Force Base, Belleville, Illinois

Malaria

Donald L. Gilbert, MD, MS

Professor of Pediatrics and Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Gilles De La Tourette Syndrome

Robert Giusti, MD

Director, NYU Pediatric Cystic Fibrosis Center, New York University School of Medicine, New York, New York

Cystic Fibrosis

Mark T. Gladwin, MD

Professor of Medicine, Division of Pulmonary, Allergy, and Critical Care Medicine; Director, Vascular Medicine Institute, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Sickle Cell Disease

Stephen J. Gluckman, MD

Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Chronic Fatigue Syndrome/Systemic Exertion Intolerance Disease

Andrew W. Goddard, MD

Professor of Psychiatry, Indiana University School of Medicine; Director, Adult Psychiatry Outpatient Clinic and Study Center, Indiana University Hospital, Bloomington, Indiana

Generalized Anxiety Disorder

Danae D. Goerl, MD

Pediatric Associates, Manhattan, Kansas

Bronchiolitis

Kyle Goerl, MD

Clinical Assistant Professor, Department of Family and Community Medicine, University of Kansas School of Medicine – Wichita, Wichita, Kansas; Team Physician, Sports and Family Medicine, Lafene Health Center, Kansas State University, Manhattan, Kansas

Bursitis and Tendinopathy

Mark S. Gold, MD

Adjunct Professor, Department of Psychiatry, Washington University School of Medicine, St. Louis, Missouri

Drug Abuse

Joshua N. Goldstein, MD, PhD

Associate Professor of Surgery, Harvard Medical School; Attending Physician, Emergency Department, Massachusetts General Hospital, Boston, Massachusetts

Intracerebral Hemorrhage

Melissa K. Gonzales, BS

Postbaccalaureate IRTA Fellow, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

Pheochromocytoma

Marlis González-Fernández, MD, PhD

Assistant Professor, Physical Medicine and Rehabilitation, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Rehabilitation of the Stroke Patient

Gregory Goodwin, MD

Assistant Professor of Pediatrics, Harvard Medical School; Attending Physician, Division of Endocrinology, Children's Hospital, Boston, Massachusetts

Diabetes Mellitus in Children

Aidar R. Gosmanov, MD, PhD, DMSc

Section Chief, Endocrinology, Albany Veterans Affairs Medical Center, Albany, New York

Diabetic Ketoacidosis

Niyaz Gosmanov, MD

Associate Professor, Section of Endocrinology and Diabetes, The University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

Diabetes Mellitus in Adults

Albina Gosmanova, MD

Associate Professor, Section of Endocrinology and Diabetes, The University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma

Diabetes Mellitus in Adults

Luigi Gradoni, PhD

Research Director, Vector-Borne Diseases and International Health, Istituto Superiore di Sanità, Rome, Italy

Leishmaniasis

Timothy P. Graham, MD

Program Director, Mount Carmel Family Medicine Residency; Chair, Department of Family Medicine, Mount Carmel St. Ann's Hospital, Westerville, Ohio

Hypertension

Jane M. Grant-Kels, MD

Professor and Chair, Dermatology, University of Connecticut Health Center, Farmington, Connecticut

Nevi

Leslie A. Greenberg, MD

Assistant Professor of Family and Community Medicine,
University of Nevada Reno School of Medicine, Reno, Nevada
Keloids

William M. Greene, MD

Assistant Professor, Psychiatry, University of Florida, Gainesville,
Florida
Drug Abuse

Joseph Greensher, MD

Professor of Pediatrics, Stony Brook University Medical Center
School of Medicine, Stony Brook, New York; Medical Director
and Associate Chair, Department of Pediatrics, Long Island
Regional Poison and Drug Information Center, Winthrop-
University Hospital, Mineola, New York
Medical Toxicology

David Gregory, MD

Associate Clinical Professor of Family Medicine, University of
Virginia School of Medicine, Charlottesville, Virginia; Assistant
Clinical Professor of Family Medicine, Virginia Commonwealth
University School of Medicine, Richmond, Virginia; Program
Director, CENTRA-Lynchburg Family Medicine Residency;
Staff Physician in Family Medicine, Lynchburg General
Hospital and Virginia Baptist Hospital, Lynchburg, Virginia
Resuscitation of the Newborn

Sriharsha Cherukumilli Grevich, MD

Psychiatric Rheumatology, Seattle Children's Hospital, Seattle,
Washington
Rheumatoid Arthritis

Eva C. Guinan, MD

Professor, Radiation Oncology, Harvard Medical School, Boston,
Massachusetts
Aplastic Anemia

Tawanda Gumbo, MD

Associate Professor of Medicine, University of Texas
Southwestern Medical School; Attending Physician, Parkland
Memorial Hospital and University Hospital-St. Paul, Dallas,
Texas
Tuberculosis and Other Mycobacterial Diseases

Melissa Hague, MD

Associate Clinical Professor, Obstetrics and Gynecology,
University of Kansas School of Medicine-Wichita, Wichita,
Kansas
Female Sexual Function

Rebat M. Halder, MD

Professor and Chair, Department of Dermatology, Howard
University College of Medicine, Washington, DC
Pigmentary Disorders

Ronald Hall, II, PharmD, MSCS

Associate Professor, Pharmacy Practice, Texas Tech University
Health Sciences Center, Dallas, Texas
Tuberculosis and Other Mycobacterial Diseases

George D. Harris, MD, MS

Professor and Chair of Family Medicine, West Virginia University
Eastern Division, Morgantown West Virginia; UHP Medical
Director-Primary Care, Martinsburg, West Virginia
Osteomyelitis

Kari R. Harris, MD

Associate Professor of Pediatrics Section Director, Adolescent
Health Division of Ambulatory Pediatrics, Department of
Pediatrics University of Kansas School of Medicine - Wichita,
Wichita, Kansas
Adolescent Health

Taylor B. Harrison, MD

Associate Professor, Neuromuscular Division, Program Director,
Clinical Neurophysiology Fellowship, Department
of Neurology, Emory University Atlanta, Georgia
Myasthenia Gravis

Adam L. Hartman, MD

Assistant Professor, Neurology and Pediatrics, The Johns
Hopkins School of Medicine, Baltimore, Maryland
Epilepsy in Infants and Children

Nelson Iván Agudelo Higuaita, MD

Associate Professor, Department of Medicine/Infectious Diseases,
University of Oklahoma Health Sciences Center, Oklahoma
City, Oklahoma
Plague

Stacey A. Hinderliter, MD

Associate Director, Riverside Brentwood Family Medicine
Residency, Newport News, Virginia
Resuscitation of the Newborn

Molly Hinshaw, MD

Associate Professor of Dermatology, University of Wisconsin
School of Medicine and Public Health, Madison, Wisconsin
Connective Tissue Disorders; Cutaneous Vasculitis

Vanessa Ho, MD

Faculty, Eisenhower Family Medicine Residency Program,
Eisenhower Medical Center, La Quinta, California
Hypopituitarism

Brandon Hockenberry, MD

University of New Mexico Health Sciences Center, Department of
Family and Community Medicine, Albuquerque, New Mexico
Sports-Related Head Injuries

Raymond J. Hohl, MD, PhD

Director, Penn State Hershey Cancer Institute, Hershey,
Pennsylvania
Thalassemia

Therese Holguin, MD

Assistant Professor of Dermatology, University of New Mexico,
Albuquerque, New Mexico
Fungal Infections of the Skin

Sarah A. Holstein, MD, PhD

Assistant Professor of Oncology, Department of Medicine,
Roswell Park Cancer Institute, Buffalo, New York
Thalassemia

Marisa Holubar, MD

Clinical Assistant Professor, Division of Infectious Diseases,
Stanford University School of Medicine, Stanford, California
Severe Sepsis

Gretchen Homan, MD

Assistant Professor, Department of Pediatrics, University of
Kansas School of Medicine-Wichita, Wichita, Kansas
Pediatric Failure to Thrive

Ahmad Reza Hossani-Madani, MD, MS

Dermatologist, Kaiser Permanente, Upper Marlboro, Maryland
Pigmentary Disorders

Steven A. House, MD

Associate Professor, Family and Geriatric Medicine, University of Louisville/Glasgow Family Medicine Residency Program, Glasgow, Kentucky
Pain; Palliative and End-of-Life Care

Sarah Houssayni, MD

Clinical Associate Professor, Department of Family and Community Medicine, University of Kansas School of Medicine–Wichita; Pediatrics, Associate Director, Via Christi Family Medicine Residency, Wichita, Kansas
Encopresis

William J. Hueston, MD

Senior Associate Dean for Academic Affairs, Medical College of Wisconsin, Milwaukee, Wisconsin
Hyperthyroidism; Hypothyroidism

Alison N. Huffstetler, MD

Department of Family Medicine, University of Virginia, Charlottesville, Virginia
Bacterial Pneumonia

Scott A. Hundahl, MD

Professor of Surgery, University of California–Davis School of Medicine, Sacramento, California
Tumors of the Stomach

Stephen P. Hunger, MD

Professor of Pediatrics, University of Colorado–Denver School of Medicine; Section Chief, Center for Cancer and Blood Disorders and Ergen Family Chair in Pediatric Cancer, The Children's Hospital, Aurora, Colorado
Acute Leukemia in Children

Wendy S. Hupp, DMD

Associate Professor of Oral Medicine, General Dentistry, and Oral Medicine, University of Louisville School of Dentistry, Louisville, Kentucky
Diseases of the Mouth

Gretchen M. Irwin, MD, MBA

Associate Professor, Department of Family and Community Medicine, University of Kansas School of Medicine – Wichita; Program Director, Wesley Family Medicine Residency, Wichita, Kansas
Otitis Media

Gerald A. Isenberg, MD

Professor of Surgery, Sidney Kimmel Medical College at Thomas Jefferson University, Philadelphia, Pennsylvania
Tumors of the Colon and Rectum

Alan C. Jackson, MD

Professor and Head, Section of Neurology, Internal Medicine (Neurology), University of Manitoba, Winnipeg, Manitoba, Canada
Rabies

Kurt M. Jacobson, MD

Assistant Professor of Medicine, Cardiovascular Medicine Division, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
Mitral Valve Prolapse

Vasudha Jain, MD

Infectious Disease, Kernersville, North Carolina
Vulvovaginitis

Jose A. Jaller, MD

Department of Dermatology and Cutaneous Surgery, University of Miami Miller School of Medicine, Miami, Florida
Venous Ulcers

James J. James, MD, DrPH

Executive Director, Society for Disaster Medicine and Public Health, Bethesda, Maryland
Biologic Agents Reference Chart; Toxic Chemical Agents Reference Chart: Symptoms and Treatment

Katarzyna Jamieson, MD

Associate Professor of Medicine, Division of Hematology and Oncology, Chapel Hill, North Carolina
Chronic Leukemias

James N. Jarvis, MD

Professor of Pediatrics and Section Chief, Pediatric Allergy/Immunology/Rheumatology, University at Buffalo, Buffalo, New York
Juvenile Idiopathic Arthritis

Roy M. John, MD, PhD

Associate Professor of Medicine, Vanderbilt University; Director, Center for Advanced Management of Ventricular Arrhythmias, Vanderbilt University Medical Center, Nashville, Tennessee
Cardiac Arrest: Sudden Cardiac Death

Lisa M. Johnson, MD

Assistant Professor, Department of Pediatrics, Cincinnati Children's Hospital, Cincinnati, Ohio
Acne Vulgaris; Rosacea

Joshua S. Jolissaint, MD

Department of Surgery, Brigham and Women's Hospital, Boston, Massachusetts
Atelectasis

Gregory Juckett, MD, MPH

Professor of Family Medicine, Family Medicine/University Health, West Virginia University School of Medicine, Morgantown, West Virginia
Campylobacter

Marc A. Judson, MD

Chief, Division of Pulmonary and Critical Care Medicine, Albany Medical Center, Albany, New York
Sarcoidosis

Tamilarasu Kadhiravan, MD

Associate Professor of Medicine, Jawaharlal Institute of Postgraduate Medical Education and Research, Puducherry, India
Typhoid Fever

Rachna Kalia, MD

Clinical Assistant Professor, Department of Psychiatry and Behavioral Sciences, University of Kansas School of Medicine–Wichita, Wichita, Kansas
Obsessive-Compulsive Disorder

Jessica Kanter, MD

Department of Obstetrics and Gynecology, Augusta University, Augusta, Georgia
Infertility

Dilip R. Karnad, MD

Consultant in Critical Care, Jupiter Hospital, Thane, India
Tetanus

Andreas Katsambas, MD, PhD

Professor of Dermatology, University of Athens School of Medicine, Athens, Greece
Parasitic Diseases of the Skin

Ben Z. Katz, MD

Professor, Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Infectious Mononucleosis

Rebecca Katzman, MD

Family Physician, Clearwater Valley Hospital and Clinics, Orofino, Idaho
Palpitations

Daniel I. Kaufer, MD

Division Chief, Cognitive Neurology and Memory Disorders, Department of Neurology, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Alzheimer's Disease

Andrew M. Kaunitz, MD

Professor of Obstetrics and Gynecology, University of Florida College of Medicine–Jacksonville, Jacksonville, Florida
Menopause

Arthur Kavanaugh, MD

Professor of Medicine, University of California–San Diego School of Medicine, La Jolla, California
Rheumatoid Arthritis

B. Mark Keegan, MD

Associate Professor of Neurology, Mayo Clinic, Rochester, Minnesota
Multiple Sclerosis

Rick D. Kellerman, MD

Professor and Chair, Department of Family and Community Medicine, University of Kansas School of Medicine–Wichita, Wichita, Kansas
Chikungunya; Zika Virus Disease

Scott Kellermann, MD, MPH

Founder, Bwindi Community Hospital, Buhoma, Uganda
Chikungunya; Zika Virus Disease

Christina Kelly, MD

Department of Family Medicine, Memorial Health Family Medicine Residency, Savannah, Georgia
Ectopic Pregnancy

Stephen F. Kemp, MD

Professor of Medicine and Pediatrics, Division of Clinical Immunology and Allergy, Department of Medicine, University of Mississippi Medical Center, Jackson, Mississippi
Anaphylaxis and Serum Sickness

Arthur Y. Kim, MD

Associate Professor of Medicine, Harvard Medical School; Division of Infectious Diseases, Massachusetts General Hospital, Boston, Massachusetts
Hepatitis C

Haejin Kim, MD

Senior Staff Allergist, Department of Allergy and Clinical Immunology, Henry Ford Health System, Detroit, Michigan
Hypersensitivity Pneumonitis

Jongoh Kim, MD

Instructor in Medicine, Division of Diabetes, Endocrinology and Metabolism, Department of Medicine, Baylor College of Medicine, Houston, Texas
Hyperaldosteronism; Hyperlipidemia

Robert S. Kirsner, MD, PhD

Professor, Vice Chairman, and Stiefel Laboratories Chair, Department of Dermatology and Cutaneous Surgery, and Chief of Dermatology, University of Miami Miller School of Medicine, Miami, Florida
Venous Ulcers

Charles Kodner, MD

Associate Professor, Department of Family and Geriatric Medicine, University of Louisville School of Medicine, Louisville, Kentucky
Fibromyalgia

Amanda Kolb, MD

Instructor, Department of Family Medicine, University of Virginia, Charlottesville, Virginia
Asthma in Children

Bhanu Prakash Kolla, MD, MRCPsych

Senior Associate Consultant, Center for Sleep Medicine, Department of Psychiatry and Psychology, Mayo Clinic and Foundation; Assistant Professor of Psychiatry and Psychology, Mayo Clinic College of Medicine, Rochester, Minnesota
Sleep Disorders

Frederick K. Korley, MD

Robert E. Meyerhoff Assistant Professor of Emergency Medicine, The Johns Hopkins University School of Medicine; Staff, The Johns Hopkins Medical Institutions, Baltimore, Maryland
Disturbances Due to Cold

Adrienne N. Kovalsky, DO, MPH

Hospitalist, Colorado Springs, Colorado
High Altitude Illness

Robert A. Kratzke, MD

John Skoglund Chair of Lung Cancer Research, University of Minnesota Medical School; Associate Professor, University of Minnesota Medical Center, Minneapolis, Minnesota
Primary Lung Cancer

Eric H. Kraut, MD

Professor of Medicine and Director, Benign Hematology, Division of Hematology-Oncology, The Ohio State University, Columbus, Ohio
Platelet-Mediated Bleeding Disorders

John N. Krieger, MD

Urology Section, Veterans Affairs Puget Sound Health Care System, Seattle, Washington
Bacterial Infections of the Male Urinary Tract

Lakshmanan Krishnamurti, MD

Professor of Pediatrics, Division of Hematology/Oncology, Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Sickle Cell Disease

Kumar Krishnan, MD

Assistant Professor of Medicine, Internal Medicine, Houston Methodist Hospital, Houston, Texas
Dysphagia and Esophageal Obstruction

Zachary Kuhlmann, DO

Clinical Associate Professor, Residency Program Director, Department of Obstetrics and Gynecology. University of Kansas School of Medicine – Wichita, Wichita, Kansas
Endometriosis

Roshni Kulkarni, MD

Professor and Director, Pediatric Hematology/Oncology; Director (Pediatric), Michigan State University Center for Bleeding and Clotting Disorders, Michigan State University College of Medicine, East Lansing, Michigan
Hemophilia and Related Conditions

Iftikhar J. Kullo, MD

Professor of Medicine, Department of Cardiovascular Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota
Peripheral Artery Disease

Seema Kumar, MD

Assistant Professor of Pediatrics, Pediatric and Adolescent Medicine, Mayo Clinic, Rochester, Minnesota
Obesity

Mary R. Kwaan, MD, MPH

Assistant Professor of Surgery, University of Minnesota, Minneapolis, Minnesota
Hemorrhoids, Anal Fissure, and Anorectal Abscess and Fistula

Robert A. Kyle, MD

Professor of Medicine, Laboratory Medicine, and Pathology, Mayo Clinic College of Medicine, Rochester, Minnesota
Multiple Myeloma

Lucius M. Lampton, MD

Clinical Associate Professor of Family and Community Medicine, Tulane University School of Medicine, New Orleans, Louisiana; Clinical Professor of Family Medicine, William Carey University College of Osteopathic Medicine, Hattiesburg, Mississippi; Private Practice, Magnolia Clinic, Magnolia, Mississippi
Yellow Fever

Richard A. Lange, MD

President, Texas Tech University Health Sciences Center El Paso; Dean, Paul L. Foster School of Medicine, El Paso, Texas
Congenital Heart Disease

Fabienne Langlois, MD

Assistant Professor, Division of Endocrinology, Department of Medicine, Université de Sherbrooke, Sherbrooke, Quebec, Canada
Adrenocortical Insufficiency

Julius Larioza, MD

Assistant Professor of Medicine, Attending Physician, Bay State Medical Center, Springfield, Massachusetts
Toxic Shock Syndrome

Jerome Larkin, MD

Assistant Professor of Medicine, Infectious Diseases, Alpert Medical School of Brown University, Providence, Rhode Island
Severe Sepsis

David Larrabee, MD, MPH

Saint Vincent Medical Group, Shrewsbury, Massachusetts
Otitis Externa

Christine L. Lau, MD

Associate Professor of Surgery, University of Virginia Health System, Charlottesville, Virginia
Atelectasis

Susan Lawrence-Hylland, MD

Clinical Assistant Professor, Rheumatology Section, University of Wisconsin Hospital and Clinics, Madison, Wisconsin
Connective Tissue Disorders; Cutaneous Vasculitis

Jerrold B. Leikin, MD

Director of Medical Toxicology, NorthShore University HealthSystem-OMEGA, Glenbrook Hospital, Glenview, Illinois
Disturbances Due to Cold

Scott M. Leikin, DO

Internal Medicine, Mount Sinai Medical Center, Chicago, Illinois
Disturbances Due to Cold

Alexander K.C. Leung, MBBS

Clinical Professor of Pediatrics, University of Calgary, Calgary, Alberta, Canada
Nocturnal Enuresis

Martin M. LeWinter, MD

Attending Physician, Cardiology, Fletcher Allen Health Care, Burlington, Vermont
Pericarditis

Ming Li, MD, PhD

Division of Diabetes, Endocrinology, and Metabolism, Baylor College of Medicine, Houston, Texas
Hyperprolactinemia

Tyler K. Liebenstein, PharmD

Departments of Infectious Diseases, University of Wisconsin School of Pharmacy-Madison, Madison, Wisconsin
Treatment and Prevention of HIV Infection

Albert P. Lin, MD

Assistant Professor, Ophthalmology, Baylor College of Medicine; Staff Physician, Eye Care Line, Michael E. DeBakey Veterans Affairs Medical Center, Houston, Texas
Glaucoma

Janet C. Lindemann, MD, MBA

Dean of Medical Student Education, Professor of Family Medicine, University of South Dakota Sanford School of Medicine, Sioux Falls, South Dakota
Fatigue

Jeffrey A. Linder, MD, MPH

Chief, Division of General Internal Medicine and Geriatrics, Michael A. Gertz Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Influenza

James Lock, MD, PhD

Professor of Psychiatry, Stanford University, Stanford, California
Eating Disorders

M. Chantel Long, MD

Clinical Assistant Professor, Department of Family and Community Medicine, University of Kansas School of Medicine – Wichita, Wichita, Kansas; Smoky Hill Family Medicine Residency, Salina, Kansas
Condylomata Acuminata; Warts (Verrucae)

James M. Lyznicki, MS, MPH

Senior Manager, Council on Scientific Affairs, Science Institute, American Dental Association, Chicago, Illinois
Biologic Agents Reference Chart; Toxic Chemical Agents Reference Chart: Symptoms and Treatment

Bahaa S. Malaeb, MD

Assistant Professor, Genitourinary Trauma and Reconstructive Surgery, Department of Urology, University of Michigan, Ann Arbor, Michigan
Trauma to the Genitourinary Tract

Uma Malhotra, MD

Department of Infectious Diseases, Virginia Mason Medical Center, Seattle, Washington
Ebola Virus Disease

Michael A. Malone, MD

Co-Medical Director, Penn State Hershey Medical Group, Hershey, Pennsylvania
Vulvovaginitis

Emily Manlove, MD

Family Medicine, IU Health Southern Indiana Physicians, Bloomington, Indiana
Cough

JoAnn E. Manson, MD, DrPH

Professor of Medicine, Harvard Medical School; Chief, Division of Preventive Medicine, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts
Menopause

Meghna P. Mansukhani, MD

Assistant Professor of Family Medicine, Senior Associate Consultant, Center for Sleep Medicine, Mayo Clinic and Foundation, Mayo Clinic College of Medicine, Rochester, Minnesota
Sleep Disorders

Claudio Marcocci, MD

Professor of Endocrinology, Department of Clinical and Experimental Medicine, University of Pisa; Head, Endocrine Unit 2, University Hospital of Pisa, Pisa, Italy
Hyperparathyroidism and Hypoparathyroidism

Paul Martin, MD

Chief, Division of Hepatology, University of Miami, Miami, Florida
Cirrhosis

Vickie Martin, MD

Assistant Professor, Department of Obstetrics and Gynecology, Kingston General Hospital, Kingston, Ontario, Canada
Amenorrhea

Mark A. Matza, MD, MBA

Department of Rheumatology, Massachusetts General Hospital, Boston, Massachusetts
Polymyalgia Rheumatica and Giant Cell Arteritis

Pinckney J. Maxwell, IV, MD

Associate Professor of Surgery, Division of Gastrointestinal and Laparoscopic Surgery, Medical University of South Carolina, Charleston, South Carolina
Tumors of the Colon and Rectum

Anthony L. McCall, MD, PhD

James M. Moss Professor of Diabetes in Internal Medicine, Division of Endocrinology and Metabolism, University of Virginia School of Medicine, Charlottesville, Virginia
Diabetes Mellitus in Adults

Christopher McGrew, MD

University of New Mexico Health Sciences Center, Department of Family and Community Medicine, Department of Orthopedics and Rehabilitation, Sports Medicine Division, Albuquerque, New Mexico
Sports-Related Head Injuries

Christopher C. McGuigan, MB, ChB, MPH

Consultant in Public Health Medicine, NHS Tayside, Dundee, United Kingdom
Psittacosis

Michael McGuigan, MD

Medical Director, Long Island Regional Poison and Drug Information Center, Winthrop-University Hospital, Mineola, New York
Medical Toxicology

Mick S. Meiselman, MD

Section Chief, Advanced Therapeutic Endoscopy, Department of Gastroenterology, NorthShore University HealthSystem, Evanston, Illinois
Calculous Biliary Disease

Genevieve B. Melton-Meaux, MD

Professor, Department of Surgery, Institute for Health Informatics, Minneapolis, Minnesota
Hemorrhoids, Anal Fissure, and Anorectal Abscess and Fistula

Moises Mercado, MD

Director, Experimental Endocrinology Unit, Hospital de Especialidades, Centro Medico Nacional Siglo XXI, Instituto Mexicano del Seguro Social, Mexico City, Mexico
Acromegaly

Ryan Merrell, MD

Neurology, NorthShore University HealthSystem, Evanston, Illinois
Brain Tumors

Steven L. Meyers, MD

Vice Chair, Quality and Informatics, Neurology, NorthShore University Health System, Evanston, Illinois
Acute Facial Paralysis

Brian J. Miller, MD, PhD, MPH

Associate Professor, Department of Psychiatry, Augusta University, Augusta, Georgia
Schizophrenia

Moben Mirza, MD

Assistant Professor, Department of Urology, University of Kansas Medical Center, Kansas City, Kansas
Hematuria

Kriti Mishra, MS

Department of Dermatology, University of New Mexico, Albuquerque, New Mexico
Fungal Infections of the Skin

Howard C. Mofenson, MD

Professor of Pediatrics and Emergency Medicine, Stony Brook University Medical Center School of Medicine, Stony Brook, New York; Professor of Pharmacology and Toxicology, New York College of Osteopathic Medicine, Old Westbury, New York

Medical Toxicology

Kris M. Mogensen, MS

Team Leader Dietitian, Department of Nutrition, Brigham and Women's Hospital, Boston, Massachusetts

Parenteral Nutrition in Adults

Enrique Morales, MD, PhD

Nephrology, Hospital Universitario 12 de Octubre, Madrid, Spain

Primary Glomerular Diseases

Jaime Morales-Arias, MD

Associate Professor of Pediatrics, Louisiana State University, New Orleans, Louisiana

Disseminated Intravascular Coagulation

Timothy I. Morgenthaler, MD

Associate Professor of Medicine, Pulmonary and Critical Care Medicine, Center for Sleep Medicine, Mayo Clinic and Foundation, Rochester, Minnesota

Sleep Disorders

Warwick L. Morison, MD

Professor of Dermatology, The Johns Hopkins University, Baltimore, Maryland

Sunburn

Rami Mortada, MD

Endocrine Center of Kansas, Wichita, Kansas

Diabetes Insipidus

Scott E. Moser, MD

Associate Dean for Curriculum, Professor, Family and Community Medicine, University of Kansas School of Medicine-Wichita, Wichita, Kansas

Attention-Deficit/Hyperactivity Disorder

Heather E. Moss, MD, PhD

Assistant Professor, Ophthalmology and Visual Sciences, University of Illinois at Chicago, Chicago, Illinois

Optic Neuritis

Ladan Mostaghimi, MD

Dermatologist, University of Wisconsin-Madison, Madison, Wisconsin

Psychocutaneous Medicine

Judd W. Moul, MD

James H. Semans, MD Professor of Surgery, Urologic Surgery, Duke University, Durham, North Carolina

Benign Prostatic Hyperplasia

Heidi E.K. Mullen, DO

General Surgery, Maricopa Integrated Health System, Phoenix, Arizona

Contact Dermatitis

Michael Murphy, MD

Professor of Dermatology, University of Connecticut School of Medicine; Attending Dermatopathologist, Department of Dermatology, University of Connecticut Health Center, Farmington, Connecticut

Nevi

Diya F. Mutasim, MD

Professor of Dermatology and Pathology, University of Cincinnati College of Medicine, Cincinnati, Ohio

Bullous Diseases

Arjun Muthusubramanian, MD, MPH

Department of Family Medicine, University of Virginia, Charlottesville, Virginia

Bacterial Pneumonia

Alykhan S. Nagji, MD

Associate Program Director, Cardiothoracic Surgery Residency Program, University of Kansas, Kansas City, Kansas

Atelectasis

Moniba Nazeef, MD

Department of Medicine, Division of Hematology/Oncology, University of Wisconsin School of Medicine and Public Health, UW Carbone Cancer Center, Madison, Wisconsin

Venous Thromboembolism

Tara J. Neil, MD

Clinical Associate Professor, Department of Family and Community Medicine, University of Kansas School of Medicine – Wichita; Senior Associate Director, Via Christi Family Medicine Residency, Wichita, Kansas

Postpartum Care

David G. Neschis, MD

Clinical Associate Professor of Surgery, University of Maryland School of Medicine, Baltimore, Maryland; Maryland Vascular Center, Glen Burnie, Maryland

Aortic Disease: Aneurysm and Dissection

Theresa Nester, MD

Associate Medical Director, Puget Sound Blood Center, Seattle, Washington

Blood Component Therapy

David H. Neustadt, MD

Clinical Professor of Medicine, Department of Medicine, Division of Rheumatology, University of Louisville School of Medicine, Louisville, Kentucky

Osteoarthritis

Tam T. Nguyen, MD

Associate Program Director, Family Medicine, San Joaquin General Hospital, French Camp, California

Papulosquamous Eruptions

Lucybeth Nieves-Arriba, MD

Assistant Professor, Gynecology Oncology, Zimmer Cancer Center, Wilmington, North Carolina

Cancer of the Uterine Cervix

Andrei Novac, MD

Clinical Professor of Psychiatry, University of California-Irvine, School of Medicine, Irvine, California

Mood Disorders: Depression, Bipolar Disease, and Mood Dysregulation

Enrico M. Novelli, MD

Assistant Professor of Medicine, Department of Medicine, Division of Hematology/Oncology, Vascular Medicine Institute; Director, Adult Sickle Cell Anemia Program, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

Sickle Cell Disease

Lauren Nye, MD

Assistant Professor of Internal Medicine, Division of Medical Oncology, Breast Cancer Prevention and Survivorship Research Center, University of Kansas Medical Center, Kansas City, Kansas
Benign Breast Disease; Breast Cancer

Andrea T. Obi, MD

University of Michigan, Section of Vascular Surgery, Department of Surgery, University of Michigan, Ann Arbor, Michigan
Venous Thrombosis

Jeffrey P. Okeson, DMD

Professor and Chair, Oral Health Science, University of Kentucky, Lexington, Kentucky
Temporomandibular Disorders

Carlos R. Oliveira, MD

Attending Physician, Pediatric Infectious Diseases, Yale University, New Haven, Connecticut
Lyme Disease

Peck Y. Ong, MD

Associate Professor of Clinical Pediatrics, Keck School of Medicine of the University of Southern California/Children's Hospital Los Angeles, Los Angeles, California
Atopic Dermatitis

Bernhard Ortel, MD

Clinical Professor, University of Chicago Pritzker School of Medicine, Chicago, Illinois; Division Head, Dermatology, NorthShore University HealthSystem, Skokie, Illinois
Cancer of the Skin

Gary D. Overturf, MD

Professor Emeritus, Pediatrics and Pathology, University of New Mexico School of Medicine, Albuquerque, New Mexico
Bacterial Meningitis

Bulent Ozgonenel, MD

Assistant Professor in Pediatric Hematology/Oncology, Children's Hospital of Michigan, Wayne State University, Detroit, Michigan
Hemophilia and Related Conditions

Karel Pacak, MD, PhD, DSc, FACE

Professor of Medicine and Chief of the Section on Medical Neuroendocrinology, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland
Pheochromocytoma

Jose A. Padin-Rosado, MD

Associate Professor, Department of Neurology, University of New Mexico School of Medicine, Albuquerque, New Mexico
Seizures and Epilepsy in Adolescents and Adults

John E. Pandolfino, MD

Hans Popper Professor of Medicine, Northwestern University, Chicago, Illinois
Dysphagia and Esophageal Obstruction

Preface

Readers of the 2019 edition of *Conn's Current Therapy* will notice that the new co-editor has a familiar name: Rakel. No, not Robert Rakel, MD, who served as an editor from 1983 to 2011, but his son: David Rakel, MD, Professor and Chair of the Department of Family and Community Medicine at the University of New Mexico School of Medicine.

David Rakel, MD, has combined successful careers in practice and in academic medicine. He practiced for 5 years in rural Driggs, Idaho, before completing a 2-year fellowship in integrative medicine at the University of Arizona Health Sciences Center. He then took a position at the University of Wisconsin School of Medicine and Public Health where he founded and directed the Integrative Medicine Program. He moved from Wisconsin to New Mexico in 2016. Dr. Rakel is editor of *Integrative Medicine* and co-edits the *Textbook of Family Medicine* with his father. Dr. Rakel has received awards that recognize his teaching and compassionate clinical care.

It astounds us—and we are greatly honored—that in the 71-year history of *Conn's Current Therapy*, Dr. David Rakel is only the fifth editor.

Howard Franklin Conn, MD, the brainchild and namesake of *Conn's Current Therapy*, edited the book from 1948 until his death in 1982. After returning from World War II to his practice in Uniontown, Pennsylvania, Dr. Conn recognized the need for a practical medical textbook that busy clinicians could use to access medicine's latest therapeutic advances: in other words, "Current Therapy."

Dr. Conn's proposal was that chapters be periodically rewritten by different contributors, keeping each edition fresh with new authors challenged to improve on the previous authors' work. Dr. Conn's belief was that the book should balance best evidence with each author's own personal experience with the subject matter. Dr. Conn understood that medicine is both an art and science and that clinical care required a nuanced understanding of the patient and the evidence.

In the beginning, Dr. Conn wrote many chapters himself. As the reputation of his book grew, Dr. Conn had little trouble recruiting authors from around the country. Dr. Conn would practice medicine during the day and edit the book at night until the early morning hours. The day before he died of a myocardial infarction on April 17, 1982, he had worked all day on the 1983 edition. At the time of his death, the book had sold more than one million copies.

In an obituary published in the *Journal of the American Medical Association* "'Country Doctor' Passes from Publishing Scene" (*JAMA*. 1982;247[2]:3177), John J. Hanley, president of the WB Saunders Company in Philadelphia, was quoted as saying this about Dr. Conn: "All of his work was accomplished, not in a great medical center, but in a small Victorian house. His greatest concern was to meet the needs of the doctor faced with ordinary problems of day-to-day delivery of care. In this he succeeded more than some of our largest institutions."

Robert Rakel, MD, was recruited to finish the editing of the 1983 edition and succeeded Dr. Conn as editor of *Conn's Current Therapy*. Dr. Conn and Dr. Rakel had already worked together as

editors on another book, and Dr. Rakel was established in his own right in the medical publishing industry, having edited other texts. Dr. Rakel served as editor of *Conn's Current Therapy* following Dr. Conn's death until the 2011 edition.

Ed Bope, MD, joined Dr. Robert Rakel as a co-editor for the 2001 edition and served until the 2018 edition. Dr. Rick Kellerman, MD, became a co-editor with Drs. Rakel and Bope for the 2010 edition. We now welcome Dr. David Rakel, MD, for the 2019 edition.

We are proud that the 70th edition of the book, the Silver Edition, received critical acclaim. We believe the 71st edition is even better.

Every chapter has been reviewed and updated. Authors continue to be rotated. The book is available online and in print. The online version has a user-friendly search function. Call-out boxes, tables, and figures highlight important information.

Miriam Chan, PharmD, is a vital member of the editorial team. Dr. Chan verifies each and every drug dosage and formulation in the book. Her work is critically important to the accuracy and usefulness of this text. The book uses generic as well as brand names so that busy practicing physicians can easily access the information. Footnotes identify drug dosages and uses that are not FDA approved. We are astonished by Dr. Chan's expertise and very much appreciate our close working relationship with her.

We greatly appreciate the exacting work of other members of the editorial staff at Elsevier. Senior Content Developmental Specialist Joan Ryan serves as the central nervous system of the editorial team. Joan has served in this role for 10 years. We communicate almost daily with Joan, and she is wonderfully helpful. We should also add that Joan is fun to work with! Thank you, Joan, for keeping us on track!

Senior Content Strategist Charlotta Kryhl is the newest member of the team, succeeding Sarah Barth. Charlotta and Sarah have worked hard to push the book forward and improve communication between the editorial and production teams. The copy editors at Elsevier do wonderful work and we thank them all. Senior Project Manager Sharon Corell helped us organize the book in the final stages of production.

We want to thank the authors. Through the editing process, we have made physician friends internationally, even though we have only met some through e-mail correspondence. As we review and edit each chapter, we recognize the talent, expertise, and devotion each author brings to his or her work. We have even consulted some of our specialty co-authors about patient problems we have experienced in practice.

Like Dr. Conn, we spend many late nights and early mornings working on the book. It is a labor of love. We appreciate the understanding, tolerance, and forbearance our families show us as we work to make *Conn's Current Therapy* a practical, useful, and clinically valuable resource.

To conclude, we would like to dedicate this edition of *Conn's Current Therapy* to our parents who taught us to read, write, and care.

Rick Kellerman, MD
David Rakel, MD

CHEST PAIN

Method of

William E Cayley, Jr., MD, MDiv

CURRENT DIAGNOSIS

- Initial evaluation of chest pain should include evaluation of clinical stability, a concise history and physical, and a chest x-ray and electrocardiogram (ECG) unless the cause is clearly not life-threatening.
- Chest pain described as exertional, radiating to one or both arms, similar to or worse than prior cardiac chest pain, or associated with nausea, vomiting, or diaphoresis indicates high risk for acute coronary syndrome. ECG identifies ST elevation myocardial infarction (STEMI), and cardiac biomarkers are essential for further evaluation of suspected chest pain in the absence of STEMI.
- The Wells, Geneva, and Pisa clinical prediction rules can help stratify a patient's risk of pulmonary embolism.
- Aortic dissection is an uncommon cause of chest pain, but patients with abrupt or instantaneous chest pain that is ripping, tearing, or stabbing should have evaluation for dissection with chest x-ray, computed tomography (CT), or magnetic resonance imaging.
- Esophageal rupture may be suspected in patients with pain, dyspnea, and shock following a forceful emesis, and prompt imaging with CT or esophagram is essential.
- Patients who have suspected tension pneumothorax and who are clinically stable should have a chest x-ray for confirmation before needle decompression is attempted.

CURRENT THERAPY

- Patients with STEMI require urgent reperfusion, and those with unstable angina or non-ST elevation myocardial infarction require admission for further monitoring and evaluation.
- Most patients with pulmonary embolism require admission for monitoring and anticoagulation, although outpatient treatment may be possible for low-risk patients after initial evaluation and anticoagulation.
- Prompt surgical consultation is required for patients with confirmed or suspected aortic dissection or esophageal rupture.
- Clinically unstable patients with suspected tension pneumothorax need immediate needle decompression.

Epidemiology

Chest pain is the chief complaint in 1% to 2% of all outpatient primary care visits. More than 50% of emergency department (ED) visits for chest pain are due to serious cardiovascular conditions such as acute coronary syndrome (ACS) or pulmonary embolism (PE), but these account for less than 15% of outpatient primary care encounters for chest pain, and up to 15% of chest pain episodes never reach a definitive diagnosis. Other potentially life-

threatening etiologies for chest pain include PE, dissecting aortic aneurysm (AA), esophageal rupture, and tension pneumothorax. In outpatient primary care the most common causes of chest pain are musculoskeletal, gastrointestinal, angina due to stable coronary artery disease (CAD), anxiety or other psychiatric conditions, and pulmonary disease.

Initial Assessment

In initial evaluation of chest pain, it is important to obtain a clear history of the onset and evolution of chest pain, especially details such as location, quality, duration, and aggravating or alleviating factors. Initial physical examination should include vital signs, assessment of the patient's overall general condition, and examination of the heart and lungs. If there are any clinical signs of instability (altered mental status, hypotension, marked dyspnea, or other signs of shock) then initial stabilization and diagnosis must both be addressed simultaneously, consistent with current guidelines for emergency cardiovascular care. Unless the history and physical examination suggest an obviously nonthreatening cause of chest discomfort, most adults with chest pain should at least have basic diagnostic testing with an ECG and a chest x-ray. Several clinical prediction rules are available to help confirm or exclude some common causes of chest pain ([Box 1](#)).

Diagnosis and Treatment

Acute Coronary Syndrome

ACS includes acute myocardial infarction (MI) (ST-segment elevation and depression, Q wave and non-Q wave) or unstable angina. A review of prospective and retrospective studies correlating specific chest pain characteristics with the likelihood of ACS found that components of the patient history that increase the likelihood of ACS include radiation of pain to the right arm or shoulder, to both arms or shoulders, or to the left arm; or pain associated with exertion, diaphoresis, nausea, or vomiting; or pain described as pressure or as "worse than previous angina or similar to a previous MI." Similarly, components of the history that predicted decreased likelihood of ACS were pleuritic, positional, or sharp chest pain; pain in an inframammary location; or pain not associated with exertion. A physical examination finding of chest pain reproducibility with palpation also decreased the likelihood of ACS. Additional physical examination findings that may be helpful are the presence of hypotension or an S₃ on cardiac auscultation, both of which suggest increased likelihood of ACS. The Marburg Heart Score can help exclude CAD in primary care patients with chest pain—most patients with a score of 2 or less will not have CAD ([Table 1](#)). Recent studies have demonstrated that the presence or absence of typical cardiac risk factors (eg, diabetes, hypertension, smoking, high cholesterol, or family history) have little diagnostic value for determining the likelihood of ACS in patients over age 40.

An ECG should be obtained promptly for any patient with suspected ACS. ST-segment elevation in two or more contiguous leads, or presumed new left bundle branch block, is diagnostic of ST-segment elevation MI (STEMI) and requires urgent revascularization with thrombolysis or angioplasty at an appropriate facility. Ischemic ST-segment depression more than 0.5 mm, dynamic T-wave inversion with chest discomfort, or transient ST-segment elevation of 0.5 mm or more are classified as unstable angina or

TABLE 1 Marburg Heart Score

FINDING	POINTS
Woman > 64 years, man > 54 years	1
Known CAD, cerebrovascular disease, or peripheral vascular disease	1
Pain worse with exercise	1
Pain not reproducible with palpation	1
Patient assumes pain is cardiac	1

Abbreviation: CAD = coronary artery disease.

Approximately 97% of patients with a MHS score of 2 or less will not have CAD. Approximately 23% of patients with a MHS score of 3 or more will have CAD. Adapted from: Haasenritter J, Bösner S, Vaucher P, Herzig L, Heinzel-Gutenbrunner M, Baum E, Donner-Banzhoff N. Ruling out coronary heart disease in primary care: external validation of a clinical prediction rule. *Br J Gen Pract.* 2012 Jun;62(599):e415-21. doi: 10.3399/bjgp12X649106. <http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3361121/>.

non-ST-elevation MI (NSTEMI). However, none of these findings is sensitive enough that its absence can exclude MI, and patients whose chest pain is not low risk still require further assessment for ACS.

In patients with high-risk chest pain who do not have STEMI, elevated cardiac biomarkers distinguish NSTEMI from unstable angina. Cardiac troponins T and I are more sensitive for detecting NSTEMI than creatine kinase (CK) or the MB isoform (CK-MB). High-sensitive troponins will be coming into use with an even greater sensitivity (negative predictive values = 99.5%).

Initial management of NSTEMI includes hospital admission for antiplatelet, antithrombin, and antianginal therapy. Patients with unstable angina should also be hospitalized for observation, and patients with either NSTEMI or unstable angina require risk stratification using the TIMI or GRACE risk scores (see Box 1). Patients with chest pain suspicious for CAD, but no definite initial diagnosis of STEMI or NSTEMI on initial presentation, are often admitted to hospital for overnight observation and serial cardiac biomarker measurements at 6 and 12 hours after symptom onset to “rule

out MI.” However, use of the TIMI, GRACE, and HEART scores may help determine who is at sufficiently low risk of major adverse cardiac events to allow discharge for close follow-up, and recent evidence suggests that the HEART score may outperform TIMI and GRACE in determining which patients are low risk. (see Box 1).

Patients at low risk for ACS or MI can usually defer further testing unless there are other risk factors in their family or past medical history markedly increasing the likelihood of CAD. Current recommendations are that all other patients with chest pain suggesting CAD should have further noninvasive testing within 7 days; however, a recent study of 4181 patients in an ED chest pain unit found that a reasonable alternative may be to test troponin levels twice over a 6-hour interval, with no stress testing done if both values are normal. Patients who can exercise and who have no left-bundle branch block, preexcitation, or significant resting ST depression on a resting ECG can be evaluated with an exercise stress ECG, and the Duke treadmill score can then be used to further quantify cardiac risk (see Box 1). Patients with baseline ECG abnormalities should have perfusion imaging performed, along with a stress ECG, and patients who cannot exercise may be evaluated with a pharmacologic stress or vasodilator test (e.g., dobutamine [Dobutrex]¹ or adenosine [Adenocard]). Patients at high risk for CAD or those with NSTEMI should generally proceed directly to angiography, which allows definitive assessment of coronary artery anatomy.

Pulmonary Embolism

There are no individual symptoms or physical examination findings that reliably diagnose or exclude pulmonary embolism (PE), but three clinical prediction rules have all been validated for use in determining likelihood of PE and therefore whether further testing is needed. The Wells prediction rule (Table 2) is based on the simplest combination of history and examination findings. The Geneva rule requires blood gas and chest x-ray findings. The Pisa rule is the most mathematically complicated and depends on clinical, ECG, and x-ray findings. The Wells rule has been the most widely studied, but a comparison of all three found the Pisa rule may be the most accurate for clinical diagnosis and for excluding PE. With the Wells and Geneva prediction rules, the likelihood of PE is approximately 10% in the low-probability category, 30% in the moderate-probability category, and 65% in the high-probability category. Routine tests done for patients with chest pain are not particularly helpful in diagnosing or excluding PE. The chest x-ray may be abnormal, but

¹Not FDA approved for this indication.

TABLE 2 Simplified Wells Scoring System for Pulmonary Embolism

CLINICAL FINDING	SCORE
Symptoms of deep vein thrombosis (DVT)	3.0
No alternative diagnosis more likely than PE	3.0
Heart rate > 100 bpm	1.5
Immobilization greater than 3 days or surgery in past 4 weeks	1.5
Previous objectively diagnosed DVT or PE	1.5
Hemoptysis	1.0
Malignancy	1.0
Probability of PE: < 2 points = low, 2–6 points = moderate, > 6 points = high.	

Abbreviations: DVT = deep vein thrombosis; PE = pulmonary embolism.

Adapted from Miniati M, Bottai M, Monti S. Comparison of 3 clinical models for predicting the probability of pulmonary embolism. *Medicine (Baltimore)* 2005;84:107–114; Torbicki A, Perrier A, Konstantinides S, et al, ESC Committee for Practice Guidelines (CPG): Guidelines on the diagnosis and management of acute pulmonary embolism. *Eur Heart J* 2008;29:2276–315. <http://eurheartj.oxfordjournals.org/content/29/18/2276.long>.

findings that typically occur with PE (atelectasis, effusion, or elevation of a hemidiaphragm) are nonspecific. ECG signs of right ventricular strain (S wave in lead I, Q wave and inverted T wave in lead III) may be helpful if present, but their absence does not exclude PE. Hypoxia may be present, but up to 20% of patients with PE have a normal alveolar-arterial oxygen gradient.

Additional tests recommended for evaluating patients with suspected PE include D-dimer testing by enzyme-linked immunosorbent assay (ELISA; sensitivity > 95%; specificity, approximately 40%) or latex agglutination (sensitivity 85%–90%), compression ultrasonography, ventilation–perfusion scintigraphy, or computed tomography (CT) angiography. Patients with suspected high-risk PE (i.e., those with shock or hypotension) should have immediate CT angiography and treatment for PE if the CT is positive, although an echocardiographic finding of right ventricular overload may be used to justify treatment for PE in the unstable patient with high clinical suspicion for PE when CT angiography is not available. Patients who have suspected PE and who are not at high risk (i.e., no shock or hypotension) and who have a high clinical probability (based on Wells, Geneva, or Pisa scoring) should also proceed directly to CT, with appropriate treatment if the scan is positive. Patients with low clinical probability of PE (based on one of the validated clinical prediction rules) do not need further D-dimer testing or imaging. Patients with intermediate clinical probability should initially have D-dimer testing; further testing or treatment for PE is unnecessary if the D-dimer is negative, and CT angiography should be performed if the D-dimer is positive.

Anticoagulation, with thrombolysis in high-risk patients, is the foundation of treatment for PE. Patients with shock or hypotension are at high risk and require hemodynamic and respiratory support, thrombolysis, or embolectomy, and then appropriate attention to anticoagulation. Normotensive patients with echocardiographic evidence of right ventricular dysfunction or serologic evidence of myocardial injury (elevated troponins or CK-MB) have intermediate risk and should be admitted for anticoagulation. Normotensive patients who have normal results on echocardiography and testing for myocardial injury are at low risk and often may be discharged early for management at home after initiation of anticoagulation. Anticoagulation for PE should be started at the time of diagnosis with unfractionated heparin, low-molecular-weight heparin, or fondaparinux (Arixtra) and continued for at least 5 days, with simultaneous initiation of oral anticoagulation with warfarin (Coumadin), titrated to maintain an international normalized ratio (INR) between 2.0 and 3.0. The newer anticoagulants dabigatran (Pradaxa), rivaroxaban (Xarelto), or apixaban (Eliquis) may be an option for patients who have difficulty maintaining steady anticoagulation with warfarin.

Aortic Dissection

Thoracic aortic dissection is a much less common cause of chest pain; prevalence estimates are 2 to 3.5 cases per 100,000 person-years. Up to 40% of patients die immediately, and 5% to 20% die during or shortly after surgery. Risk factors for acute thoracic aortic dissection include hypertension, presence of a pheochromocytoma, cocaine use, weight lifting, trauma or a rapid deceleration event, coarctation of the aorta, and certain genetic abnormalities. Pain due to acute aortic dissection is perceived as abrupt and severe in 84% to 90% of cases, and more than 50% of patients describe the pain as sharp or stabbing. No physical findings are sensitive or specific for detecting aortic dissection, because approximately equal percentages of patients are hypertensive, normotensive, or have hypotension or shock, and the most common physical findings (a murmur of aortic insufficiency or a pulse deficit) occur in less than half of patients.

In any patient with severe chest pain that is abrupt or instantaneous in onset or has a ripping, tearing, or stabbing quality, acute thoracic aortic dissection should be suspected. Physical examination should assess for a pulse deficit, a systolic pressure differential between limbs of greater than 20 mm Hg, a focal neurologic deficit, or a new aortic regurgitation murmur. It is also important to ask

about a family history of connective tissue disease (including Marfan syndrome), about any family or personal history of aortic dissection or thoracic aneurysm, and about any known aortic valve disease or recent aortic interventions. D-dimer testing has been proposed as a way to screen for aortic dissection, but it is more important to obtain prompt imaging and surgical intervention for those in whom dissection is confirmed.

An ECG should be obtained in all patients with suspected aortic dissection to exclude STEMI (which can manifest with similar symptoms). In all low- and intermediate-risk patients, a prompt chest x-ray can help by either confirming an alternative diagnosis or confirming the presence of thoracic aortic disease. High-risk patients should have prompt imaging with CT or magnetic resonance imaging (MRI), and those who are in shock or clinically unstable may be evaluated by bedside transesophageal echocardiography. If thoracic aortic dissection is confirmed on imaging, urgent surgical consultation is required. Medical therapy should be started with intravenous β -blockers. Patients with dissection of the ascending aorta require urgent surgery, whereas those with descending thoracic aortic dissection may be managed medically unless hypotension or other complications develop.

Esophageal Rupture

Esophageal rupture, or Boerhaave's syndrome, has a high mortality rate. Esophageal rupture is rare, and the most common cause is endoscopically induced injury, but it can happen in other settings as well. Common misdiagnoses include perforated ulcer, MI, PE, dissecting aneurysm, and pancreatitis. The "classic" presentation has been described as pain, dyspnea, and shock followed by forceful emesis, but history and physical are commonly nonspecific. Diagnosis most commonly is made by contrast esophagram or CT scan of the chest.

Patients whose rupture is diagnosed less than 48 hours after symptom onset should be treated surgically (especially if sepsis is present) or endoscopically. Those who present more than 48 hours after symptom onset may be considered for conservative treatment with hyperalimentation, antibiotics, and nasogastric suction.

Tension Pneumothorax

Tension pneumothorax is relatively rare among patients presenting with chest pain, but it is potentially life-threatening if not treated properly. Common symptoms and physical findings include chest pain, respiratory distress, decreased ipsilateral air entry, and tachycardia; hypoxia, tracheal deviation, and hypotension are less common.

Emergency needle decompression is usually recommended if tension pneumothorax is suspected, but this is ineffective in some cases and is associated with risks to the patient of pain, bleeding, infection, and cardiac tamponade. However, waiting for radiographic confirmation of the diagnosis is associated with up to a four fold increase in mortality due to delay in decompression of the pneumothorax. Patients most likely to benefit from an immediate attempt at needle decompression are those with an oxygen saturation <92% while on oxygen, a decreased level of consciousness while on oxygen, a systolic blood pressure less than 90 mm Hg, or a respiratory rate <10. Patients without these signs of instability may be better managed by waiting for chest imaging to confirm or exclude the presence of a pneumothorax. Although plain chest x-rays have typically been used for diagnosing a pneumothorax, one study has found that pleural ultrasound may have higher sensitivity.

Other Causes of Chest Pain

A patient with chest pain and cough, fever, egophony, or dullness to percussion might have pneumonia, but none of these individual findings are specific enough to confirm the diagnosis. A large study in 1984 developed a decision rule (Table 3) using seven clinical findings to predict the likelihood of pneumonia. Although there is ongoing debate over the reliability of pneumonia diagnosis based solely on history and physical examination and chest x-ray is usually considered the reference standard, a recent Cochrane review found two trials suggesting routine chest radiography does not

Adapted from Cayley Jr WE. Diagnosing the cause of chest pain. *Am Fam Physician* 2005;72:2012–2021. <http://www.aafp.org/afp/2005/1115/p2012.html>.

affect the clinical outcomes in adults and children presenting suggestive of a lower respiratory tract infection. Thus, at least for clinically stable outpatients, treatment for pneumonia based on appropriate clinical findings alone may be reasonable.

Heart failure alone is an uncommon cause of chest pain, but it may accompany ACS or cardiac valve disease. A displaced apical impulse and a prior history of CAD support this diagnosis, and because virtually all patients with heart failure have exertional dyspnea, its absence is very helpful in excluding this diagnosis. An abnormal ECG and cardiomegaly on chest x-ray can increase the likelihood of heart failure among patients with chest pain, and B-natriuretic peptide (BNP) is now commonly used for detecting heart failure in patients presenting with acute dyspnea. One recent study also found that point-of-care ultrasound (POCUS) may have high sensitivity and specificity for diagnosing acute cardiogenic pulmonary edema.

A 3-item questionnaire has been developed specifically to assess for panic disorder among patients with chest pain referred for cardiac evaluation (Table 4), and there is good evidence that psychological interventions such as cognitive behavioral therapy (CBT) and breathing exercises can improve chest pain symptoms for patients with nonspecific chest pain who do not have CAD. However, even in patients with possible panic disorder, further cardiac testing should be done if there are significant cardiac risk factors.

Gastrointestinal disease can cause chest pain, but the history and physical examination are relatively inaccurate for diagnosing or excluding serious gastrointestinal pathology. However, if life-threatening cardiovascular or pulmonary causes of chest pain have been excluded, it is appropriate to try a course of high dose PPI (omeprazole [Prilosec] 40 mg twice daily³, lansoprazole [Prevacid] 30 mg daily, or esomeprazole [Nexium] 40 mg twice daily³) to evaluate for undiagnosed gastroesophageal reflux disease (GERD) as the cause of chest pain (even for patients without typical GERD symptoms.)

Chest wall pain can usually be diagnosed by history and examination if other etiologies have been excluded, and chest wall pain is more likely if the patient's pain is reproducible by palpation.

³Exceeds dosage recommended by the manufacturer.

CONSTIPATION

Method of

Melissa Gaines, MD

CURRENT DIAGNOSIS

- While constipation is a benign process, it is important to recognize signs of a serious condition.
- Classification of normal transit constipation, slow transit constipation, or pelvic floor dysfunction guides therapy.
- Clinical testing has low benefit, but colonoscopy or imaging can assess for organic causes.

CURRENT THERAPY

- Initial therapy includes soluble dietary fiber to improve symptoms in chronic constipation.
- Osmotic laxatives are preferred while using stimulant laxatives as rescue agents.
- Surgery is reserved for pelvic floor dysfunction after optimal therapies have failed.

Epidemiology

Constipation is common, with a prevalence of 1.9% to 27.2%, but the description of symptoms is variable. A thorough history and focused physical examination aids diagnosis. Treatment is directed toward relief of symptoms, alleviation of precipitating factors, and prevention of recurrence. While constipation is a benign process, it is important to recognize concerning signs for a more serious medical condition such as malignancy.

Risk Factors

Vulnerable populations include female, elderly, neurodegenerative disease, low-fiber diet, painful rectal disorders, hypothyroidism, and diabetes mellitus.

Pathophysiology

With aging, there is decreased rectal compliance, diminished rectal sensation, and decreased resting anal pressures, while colonic transit time is preserved. Normal transit constipation is a component of irritable bowel syndrome with normal transit time and stool frequency. Slow transit constipation is a condition with colonic dysmotility resulting from altered enteric nervous system. Defecatory disorders include structural disturbances of the pelvic floor. Pelvic floor dysfunction is the paradoxical contraction of the external anal sphincter and puborectalis muscles during defecation. Secondary causes of constipation are listed in [Table 1](#).

TABLE 1 Causes of Constipation

Dietary	Low-fiber diet, dementia, depression, anorexia, dehydration
Metabolic	Diabetes mellitus, hypercalcemia, hypokalemia, hypothyroidism, systemic sclerosis
Neurologic	Parkinson's disease, spinal cord disorder, multiple sclerosis, cerebrovascular disease (stroke)
Iatrogenic	Antacids, iron, anticholinergics, antidepressants, antipsychotics, opiates, antiepileptics
Painful anorectal condition	Anal fissure, hemorrhoids, abscess, fistula, pelvic floor dysfunction, malignancy

Prevention

Provide an environment of privacy and comfort to allow for natural defecation. Prescribe an adequate fluid and fiber intake with specific amounts that vary depending on the patient's condition. Encourage physical activity, with a low to moderate level of exercise depending on the patient's functional status. Develop a routine for defecation with a prompt response to a call to defecate urgently. Recurrent fecal impaction can be prevented with polyethylene glycol (PEG, MiraLax).

Clinical Manifestations

Patients will complain using qualitative terms of hard stools, a feeling of incomplete voiding, straining, prolonged time for laxation, the need for additional maneuvers, abdominal bloating, and abdominal pain ([Table 2](#)). A change in bowel habit differentiates the current complaint from a serious medical condition. Red flags include acute onset, weight loss, abdominal pain or cramping, rectal bleeding, nausea or vomiting, rectal pain, fever, or a change in stool caliber. Infants with abdominal distension and failure to pass meconium within 24 hours indicate Hirschsprung's disease. Patients should be asked if they have had loose stools or bowel incontinence to assess for fecal impaction. A medication review is required (see [Table 1](#)). Classification of patients with normal transit constipation, slow transit constipation, or pelvic floor dysfunction/defecatory disorders guides therapy.

Diagnosis

Diagnostic criteria have been established because the symptoms can vary (see [Table 2](#)). Conduct a physical examination that includes an assessment of vital signs, weight, volume status, auscultation of bowel sounds, abdominal percussion for tympani, and abdominal palpation for tenderness or mass. A rectal examination can detect resting rectal tone, fecal impaction, anorectal disorders, or rectal mass. Defecatory disorders show an increased resistance to the insertion of the examiner's finger with an impaired relaxation of the sphincter complex and reduced perineal descent during a Valsalva maneuver. Conduct laboratory testing on electrolytes, hemoglobin, thyroid-stimulating hormone, and fecal occult after initial measures fail. Red flag symptoms require imaging with CT of the abdomen and pelvis or endoscopy to diagnose malignancy or fecal impaction. Anorectal testing with manometry and a rectal balloon expulsion test is appropriate for pelvic floor dysfunction or defecatory disorders. Hirschsprung's disease is diagnosed with barium enema, rectal manometry, or a rectal suction biopsy. Colonic transit rates with radiopaque markers (Sitz) on serial abdominal radiographs over 4 to 7 days diagnose slow transit constipation disorders.

Treatment

Nonpharmacologic therapies have limited benefit. Unless there are signs of dehydration, increasing fluid intake is not indicated. Moderate-intensity exercise improves symptoms of irritable bowel syndrome. Probiotics are not beneficial.

There is moderate evidence for pharmacologic agents ([Table 3](#)). Normal transit constipation responds to soluble dietary fiber

TABLE 2 Rome III Criteria

- More than two present:
- Straining in more than 25% of defecations
 - Hard or lumpy stool in more than 25% of defecations
 - Sensation of incomplete evacuation
 - Sensation of anorectal blockage
 - Manual maneuvers
 - Fewer than three defecations per week

Loose stools are rare without laxative use

Insufficient criteria for irritable bowel syndrome

Symptoms for 3 months with onset 6 months before diagnosis

TABLE 3 Drug Dosing and Adverse Effects

CLASS	DRUG NAME (BRAND)	ADULT DOSING	MECHANISM OF ACTION	TIME TO ONSET (H)	ADVERSE EFFECT
Fiber	Bran	1 cup/day	Increase water content and bulk of stool decreasing transit time	Unknown	Bloating excessive gas
	Psyllium (Metamucil)	1 tsp			
	Methylcellulose (Citrucel)	1 tbsp or 1 tab twice daily			
	Calcium polycarbophil (FiberCon)	2–4 tabs/day			
Hyperosmolar agent	Sorbitol 70% Lactulose (Chronulac)	15–30 mL twice daily	Disaccharide metabolized by colonic bacteria into acetic acid and short-chain fatty acids	24–48	Sweet tasting, transient abdominal cramps, flatulence
Hyperosmolar agent	PEG-ES (GoLyteLyte*, CoLyte*) PEG (Miralax)	8–32 oz daily 17 g (1 tbsp) qd	Osmotic effect increasing intraluminal fluids	0.5–1	Incontinence
Hyperosmolar agent	Plecanatide (Trulance)	3 mg daily	Osmotic effect increasing intraluminal fluids, increase transit time	Cannot be calculated	Diarrhea
Stimulant	Glycerin suppository Bisacodyl (Dulcolax) Senna (Senokot, Perdiem) Senna/docusate (Peri-Colace) Cascara [†]	1 daily 10 mg suppository or 5–10 mg PO 3 times a week 2–4 tabs twice daily 20–30 mg/day	Local rectal stimulation, secretory and prokinetic effect	8–12	Degeneration of Meissner's and Auerbach's plexus
Enemas	Mineral oil retention enema Tap water enema Sodium phosphate enema (Fleet)	199–250 mL daily PR 500–1000 mL PR 1 unit PR	Evacuation induced by distended colon and mechanical lavage	6–8 for a mineral oil enema 5–15 min for all other enemas	Mechanical trauma, incontinence, rectal damage
Opioid antagonist	Methylnaltrexone (Relistor)	8–12 mg 1 dose SC every other day as needed for opioid-induced constipation (OIC) with advanced illness. 450 mg PO once daily or 12 mg SC once daily for OIC with chronic non-cancer pain.	Opioid mu receptor antagonist in gut decreasing transit time	4	Diarrhea, intestinal perforation
Opioid antagonist	Naloxegol (Movantik)	12.5–25 mg PO daily	Same as Relistor	6–36	Abdominal pain, opioid withdrawal reported

*Not FDA approved for this indication.

[†]Available as dietary supplement.

supplements (e.g., psyllium [Metamucil]); however, these should not be used in the case of slow transit constipation or drug-induced constipation. Osmotic agents with PEG (Miralax) or lactulose (Chronulac) can be dose increased for soft stools. Stimulant laxatives are used as rescue therapy if patients do not have a bowel movement for 2 days.

New classes of drugs to manage constipation include intestinal secretagogues, serotonin 5-HT₄ receptor antagonists, and opiate antagonists. Lubiprostone (Amitiza) requires a negative pregnancy test with contraception. Linaclotide (Linzess) is a 14-amino acid peptide similar to heat-stable enterotoxins that cause diarrhea. Lubiprostone and linaclotide are FDA-approved for chronic idiopathic constipation and irritable bowel syndrome with constipation. Plecanatide (Trulance) is an approved drug for chronic idiopathic constipation in adults. It is a guanylate cyclase-C agonist that increases fluid secretion into the upper intestine. Methylnaltrexone (Relistor) and naloxegol (Movantik) are opiate receptor

antagonists that can cause laxation in patients on chronic opiate therapy with NNT 5.

Pelvic floor dysfunction or defecatory disorders respond to bio-feedback therapy by using manometry and visual or auditory feedback. Patients practice expelling a balloon and improve pelvic floor muscle coordination with Kegel exercises. Surgical intervention with subtotal colectomy with ileorectal anastomosis is indicated for slow transit constipation or defecatory disorders after failure of optimal medical management.

Complications

Fecal impaction a complication and a large bowel obstruction with colonic perforation has high mortality. Pediatric and geriatric patients are most susceptible, with signs and symptoms of fecal incontinence, abdominal pain, abdominal distention, anorexia, weight loss, and delirium. Treatments for adults include a large-volume tap-water enema (500–1000 mL), local anesthetics

administered topically with abdominal massage, a colonoscopy, or surgery. The prevention of recurrence requires maintenance bowel regimen with osmotic agents such as PEG (Miralax).

COUGH

Method of

Emily Manlove, MD

CURRENT DIAGNOSIS

- Acute Cough
 - Noninfectious
 - Chronic obstructive pulmonary disease exacerbation
 - Asthma exacerbation
 - Congestive heart failure exacerbation
 - Pulmonary embolism
 - Infectious
 - Viral rhinosinusitis (the common cold)
 - Acute bacterial sinusitis
 - Acute bronchitis (chest cold)
 - Pneumonia
 - Pertussis (whooping cough)
 - Bronchiolitis (infants)
- Chronic cough
 - First, evaluate/rule out
 - Tobacco smoking and risk for lung cancer
 - Angiotensin-converting enzyme (ACE) inhibitor associated cough
 - Next, evaluate for the three most common etiologies
 - Chronic upper airway cough syndrome
 - Cough variant asthma/nonasthmatic eosinophilic bronchitis
 - Gastroesophageal reflux disease
 - Last, consider other causes and more advanced testing (bronchoscopy, high-resolution computed tomography [CT] scanning, referral) and consider earlier if history, physical, or chest x-ray suggests an alternative diagnosis
 - Oral pharyngeal dysphagia
 - Lung tumors
 - Interstitial pulmonary diseases
 - Bronchiectasis
 - Occupational and environmental exposures
 - Sarcoidosis
 - Tuberculosis
 - Somatic cough syndrome
 - Tic cough

CURRENT THERAPY

- Acute cough due to viral rhinosinusitis
 - Dextromethorphan (Delsym) 30 mg PO every 6 to 8 hours × 1 week
 - Diphenhydramine (Benadryl) 25 mg PO every 4 hours × 1 week
 - Nasal saline irrigation twice daily × 1 week
- Acute or subacute cough caused by *Bordetella pertussis*
 - Azithromycin (Z-Pak)¹ 500 mg PO on day 1 followed by 250 mg PO daily on days 2 to 5
- Treatment of unexplained chronic cough
 - Multimodality speech pathology therapy
 - Gabapentin (Neurontin) 300 mg PO daily, can be titrated up to a maximum daily dose of 1800 mg a day in two divided doses (off label use)

¹Not FDA approved for this indication.

Acute Cough

Acute cough is a cough that lasts fewer than 3 weeks. It is a common presenting complaint in the primary care physician's office and also in the emergency room. The key goal is to differentiate between those patients whose cough has a benign cause and those who may be at risk for more serious illness. Infectious causes of cough are most common, but noninfectious causes should also be considered. Exacerbations of preexisting pulmonary conditions such as asthma and chronic obstructive pulmonary disease (COPD) can be associated with cough, therefore a thorough medical history should be obtained. Cough can also be associated with decompensated heart failure; in fact, cough is present in 70% of congestive heart failure (CHF) exacerbations. Also, 30% to 40% of patients with acute pulmonary embolism (PE) have a new cough at presentation of symptoms, and the classic signs and symptoms of chest pain, dyspnea, and hypoxia may not always accompany the cough.

Upper respiratory tract infections are a common cause of benign acute cough. The common cold, also known as viral rhinosinusitis, is probably the most common cause of acute cough. The lung exam is normal. If fever is present it is low grade and is only present on the first or second day of illness. Most symptoms begin to resolve by 7 to 10 days, but cigarette smokers may be ill for twice as long. Symptomatic treatment is the mainstay of therapy. First-generation antihistamines combined with a decongestant and naproxen have been proven to reduce the length of cough. Second-generation antihistamines are not effective in the treatment of cough associated with viral rhinosinusitis; it is likely that first-generation antihistamines are effective because of their anticholinergic properties. Other treatments that may be helpful include nasal saline irrigation, nasal glucocorticoids, and nasal decongestants. It is necessary to distinguish viral rhinosinusitis from acute bacterial rhinosinusitis, which may also be associated with cough. Less than 2% of all rhinosinusitis has a bacterial cause. Acute bacterial rhinosinusitis should not be diagnosed in the first week of symptoms unless the patient displays severe symptoms such as high fever. Sinus imaging studies are unlikely to be helpful, as both viral and bacterial sinusitis will have radiologic evidence of inflammation.

It is also necessary to distinguish an acute cough caused by an upper respiratory tract infection and that caused by a lower respiratory tract infection. Furthermore, it is necessary to distinguish between acute bronchitis, which almost always has a viral cause, versus pneumonia, which has a bacterial cause. Both illnesses often have a presenting symptom of cough, which may be productive. If there is any derangement in vital signs or evidence of pulmonary consolidation on the lung exam, a chest x-ray should be performed. Infectious Diseases Society of America (IDSA) guidelines require the presence of consolidation on chest x-ray to diagnose pneumonia. Influenza should also be considered for those patients who have fever and cough during flu season. An elevated procalcitonin level may help

administered topically with abdominal massage, a colonoscopy, or surgery. The prevention of recurrence requires maintenance bowel regimen with osmotic agents such as PEG (Miralax).

Acute Cough

Acute cough is a cough that lasts fewer than 3 weeks. It is a common presenting complaint in the primary care physician's office and also in the emergency room. The key goal is to differentiate between those patients whose cough has a benign cause and those who may be at risk for more serious illness. Infectious causes of cough are most common, but noninfectious causes should also be considered. Exacerbations of preexisting pulmonary conditions such as asthma and chronic obstructive pulmonary disease (COPD) can be associated with cough, therefore a thorough medical history should be obtained. Cough can also be associated with decompensated heart failure; in fact, cough is present in 70% of congestive heart failure (CHF) exacerbations. Also, 30% to 40% of patients with acute pulmonary embolism (PE) have a new cough at presentation of symptoms, and the classic signs and symptoms of chest pain, dyspnea, and hypoxia may not always accompany the cough.

Upper respiratory tract infections are a common cause of benign acute cough. The common cold, also known as viral rhinosinusitis, is probably the most common cause of acute cough. The lung exam is normal. If fever is present it is low grade and is only present on the first or second day of illness. Most symptoms begin to resolve by 7 to 10 days, but cigarette smokers may be ill for twice as long. Symptomatic treatment is the mainstay of therapy. First-generation antihistamines combined with a decongestant and naproxen have been proven to reduce the length of cough. Second-generation antihistamines are not effective in the treatment of cough associated with viral rhinosinusitis; it is likely that first-generation antihistamines are effective because of their anticholinergic properties. Other treatments that may be helpful include nasal saline irrigation, nasal glucocorticoids, and nasal decongestants. It is necessary to distinguish viral rhinosinusitis from acute bacterial rhinosinusitis, which may also be associated with cough. Less than 2% of all rhinosinusitis has a bacterial cause. Acute bacterial rhinosinusitis should not be diagnosed in the first week of symptoms unless the patient displays severe symptoms such as high fever. Sinus imaging studies are unlikely to be helpful, as both viral and bacterial sinusitis will have radiologic evidence of inflammation.

It is also necessary to distinguish an acute cough caused by an upper respiratory tract infection and that caused by a lower respiratory tract infection. Furthermore, it is necessary to distinguish between acute bronchitis, which almost always has a viral cause, versus pneumonia, which has a bacterial cause. Both illnesses often have a presenting symptom of cough, which may be productive. If there is any derangement in vital signs or evidence of pulmonary consolidation on the lung exam, a chest x-ray should be performed. Infectious Diseases Society of America (IDSA) guidelines require the presence of consolidation on chest x-ray to diagnose pneumonia. Influenza should also be considered for those patients who have fever and cough during flu season. An elevated procalcitonin level may help

guide the physician in his or her decision to prescribe antibiotics. Beta agonists should not be routinely used to alleviate cough in acute viral bronchitis, but may be helpful for the alleviation of wheezing and are more likely to benefit patients with airflow obstruction at baseline.

In pediatric patients, bronchiolitis should be considered as a cause of cough and fever. It is the most common cause of hospitalization in those less than 1 year old. The most recent guidelines recommend abstaining from lab testing (including viral swabs), radiographic imaging, and treatment with beta agonists, epinephrine, or glucocorticoids as these interventions do not change the course of illness. Exclusive breastfeeding for the first 6 months of infancy can decrease the morbidity of respiratory infections. *Bordetella pertussis* can cause severe illness with cough and apnea in infants. However, adults have subtle symptoms and lack the classic “whooping cough” and posttussive emesis seen in children. The physician should have suspicion for pertussis in patients who have a cough lasting longer than 2 weeks and paroxysms of coughing; the cough can last up to 2 months. The diagnosis can be confirmed with polymerase chain reaction (PCR). Antibiotics do not alter the course of illness but reduce the spread of infection; azithromycin (Zithromax)¹ should be given for 3 to 5 days. Vaccination rates remain low. Pregnant women should be vaccinated with each pregnancy and other adults should replace 1 dose of Td at the earliest convenience.

Chronic Cough

A chronic cough is a cough lasting more than 8 weeks. Patients may have a presenting symptom of a cough that has been present for more than 3 but fewer than 8 weeks; this is considered a subacute cough. In this case, the physician should illicit a history of respiratory infection; the patient is likely suffering from a postinfectious cough, which is related to inflammation of the airway epithelium, mucus hypersecretion, and/or increased cough reflex sensitivity. Inhaled corticosteroids may provide some benefit. If there is no history of recent infection, then the cough should be managed as a chronic cough. Chest x-ray can be considered during this time frame, but if no red flags are present (fever, unintended weight loss, night sweats, dysphagia, odynophagia, hemoptysis) the physician and patient together can decide to wait on radiography.

Chronic cough must be approached in a systematic manner, which is more likely to identify the causative agent of the cough and provide alleviation of symptoms. All of the common causes of chronic cough (see later) must be considered, as the associated symptoms and the patient's description of the cough do not alter the diagnostic algorithm. It is important to confirm compliance throughout the treatment course and identify barriers to compliance with the patient. Failure to respond to empiric treatment does not necessarily rule out a diagnosis, as the patient may have two diagnoses. Therefore, it is prudent to continue any partially effective treatment for chronic cough.

First, it must be determined if the patient smokes. If so, the differential diagnosis is altered. The physician must determine if the cough is a simple smoker's cough, chronic bronchitis, or possibly lung cancer; cough is the most common presenting symptom of lung cancer. Smokers are less likely to seek help for a cough and may not see a physician until a more serious problem has advanced. It is possible for a cough to worsen initially after smoking cessation, but a cough persisting more than 1 month after cessation should be investigated. Any change in a smoker's cough, a new cough, and cough with hemoptysis should be investigated. Physicians should consider low dose CT scanning as screening for lung cancer in qualifying smokers. The second factor to rule out in all chronic cough cases is cough induced by an angiotensin-converting enzyme (ACE) inhibitor. All patients with chronic cough should stop taking an ACE inhibitor. The medication is more likely to cause a cough if it was started in the prior year, and the cough should resolve within 1 month after cessation of the ACE inhibitor. The next step to determining the cause of a chronic cough is to rule out the three

most common causes of cough. Last, all patients with a cough lasting more than 8 weeks should be evaluated with chest radiography to identify any obvious causative factors.

Upper Airway Cough Syndrome

Upper airway cough syndrome (UACS), previously called postnasal drip syndrome, is likely caused by activation of cough receptors in the hypopharynx or larynx and increased sensitivity of these receptors. It is likely the most common cause of chronic cough. UACS is almost always associated with rhinosinusitis, which can be caused by a number of factors (allergic rhinitis, postinfectious rhinitis, perennial nonallergic rhinitis, rhinitis resulting from chemical irritants, rhinitis medicamentosa, pregnancy-associated rhinitis, bacterial sinusitis, allergic fungal sinusitis, etc.). The patient may complain of frequently needing to clear the throat or a sensation of “dripping” in the back of the throat; however, absence of these symptoms does not rule out UACS, nor does a history of wheezing. Physical exam may reveal mucus in the posterior oropharynx and cobblestoning of the mucosa. If the cause of rhinitis is obvious, it should be specifically treated. Otherwise, a trial of a first-generation antihistamine should be started; improvement should be seen in 2 weeks. If the side effects of this therapy are intolerable, a nasal antihistamine, nasal anticholinergic, or nasal corticosteroid can be used. If the diagnosis of UACS is highly suspected but the patient does not respond to empiric therapy, sinus CT imaging may be necessary to guide diagnosis and treatment.

Cough Variant Asthma and Nonasthmatic Eosinophilic Bronchitis

Cough variant asthma and nonasthmatic eosinophilic bronchitis (NAEB) both primarily present with a cough, and the patient may have few other symptoms. Patients with cough variant asthma will have abnormal spirometry, whereas those with NAEB will not. When spirometry is performed, bronchoprovocation testing with methacholine should be performed as it increases the negative predictive value of the test. If spirometry is negative, the sputum should be evaluated for eosinophils, which are present in both diseases. Both diseases are treated as asthma; an inhaled corticosteroid should be started and long-acting beta agonists and leukotriene receptor antagonists can be considered as adjunctive therapy. A positive response should be expected within 2 weeks.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is common, but not all patients with GERD have an associated cough; therefore, the presence of GERD does not ensure that it is the source of the patient's cough. However, those patients whose cough is clearly not caused by UACS, cough variant asthma, or NAEB are very likely to have a GERD-induced cough. Cough can be caused by acidic and nonacidic reflux, so a proton pump inhibitor (PPI) may not always be of benefit. A pH probe can be performed in cases when it is unclear whether reflux is occurring. All patients should utilize lifestyle changes to attenuate reflux, such as smoking cessation, avoidance of alcohol and acidic foods, weight loss, and treatment of sleep apnea. It may take 3 to 6 months of treatment to see improvement in cough. If the patient does not improve and GERD is highly suspected, referral to a surgeon may be necessary for fundoplication.

Other Causes of Chronic Cough

In those patients who still suffer from chronic cough and the above causes have been ruled out, further investigation should be sought. Referral to a pulmonologist may be necessary, in addition to high-resolution CT scanning and bronchoscopy. Causative factors may include oral pharyngeal dysphagia, lung tumors, interstitial pulmonary diseases, bronchiectasis, occupational and environmental exposures, sarcoidosis, and tuberculosis. Somatic cough syndrome (previously referred to as psychogenic cough) and tic cough (previously referred to as habit cough) may be considered in some patients; hypnosis, suggestion therapy, and/or counseling may be beneficial. In patients who remain symptomatic, regardless of known or unknown causes, the diagnosis of “difficult to treat”

¹Not FDA approved for this indication.

cough is made. Assessing cough severity and quality of life with validated tools may be beneficial. Options do remain for these patients, including speech language pathology intervention, empiric gabapentin, and/or referral to a cough clinic.

DIZZINESS AND VERTIGO

Method of

Jennifer Wipperman, MD, MPH

CURRENT DIAGNOSIS

- Benign paroxysmal positional vertigo
 - Repeated, brief episodes lasting less than 1 minute
 - Triggered by changes in head position
 - Positive Dix-Hallpike or Supine Roll Test
- Vestibular neuritis
 - Single, severe, constant episode lasting days
 - Subacute onset
 - Positive head impulse test
 - Nystagmus is unilateral and horizontal
- Vestibular migraine
 - Recurrent episodes lasting hours to days
 - Associated with migraine headache
 - Responds to traditional migraine treatment
- Ménière's disease
 - Recurrent episodes of vertigo lasting hours
 - May have hearing loss, tinnitus, or ear fullness
- Red flags for stroke include:
 - Sudden onset
 - Risk factors for stroke
 - Nystagmus with a central pattern
 - Abnormal HINTS exam
 - Additional neurologic signs
 - Inability to walk

CURRENT THERAPY

- Benign paroxysmal positional vertigo
 - The canalith repositioning procedure (Epley maneuver) is the most effective treatment.
 - Avoid vestibular suppressant medications
 - Consider observation with close follow-up if a patient will not tolerate the canalith repositioning procedure or if symptoms are mild
- Vestibular neuritis
 - Brief symptomatic care with benzodiazepines, antiemetics, and antihistamines
 - Early vestibular rehabilitation speeds recovery.
 - Use of corticosteroids is controversial.

The “dizzy” patient is often a frustrating phenomenon in clinical medicine. However, after a careful history and physical examination, most patients can be diagnosed and serious causes excluded. Peripheral causes of vertigo are usually benign and include vestibular neuritis and benign paroxysmal positional vertigo (BPPV). Life-threatening central causes include stroke, demyelinating disease, and an intracranial mass. The first step in evaluating vertigo is differentiating among the four types of dizziness: near syncope or light-headedness, disequilibrium, psychogenic dizziness, and true vertigo.

True vertigo is a false sense of motion, and patients often report that “the room is spinning.” This chapter will focus on the two most common causes of episodic vertigo: BPPV and vestibular neuritis.

Epidemiology

Vertigo is a common office complaint. Every year, 7.5 million Americans are evaluated for dizziness in ambulatory care settings, and approximately 50% of these cases are vertigo. In primary care office setting, BPPV and vestibular neuritis account for the majority of vertigo diagnoses, followed by vestibular migraine, Ménière's disease, and vascular causes.

Risk Factors

BPPV is seven times more likely in individuals over age 60, and it is also more common in women. A history of prior head trauma and other vestibular disorders places patients at risk for BPPV. There are no identified risk factors for vestibular neuritis.

Pathophysiology

BPPV is thought to occur when calcium carbonate debris (otoconia) are dislodged and float freely in the semicircular canals of the inner ear. The posterior canal is most often involved. During head movement, loose otoconia move in the canal and cause a continued sense of motion for a few seconds until they settle. The pathophysiology of vestibular neuritis is uncertain. Evidence supports a viral infection, most likely HSV-1, which causes inflammation of the eighth cranial nerve. When hearing loss accompanies vertigo, the condition is called *acute labyrinthitis*.

Clinical Manifestations

The history and physical examination are fundamental in the evaluation of vertigo. Key questions include the frequency and duration of attacks, triggers such as positional or pressure changes, prior head trauma, associated neurologic symptoms, hearing loss, and headache. A personal history of diabetes, hypertension, and hyperlipidemia are risk factors for stroke. BPPV, stroke, and migraine can have a familial preponderance, and a family history of these disorders should be elicited. Many medications, including anticonvulsants and antihypertensives, cause dizziness.

BPPV causes brief, recurrent episodes that last less than 1 minute and are brought on by changes in head movement or position. Nausea and vomiting may be associated. Vestibular neuritis usually has a subacute onset over several hours, peaks in intensity for 1 to 2 days, and then gradually subsides over the next few weeks. Symptoms of vertigo are constant, and nausea and vomiting can be severe during the first few days. Patients with vestibular neuritis may have difficulty standing and veer toward the affected side. Although changes in position worsen the vertigo in vestibular neuritis, vertigo is always present at baseline. In BPPV, patients have no vertigo between attacks.

General physical examination should include a thorough cardiovascular, ear, nose, throat, and neurologic examination. The neurologic examination can differentiate between benign (peripheral) and life-threatening (central) causes based on the ability to walk, type of nystagmus, results of the head impulse test, and presence of associated neurologic signs (Table 1).

Patients with vestibular neuritis may have difficulty walking, but the inability to walk is a red flag for a central lesion. Nystagmus is unidirectional (always beats in the same direction) and horizontal in vestibular neuritis, and is suppressed by visual fixation. Having a patient focus on an object in the room will stop the nystagmus, which reappears if a blank sheet of paper is placed a few inches in front of the patient's face. Nystagmus in central causes is not suppressed by visual fixation and may be direction-changing (nystagmus beats to the right when the patient looks right, and beats to the left when the patient looks left) or pure vertical. The head impulse test (Figure 1) is positive in peripheral causes like vestibular neuritis. The examiner holds the patient's head while the patient fixes her eyes on the examiner's nose, and then the examiner quickly moves the patient's head 10 degrees to the right and left. If a saccade (the eyes look away and then re-fixate on the examiner's nose) is found, this indicates a peripheral lesion

cough is made. Assessing cough severity and quality of life with validated tools may be beneficial. Options do remain for these patients, including speech language pathology intervention, empiric gabapentin, and/or referral to a cough clinic.

A personal history of diabetes, hypertension, and hyperlipidemia are risk factors for stroke. BPPV, stroke, and migraine can have a familial preponderance, and a family history of these disorders should be elicited. Many medications, including anticonvulsants and antihypertensives, cause dizziness.

BPPV causes brief, recurrent episodes that last less than 1 minute and are brought on by changes in head movement or position. Nausea and vomiting may be associated. Vestibular neuritis usually has a subacute onset over several hours, peaks in intensity for 1 to 2 days, and then gradually subsides over the next few weeks. Symptoms of vertigo are constant, and nausea and vomiting can be severe during the first few days. Patients with vestibular neuritis may have difficulty standing and veer toward the affected side. Although changes in position worsen the vertigo in vestibular neuritis, vertigo is always present at baseline. In BPPV, patients have no vertigo between attacks.

General physical examination should include a thorough cardiovascular, ear, nose, throat, and neurologic examination. The neurologic examination can differentiate between benign (peripheral) and life-threatening (central) causes based on the ability to walk, type of nystagmus, results of the head impulse test, and presence of associated neurologic signs (Table 1).

Patients with vestibular neuritis may have difficulty walking, but the inability to walk is a red flag for a central lesion. Nystagmus is unidirectional (always beats in the same direction) and horizontal in vestibular neuritis, and is suppressed by visual fixation. Having a patient focus on an object in the room will stop the nystagmus, which reappears if a blank sheet of paper is placed a few inches in front of the patient's face. Nystagmus in central causes is not suppressed by visual fixation and may be direction-changing (nystagmus beats to the right when the patient looks right, and beats to the left when the patient looks left) or pure vertical. The head impulse test (Figure 1) is positive in peripheral causes like vestibular neuritis. The examiner holds the patient's head while the patient fixes her eyes on the examiner's nose, and then the examiner quickly moves the patient's head 10 degrees to the right and left. If a saccade (the eyes look away and then re-fixate on the examiner's nose) is found, this indicates a peripheral lesion

TABLE 1 Differentiating Peripheral and Central Causes of Vertigo

	PERIPHERAL CAUSES		CENTRAL CAUSES
	BPPV	VESTIBULAR NEURITIS	
History	Brief, recurrent attacks of vertigo lasting less than 1 minute Triggered by positional changes No vertigo between attacks	Subacute onset Constant and severe vertigo lasting days Nausea and vomiting may be severe	Sudden onset Risk factors for stroke May have severe headache
Nystagmus	Up-beating and torsional	Horizontal and unidirectional	Direction changing Pure vertical Pure torsional
Gait	Unaffected between episodes	May veer towards affected side	Unable to walk
Specialized physical examination tests	Positive Dix-Hallpike maneuver Positive supine roll test	Positive head impulse test Visual fixation stops nystagmus	HINTS exam abnormal Visual fixation does not stop nystagmus
Additional neurologic signs	Rare	Rare	Common (e.g., dysarthria, aphasia, incoordination, weakness, or numbness)

Abbreviation: BPPV = benign paroxysmal positional vertigo.

Figure 1 Head impulse test. Top panel shows a positive head impulse test. The examiner moves the patient's head quickly 10 degrees to the side, in this case to the patient's left. A catch-up saccade is observed when the patient looks away and then reflexes on the visual target, indicating a peripheral lesion on the left. Lower figure shows a normal head impulse test. The patient maintains visual fixation during head movement. (Adapted from Seemungal BM, Bronstein AM. A practical approach to acute vertigo. *Pract Neurol* 2008; 8:211–21.)

on the side that the head is turned toward. Central lesions will not cause saccades, and the head impulse test will be negative. HINTS (Head Impulse test, Nystagmus, Test of Skew), which combines three physical examination findings, has been found to have a 97% sensitivity and 99% specificity for a central cause of vertigo in the acute setting and to be more accurate than MRI in the initial 24 hours after symptom onset. If one or more of the tests indicate a central cause, (e.g., a negative head impulse test, direction-changing horizontal nystagmus, or vertical eye misalignment), then the HINTS test is considered positive for a central cause and imaging should be obtained. A negative HINTS exam is an excellent rule-out test for stroke, with a negative likelihood ratio of 0.02.

Figure 2 Treatment maneuver for posterior canal benign paroxysmal positional vertigo affecting the right ear. To treat the left ear, the procedure is reversed. The drawing of the labyrinth in the center shows the position of the particle as it moves around the posterior semicircular canal (PSC) and into the utricle (UT). The patient is seated upright, with head facing the examiner, who is standing on the right. **A**, The patient is rapidly moved to head-hanging right position (Dix-Hallpike test). This position is maintained until the nystagmus ceases. **B**, The examiner moves to the head of the table, repositioning hands as shown. **C**, The head is rotated quickly to the left with right ear up. This position is maintained for 30 seconds. **D**, The patient rolls onto the left side while the examiner rapidly rotates the head leftward until the nose is directed toward the floor. This position is then held for 30 seconds. **E**, The patient is rapidly lifted into the sitting position, now facing left. The entire sequence should be repeated until no nystagmus can be elicited. After the maneuver, the patient is instructed to avoid head-hanging positions to prevent the particles from reentering the posterior canal. (Reprinted with permission from Rakel RE. *Conn's Current Therapy* 1995. Philadelphia, WB Saunders, 1995, p 839.)

The Dix-Hallpike maneuver is diagnostic of posterior canal BPPV (Figure 2). The patient should be warned that nausea and vomiting may occur. After the patient is placed in the head-hanging position, there is a 5- to 20-second latency period before the

nystagmus and symptoms appear. Both the nystagmus and vertigo will increase in severity and then resolve within 60 seconds. The nystagmus observed is up-beating and torsional. The maneuver should be repeated with the head held to the opposite side. The side that elicits the symptoms and nystagmus diagnoses BPPV in the ipsilateral ear. If both sides elicit symptoms, the patient may have bilateral BPPV. If the test is negative and BPPV is strongly suspected, the patient should lie supine and the examiner can turn the head to each side (supine roll test). This maneuver will cause vertigo and nystagmus in patients with horizontal canal BPPV.

Diagnosis

BPPV and vestibular neuritis are diagnosed clinically. Further diagnostic testing is indicated if the diagnosis is uncertain or a central cause is suspected. Audiometry may be abnormal in Ménière's disease. MRI is the best imaging test for central lesions because it includes the posterior fossa and is most sensitive for stroke. Vestibular function testing is useful if the diagnosis is unclear or in cases of refractory vertigo. Vestibular function testing evaluates the ocular and vestibular response to position changes and caloric stimulation. Video-oculographic recordings of nystagmus can magnify the eye and allow for repeated viewings for further study. Some patients with BPPV may have additional vestibular disorders causing vertigo that vestibular function testing can elucidate.

Differential Diagnosis

Ménière's disease is suspected in patients with the triad of tinnitus, fluctuating hearing loss, and vertigo. Episodes usually last hours, are disabling, and are recurrent over years, over time leading to permanent dysfunction. Migrainous vertigo features episodes lasting hours to days in patients with other migraine symptoms such as headache, photophobia, phonophobia, or aura. Central lesions such as stroke or intracranial mass are most concerning. Red flags for stroke include sudden onset, risk factors for stroke, associated neurologic signs, inability to walk, positive HINTS exam, severe associated headache, and characteristic nystagmus. Posttraumatic vertigo may occur in patients after head trauma who present with vertigo, tinnitus, and headache. A perilymphatic fistula is rare, but may be suspected in a patient with episodic vertigo after head trauma, heavy lifting, or barotrauma. Pressure changes with sneezing or coughing trigger vertigo attacks. Postural hypotension should be ruled out in all patients. An acoustic neuroma presents with slowly progressive, unilateral sensorineural hearing loss and tinnitus. Many patients may have an unsteady gait, but true vertigo is rare.

Treatment

Posterior canal BPPV is best treated with the *canalith repositioning procedure* (CRP), also known as the Epley maneuver (Figure 2). Studies have shown the procedure is safe and effective with an odds ratio of 4.2 (95% CI. 2.3-11.4) for symptom resolution. Patients should be warned that nausea or vomiting may occur during the procedure, and may be pretreated with an antiemetic medication. The procedure can be repeated immediately if unsuccessful, and the majority of patients will respond after three attempts. Posttreatment activity restrictions are unnecessary. Horizontal canal BPPV can be treated with the barbeque roll maneuver. Vestibular rehabilitation (VR) is a treatment option for BPPV but is significantly less effective than the canalith repositioning procedure. VR is helpful in patients with chronic, nonspecific dizziness after successful treatment with CRP and for improving gait stability in those with increased fall risk, such as the elderly. Observation is an option if symptoms are mild or if a patient will not tolerate the canalith repositioning procedure or vestibular rehabilitation. However, time to resolution with observation is 1–3 months, and recurrence rates are higher compared to treatment with CRP. Vestibular-suppressant medications such as antihistamines and benzodiazepines are discouraged because they increase fall risk and treatment with CRP is effective. Surgery is rarely needed for BPPV, but may be helpful in refractory cases.

Vestibular neuritis is primarily treated with rest, vestibular suppressant medications, and vestibular rehabilitation. Patients may initially be admitted if symptoms, such as nausea and vomiting, are severe or if stroke is suspected. Treatment with antihistamines (dimenhydrinate [Dramamine]¹ 50 mg every 6 hours), antiemetics (promethazine [Phenergan]¹ 25 mg every 6 hours), or benzodiazepines (lorazepam [Ativan]¹ 1 to 2 mg every 4 hours) may be used to treat severe symptoms. However, these should not be continued for more than 2 to 3 days because they inhibit central compensation. In vestibular neuritis, patients' vertigo improves not due to return of vestibular nerve function, but due to central compensation for the peripheral deficit. Using vestibular suppressants blocks central compensation and lengthens the course of the disease. The use of corticosteroids is controversial. Although studies show that vestibular-function testing improves more quickly in patients treated with corticosteroids, there is conflicting evidence that corticosteroids hasten the recovery of clinical signs and symptoms of vestibular neuritis. A 2011 Cochrane review concluded that there is insufficient evidence to recommend corticosteroids for the treatment of vestibular neuritis. Finally, antiviral medications have not been proven effective for vestibular neuritis.

For patients with vestibular neuritis, vestibular rehabilitation should be started as soon as symptoms improve and a patient can tolerate the exercises. Exercises include balance and gait training as well as coordination of head and eye movements. Vestibular rehabilitation hastens recovery and improves balance, gait, and vision by increasing central compensation for vestibular dysfunction. Exercises may be home-based for compliant patients with mild symptoms, whereas formal referral may be more beneficial for patients with severe symptoms, or for the elderly.

Monitoring

Patients diagnosed with BPPV should be reassessed in 1 month regardless of treatment. Failure to improve warrants further evaluation for other etiologies, including central causes. Similarly, patients with vestibular neuritis should slowly improve over several weeks, and failure to do so suggests alternative diagnoses.

Complications

Patients with BPPV are at increased risk for falls. Thirty percent of elderly patients with BPPV have multiple falls in a year. Thus patients should be assessed for fall risk, functional mobility, and balance. Home safety evaluation and home supervision should be considered. BPPV often recurs, with an estimated rate of 15% per year. Counseling patients about recurrence can lead to earlier recognition, earlier treatment, and avoidance of falls. Patients with vestibular neuritis are at increased risk for BPPV and Ménière's disease. Vestibular neuritis rarely recurs.

¹Not FDA approved for this indication.

FATIGUE

Method of

Janet C. Lindemann, MD, MBA

CURRENT DIAGNOSIS

- The clinical evaluation of fatigue begins with a thorough medical and psychosocial history.
- Consider monitoring for a month before beginning a laboratory evaluation, because it usually does not yield a diagnosis. Initial evaluation should include a complete blood count (CBC), electrolytes, glucose, liver and kidney function tests, thyroid function tests, and urinalysis.
- Among the many possible causes of fatigue, the most common include depression, environmental stress, anemia, and diabetes. In many cases, a cause is not determined.

CURRENT THERAPY

- Any underlying cause discovered in the history, examination, or laboratory evaluation should be treated.
- If depression, anxiety, or environmental stress is suspected, early assessment and treatment is important.
- Symptom relief includes exercise, regular sleep habits, family discussion about the impact of fatigue, and a symptom and sleep diary.

Epidemiology

Fatigue or tiredness is a common complaint in the general population, representing the chief complaint in nearly 10% of patients presenting to a primary care physician and reported as a symptom in 21% of all patient encounters. While acute, prolonged, and chronic fatigue are relatively common, chronic fatigue syndrome is relatively rare.

Risk Factors

Risk factors for fatigue in adolescence include having depressive symptoms, being highly sedentary, and, conversely, being highly physically active. In adults, risk factors include age over 65 years, presence of one or more chronic medical conditions, and female gender. Precipitating factors include physical stresses such as infectious mononucleosis and psychological stresses such as job-related problems. Perpetuating factors include physical inactivity, emotional disorders, and disturbances of sleep.

Prevention

Because physical inactivity, psychological stress, and lack of sleep are predisposing and perpetuating factors for fatigue, it is helpful to advise patients about stress reduction, regular exercise, and proper sleep habits.

Clinical Manifestations

Fatigue is characterized by general malaise, vague physical discomfort, and an inability to perform routine activities. Acute fatigue is short-lived and generally attributable to physical exertion or an acute illness. Prolonged fatigue is defined as self-reported, persistent fatigue lasting 1 month or longer, whereas chronic fatigue is defined as similar symptoms lasting 6 months or more.

Diagnosis

The clinical evaluation begins with a thorough medical and psychosocial history. It is important to allow the patient to speak uninterrupted for the first minute or two of the interview, because this often provides pertinent clues. The history should include

exploration of all medically unexplained symptoms, inquiry into work and life stressor issues, questions regarding alcohol and other substance use, and the current use of prescription, over-the-counter, and alternative therapies. A mental status examination and screening for depression and anxiety should follow. The Beck Depression Inventory or SIG-E-CAPS mnemonic (Sleep, Interest, Guilt, Energy, Concentration, Appetite, Psychomotor retardation, Suicidal) are useful screening tools. The challenge with the diagnostic workup for fatigue is that most laboratory tests do not yield a significant diagnosis. Repeated studies show that only about 15% of patients in primary care settings will have an organic cause for their fatigue (Harrison, Ponka), and laboratory results affect management in as little as 5% of patients (Rosenthal). The following recommendations for the laboratory investigation of fatigue are adapted from guidelines developed by Dutch, Canadian, and Australian general practice groups (Harrison):

- Consider monitoring for a month after initial presentation, while initiating conservative management.
- CBC, electrolytes, glucose, liver and kidney function tests, thyroid function tests, urinalysis.
- Clues from the history and examination may indicate the need for erythrocyte sedimentation rate, monospot, antinuclear antigen testing, or chest radiography.

Differential Diagnosis

The common causes of fatigue are represented in the mnemonic DEAD TIRED (Box 1). Depression, environmental factors such as lifestyle, anxiety, and anemia are among the most common causes of fatigue. Diabetes and other endocrine disorders, including thyroid disease, should be considered, as well as an undiscovered tumor. Many infections, especially those of viral origin, cause fatigue, as well as insomnia and sleep disorders such as obstructive sleep apnea. Rheumatologic disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia, are often accompanied by fatigue. Endocarditis, while rare, is a must-not-miss diagnosis, as are other cardiac conditions such as coronary artery disease. Finally, drugs, either prescription or of personal use or abuse, should be considered.

Chronic fatigue syndrome is a specific clinical diagnosis characterized by unexplained persistent or relapsing fatigue, not relieved by rest, that substantially limits daily activity. In addition, there must be at least four of the following: memory or concentration impairment, sore throat, tender cervical or axillary lymph nodes, muscle pain, multijoint pain without swelling or tenderness, new headaches, unrefreshing sleep, or postexertional malaise lasting more than 24 hours.

Treatment

The treatment of fatigue begins with acknowledging the patient's concern and providing reassurance and information about the natural course and most frequent causes of fatigue. Any underlying cause discovered in the history, examination, or laboratory evaluation should be treated. If depression, anxiety, or environmental stress is suspected, early assessment and treatment is important. In fatigue that remains unexplained, therapy should emphasize symptom relief and include exercise, regular sleep habits, family discussion about the impact of fatigue, and a symptom and sleep diary. These same therapies, along with cognitive behavioral therapy, have been shown to have moderate benefit in chronic fatigue syndrome.

BOX 1 Common Causes of Fatigue: DEAD TIRED

D Depression	T Thyroid, Tumors
E Environment/lifestyle	I Infection, Insomnia
A Anxiety, Anemia	R Rheumatologic
D Diabetes/endocrine	E Endocarditis/cardiovascular
	D Drugs (medications or substance abuse)

Monitoring

Ongoing fatigue can be monitored through a three question assessment:

- Are you experiencing fatigue?
- If so, how severe has it been, on average, during the past week? (0–3 is mild fatigue, 4–6 moderate, and 7–10 severe)
- How does fatigue interfere with your ability to function?

FEVER

Method of

Alan R. Roth, DO; and Gina M. Basello, DO

CURRENT DIAGNOSIS

- Fever is one of the most common clinical presentations encountered in primary care.
- Numerous endogenous and exogenous factors play a role in determining body temperature. Current standards define fever as an oral temperature of $\geq 100.4^{\circ}\text{F}$ ($\geq 38^{\circ}\text{C}$).
- Though temperature varies with measurement technique, in clinical practice, most recommendations refer to oral, rectal, and axillary temperature measurements, with rectal temperature being the standard of care in infants and young children.
- With improvement in modern techniques, tympanic thermometers are commonly used due to parental convenience and ease of use along with improved accuracy. They should not be used in young children.
- Fever is not an illness. It is the body's physiologic response to a disease process and has beneficial effects in fighting infection.
- All neonates with a fever should be admitted to the hospital for a full sepsis evaluation. For infants between 1 and 3 months of age, evidence-based guidelines, along with clinical evaluation, determine the diagnostic and therapeutic approach.
- *Fever of unknown origin* (FUO) is defined as a temperature greater than 100.9°F (38.3°C) for longer than 3 weeks with no identified cause after 3 days of hospitalization or three outpatient visits.
- FUO requires a systematic, thoughtful, and thorough evaluation based on the age of the patient and the existing clinical evidence, with repeated clinical assessments being essential.
- Hyperthermia is an unregulated, significant elevation of core body temperature above the normal diurnal range due to failure of thermoregulation from a hypothalamic insult, not a pyogenic source, and is considered a medical emergency. It is not synonymous with fever and often requires immediate intervention to avoid deleterious central nervous system (CNS) effects.

CURRENT THERAPY

- Treating a fever significantly increases the patient's level of comfort, activity, and oral feeding and fluid intake, in addition to decreasing the body temperature.

- Multiple randomized, controlled trials reveal that treating fever does not shorten or prolong the overall duration of illness or reduce the occurrence of febrile seizures.
- Many clinical recommendations state that a temperature less than 102.2°F (39°C) in healthy children does not require treatment. Antipyretics are known to provide comfort to children and their caregivers.
- Antipyretic treatment for children includes acetaminophen (Tylenol) 10 to 15 mg/kg every 4 to 6 hours or ibuprofen (Advil, Motrin) 10 mg/kg every 6 hours.
- Ibuprofen and acetaminophen have both been shown to reduce fever effectively and safely. Combination therapy has been shown in some studies to have an added benefit in both reduction of temperature and comfort without an increase in side effects, though caution should be taken to avoid dosing errors.
- Antipyretic therapy for adults and adolescents includes acetaminophen 650 to 1000 mg orally (PO) every 6 hours to a maximum of 3 g per day, ibuprofen 200 to 400 mg PO every 6 hours, or aspirin (ASA) 325 to 650 mg every 6 hours as needed (PRN) for fever.
- ASA should not be used in children due to the risk of Reye's syndrome.
- Sponge bathing should be done with tepid water and no alcohol. Recommendation: sponge bathing and other home remedies should not be used as sole treatment.

Fever is one of the most common clinical presentations encountered by primary care physicians and the most common complaint of acute visits for children in the ambulatory or emergency department setting. Fever is a symptom and one of the most reliable signs of illness rather than a disease process itself. Most causes of fever are secondary to acute viral illnesses such as upper respiratory infections (URIs), which account for 50 million visits to primary care providers annually. Less commonly, bacterial infections may cause pharyngitis, otitis, sinusitis, pneumonia, and urinary tract infections (UTIs). A cost-effective, evidence-based approach using clinical protocols, guidelines, and consensus recommendations to the diagnosis and management of febrile illness, including the appropriate use of antibiotic therapy, is the cornerstone of quality medical care for this presentation. Fever produces significant anxiety for patients, parents, and health care providers, which can lead to overtreatment. Typically, fever is transient and only requires treatment to provide patient comfort.

Definitions

The definition of fever is dependent on numerous endogenous and exogenous factors that play a role in determining body temperature, including age, time of day, site, and measuring device, as well as operator variables. Fever is an elevation of body temperature due to the adjustment of the hypothalamic-pituitary set point. This usually occurs in response to a pathologic stimulus. Fever is a beneficial physiologic mechanism that helps to promote an augmented immunologic response.

Despite individual variability, core body temperature is maintained at about 98.6°F (37°C). Diurnal variation results in lower body temperatures in the early morning and a temperature higher in the late afternoon or early evening, which is consistent with what is encountered in clinical practice.

In adults, a morning oral temperature of 98.9°F (37.2°C) or higher, or an evening temperature of 99.9°F (37.7°C) or higher defines a fever. Rectal temperatures are generally considered to be 0.7°F (0.4°C) higher than oral readings.

In infants and young children, rectal temperatures are still considered the standard of care and a rectal temperature greater than 100.4°F (38°C) is considered a fever.

Axillary temperatures of greater than 98.6°F (37°C) are regarded as a fever, though this measurement site is generally considered less accurate. An accurate measurement of body temperature is dependent on site, measuring device, and the clinical skills of the operator. Site selection should be determined by the age of the patient.

Monitoring

Ongoing fatigue can be monitored through a three question assessment:

- Are you experiencing fatigue?
- If so, how severe has it been, on average, during the past week? (0–3 is mild fatigue, 4–6 moderate, and 7–10 severe)
- How does fatigue interfere with your ability to function?

A cost-effective, evidence-based approach using clinical protocols, guidelines, and consensus recommendations to the diagnosis and management of febrile illness, including the appropriate use of antibiotic therapy, is the cornerstone of quality medical care for this presentation. Fever produces significant anxiety for patients, parents, and health care providers, which can lead to overtreatment. Typically, fever is transient and only requires treatment to provide patient comfort.

Definitions

The definition of fever is dependent on numerous endogenous and exogenous factors that play a role in determining body temperature, including age, time of day, site, and measuring device, as well as operator variables. Fever is an elevation of body temperature due to the adjustment of the hypothalamic-pituitary set point. This usually occurs in response to a pathologic stimulus. Fever is a beneficial physiologic mechanism that helps to promote an augmented immunologic response.

Despite individual variability, core body temperature is maintained at about 98.6°F (37°C). Diurnal variation results in lower body temperatures in the early morning and a temperature higher in the late afternoon or early evening, which is consistent with what is encountered in clinical practice.

In adults, a morning oral temperature of 98.9°F (37.2°C) or higher, or an evening temperature of 99.9°F (37.7°C) or higher defines a fever. Rectal temperatures are generally considered to be 0.7°F (0.4°C) higher than oral readings.

In infants and young children, rectal temperatures are still considered the standard of care and a rectal temperature greater than 100.4°F (38°C) is considered a fever.

Axillary temperatures of greater than 98.6°F (37°C) are regarded as a fever, though this measurement site is generally considered less accurate. An accurate measurement of body temperature is dependent on site, measuring device, and the clinical skills of the operator. Site selection should be determined by the age of the patient.

Young infants and older adults often have a diminished febrile response due to physiologic factors, thereby warranting the use of other clinical factors to guide diagnosis.

Recent technologic advances, including electronic devices, tympanic membrane scanning, and temporal artery scanning, have replaced the older mercury-in-glass thermometers. These devices offer faster results and minimal inconvenience to the patient and are becoming increasingly reliable. Chemical content or liquid crystal thermometers applied to the skin are neither accurate nor cost-effective.

Hyperthermia is an uncontrolled elevation of core body temperature that exceeds the body's ability to lose heat. In hyperthermia, the setting of the hypothalamic thermoregulatory center is unchanged, in contrast to fever. Hyperthermia requires urgent medical intervention because it could be rapidly fatal and does not respond to antipyretics. Common etiologies include heat stroke, neuromalignant syndrome, serotonin syndrome, malignant hyperthermia, endocrinopathy, and CNS damage.

Classic *fever of unknown origin* (FUO) is defined as a disorder with temperatures $\geq 100.9^{\circ}\text{F}$ (38.3°C) that have persisted for at least 3 weeks, with no definitive cause elucidated after initial comprehensive inpatient or outpatient workup. The etiologies of FUO generally fall into four diagnostic categories: infectious, autoimmune or inflammatory, neoplastic, and miscellaneous.

Pathophysiology

Fever occurs as part of an inflammatory response to an inciting stimulus. The response includes the production of various cytokines that ultimately increase the production of prostaglandin E_2 (PGE_2), which resets the hypothalamic thermoregulatory set point at a higher level. Important pyrogenic cytokines include interleukin-1 (IL-1), interleukin-6 (IL-6), tumor necrosis factor α ($\text{TNF-}\alpha$), interferon- β ($\text{IFN-}\beta$), and interferon- γ ($\text{IFN-}\gamma$).

Risks and Benefits of Fever

Fever is known to enhance the immunologic response while suppressing the growth and replication of bacterial and viral infections. Though often uncomfortable for patients, caregivers, and health care providers, evidence supports the notion that fever is beneficial and ultimately protects against the development of asthma and other allergic disorders. In most instances, fever is not harmful. It does increase cardiac demand and metabolic needs, resulting in the common associated signs and symptoms of tachycardia, tachypnea, shivering, malaise, and diaphoresis.

The use of antipyretic agents has not been shown to either prolong or shorten the duration of illness. Febrile seizures cause significant anxiety for parents. They occur most commonly in children between the ages of 6 months and 6 years. Most febrile seizures are uncomplicated and have not been shown to be associated with significant bacteremia or to lead to the development of seizure disorder in older children. Antipyretic agents have not been shown to decrease the incidence of febrile seizures.

Diagnostic Evaluation of Fever

In most cases, the etiology of a febrile illness is a self-limiting viral infection. From 5% to 10% of fevers may be associated with a more serious bacterial infection such as pneumonia, UTI, bacteremia, meningitis, or bone and joint infections. At times, these conditions may be challenging to distinguish, and a thoughtful, systematic, evidence-based approach to the diagnostic evaluation will be most cost-effective while avoiding the inappropriate use of antibiotics.

All infants less than 28 days old with a fever should be admitted to the hospital for a full sepsis workup and empiric intravenous antibiotic therapy.

Young infants, 1 to 3 months of age, with a febrile illness can be especially challenging. Numerous studies addressing this challenging population have led to the development of multiple guidelines and clinical protocols that utilize risk stratification criteria. The use of these age-specific stratification criteria, along with clinical treatment guidelines, helps guide the clinician in the evaluation of febrile illness. Clinical judgment remains the cornerstone of good clinical care.

With the widespread use of *Haemophilus influenzae* type B (Hib) and pneumococcal vaccinations, the incidence of bacteremic illness

has decreased significantly. Clinical judgment and a comprehensive assessment are required to guide appropriate diagnostic and therapeutic interventions. The increased use of rapid viral testing in the office and emergency department settings may alleviate the need for more invasive testing and antibiotic use because the risk of concurrent bacterial infection has been reported to be negligible.

In this age group, an initial workup that reveals a white blood cell (WBC) count of less than 5000 or greater than 15,000 indicates an increased likelihood of a significant bacterial illness (SBI). Blood cultures, urinalysis, urine culture, and cerebrospinal fluid (CSF) evaluation should then be obtained and accompanied by intravenous antibiotic therapy. Elevated C-reactive protein (CRP) or procalcitonin levels have also been associated with SBI in children with a febrile illness and have shown increased specificity and sensitivity when compared to the WBC count. Using a combination of these tests has not been proven to be beneficial.

Children age 3 to 36 months, who appear well and do not have any underlying medical history, require only a comprehensive clinical evaluation and do not warrant antibiotic therapy or diagnostic testing in most instances. Septic or ill-appearing children need a more aggressive evaluation, including complete blood count (CBC), inflammatory markers, urinalysis, urine culture, blood cultures, and a chest x-ray. High-risk children in this age group require empiric antibiotic therapy, and clinical judgment should guide the decision to hospitalize.

Classic FUO is defined as a disorder with temperatures greater than 100.9°F (38.3°C) that has persisted for at least 3 weeks with no clear etiology determined after 3 days of hospital evaluation or three outpatient visits. Common etiologic categories include infectious, neoplastic, inflammatory, and miscellaneous causes, of which drug fever has been shown to be the most prevalent.

The initial approach includes a thorough history, physical examination, and appropriate laboratory testing. The initial choice of imaging should be guided by clinical findings and most commonly includes a chest x-ray and a CAT scan of the abdomen and pelvis. If the etiology remains elusive, positron emission tomography (PET) scanning or invasive diagnostic testing should then be considered.

Differential Diagnosis

Hyperthermia is an unregulated, significant elevation of core body temperature above the normal diurnal range due to failure of thermoregulation from a hypothalamic insult, not a pyrogenic source, and is considered a medical emergency. It is not synonymous with fever and often requires immediate intervention to avoid deleterious CNS effects. Since the hypothalamic set point remains unchanged, antipyretics are ineffective in hyperthermia. The most common etiology is the inability to regulate or dissipate excess body heat. Hyperthermia is a medical emergency that requires immediate treatment to prevent excessive morbidity and mortality.

Treatment

Though controversy exists regarding the necessity of lowering fever, antipyretics have been shown to effectively and safely reduce temperature and improve symptoms with minimal side effects. Acetaminophen (Tylenol) is available in many formulations. Dosing should be based on body weight and not age of the patient. The dose is 10 to 15 mg/kg every 4 to 6 hours, not to exceed 3 g daily or 2 g in patients with renal or hepatic impairment. Ibuprofen (Advil, Motrin) is a nonsteroidal antiinflammatory drug (NSAID) that has both antiinflammatory and antipyretic effects. Dosing is 10 mg/kg every 6 to 8 hours in children and 200 to 400 mg every 6 hours in adolescents and adults. Ibuprofen is also available in multiple formulations, including a newer intravenous preparation (ibuprofen [Caldolor]) that may be beneficial in oral-intolerant hospitalized patients. Some studies suggest that ibuprofen may be a more effective antipyretic agent than acetaminophen.

In adults, aspirin (ASA) remains a therapeutic alternative for lowering fever at a dose of 325 to 650 mg every 4 to 6 hours. It should not be used in children with a febrile illness due to the risk of Reye's syndrome.

A combination of acetaminophen and ibuprofen in alternating doses has been shown in some studies to have an added benefit in

both reduction of temperature and comfort without an increase in side effects, though caution should be taken to avoid dosing errors.

Nonpharmacologic therapies such as sponge bathing with tepid water and other environmental measures to control temperature, including adjusting room temperatures and sipping cool fluids to avoid dehydration, are used commonly and do provide symptom relief and comfort. These measures should never be used as the sole therapy for fever reduction.

GASEOUSNESS, INDIGESTION, NAUSEA, AND VOMITING

Method of

Justin Bailey, MD

Nausea is a vague, subjective feeling that vomiting (forceful expulsion of gastric contents) is imminent. Dyspepsia (based on ROME III criteria) can include postprandial fullness, early satiety, epigastric pain, burning, and reflux (return of gastric content to the lower esophagus or mouth, accompanied by a sour taste or “heartburn” sensation). Gaseousness can present with a variety of complaints including belching, bloating, abdominal pain, or flatulence.

Epidemiology

Nausea and vomiting (ICD-9 Code 787.01) is one of the top reasons patients see a primary care provider. Infectious diseases causing nausea and vomiting, gastroenteritis, diarrhea, and dehydration are leading causes of death in developing countries, and of sick days and reduction of employee productivity in the United States. Nausea and vomiting postoperatively and during cancer chemotherapy add significant costs, pain, and discomfort to hospital and ambulatory treatment. Dyspepsia occurs in an estimated 25% of the U.S. population every year, many of whom do not seek care. Gaseousness is ubiquitous in the population and is troubling to a small portion.

Risk Factors

Previous gastrointestinal surgery, certain medications, chemotherapeutic regimens, substance abuse, pregnancy, infectious diseases, medical conditions, and central nervous system disorders increase the risk for nausea and vomiting symptoms. Dyspepsia risk is increased significantly with ingestion of NSAIDs, tobacco use, *H. pylori* infection, obesity, anxiety, somatization, neuroticism, depression, and unemployment. Increased upper gastrointestinal gaseousness can be seen with air swallowing from gum chewing and eating quickly as well as consumption of foods that relax the lower esophageal sphincter (e.g., chocolate, fats, mints). Ingestion of lactose, fructose, sorbitol, undigested starches (e.g., bran) and carbonated beverages can all increase the risk of bloating and flatulence.

Pathophysiology

The pathophysiologic regulation of nausea and vomiting is complex and incompletely understood. Multiple neurotransmitters are involved, including acetylcholine, dopamine, histamine, and

serotonin. The therapeutic action of antiemetics is often based on blocking the action of these neurotransmitters. Neurologic regulation of nausea and vomiting involves the chemoreceptor triggers in the fourth ventricle, the nucleus tractus solitarius in the medulla, motor nuclei that control the vomiting reflex, and vagal afferent nerves from the GI tract. The sympathetic and parasympathetic nervous systems are involved in conjunction with the smooth muscle cells and the enteric brain within the wall of the stomach and intestine.

The pathophysiology of dyspepsia is unclear, but probably has multiple causes. Delayed gastric motility can occur in up to 30% of patients with dyspepsia. Additionally, decreased gastric compliance can be seen in dyspeptic patients.

Sensations of lower tract gaseousness result from one of three different mechanisms: excess gas production, abnormal intestinal transit, and increased visceral sensitivity. Gas production caused by carbohydrate maldigestion, (e.g., lactose intolerance, poorly absorbed starches) results in bloating and a sensation of fullness. High-fiber diets, celiac disease, and small intestine bacterial overgrowth can increase gas production. Dysmotility associated with diabetes mellitus, scleroderma, amyloidosis, and endocrine disease may result in gastroparesis and chronic intestinal pseudo-obstruction. Additionally, previous Nissen fundoplication, fat intolerance, and various familial conditions may cause dysmotility. Increased visceral sensitivity is thought to be a main cause of pain and fullness in patients with functional bowel disorders such as irritable bowel syndrome (IBS) and functional dyspepsia.

Prevention

Once the diagnosis has been established, appropriate treatment of the underlying cause of the symptoms can be instituted. When the cause of nausea and vomiting is related to medication, the dose can be adjusted or the medication changed as appropriate.

Upper GI bloating and fullness is almost exclusively caused by excess air swallow and can be improved with altering behaviors such as gulping food and gum chewing. Lower GI symptoms can be prevented by avoiding problem foods such as milk products in patients with lactose intolerance.

Clinical Manifestations

Nausea and vomiting are extremely common and are associated with many conditions. Associated symptoms are helpful in sorting out causes. Many common historical associations are listed in Table 1.

The diagnosis of dyspepsia is based mainly on clinical symptoms. The Rome III criteria are listed in the opening paragraph. Alarm symptoms that should raise suspicions for gastric cancer include unintended weight loss, persistent vomiting, progressive dysphasia, odynophagia, unexplained anemia, iron deficiency, hematemesis, palpable abdominal mass, lymphadenopathy, family history of gastric cancer, previous gastric surgery, or jaundice.

Gaseousness usually presents with abdominal fullness and bloating. Pain associated with the fullness is often relieved with eructation or flatulence (see Table 1).

Diagnosis

The first step in the assessment of patients with abdominal complaints is complete history of the duration of symptoms, the frequency of episodes, work environment, recent travel, household member illness, association of symptoms with certain foods or beverages (i.e., pain relief or worsening with food), and determination of the success or failure of what the patient has tried to alleviate the symptoms, all of which may offer diagnostic clues. Focused inquiries into surgeries, sexual activity, and other elements of a review of symptoms may be helpful. A complete review of medication usage, with particular attention to GI-irritating medications such as NSAIDs and over-the-counter medications, illicit drugs, and herbal products is important. Physical examination and diagnostic workup can help isolate the cause (Table 2).

In patients with acute (<24 hours) nausea and vomiting, a laboratory workup is often unnecessary. Patients with the most commonly identified acute causes, such as acute gastroenteritis, vestibular neuritis, chemotherapy, medication, and alcohol ingestion, and those who are postoperative, can be started on

both reduction of temperature and comfort without an increase in side effects, though caution should be taken to avoid dosing errors.

Nonpharmacologic therapies such as sponge bathing with tepid water and other environmental measures to control temperature, including adjusting room temperatures and sipping cool fluids to avoid dehydration, are used commonly and do provide symptom relief and comfort. These measures should never be used as the sole therapy for fever reduction.

Patients with the most commonly identified acute causes, such as acute gastroenteritis, vestibular neuritis, chemotherapy, medication, and alcohol ingestion, and those who are postoperative, can be started on

TABLE 1 Key Symptoms and Differential Vomiting, Dyspepsia, and Bloating

SYMPTOMS	DIFFERENTIAL
Abdominal Pain \pm N/V <ul style="list-style-type: none"> • RUQ • Epigastric • RLQ • LLQ • Pelvic 	Organic etiologies <ul style="list-style-type: none"> • Cholelithiasis, cholecystitis • Dyspepsia, pancreatitis, GERD, gastritis, MI • Appendicitis • Diverticulitis • PID, ovarian torsion, ectopic pregnancy
Abdominal pain + distention + N/V	Bowel obstruction
Abdominal distention associated with foods (lactose, wheat-based products, bran, legumes)	Lactose intolerance Celiac disease Carbohydrate malabsorption, Oligosaccharide fermentation (legumes)
Vomiting several hours after eating + succussion splash + N/V	Gastric obstruction Gastroparesis
Heartburn \pm N/V	GERD, dyspepsia
Early morning + N/V	Pregnancy
Feculent vomiting + N/V	Intestinal obstruction Gastrocolic fistula
Vertigo + nystagmus + N/V	Vestibular neuritis
Dental erosions, parotid gland enlargement, lanugo-like hair, callus on dorsal surface of hands	Bulimia
Positional N/V	Neurogenic

Abbreviations: GERD = gastroesophageal reflux disease; LLQ = left lower quadrant; MI = myocardial infarction; N/V = nausea and vomiting; PID = pelvic inflammatory disease; RLQ = right lower quadrant; RUQ = right upper quadrant.

symptomatic therapy. For persistent symptoms of nausea and vomiting, laboratory workup is guided by the history and physical examination and can include a complete blood count and differential, serum chemistries, renal function, liver function tests, serum protein and albumin, thyroid-stimulating hormone, amylase or lipase, drug screen, and a pregnancy test in women of childbearing age. Imaging should not be routine but should be directed by the history and physical findings as well as pertinent laboratory results. Useful studies may include acute abdominal series (chest x-ray, flat and upright views of the abdomen), abdominal computed tomography (CT), and abdominal ultrasound.

Similarly, in patients with dyspeptic symptoms, laboratory tests should be obtained based on the history and physical examination. Many therapies, such as discontinuing offending medications (e.g., NSAIDs) or acid suppression in patients without alarm symptoms, may be started without a laboratory work-up. Blood count chemistries and *H. pylori* testing can be considered if warranted. Alarm symptoms may warrant further imaging or direct visualization with esophagogastroduodenoscopy (EGD).

In gaseousness and bloating, the most sensitive work-up is the history and physical examination. Further work-up should be directed by initial findings. Patients with alarm symptoms such as weight loss, diarrhea, abdominal pain, distention, and anorexia may benefit from a malabsorption work-up including lactose tolerance test, stool fat, ova and parasites, stool culture, *C. difficile*, acute abdominal series, or EGD. A hydrogen breath test may be beneficial in selected patients to assess the relationship between specific foods and symptoms. Other blood work, tests, and imaging, such as CT, magnetic resonance imaging (MRI), and EGD are guided by availability of testing and the history, examination and laboratory findings.

TABLE 2 Physical Examination: Nausea, Vomiting, Dyspepsia, and Gaseousness

FINDINGS	POSSIBLE ETIOLOGY
Fever	Infectious
Tachycardia, hypotension	Dehydration, volume depletion, sepsis (infectious), ectopic pregnancy, myocardial infarction, aortic aneurysm
Exophthalmos	Hyperthyroid
Papilledema	Increased intracranial pressure (tumors, subdural hemorrhage)
Bulging tympanic membrane	Otitis media, effusion
Thyromegaly	Hypothyroid
Lymphadenopathy	Infection, malignancy
Dry mucous membranes	Dehydration, volume depletion
Dental erosions	Bulimia
Abdominal distention	Obstruction, ileus, gastroparesis, irritable bowel, hepatic/splenic flexure syndrome, postoperative gas-bloat syndrome
Absent bowel sounds	Ileus, perforation
Sense of abdominal distention without bloating	Irritable bowel syndrome
Abdominal bloating	Irritable bowel syndrome, obstruction
RUQ abdominal pain/guarding	Cholecystitis, cholelithiasis
RLQ/LLQ abdominal pain/guarding	Appendicitis (RLQ), ovarian torsion, diverticulitis, ectopic pregnancy
Cervical motion tenderness	Pelvic inflammatory disease, endometriosis
Bladder tenderness	Urinary tract infection
Testicular pain	Torsion, epididymitis
Abnormal rectal examination	Fecal impaction, prostatitis, appendicitis, ovarian tumor, ectopic pregnancy, endometriosis
Delayed cap refill, poor skin turgor	Dehydration
Jaundice	Gallbladder disease, biliary obstruction

Abbreviations: LLQ = left lower quadrant; RLQ = right lower quadrant; RUQ = right upper quadrant.

Differential Diagnosis

Tables 3, 4, and 5 summarize the wide differential diagnosis of nausea and vomiting, dyspepsia, and gaseousness.

Treatment

Antiemetics, hydration, and dietary changes are the first-line treatments for acute episodes of nausea and vomiting. Controlling the symptoms is often all that is necessary in acute, self-limited bouts of nausea and vomiting symptoms. If patients are dehydrated, oral rehydration can be accomplished by encouraging the patient to take small amounts (6 ounces or less) of cool water or electrolyte solutions on a frequent basis. If patients are unable to accomplish this, parenteral rehydration and antiemetics may be warranted.

TABLE 3 Differential Diagnosis for Nausea and Vomiting

Central Nervous System Multiple sclerosis, tumor, intracranial bleeding, infarction, abscess, meningitis, trauma, labyrinthitis, Ménière's disease, vestibular neuritis, motion sickness Migraine headaches, seizure disorders	Psychiatric Anorexia, anxiety, bulimia, depression Medication Related Acetaminophen (Tylenol) Acyclovir (Zovirax) Alcohol abuse Antibiotics: azithromycin (Zithromax), sulfasalazine (Azulfidine), erythromycin, metronidazole (Flagyl), sulfonamides (e.g., sulfamethoxazole-trimethoprim [Bactrim]), tetracycline Antidepressants: Selective serotonin reuptake inhibitors (SSRIs) Antihypertensives: β -blockers (atenolol [Tenormin], metoprolol [Lopressor]), calcium channel blockers, diuretics (hydrochlorothiazide) Chemotherapeutic agents: cisplatin (Cisplatin [Platinol]), cyclophosphamide (Cytoxan), nitrogen mustard (Mustargen), dacarbazine (DTIC-Dome), methotrexate (Trexall), vinblastine (Velban) Diabetes treatment: metformin (Glucophage), sulfonylureas (Glixin) Digoxin (Lanoxin) Ergotamines: dihydroergotamine (Migranal), methysergide (Sansert) ² Ferrous gluconate, ferrous sulfate Gout treatment: allopurinol (Zylprim) Hormones: estrogen, progesterone and oral and injected contraceptives Levodopa (L-dopa), carbidopa (Lodosyn) Nicotine (patch, gum, smokeless tobacco, cigarette/pipe/cigar) Nonsteroidal antiinflammatory: aspirin, ibuprofen (Motrin), naproxen (Naprosyn) Opioids: codeine, heroin, hydrocodone, oxycodone, morphine, buprenorphine/naloxone (Suboxone) Prednisone Seizure medications: phenobarbital, phenytoin (Dilantin) Theophylline (Uniphyll)
Gastrointestinal Disorders Appendicitis, gastric bypass, gastroparesis, hepatobiliary disease cholecystitis, hepatitis, neoplasia Ileus Crohn's disease, ulcerative colitis Irritable bowel syndrome Ischemia: mesenteric, small bowel Obstruction: scarring/adhesions from previous surgeries, small bowel obstruction, esophageal spasm Pancreatitis Peptic ulcer disease: esophagitis, gastritis, gastroesophageal reflux Peritonitis	
Endocrine Addison's disease, diabetes (ketoacidosis, gastroparesis), hyperthyroidism, hypothyroidism, hyperparathyroidism, hypoparathyroidism, porphyria	
Genitourinary Nephritis, nephrolithiasis, torsion (ovary, testicle), uremia, kidney stone	
Infectious Etiologies Bacterial: <i>Campylobacter</i> , <i>Salmonella</i> , <i>Shigella</i> , Enterogenic <i>E. coli</i> , Viral: rotavirus, influenza Otitis media: bacterial or viral Sexually transmitted infection: cervicitis, epididymitis, pelvic inflammatory disease, prostatitis, urethritis; multiple organisms including gonorrhea and chlamydia Urinary tract infection: lower (cystitis) or upper (pyelonephritis)	
Pregnancy Morning sickness, hyperemesis gravidarum, intrauterine and ectopic pregnancies	

²Not available in the United States.

Table 6 lists the common antiemetics agents, indications, dosages, side effects, and relative cost of medications.

Location of the cause with directed treatment is most effective for gaseousness. If no cause is found, it can be difficult to treat. Avoiding foods that are contributory, such as those containing lactose, fructose, sorbitol, high fiber, and starches, may be all that is necessary. Symptoms associated with increased sensitivity to normal levels of gas (i.e., IBS) can be difficult to treat. Therapeutic relationships, education, and dietary modification are the mainstays of IBS

TABLE 4 Differential Diagnosis of Dyspepsia

Gastrointestinal Disorders Functional or nonulcer (most common) Peptic ulcer disease Gastroesophageal reflux Gastritis Pancreatitis Gastroparesis Gastric cancer Intestinal ischemia Esophageal rupture	Medications NSAIDs Antibiotics (macrolides and metronidazole) Corticosteroids Digoxin Narcotics Theophylline
Malabsorption Lactase deficiency Celiac	Respiratory Pneumonia Cardiac Myocardial ischemia or pericarditis
Infectious Parasite infection <i>H. pylori</i>	Musculoskeletal Abdominal hernia Psychiatric Physical sexual abuse
Pregnancy	

Abbreviation: NSAIDs = nonsteroidal antiinflammatory drugs.

TABLE 5 Differential Diagnosis of Bloating and Gaseousness

Upper GI Air swallowing	Gas-Producing Foods Beans, peas, lentils, broccoli, Brussels sprouts, cauliflower, cabbage, parsnips, leeks, onions, beer, coffee, pork
Small Bowel <i>Pneumatosis cystoides intestinalis</i>	Infectious Parasites Bacterial overgrowth
Carbohydrate Malabsorption Lactase deficiency Legumes (indigestible oligosaccharides) Fructose malabsorption Undigested starch (bran)	Malabsorption Celiac Crohn's disease
Irritable Bowel Syndrome	

treatment. For moderate to severe symptoms, short-term treatment with antispasmodics, tricyclic antidepressants, and antidiarrheal agents may have some benefit. Medical treatments for bloating are listed in Table 7.

For most patients with dyspepsia, information can be powerful. Validation of symptoms and working toward a goal of management rather than cure are therapeutic. In patients with dyspepsia in which a concern for *H. pylori* exists, a test-and-treatment strategy can be effective. In other patients, proton pump inhibitors, H-2 receptor antagonists, prokinetic agents, and peppermint oil are all effective short-term therapies.

Monitoring

For patients who have complications related to nausea and vomiting, monitoring serum electrolytes, renal function, nutritional status, and other parameters may be necessary until hydration improves, electrolytes are replaced, and laboratory results and clinical status return to normal.

Further testing is needed in patients with dyspepsia and alarm symptoms; however, in patients without alarm symptoms, no further testing is needed.

Complications

The complications of prolonged nausea and vomiting are dehydration, electrolyte disturbances (e.g., hypokalemia, hypophosphatemia and hypomagnesemia), depletion of vitamins and trace elements, metabolic alkalosis, and malnutrition. Usually these can be corrected with oral or intravenous hydration, correction

TABLE 6 Medications for Nausea and Vomiting

DRUG	USE	SIDE EFFECTS	DOSAGE	COST*
Anticholinergics Act as antimuscarinic agents		Sedation, dry mouth, dizziness, hallucinations, confusion, exacerbate narrow angle glaucoma, blurred vision.		
Scopolamine	Nausea associated with motion sickness		1–1.5 mg patch TD q3d	Patches: 4 ct = \$60
Antihistamines		Sedation, dry mouth, confusion, urinary retention, blurred vision		
Diphenhydramine (Benadryl)	Nausea associated with motion sickness		50 mg PO q6h or 10–50 mg IV or IM	25-mg capsules: 50 ct = \$6
Doxylamine (Aldex)	Nausea associated with pregnancy		5–10 mg PO qd	Capsules: 30 ct = \$7
Hydroxyzine (Vistaril)	Nausea associated with motion sickness		25–100 mg q6h	100 mg: 30 ct = \$20
Meclizine (Antivert)	Nausea associated with motion sickness		25–50 mg q6h	25 mg: 30 ct = \$20
Promethazine (Phenergan)	Nausea associated with motion sickness		12.5–25 mg (PO, IM, IV, PR) q4–6h	50 mg: 30 ct = \$22
Benzamides: Prokinetic agents; work on peripheral and central dopamine, weak 5-HT3		Sedation, hypotension, extrapyramidal effects, diarrhea, neuroleptic syndrome, supraventricular tachycardia, CNS depression		
Metoclopramide (Reglan)	2nd-line therapy for chemotherapy-induced nausea		10 mg (PO, IM, IV) q6h	10 mg: 30 ct = \$6
Trimethobenzamide (Tigan)	Chemotherapy-induced nausea		250 mg PO q6h	30 ct = \$65
Butyrophenones: Dopamine antagonists		Sedation, hypotension, extrapyramidal effects, tachycardia, dizziness, QT prolongation and torsades de pointes, neuroleptic malignant syndrome		
Droperidol (Inapsine)			0.625–1.25 mg (IM, IV) q4h	IV and IM only
Haloperidol (Haldol)			0.5–5 mg (PO, IM, IV) q8h	5 mg: 90 ct = \$26
Phenothiazines: Dopamine antagonists		Sedation, hypotension, extrapyramidal effects, neuroleptic malignant syndrome, cholestatic jaundice		
Chlorpromazine (Thorazine)	Generalized nausea		10–25 mg (PO, IM, PR) q6h	10 mg: 30 ct = \$12
Prochlorperazine (Compazine)	Generalized nausea		10 mg (PO, IM, IV) q6h; 25 mg q12h PR	10 mg: 30 ct = \$30
5-Hydroxytryptamine type 3 (5-HT3): Serotonin Antagonists		Fever, constipation, diarrhea, dizziness, sedation, nervousness, altered liver function tests, headache, fatigue		
Dolasetron (Anzemet)	Chemotherapy-induced nausea		100 mg (PO, IV) q24h	100 mg: 5 ct = \$360
Granisetron (Kytril)	Chemotherapy-induced nausea		2 mg (PO, IV) q24h	1 mg: 2 ct = \$130
Ondansetron (Zofran)	Chemotherapy-induced nausea		4–8 mg (PO, IV) q8-12h)	8 mg: 30 ct = \$40
Palonosetron (Aloxi)	Prevention of chemotherapy-induced nausea		0.5 mg PO or 0.25 mg IV ×1	0.25 mg: \$406
Neurokinin Receptor Antagonists		Headache, site reaction		
Aprepitant capsule (Emend)	Prevention of postoperative nausea and vomiting (PO)		40 mg PO × 1 prior to anesthesia	40 mg cap #1: \$40

Continued

TABLE 6 Medications for Nausea and Vomiting—cont'd

DRUG	USE	SIDE EFFECTS	DOSAGE	COST
Fosaprepitant (Emend)	Prevention of chemotherapy-induced nausea		115 mg IV × 1, 125 mg PO × 1	115 mg: \$223
Steroids		GI upset, anxiety, euphoria, flushing, insomnia		
Dexamethasone (Decadron)	Prophylaxis of chemotherapy-related nausea and vomiting		4 mg–10 mg (PO, IM, IV) q6–12h	4 mg: 90 ct = \$20
Methylprednisolone (Medrol)			40–100 mg (PO, IM, IV) q24h	8 mg: 25 ct = \$25
Cannabinoids		Vertigo, xerostomia, hypotension, dysphoria		
Dronabinol (Marinol)	Chronic or chemotherapy-induced nausea and vomiting		5 mg PO q2–4h; 4–6 per day	5 mg: 30 ct = \$1200
Miscellaneous				
Erythromycin SE nausea, abdominal pain	Nausea associated with gastroparesis		250 mg PO q8h × 5–7 d	250 mg: 30 ct = \$70
Ginger	Nausea associated with pregnancy		250 mg PO q6h or 1 g qd	250 mg: 60 ct = \$8
Pyridoxine (vitamin B6)	Nausea associated with pregnancy (traditionally combined with doxylamine)		10 mg q6h	100 mg: 100 ct = \$15

TABLE 7 Medications for Treatment of Gaseousness and Bloating

MEDICATION	INDICATION	DOSE	SIDE EFFECTS/COST
Rifaximin (Xifaxan)	Bloating (flatulence) from suspected bacterial overgrowth	200 mg PO tid × 7 d	Edema, nausea, dizziness, flatulence 200 mg: 30 ct = \$355
Probiotics (multi-component)	Bloating (flatulence)	Varies by preparation	Varies by preparation
Alpha-galactosidase (Bean-o)	Bloating associated with gas-producing foods	300–1200 mg with meals high in fermentable carbs	300 mg: 100 ct = \$10
Simethicone	Bloating (flatulence) (indicated but not found to be effective)	80–120 mg qid prn	80 mg: 100 ct = \$5
Bismuth subsalicylate	Odor from flatus	525 mg PO qid prn	525 mg: 15 ct = \$5
Odor-neutralizing devices (briefs, pillows)	Odor from flatus	prn	Pillows: ~\$25 Briefs: ~\$20

of electrolyte deficiencies, and treatment of the underlying cause. In patients whose nausea and vomiting are accompanied by gastroenteritis, symptoms and clinical status may not return to baseline unless all electrolytes such as potassium, magnesium, phosphorus, and trace elements such as zinc are replaced.

Dyspeptic patients without alarm symptoms rarely have complications. In patients with chronic bloating, complications are uncommon.

HEADACHE

Method of

R. Michael Gallagher, DO

Interest and understanding of the headache problem have increased during recent years, allowing physicians to help more sufferers. This interest was the result of Food and Drug Administration (FDA) approvals of medications for the treatment of headache

and subsequent pharmaceutical company support of medical and community education. Although the more recently approved treatments are for migraines, the overall increase in headache awareness of medical professionals has resulted in help for patients afflicted with all types of headache.

- Headache is a disturbing and sometimes fearsome affliction that has plagued humankind throughout recorded history. It often is debilitating and particularly disturbing to the sufferer because the pain is located in the head, the very center of the body's cognitive and control functions. With its accompanying pain and debilitating symptoms, stress can mount and the headache can become all consuming.
- Headache is experienced by all age groups, from young children to the elderly. It is more common than asthma, diabetes, mental illness, and rheumatoid arthritis. In fact, the World Health Organization identifies severe migraine, along with psychosis and quadriplegia, as "one of the most debilitating chronic conditions."

Although the majority of Americans experience tension-type headaches (TTHAs) at some time in their lives, approximately 30 million experience migraine headache: 13% of women and 6% of men, predominantly in their most productive years between the ages of 13 and 55 years. **One out of every four households are affected by migraine headache.** Prepubescent boys and girls suffer equally; however, boys often outgrow their migraine attacks as they mature, and they are less subjected to hormonal influences. Smaller percentages of people, by comparison, suffer with other chronic headaches, such as cluster headache and chronic daily headache.

- No sure diagnostic tests are available to differentiate headache types. The headache condition can progress or change over time in frequency, severity, and debilitation. Each sufferer can be different and may require a detailed evaluation and individualized treatment plan; more frequent or prolonged attacks often necessitate a more comprehensive treatment plan. Thus, the headache problem can be a challenge for both the sufferer and the clinician.
- During the twentieth century, dramatic advancements were made in medicine. Longevity and quality of life improved for many individuals. Unfortunately, for headache sufferers, most of these advances were for maladies that killed or maimed rather than for non-life-threatening conditions. It was not until the 1960s that even a reasonable preventive medication, propranolol (Inderal), was introduced, and by the 1980s only a handful of medications were available for wide use. Physicians had to improvise with medications and treatments that were originally designated for other medical conditions.

In the late 1980s and 1990s, epidemiologic, psychosocial, and pharmacologic research resulted in an increase in available headache information and treatment possibilities. The development of the triptans, serotonin agonists, brought a new awareness to both physicians and sufferers. Today, seven triptans and two relatively new preventive medications are available. In spite of this, a minority of migraine sufferers use these options, and more than 50% continue to self-treat without benefit of professional care.

In the past, surveys indicated that patients wanted their physician to believe their headache problem was real. They hoped that they would be taken seriously and that the physician would make a sincere attempt to help them. The headache patient has changed. The headache sufferer who seeks treatment today is more knowledgeable and interested in rapid relief and tolerability of medication.

Evaluation and Diagnosis

An accurate diagnosis is essential for effective management of patients with the more commonly encountered headaches. Because no biologic markers or diagnostic tests exist to determine headache type, the history is the single most important element in the evaluation of the headache patient. Various headache types sometimes have similar initial presentations, or patients may suffer with more than one type of headache (e.g., migraine and tension-type

TABLE 1 Current Diagnosis

TYPE	SYMPTOMS	FREQUENCY	DURATION
Tension type	Bilateral variable pain Squeezing or band-like Tightness of neck and shoulders	Variable Recognizable cause	Hours to days
Migraine	Mostly unilateral Throbbing or constant pain Nausea, vomiting Photophobia/ phonophobia Fluid disturbances Mood changes Incapacitating Can be associated with aura	1–4/mo Can be cyclic	Hours to days
Cluster	Unilateral, severe boring or burning pain Ipsilateral lacrimation Scleral injection, eyelid droop Rhinorrhea Restlessness	Multiple daily or near daily	45–90 min Cycles of attacks
Chronic daily	Dull, whole headed Variable	Daily	Months

headache), which can be confusing at first, but the careful history usually differentiates the headache type. In general, little in the way of diagnostic testing is needed unless a physical cause is suspected. Some physicians prefer to perform simple laboratory tests to establish a baseline for medication toleration and monitoring as necessary (Table 1).

- The headache complaint on occasion can be a sign of a more serious medical condition, such as a tumor, infection, or aneurysm. For this reason, the clinician always must be cautious and diligent in establishing an accurate and timely diagnosis. Certain so-called red flags in the history require immediate attention. These include any complex of symptoms or history that does not fit a typical headache type; report of a significant neurologic deficit; significant or prolonged neurologic deficit with aura; late-onset migraine (in a patient older than 30 years); sudden onset of a new head pain without history of similar headaches; changes in headache character; headache associated with elevated temperature; or completely unresponsive attacks in the absence of analgesic or caffeine overuse. When any of these symptoms are present or physical examination reveals significant findings, further diagnostic evaluation with imaging studies and consultation is imperative.

The appropriate headache patient evaluation includes a thorough history; physical examination with special attention to the head and the neurologic, cardiovascular, and musculoskeletal systems; and diagnostic tests when appropriate. The history should include headache onset, location, pain character (e.g., pressure, throbbing), frequency, duration, associated symptoms, aura or prodrome, triggers, previous treatment, and family history. Certain clues in the history may lean toward the diagnosis of migraine, such as motion sickness; absence of headache during pregnancy; and headache relationship to menses, sun glare, oversleep, fatigue, fasting, foods, or alcohol.

Various diagnostic screening questionnaires and tools have been developed over the years to assist busy clinicians in establishing the diagnosis of migraine. Most are long and cumbersome and do not

easily become a part of routine patient evaluation. A simple three-question screener for migraine is helpful for generalist clinicians.

A “yes” answer to all three questions indicates a strong possibility of the migraine diagnosis:

1. Do you experience headaches severe enough to see a physician?
2. Are your headaches accompanied by other symptoms?
3. Are your headaches intermittent (i.e., nondaily)?

Note: This screener should not be substituted for a complete history; it should be used only for screening purposes.

Tension-Type Headache

Tension-type headache (TTHA) is the most common of headaches and first was believed to be caused by sustained muscle contraction of the neck, jaw, scalp, or facial muscles. However, consideration is being given to the possibility that sustained muscle contraction can, in fact, be an epiphenomenon to possible central disturbances rather than a primary process. Evidence suggests that altered levels of serotonin, substance P, and neuropeptide Y in the serum or platelets of patients with TTHA are responsible.

- TTHA is characterized by intermittent or persisting bilateral pain, usually described as a squeezing pressure or a band-like sensation around the head. Most patients experience their symptoms in the frontal, temporal, or occipital areas of the head. Location frequently varies with the attack, and tightness of the neck and shoulders is common. Intensity varies greatly. The attacks can last from hours to days, and in some extreme cases they may last for months. Aura, nausea, photophobia and phonophobia, and incapacitation are not typically associated with TTHA.

Many TTHA sufferers easily recognize the origin of their attacks. TTHA typically results from emotional upset, periods of stress, and major life changes. Anxiousness, poor adaptation skills, and anxiety and depression often are present. Physical causes, such as degenerative joint disease, trauma to the head or neck, awkward neck position, poor posture, temporomandibular joint dysfunction, bruxism, or heavy chewing also can precipitate attacks. Persons older than 50 years are prone to excessive muscle contraction because of arthritis of the neck and jaw, poor posture, or stress. TTHA that is consistently precipitated by tension or pathology of the neck frequently is referred to as a cervicogenic headache. In contrast to migraine headache, TTHA is more likely to begin in later life.

Migraine Headache

Migraine headache is a familial disease characterized by unilateral or bilateral paroxysmal headache lasting hours to days. Adult women experience attacks more than men by a ratio of 3:1. Children and the elderly experience migraine equally. Attacks occur from as infrequently as one or two per year to several times weekly. Associated symptoms usually occur and frequently include throbbing, nausea, vomiting, photophobia, phonophobia, fluid retention, and mood changes.

The two basic types of migraine headache are migraine with aura (previously called classic migraine) and migraine without aura (previously called common migraine). Migraine with aura is preceded by an aura, a transient neurologic symptom that usually is visual, such as scotoma, teichopsia, tunnel vision, or visual field deficit, lasting 5 to 30 minutes. However, aura can manifest as any neurologic deficit. Migraine without aura is more commonly experienced and comes on gradually or is present on awakening from sleep. In some patients, these headaches are associated with a nonspecific prolonged prodrome, such as mood changes, food cravings, or fluid retention hours before the pain.

The underlying cause of migraine headache is not clearly established, and various theories are proposed. Migraine appears to be of genetic origin and to be an inflammatory disease that causes disturbances in serotonin use and activity. Strong evidence indicates that the migrainous attack originates in the central nervous system by stimulation of the locus ceruleus and dorsal raphe nuclei. Resultant changes alter cerebral and extracranial blood flow; activate the trigeminovascular system; and cause vascular dilation, neurogenic

BOX 1 Common Migraine Dietary Triggers

- Dairy: ripened cheese (cheddar, brie, camembert), sour cream >½ cup
- Meats: processed lunch meats, hot dogs, sausage, bologna, salami, chicken liver
- Fish: pickled or dried herring
- Grains: sourdough bread
- Fruits: bananas, raisins, figs, avocado, citrus >½ cup
- Vegetables: broad and fava beans, onions, snow peas, garlic
- Other: chocolate, nuts, peanut butter, pickled foods, most Chinese food
- Beverages: most wines and alcohol, caffeine > 200 mg
- Additives: MSG, soy sauce, meat tenderizers, aspartame, sulfites

BOX 2 Migraine Triggers

- Altitude
- Alcohol
- Caffeine withdrawal
- Fatigue
- Fluorescent or flickering lights
- Sun glare
- Weather changes
- Stress, stress letdown
- Foods
- Skipping meals
- Smoky environment
- Noisy environment
- Strong odors

inflammation, and pain. Various precipitants are known, and many sufferers report that migraine attacks frequently are associated with menstruation or are triggered by foods containing vasoactive amines, strong odors, too much or too little sleep, sun glare, stress, altitude, weather changes, exertion, or fasting (Boxes 1 and 2).

Some physicians classify migraine according to its precipitant or description (e.g., menstrual migraine, exertional migraine, coital migraine, cervicogenic migraine, cyclic migraine, “painless” or acephalic migraine). When a sufferer experiences headache for 50% of the month, it is referred to as chronic migraine. Regardless, the fundamentals of evaluation and treatment are similar.

Cluster Headache

The cause of cluster headache is unknown, and little credible research is available. Various possibilities or theories are suggested and include, but are not limited to, disturbances in histamine production or use; hypothalamic biorhythm dysfunction; or serotonin and neurotransmitter mechanisms similar to those of migraine. Some authorities consider cluster headache one of the most severe pain conditions known to humankind.

- Cluster headache predominantly affects men, with a male-to-female ratio of 6:1. It occurs in well under 0.5% of the population. Onset later in life (after age 30 years) is common, and patients sometimes report head injury or a traumatic event occurring months before onset. Attacks occur on a daily or near-daily basis for weeks or months at a time and mysteriously disappear for months to years regardless of treatment, only to recur and cycle again. Although nonspecialist physicians only occasionally encounter the patient with cluster headaches, it is important to consider cluster headaches in the differential diagnosis.

The typical patient with a cluster headache experiences relatively brief attacks (45–90 minutes) of horrible unilateral head pain associated with ipsilateral lacrimation, scleral injection, rhinorrhea, or

eyelid droop. The hallmark of the syndrome is its associated symptoms and its severe and intense pain. During attacks, most cluster patients move about, trying unsuccessfully to get more comfortable, similar to renal colic; this is in contrast to migraine sufferers, who prefer to lie quietly in a dark quiet room. Few triggers are identified, and alcohol almost always precipitates an attack during a cluster “on” cycle. A rare form of cluster headache, chronic cluster, does not cycle and continues on a daily or *near-daily* basis without cessation.

Chronic Daily Headache

A small percentage of headache sufferers present with chronic daily headache. The majority of these daily headaches are of the tension or migraine type. However, patients may present with daily nonincapacitating generalized headache. These headaches frequently are associated with major life changes (negative or positive), financial or relationship difficulties, and depression or emotional problems.

The assessment of the chronic daily headache patient is similar to other headache syndromes, but may require particular attention to mental health and medication rebounding issues.

Posttraumatic Headache

Posttraumatic headaches are headaches resulting from physical injury to the head. The trauma can be direct or the result of a contra-coups type injury encountered with whiplash or forced movement of the head or neck. The degree of injury and headache is not necessarily related to the degree of trauma. Seemingly minor injuries sometimes can result in significant and prolonged headache, while apparent severe blows to the head sometimes do not result in significant headache.

Complicating the posttraumatic headache can be an associated spasm of shoulder, neck, and scalp muscles or reactive anxiety and depression. Patients with preexisting headaches may experience an increase in severity or frequency of headaches. It is not unusual for there to be a delay in the onset of headache.

It is imperative that the detailed evaluation of the posttraumatic headache patient include psychological and cognitive examination while keeping in mind that presumed trivial injuries can have significant sequelae. The more frequent type of headache encountered is of the tension or chronic daily type. Migraine and cluster are reported.

Treatment

The doctor–patient relationship frequently is the key to successful treatment in the headache patient. Although to some this statement seems an obvious truism, its importance cannot be overemphasized.

Patients who experience frequent, near-daily or daily headaches invariably require a comprehensive treatment program that necessitates good communication. Anxious patients sometimes do not comprehend medical explanations or instructions; busy doctors sometimes do not have or take the time to ensure that the patient understands.

The two elements of headache treatment are abortive treatment, directed at attacks once they have begun, and prophylactic treatment, directed at preventing or reducing the frequency or necessarily related to *the frequency or* the degree of attacks. In general, the abortive approach is used for patients who suffer infrequent attacks and for those who experience breakthrough attacks while undergoing prophylactic therapy.

Prophylactic therapy should be instituted when headaches are frequent, when headaches are unresponsive to abortive medication, or when there are contraindications to abortive medications.

- Headache treatment can include nonpharmacologic measures, such as physical exercise, stretching, stress avoidance, relaxation exercises, biofeedback, manipulation, massage, cold/warm packs or neuromodulation devices. Pharmacologic therapies can include a vast array of medicaments from over-the-counter (OTC) drugs to prescription drugs such as triptans, other vasoconstrictors, β -blockers, calcium channel blockers, antiepileptic

agents, antidepressants, nonsteroidal antiinflammatory drugs (NSAIDs), analgesics, muscle relaxants, anxiolytics, and others.

Treatment, whether prophylactic or abortive, should follow a definite plan incorporating the clinician and the patient into a team focused on reducing the headache frequency, severity, and disability.

As mentioned earlier, impressions and physical findings should be explained to the patient in as much detail as necessary to ensure the patient's complete understanding. The complexity of the headache condition needs to be explained, emphasizing its chronicity, rather than its curability, and that the goal of treatment is disease control.

- The comprehensiveness of the treatment plan depends on the frequency of the patient's attacks. The more frequent and severe the attacks, the more detailed plan may be necessary. Patients experiencing infrequent attacks (e.g., once or twice monthly) may require only an abortive medication and little else. Patients with more frequent attacks may benefit from dietary restrictions, psychosocial intervention, biofeedback relaxation training, manipulation, and physical modality intervention, in addition to medication (Table 2).

TTHA Treatment

TTHA is often associated with emotional stress and muscle strain or tension of the shoulders and neck. Simple self-administered measures, such as stress avoidance, stretching, warm packs, or relaxation techniques, can be helpful in reducing or relieving attacks. More comprehensive professional intervention, such as manual manipulation, physical therapy, local injections, or biofeedback training, is a consideration for more frequent or severe cases. The ultimate goal is to restore normal function of involved muscles.

- Prophylactically, the use of OTC or prescription medications can be considered in addition to nonmedicinal measures for reducing the frequency and duration of attacks. NSAIDs, muscle relaxants, tricyclic antidepressants (TCA), selective serotonin reuptake inhibitors (SSRI), or serotonin-norepinephrine reuptake inhibitors (SNRI), at the lowest effective doses, are more commonly used. Other categories of antidepressants are reported to be effective in some sufferers.

TABLE 2 Current Therapy

HEADACHE TYPE	PRN	PROPHYLAXIS

*FDA indication.

Abbreviations: NSAID = nonsteroidal anti-inflammatory drug; OTC = over-the-counter drug; TCA = tricyclic antidepressant.

- Daily use of the longer-acting NSAIDs, such as naproxen¹ (Naprosyn) or celecoxib¹ (Celebrex), in the appropriately screened patient over a 2- to 3-week period, can be an effective preventative.

TCAs, such as nortriptyline¹ (Pamelor) or amitriptyline¹ (Elavil), in low doses at night over 1 to 3 months, are frequently effective, especially in patients with anxiety or mild depression. The SSRI drugs, such as fluoxetine¹ (Prozac) or sertraline¹ (Zoloft), or the SNRI drugs such as duloxetine¹ (Cymbalta) or venlafaxine¹ (Effexor), similarly can be useful.

The muscle relaxant cyclobenzaprine¹ (Flexeril), at low doses, with a similar mechanism to the TCAs, can be administered at night for limited periods. Other muscle relaxants occasionally can be helpful. Potential side effects can limit the use of NSAIDs (gastrointestinal irritation) and the TCAs (fatigue and weight gain).

OnabotulinumtoxinA (Botox)¹ reportedly is helpful in the treatment of the tension-type headache, but controlled studies are limited. In this treatment, a diluted solution of botulinum toxin is injected into various muscles of the face, scalp, neck, or shoulders. It is imperative that these injections be administered by physicians skilled in the procedure to avoid complication and adverse events.

- Abortive or symptomatic treatment of TTHA can include simple OTC medications (e.g., aspirin or acetaminophen), NSAIDs (short acting), muscle relaxants, combination analgesics, and, in rare cases, opioid or opioid-like drugs. Limited studies have shown analgesic qualities of riboflavin (vitamin B₂)⁷ 200 mg is recommended for patients who cannot tolerate NSAID type medications. Caution should be exercised in prescribing potentially habituating drugs. Daily or near-daily use of analgesics, and especially those containing caffeine, can lead to analgesic rebound headache or medication overuse headache, which can compound the patient's headache problem.

Migraine Treatment

Migraineurs are unique individuals, and the effectiveness and tolerance of medications can vary from patient to patient. Medication changes, combinations of medications, and trial and error may be necessary in the early stages of treatment.

- Nonmedicinal measures for migraine sufferers include biofeedback, stress reduction, neuromodulation devices, caffeine and dietary restrictions, regimentation of meals and sleep, rest, exercise, stretching, and avoidance of work or activity overload. Strict limitation of caffeine to less than 200 mg/day is important to prevent caffeine headache (rebound headache) in most patients. Elimination of vasoactive foods, such as chocolate, aged cheese, and processed meats, and avoidance of fasting for more than 4 hours can be helpful for patients with more frequent attacks (see Box 1). Regular exercise and stretching, planned relaxation, regular sleep schedules, and following a healthy lifestyle are frequently included in a comprehensive treatment regimen. In some patients, especially children and adolescents, biofeedback stress reduction or psychotherapeutic intervention may be necessary.
- The more commonly used medications for prophylaxis are β -blockers, calcium channel blockers, antiepileptics (neurostabilizers), and the antidepressants. Treatment should be continued for a 6- to 8-week trial before discontinuation for ineffectiveness. The determination of which medication to use depends on comorbidities, interactions with concomitant medications, and tolerability.

β -Blockers such as propranolol and timolol (Blocadren) are non-selective and are approved by the FDA for migraine prevention. Other β -blockers, such as nadolol (Corgard)¹, metoprolol (Lopresor)¹, and atenolol (Tenormin)¹, also can be effective. The mechanism of action in migraine is not wholly understood, but it is thought to involve anxiolytic effects and vascular changes and stabilization. The usual dosage is recommended (e.g., timolol

10–30 mg/day, propranolol 120–160 mg/day), and many consider the nighttime dose the more significant.

Calcium channel antagonists are well tolerated in general and can be effective in many patients. They are believed to alter serotonin release and inhibit platelet serotonin uptake and release within the brain. Verapamil (Calan)¹ is considered the more effective and is commonly recommended to patients. Dosage can vary from 120 to 480 mg/day. Nimodipine (Nimotop)¹ is equally effective but has been rarely used in the United States because of its high cost.

- Antiepileptic medications such as phenytoin (Dilantin)¹ and carbamazepine (Tegretol)¹ have been prescribed for migraine prevention over the years, with mixed results. Their use is now limited with the advent of newer, more easily tolerated agents, such as divalproex sodium (Depakote ER) and topiramate (Topamax, Trokendi XR).
- Divalproex sodium is effective in reducing migraine attacks and is particularly useful in patients with coexisting head injury, seizure disorders, and bipolar disorders. It is thought to improve inhibitory and excitatory amino acid imbalance in the brain. It is best to start with a lower dose and to gradually increase as needed and tolerated. The dosage of 500 to 1000 mg/day is more frequently prescribed. A commonly experienced side effect is sedation, which can sometimes be used to the patient's advantage when anxiolytic effects are needed.
- Topiramate is a preventive medication approved by the FDA for migraine prophylaxis. It has multiple mechanisms of action, but its exact mechanism in migraine headache is unknown.

Its effectiveness is believed to involve sodium ion channel stabilization, calcium ion channels, GABA (γ -aminobutyric acid) receptors, and neuronal membrane stabilization. The average daily dose is variable and ranges from 30 to 100 mg/day. A most unusual side effect of weight loss or appetite suppression can be used to the patient's advantage in preventing weight gain, which frequently accompanies migraine prophylactic medications.

The TCAs can be useful for patients who experience frequent attacks and for those who experience anxiety and depression. The TCAs inhibit synaptic reuptake of serotonin, thereby reducing neuron firing and release of neurotransmitters. Starting with a low dose in the evening and titrating up to efficacy and tolerability is recommended. Significant anticholinergic and sedation effects sometimes limit their use. The SSRIs are reported helpful in some patients, but their use in migraine prevention is limited.

Other medications have been utilized in migraine prophylaxis with varying success. These include NSAIDs, cyproheptadine (Periactin)¹, clonidine (Catapres)¹, phenothiazines, anxiolytics, ergotamine (Ergomar), magnesium¹, feverfew⁷, and others.

- In general, prophylactic medications should be taken for 6 to 8 weeks to determine efficacy. If effective, a course of 4 to 6 months is recommended before an attempt is made to discontinue medication.
- OnabotulinumtoxinA (Botox) has been approved by the FDA for the treatment of chronic migraine. Multiple injections to the head and neck can be helpful for patients who experience symptoms for more than 14 days per month and it can be repeated after 3 months. Because this treatment is administered by physicians in headache specialty and pain practices, simultaneous comprehensive treatment measures and medication can contribute to positive patient results. Side effects are relatively low when injected by experienced physicians; alteration of facial expressions is the most common. Proper administration of the toxin is imperative.

A large meta-analysis of 27 controlled clinical trials concluded that onabotulinumtoxinA injections showed a small to moderate benefit over placebo in patients experiencing chronic migraine and chronic daily headache. Patients with chronic tension type or episodic migraine showed no benefit.

TABLE 3 Triptans

MEDICATION	BRAND NAME	HALF-LIFE (h)	FORM/STRENGTH
Sumatriptan	Imitrex	1.5	Oral: 25, 50, 100 mg NS: 5, 20 mg Injection: 4, 6 mg
	Treximet		Oral: Sumatriptan 85 mg + naproxen sodium 500 mg
	Zembrace Onzetra Xsail		Injection: 3 mg NS 22 mg
Naratriptan	Amerge	6	Oral: 1, 2.5 mg
Zolmitriptan	Zomig	3	Oral: 2.5, 5 mg MLT: 2.5, 5 mg NS: 2.5, 5 mg
Rizatriptan	Maxalt	2–3	Oral: 5, 10 mg MLT: 5, 10 mg
Almotriptan	Axert	3–4	Oral: 6.25, 12.5 mg
Frovatriptan	Frova	25	Oral: 5 mg
Eletriptan	Relpax	4	Oral: 20, 40 mg

Abbreviations: MLT = oral disintegrating; NS = nasal spray; TD = transdermal.

- A trigeminal nerve stimulator, Cefaly device, was approved by the FDA in 2014. The Cefaly head-band apparatus can be self-administered 20 minutes daily to reduce migraine frequency. Experience with this TENS device is limited.
- A variety of abortive treatment options are available for migraine sufferers. Although the triptans (Table 3) have generated much interest and are frequently prescribed, other medications continue to be used, including ergotamine and its derivatives, isometheptene, and NSAIDs. Many of the abortive medications carry significant prescribing limitations that must be taken into consideration. Vasoconstrictor medications are contraindicated in patients with cardiovascular or peripheral vascular disease. NSAIDs should not be used in those with gastrointestinal or bleeding disorders. As with all medications, the clinician must consider appropriate prescribing, contraindications, and side-effect information.
- The vasoconstrictor ergotamine is available in oral, rectal (with caffeine [Cafergot]), and sublingual forms (Ergomar). Ergotamine has a relatively long half-life and duration of action (up to 3 days) and should be used no more frequently than every 4 to 5 days to avoid ergotamine rebound headache. The ergot derivative dihydroergotamine (DHE, Migranal NS) is available for intramuscular, subcutaneous (SC), and intranasal use. Intravenous DHE sometimes is used for intractable migraine (status migrainosus) in emergency departments and inpatient settings. The intranasal form (Migranal) is an effective treatment when administered correctly by the patient. Unfortunately, DHE is not absorbed by the gastrointestinal tract, and unlike other abortive nasal sprays, any swallowed medication will be wasted. DHE has a low headache recurrence rate of approximately 12%. All forms of ergotamine and DHE are more effective when taken early in attacks.

Isometheptene is used in combination with dichloralphenazone and acetaminophen (Midrin). It is slow acting and more effective when taken early in attacks and when used for attacks preceded or accompanied by stress and muscle tension of the neck. Although isometheptene is considered less potent than ergotamine and triptans, it is preferred by many patients whose headaches have features of both migraine and tension type.

At the present time, seven serotonin agonists (triptans) are approved for abortive migraine treatment in the United States (see Table 3). As a category, the triptans are approximately 65% to 70% effective in published clinical trials. Their similarities are greater than their differences, but each triptan is not necessarily

effective for all patients, and familiarity with their differences can be helpful to the treating physician. Half-life, onset and duration of action, adverse events, tolerability, recurrence of headache, and routes of administration may vary and allow the physician to match the medication to the individual patient. For example, a slower onset of action and longer-lasting triptan may be appropriate for slow-onset, longer-lasting migraine attacks.

- As with other headache treatments, oral triptan tablets are more effective in the early phases of migraines. It is thought that peripheral sensitization—allodynia—is a sign of later-phase migraine, and treating the attack before this phenomenon occurs is important. When treatment is delayed or the patient awakens with severe migraine, the injection, nasal spray, or rapidly acting triptans may be more beneficial. Although triptans as a group are very effective, recurrence of headache, after initial relief, requiring retreatment is common and can be as high as 40%. The recurrence rate tends to be less with triptans having a longer half-life.

The ergotamines and triptans are contraindicated in patients with ischemic heart disease, uncontrolled hypertension, and cerebrovascular disease. Physicians initially were extremely cautious about recommending triptans to their patients when they were first introduced in the United States. However, significant human exposure to the triptans has shown that myocardial infarction or serious ischemia is rare. Chest pain following triptan use affects a small percentage of patients, and because its significance continues to be unclear, it is recommended that triptan use be held pending cardiac evaluation.

- Sumatriptan (Imitrex, Zembrace, Onzetra), the first triptan approved in the United States, is available in nasal spray (5, 20, 22 mg), SC (3, 4, 6 mg), and oral formulations (25, 50, 100 mg). Its half-life is approximately 1.5 hours, and its duration of action is less than 4 hours. The injectable form produces rapid relief in 70% to 80% of patients, and it appears to be the most effective of all the available triptan forms. Conversely, it appears to cause the most side effects, and for this reason it should be used only for the more severe attacks. The oral forms are more favorable with regard to adverse effects, and their effectiveness is similar to that of other triptans (approximately 65%). Because of sumatriptan's short half-life and duration of action, recurrence of headache is common, necessitating repeat dosing.
- Naratriptan (Amerge) was the first to be approved of the gradual onset, longer-acting triptans. It is available as oral 1 and 2.5 mg tablets and has a half-life of 6 hours. Naratriptan is well tolerated by patients and often is used by patients with slow-onset migraine. Some specialists prescribe daily naratriptan¹ for limited periods for treatment of menstrual or intractable migraine attacks.
- Zolmitriptan (Zomig) is available in 2.5 and 5 mg oral and oral disintegrating tablets (ZMT) and as 2.5 and 5 mg nasal sprays. The efficacy of oral zolmitriptan is approximately 65% and that of the nasal form is 70%. The half-life of oral zolmitriptan is 3 hours, and its duration of action is longer than the nasal form, which improves on the need to remedicate. The nasal spray has a biphasic absorption curve, which accounts for its favorable adverse effect profile over the 5 mg oral tablet.
- Rizatriptan (Maxalt) is available as oral 5 and 10 mg tablets and as an oral disintegrating form (MLT). Its half-life is 2 to 3 hours and it has a favorable one-dose 2-hour response rate. Patients who are undergoing concomitant treatment with propranolol should take the lesser 5 mg rizatriptan dose because of higher resultant rizatriptan plasma levels.
- Almotriptan (Axert) is available in 6.25 and 12.5 mg tablets. It has a half-life of 3.5 hours and, because of a broad T_{max} (time of maximal concentration) range of 1.4 to 3.8 hours, a relatively rapid onset of action. Almotriptan has favorable adverse effect and headache recurrence profile. Chest pain symptoms after almotriptan use were similar to placebo in clinical trials.

¹Not FDA approved for this indication.

- Frovatriptan (Frova) is a long-acting triptan available in 2.5 mg oral tablets. It has the longest half-life of 25 hours and a favorable recurrence rate. Frovatriptan is frequently used for treatment of menstrual migraine and for attacks of longer duration. Some specialists prescribe daily frovatriptan for a limited period for menstrual and prolonged migraine attacks.¹
- Eletriptan (Relpax) was the last triptan to be approved. It is available in 20 and 40 mg oral tablets and has a half-life of nearly 5 hours. Eletriptan has a relatively rapid onset but a longer duration of action and a favorable recurrence rate. In studies, some patients who were unresponsive to other triptans responded to eletriptan.

Various attempts have been made to compare triptans. Head-to-head trials mostly have compared one triptan to sumatriptan. A meta-analysis of 53 clinical trials published in 2001 compared the efficacy, recurrence, duration of action, and tolerability of all available triptans. Almotriptan and eletriptan were rated favorably across the major parameters of onset of action, efficacy, adverse events, and recurrence. In spite of efforts to adjust for variations in protocols and placebo response, specialists reached no clear consensus as to the validity or value of the meta-analysis or the preferability of one triptan over another.

- NSAIDs frequently are recommended for treatment of acute migraine and can be effective when taken early. Their effects on the physiology of pain, inflammation, and platelets are thought to be the mechanisms responsible. Some physicians recommend taking a NSAID with the first dose of a triptan for added efficacy. Various agents are used, but none of the rapid-acting NSAIDs appears to have significant efficacy superiority. Naproxen sodium 500 mg in combination with sumatriptan 85 mg (Treximet), OTC ibuprofen (Motrin, Advil), and aspirin combination with caffeine and acetaminophen (Excedrin Migraine) are approved by the FDA for treatment of acute migraine.
- Symptomatic treatment of pain may be necessary in patients who do not respond to recommended abortive treatment. Any effective analgesic can be appropriate, provided it is used infrequently and not on a daily or near-daily basis. In general, the more effective analgesics have antiinflammatory and sedative properties.
- Three neuromodulation devices are FDA approved for the treatment of migraine headache. "The Cefaly Unit", a trigeminal nerve stimulator, can be self-administered to the forehead for 20 minutes as needed for acute migraine pain. The "Cerenia", a self-administered transcranial magnetic stimulator delivers two consecutive impulses at regular intervals to the occipital area as needed for pain of migraine with aura. A vagus nerve stimulator, "gammaCore", can be self-administered to the neck for pain of migraine. Mild electrical charges are released to stimulate the vagus nerve, which has been shown to be involved in migraine and cluster headache symptoms.
- Newly developed anti-CGRP (calcitonin gene related peptide) humanized monoclonal antibody drugs have demonstrated efficacy in reducing the frequency of migraine attacks in phase III clinical trials. These medications are administered once monthly and are well tolerated. Erenumab (Aimovig) has been approved by the FDA for use. FDA approvals are anticipated for galcanezumab⁵ and fremanezumab⁵. Eptinezumab⁵ is undergoing clinical trials.

Cluster Headache Treatment

Cluster headache is one of the more unusual pain conditions occasionally encountered by physicians. Pain onset is rapid, and the duration of the attack is brief. For this reason, prophylactic treatment usually is the most practical. Abortive prescriptions frequently are given, but, for the most part, the cluster attack is resolving by the time medication is absorbed.

- Nonmedicinal prophylactic measures are extremely limited. The reduction of cigarette smoking and the addressing of individual

stress and hostility during cluster periods should be part of any treatment program. There are no FDA-approved medications for the prophylactic treatment of cluster headache. Numerous medications can be helpful and include the calcium channel blockers verapamil (Calan, Isoptin, Verelan, Covera, Verap)¹ and nimodipine (Nimotop)¹, the neurostabilizers valproate (Depakote)¹ and topiramate (Topamax, Trokendi XR)¹, various NSAIDs, ergotamine¹, lithium (Eskalith)¹, cyproheptadine¹, combination H₁ and H₂ histamine antagonists, and, in extreme cases, short intervals of steroids. The addition of magnesium⁷ 500 to 750 mg can be helpful in some sufferers. These medications are used in average therapeutic doses, and combinations of medications are commonly needed. The preventatives should be used during the cluster cycle and discontinued during off-cycle periods.

- Abortive treatment is less preferred for cluster headache, as noted previously. However, inhalation oxygen via facial mask at 6 L/min terminates cluster attacks in 75% to 80% of sufferers within 12 minutes. The vagus nerve stimulator, "gammaCore" mentioned above, can be self-administered to the neck for pain reduction. Other possibilities include sumatriptan¹ SC or nasal spray, zolmitriptan¹ nasal spray, ergotamine¹ sublingual, or DHE-45 injection¹ or nasal spray (Migranal)¹. The occasional patient reports relief with the oral triptans or potent analgesics. When triptans, ergotamine, or analgesics are used, appropriate prescribing and frequency guidelines should be followed. In general, with the exception of oxygen, daily as-needed medications should be avoided.

Chronic Daily and Posttraumatic Headache Treatment

The care of patients with chronic daily and posttraumatic headaches is determined by the type or types of headache being experienced. Treatment of each type follows what has been described above. In the patient experiencing posttraumatic headache, frequent follow-up visit monitoring is most appropriate. Extra care should be taken when prescribing medications, especially those that could affect cognitive function and recovery. Often, posttraumatic headache patients benefit with concomitant psychological and cognitive professional support.

Conclusion

Headache continues to present a challenging problem for clinicians as well as for suffering patients. In spite of recent treatment advances and more public awareness, millions continue to needlessly endure pain and debilitation. Desperate sufferers in a quest for relief sometimes resort to unorthodox therapies or anxiolytics, habituating analgesics, or excessive caffeine that ultimately worsen their headache problems.

At first glance, the headache problem appears complex and difficult when, in actuality, most sufferers experience straightforward, easily diagnosed headaches. The interested generalist or specialist who takes the time to elicit a careful history can establish the headache diagnosis and direct a simple treatment plan that can make a tremendous difference in the headache sufferer's life.

HEMATURIA

Method of

Moben Mirza, MD; and J. Brantley Thrasher, MD

CURRENT DIAGNOSIS

- Hematuria is defined as the presence of red blood cells in the urine. Hematuria can be gross (readily visible) or microscopic (detected by dipstick or microscopy). In the adult population, any unexplained hematuria should be presumed to be of malignant origin until proven otherwise. Urologic evaluation of the upper and lower urinary tract is compulsory for patients with gross hematuria. Patients with asymptomatic microscopic hematuria (>3 rbc/hpf) should undergo urologic evaluation once benign causes have been ruled out. The urologic evaluation includes urine analysis, serum creatinine, cystoscopy, and multiphasic computed tomography. Concurrent nephrologic evaluation should occur in select cases.

Epidemiology

Hematuria is a common clinical finding in adults. The prevalence of hematuria ranges from 0.2% to 16%. Prevalence varies based on age, gender, frequency of testing, threshold used to define hematuria, and study group characteristics (Davis et al., 2012). Transient microscopic hematuria may occur in up to 40% of patients; however, persistent microscopic hematuria in greater than three evaluated urine samples is limited to 2% of the population (Masahito, 2010). A wide range of causes can result in hematuria. Transient hematuria may be caused by vigorous exercise, sexual intercourse, mild trauma, menstrual contamination, and instrumentation. Patients with underlying urinary tract disease can have transient or persistent hematuria. The difference between gross and microscopic hematuria is that the chances of finding significant pathology are higher in patients with gross hematuria. For example, approximately 5% of patient with microscopic hematuria in contrast to 40% of patient with gross hematuria are found to have urologic malignancy on evaluation (Khadra et al., 2000). The most common cause of gross hematuria in adults older than age 50 is bladder cancer (Gerber and Brendler, 2011).

Risk Factors

Given the wide range of etiologies for hematuria, the risk factors are dependent on the etiology itself. The most concerning etiology of hematuria is urothelial malignancy. Smoking is the best-established and the most significant risk factor for the development of urothelial malignancies of the kidney, ureter, and bladder.

Pathophysiology

The presence of blood in the urine can be separated into glomerular and nonglomerular origin. Normal urine contains less than three red blood cells per high power field. The kidney does not excrete red blood cells under physiologic conditions. Therefore, presence of blood in the urine is due to pathology at the glomerulus (glomerular hematuria), allowing excretion of red blood cells into the urine or pathology in the urinary tract distal to the glomerulus

(nonglomerular hematuria), which results in blood mixing into the already excreted urine. Nonglomerular hematuria can be further divided into medical and surgical disorders. Except for renal tumors, nonglomerular hematuria of medical/renal origin is due to tubulointerstitial, renovascular, or systemic disorders. Surgical nonglomerular hematuria or essential hematuria includes urologic tumors, stones, and urinary tract infections (Gerber and Brendler, 2011).

The urine dipstick commonly used for the detection of blood in the urine is dependent on the peroxidase-like activity of hemoglobin, which catalyzes the reaction and causes oxidation of the chromogen indicator. False positives can occur in states of hemoglobinuria and myoglobinuria, and microscopic examination of the urine for red blood cells can distinguish hematuria. Glomerular hematuria is suggested when dysmorphic erythrocytes, red blood cell casts, and proteinuria are present. Nonglomerular hematuria can be distinguished from glomerular hematuria in the presence of circular erythrocytes and the absence of erythrocyte casts. In the surgical and medical subcategories of nonglomerular hematuria, surgical hematuria is suggested by the absence of significant proteinuria.

Anticoagulation at normal therapeutic levels does not predispose patients to hematuria. Therefore, patients who have hematuria while receiving anticoagulation therapy should undergo evaluation similarly to patients who are not receiving anticoagulation therapy. In fact, super therapeutic anticoagulation may serve to unmask underlying pathology.

Prevention

Hematuria can be caused by a spectrum of causes. Prevention can be achieved by the prevention of what results in the pathologic state. For example, smoking is a modifiable risk factor in urothelial malignancy. Patients who have never smoked are at low risk for bladder cancer. Smoking cessation can also reduce the risk of developing bladder cancer. Liberal fluid intake and balanced sodium and protein intake can help prevent urolithiasis. Urinary tract infections can also be prevented by good voiding habits, facilitation of complete bladder emptying, and use of vaginal estrogen cream¹ in postmenopausal women.

Clinical Manifestations

The presentation of hematuria is often dependent on the cause. Certain characteristics of the presentation can help in the investigation. Is the hematuria gross or microscopic? Is the hematuria associated with pain? Are there any irritative voiding symptoms? Is there a presence of blood clots? Is it related to exercise? Is there any family history? Is there a presence of rash, arthritis, hemoptysis, upper respiratory infection, skin infection? Is there a history of radiation, diabetes, analgesic abuse? Is there a history of smoking or occupational exposures? Table 1 highlights findings in etiologies of hematuria. Patients with bladder cancer generally present with gross painless hematuria.

Diagnosis

The diagnosis and evaluation of hematuria starts with a careful history, physical examination, and microscopic urine analysis. The cause in an adult patient is urologic malignancy until proven otherwise. Some important questions are outlined in the clinical manifestation section. The physical examination should focus on blood pressure, a cardiovascular examination, an abdominal examination, a palpable mass, costovertebral angle tenderness, and a complete genitourinary examination inclusive of a prostate examination in the male and vaginal examination in the female patient. The assessment should help rule out causes such as infection, menstruation, vigorous exercise, medical renal disease, viral illness, trauma, or recent urologic procedures.

The urine should be collected as a midstream sample, and patients should be instructed to discard the initial 10 mL. The

¹Not FDA approved for this indication.

TABLE 1 Differential Diagnosis and Findings in Etiologies of Hematuria

DIAGNOSIS	FINDINGS	OTHER
<i>Glomerular</i>		
Familial Hematuria	Abnormal urine analysis	Family history
Systemic Lupus Erythematosus	Elevated C3, C4, ANA	Rash, arthritis
Goodpasture Syndrome	Microcytic anemia	Hemoptysis, bleeding tendency
Poststreptococcal Glomerulonephritis	Elevated ASO titer, C3	Recent upper respiratory infection, rash
IgA Nephropathy	Normal ASO and C3, renal biopsy positive for IgA, IgG	Related to exercise
<i>Nonglomerular Medical</i>		
Exercise-Induced Hematuria	Abnormal urine analysis	After strenuous exercise
Papillary Necrosis	Gross hematuria, absence of urolithiasis on CT	Flank pain, African American, analgesic abuse, diabetes
Medullary Sponge Kidney, Polycystic Kidney Disease	Abnormal CT	Family history of renal cystic disease
Renovascular Disease	Renal artery embolus, vein thrombus, AV fistula	Atrial fibrillation, dehydration, bruit
<i>Nonglomerular Surgical</i>		
Urinary Tract Infection	Urine dip with LCE, Nit. Positive urine culture, elevated WBC	Dysuria, fever
Urolithiasis (renal, ureteral, or bladder stone)	Demonstrated on imaging such as CT, ultrasound, KUB	Flank pain, pelvic pain, vomiting, infection, renal obstruction
Urologic Tumor (kidney, ureter, bladder, urethra)	Demonstrated on CT, cystoscopy, ureteropyeloscopy	Constitutional, irritative symptoms, pain if obstruction, blood clots
Enlarged Prostate or Benign Prostatic Hyperplasia	Enlarged prostate on examination or cystoscopy	Irritative and obstructive voiding symptoms
Radiation Cystitis	Generally gross hematuria, friable tissue on cystoscopy	Irritative voiding symptoms, history of pelvic radiation
Urothelial Strictures (ureter or urethra)	Demonstrated on ureteroscopy, pyelography, cystoscopy, or urethrography	Flank pain, renal insufficiency, bladder outlet obstruction

sample should be collected in a sterile cup after gently cleaning the urethral meatus with a sterilization towelette. Uncircumcised men should retract the foreskin before collection. Female patients should be asked to spread the labia adequately to allow cleansing of the urethral meatus and avoid introital contamination. The following patients may require catheterization for collection: menstruating women, obese patients, patient with a nonintact urinary tract, and patients who do intermittent catheterization or have an indwelling urinary catheter (Davis et al., 2012). A urine dipstick can be performed in the office setting, but all samples should be sent for microscopic analysis. As mentioned previously, attention should be paid to dysmorphic erythrocytes, red blood cell casts, and the presence of protein. A urine culture should be performed based on the clinical presentation and findings of urine analysis. Urine cytology does need to be performed as part of the standard workup. The laboratory workup should include an evaluation of the serum creatinine (Davis et al., 2012). Additional helpful tests are serum electrolytes and a complete blood count.

Patients with a urinary tract infection should be treated appropriately and should have a urine analysis repeated in 2 to 6 weeks after treatment. Patients with an identified etiology such as urolithiasis should have a reevaluation of urine after the stone has been passed or treated.

A urologic evaluation of the upper and lower urinary tract is compulsory for patients with gross hematuria. Patients with asymptomatic microscopic hematuria (>3 rbc/hpf) should undergo urologic evaluation once benign causes have been ruled out. The urologic evaluation is especially important for patients with high risk factors for urothelial malignancy, such as age >35 , irritative voiding symptoms, chemical exposures, smoking history, or history of urologic disorder or malignancy. Urologic evaluation should include a

cystoscopy to evaluate the urethra and bladder. Multiphasic computed tomography with and without intravenous contrast should be performed to evaluate the upper tracts. Sufficient imaging phases should be performed. Ideally, a three-phase study including a non-contrast phase (e.g., stone disease), arterial phase (e.g., renal masses), and excretory phase (e.g., ureteral masses) should be performed (Sudakoff et al., 2008). The urologist can determine the appropriate study if contrasted CT cannot be performed because of allergy or renal insufficiency. Concurrent nephrologic evaluation should occur for patients who are suspected to have glomerular causes, and the evaluation may include further serum testing and renal biopsy (Davis et al., 2012).

Differential Diagnosis

The differential diagnosis of hematuria includes glomerular diseases, nonglomerular medical diseases, and nonglomerular surgical diseases. Table 1 shows a differential diagnosis for hematuria. Hematuria is considered to be from a malignant source until proven otherwise.

Therapy, Monitoring, and Complications

Therapy, monitoring, and complications for hematuria are dependent on the etiology. It is important that hematuria not be ignored even when treated empirically. For example, it is important to recheck a urine analysis after a course of antibiotics for a presumed urinary tract infection. Often, the transient nature of hematuria fools clinicians into thinking that an intervention or observation without the appropriate workup is adequate. Unfortunately, this can result in significant morbidity from the progression of disease, especially in the case of urothelial malignancies.

HICCUPS

Method of

George A. Petroianu, MD, PhD

Mechanistic Description

Hiccup (Latin, *singultus*) is caused by an involuntary, usually repetitive and rhythmic, spasmodic contraction of the diaphragm (or hemidiaphragm) and accessory inspiratory muscles followed shortly (within 35 msec) by the sudden closure of the glottis. The forcefully inspired air meeting a closed glottis causes the typical hiccup sound. Occasional hiccups are generally perceived as being “funny”; however, hiccupping of extended duration can be incapacitating. Its most common direct consequence is esophagitis, due to concomitant relaxation of the lower esophageal sphincter favoring reflux, but extended hiccupping can also lead to wound dehiscence, depression, weight loss, malnutrition, insomnia, and exhaustion.

Classifications

Most classifications use arbitrary time limits to categorize hiccupping. Generally hiccups lasting less than 1 day are considered transient (acute), those lasting less than 1 week are labeled persistent, and hiccupping for more than 1 week is described as chronic. A simplified categorization draws the line at 48 hours: any hiccupping episode lasting longer is described as chronic. The practical value of these classifications is questionable; by the time the practitioner sees the patient, almost invariably the case involves persistent or chronic hiccup forms requiring drug therapy. The exceptions (in terms of time between appearance and presentation) are hiccup forms presenting immediately postoperatively or in critical care units. Brief episodes of hiccupping, as experienced by the vast majority of people at some point in time, are certainly physiologic. The point of transition to a pathologic form is not well defined. The rule of thumb of hiccup therapy, however, is that the longer the duration of the hiccupping, the less amenable it will be to nonpharmacologic interventions.

Etiologic classifications are also fraught with problems. Hiccup is not a disease, but a symptom. Literally, there is no known disease that has not been associated with hiccups. Although the categories psychogenic, organic, and idiopathic are most commonly used in practice, the situation most commonly encountered is that of hiccup of unknown (idiopathic) origin. In this context, “idiopathic” describes one’s inability to demonstrate, rather than the absence of, an organic origin.

Epidemiology

During intrauterine life, hiccups are universally present, their incidence peaking in the third trimester. They can also be seen regularly in the newborn, the frequency of occurrence decreasing slowly over the first year of life. In adults, occasional transient hiccup is also so frequent that it can be viewed as physiologic. Persistent and chronic idiopathic singultus, the pathologic forms, are rare, their prevalence being estimated at 1 in 100,000. Males are almost exclusively affected (the male-to-female patient ratio is approximately 80:1), suggesting a hormone (estrogen) protective effect. The incidence increases with age. The psychogenic form, though less frequent

overall by one order of magnitude, is believed to be more prevalent in females, with an even distribution among all age groups; however, data to support this view are almost nonexistent.

Pathophysiology

The universality of hiccups during fetal life begs the question of purposefulness. As early as 1887, it was suggested that hiccups might represent a necessary and vital primitive reflex that would permit intrauterine training of the diaphragm without aspiration of amniotic fluid. During intrapartum and postpartum maturation, higher centers would then suppress this primitive reflex. Immaturity or damage to the central nervous system would favor the persistence or reappearance of the reflex. The putative reflex arch includes autonomic afferent fibers (the majority vagal fibers) from the digestive tract to a putative medullary hiccup center and motor efferent fibers via the phrenic nerve (diaphragm) and other branches of the vagus nerve to the intrinsic muscles of the larynx adducting the vocal cords. In an analogy with the vomiting center, the assumed role of the medullary hiccup center is to coordinate and fine-tune the sequence of events required for hiccupping; it is therefore a “pattern generator.” The concept described, though useful for the purpose of designing a quasi-rational treatment protocol for hiccup, is neither proven nor generally accepted.

Another school of thought that questions the assumption that hiccupping is a reflex phenomenon suggests instead a similarity with cardiac arrhythmias: hiccups would therefore be due to arrhythmias of the breathing center. Still other researchers work on the assumption that hiccup is a myoclonic event, or that it represents brainstem seizures. These views are not necessarily mutually exclusive, because hiccup is not primarily a disease but a symptom, possibly representing different pathophysiologies.

Evaluation of the Hiccup Patient

Hiccup is a symptom associated with a multitude of pathologies. The practitioner must take the hiccupping patient seriously, and for the purpose of finding and treating hidden pathology, persistent and chronic hiccups should be investigated. No consensus exists, however, concerning the extent of such investigations. Even the most enthusiastic users of modern imaging technologies will in most cases end up with a working diagnosis of chronic idiopathic singultus. Nonetheless, a detailed history, a thorough physical examination, and basic laboratory and diagnostic procedures are essential.

History

Ask about previous episodes, as well as precipitating and alleviating factors. The patient who describes vomiting as a “cure” for previous hiccup episodes gives a telltale sign that acidity is an etiologic factor, and omeprazole is a drug to consider. If the patient indicates that hyperventilation is a “sure bet” to worsen his or her hiccups, you can assume that drugs lowering the excitability of the nervous system are likely to help. Elucidating present drug consumption (medical and recreational) is essential: benzodiazepines, barbiturates, alcohol, and steroids are well-known hiccup inducers.

Physical Examination

Foreign bodies in the external auditory canal can induce hiccups, so look in the ears. Examine neck, chest, and abdomen, looking for possible sources of irritation (infection, neoplastic processes, or both) to the vagus and phrenic nerves and the diaphragm. Perform a neurologic examination, keeping in mind the association of hiccup with multiple sclerosis and intracranial processes.

Laboratory and Diagnostic Procedures

An upright chest x-ray, together with complete blood count (CBC) with differential, will help exclude neoplastic or infectious disease. An electrocardiogram (ECG) will help exclude pericarditis and malfunctioning pacemakers, and electrolyte and urea determinations will exclude known metabolic causes (hyponatremia and uremia).

The psychogenic form, though less frequent

overall by one order of magnitude, is believed to be more prevalent in females, with an even distribution among all age groups; however, data to support this view are almost nonexistent.

Pathophysiology

The universality of hiccups during fetal life begs the question of purposefulness. As early as 1887, it was suggested that hiccups might represent a necessary and vital primitive reflex that would permit intrauterine training of the diaphragm without aspiration of amniotic fluid. During intrapartum and postpartum maturation, higher centers would then suppress this primitive reflex. Immaturity or damage to the central nervous system would favor the persistence or reappearance of the reflex. The putative reflex arch includes autonomic afferent fibers (the majority vagal fibers) from the digestive tract to a putative medullary hiccup center and motor efferent fibers via the phrenic nerve (diaphragm) and other branches of the vagus nerve to the intrinsic muscles of the larynx adducting the vocal cords. In an analogy with the vomiting center, the assumed role of the medullary hiccup center is to coordinate and fine-tune the sequence of events required for hiccupping; it is therefore a “pattern generator.” The concept described, though useful for the purpose of designing a quasi-rational treatment protocol for hiccup, is neither proven nor generally accepted.

Another school of thought that questions the assumption that hiccupping is a reflex phenomenon suggests instead a similarity with cardiac arrhythmias: hiccups would therefore be due to arrhythmias of the breathing center. Still other researchers work on the assumption that hiccup is a myoclonic event, or that it represents brainstem seizures. These views are not necessarily mutually exclusive, because hiccup is not primarily a disease but a symptom, possibly representing different pathophysiologies.

Evaluation of the Hiccup Patient

Hiccup is a symptom associated with a multitude of pathologies. The practitioner must take the hiccupping patient seriously, and for the purpose of finding and treating hidden pathology, persistent and chronic hiccups should be investigated. No consensus exists, however, concerning the extent of such investigations. Even the most enthusiastic users of modern imaging technologies will in most cases end up with a working diagnosis of chronic idiopathic singultus. Nonetheless, a detailed history, a thorough physical examination, and basic laboratory and diagnostic procedures are essential.

History

Ask about previous episodes, as well as precipitating and alleviating factors. The patient who describes vomiting as a “cure” for previous hiccup episodes gives a telltale sign that acidity is an etiologic factor, and omeprazole is a drug to consider. If the patient indicates that hyperventilation is a “sure bet” to worsen his or her hiccups, you can assume that drugs lowering the excitability of the nervous system are likely to help. Elucidating present drug consumption (medical and recreational) is essential: benzodiazepines, barbiturates, alcohol, and steroids are well-known hiccup inducers.

Physical Examination

Foreign bodies in the external auditory canal can induce hiccups, so look in the ears. Examine neck, chest, and abdomen, looking for possible sources of irritation (infection, neoplastic processes, or both) to the vagus and phrenic nerves and the diaphragm. Perform a neurologic examination, keeping in mind the association of hiccup with multiple sclerosis and intracranial processes.

Laboratory and Diagnostic Procedures

An upright chest x-ray, together with complete blood count (CBC) with differential, will help exclude neoplastic or infectious disease. An electrocardiogram (ECG) will help exclude pericarditis and malfunctioning pacemakers, and electrolyte and urea determinations will exclude known metabolic causes (hyponatremia and uremia).

To what extent magnetic resonance imaging (MRI), ultrasound scanning, or endoscopic examinations are necessary is a judgment call, and no generalizations are possible; they might occasionally be indicated.

Nonpharmacologic Interventions

A multitude of nonpharmacologic interventions to terminate hiccup belong to the public-domain hiccup “mythology” or have been described in the medical literature as case reports. Though usually effective in terminating bouts of acute hiccup, they are mostly ineffective in cases of hiccups that has been present for an extended period. The common denominator of these maneuvers (also used to terminate paroxysmal supraventricular tachycardia) is their ability to directly or indirectly increase efferent vagal activity; the increased parasympathetic tone has a limiting effect on hiccups. Interestingly, estrogens are also considered to be parasympathomimetic, which offers a plausible explanation of why the singultus prevalence in females is much lower than in males.

Pharmacologic Interventions

Probably only a few drugs in the *Physician's Desk Reference* have not been tried in the therapy of singultus, and anyone who looks hard enough at the literature will be able to find anecdotal support for the use of almost any drug. However, prospective controlled studies to support the use of a particular therapy are very few and rare.

Conceptually, all drugs potentially successful in the therapy of chronic hiccups work either by decreasing the input from the gastrointestinal tract to a (putative) hiccup center or by decreasing the excitability of the nervous system and therefore the output from the (putative) hiccup center.

Sedative-Hypnotics

Both benzodiazepine and barbiturate γ -aminobutyric acid receptor type A ($GABA_A$) agonists have been tried for treatment of hiccups. The consensus is that these substances not only are ineffective but can actually worsen the clinical picture, producing a situation similar to the paradoxical excitation seen with the use of sedatives and explained by inhibitory effects on inhibitory centers.

Antiemetics

Following up on the analogy between the vomiting center and hiccup center as pattern generators, “setron”-class antiemetics (5-HT₃ receptor antagonists) have been tried, with no success. Anecdotal evidence hints at possible worsening of the hiccup under the influence of ondansetron (Zofran).¹

Analeptics

The use of analeptics derives from the concept that hiccup is a suppressed primitive reflex. Analeptics potentiate the central suppression. Although some success has been reported with methylphenidate (Ritalin),¹ caffeine produced failure.

Anticonvulsants

Anticonvulsants (phenytoin [Dilantin],¹ carbamazepine [Tegretol],¹ valproate [Depacon]¹) have been used to try to suppress hiccups. Considering the multitude of pharmacodynamic effects of anticonvulsants, it is not surprising that some success was achieved.

Antipsychotics

Historically, chlorpromazine (Thorazine) has been the most widely used drug for treatment of hiccup, and it is the only drug approved by the FDA for the disorder. Aliphatic phenothiazines such as chlorpromazine have strong sedative, hypotensive, and anticholinergic properties and mild to moderate extrapyramidal effects. For hiccup control, results are mixed at best, and in view of the side effects, routine use is not warranted. Haloperidol (Haldol),¹ a

butyrophenone derivative, has also been used for hiccup control; again, results are mixed at best, and the possibility of developing tardive dyskinesia weighs heavily against the routine use of this drug.

Antidepressants

The tertiary amine tricyclic antidepressant amitriptyline (Elavil)¹ is one of the oldest players in the therapy of hiccup; its use was being suggested in the mid-1960s. As with anticonvulsants, considering the multitude of pharmacodynamic effects of tricyclic antidepressants, it is not surprising that some success was achieved with these drugs. Their effectiveness is not related to their ability to inhibit monoamine uptake, but probably to their sodium channel blocking properties.

Calcium Channel Blockers

Nifedipine (Adalat)¹ is the dihydropyridine derivative most commonly used for hiccup control. Nimodipine (Nimotop)¹ has also been tried for the same purpose. Interestingly, anecdotal reports about the use of calcium for the same purpose also exist.

Sodium Channel Blockers

The local anesthetic class Ib antidysrhythmic lidocaine (Xylocaine)¹ and its oral analogue mexiletine (Mexitil)¹ have been used for hiccup control, with mixed results.

GABA_B Agonists

Among the substances acting on the nervous system, baclofen (Lioresal)¹ has by far the best credentials in the treatment of chronic hiccup. It is one of the very few substances proven in clinical studies (albeit with small patient numbers) to be efficacious. This γ -aminobutyric acid receptor type B ($GABA_B$) agonist, normally used to lower an increased muscle tone (spasticity), has also been shown to suppress hiccups in an animal (cat) hiccup model. $GABA_B$ agonists, by reducing transmitter release, are generally able to depress complex reflexes.

Antacids

Lowering the acidity of the stomach using H₂-receptor blockers or proton pump inhibitors conceptually decreases the input from the gastrointestinal tract to the hiccup center. Omeprazole (Prilosec)¹ has been shown in a limited number of trials to be effective in hiccup treatment.

Gastrokinetic Drugs

One of the few reliable methods to induce a physiologic hiccup in humans is rapidly drinking an ice-cold can of beer on a hot summer day. Although it is highly debatable whether it has to be beer, stomach distention by carbon dioxide induces hiccups. Conversely, reducing stomach distention by using a gastrokinetic drug is helpful in alleviating hiccups. The strongest evidence available for the usefulness of a gastrokinetic drug was for cisapride (Propulsid); however, this selective serotonin 5-HT₄-receptor agonist was withdrawn from the market because of its propensity to prolong the QT interval and induce torsades de pointes. The available alternative is the related benzamide metoclopramide (Reglan),¹ a mixed dopamine receptor antagonist, 5-HT₄-receptor agonist, and cholinesterase inhibitor, with a long tradition in the treatment of hiccups, going back to the late 1960s.

Physical Interventions

Phrenic Nerve Destruction

Irreversible surgical destruction of the phrenic nerve cannot be recommended. Even if hiccup relief is achieved after unilateral local anesthetic blockade of the phrenic nerve without serious compromise in respiratory function, the long-term effects of phrenic nerve destruction are unpredictable. Possible effects include both hiccup reappearance—even after bilateral phrenic nerve transection—and

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

deterioration in respiratory function. More recently, diaphragmatic (phrenic) pacing has been described; however, experience is very limited.

Hypercapnia

Rebreathing in a paper bag is a well-known and reliable remedy for hyperventilation tetany. The increase in blood CO₂ levels (hypercapnia) thus induced leads to mild acidosis and thus to a liberation of calcium ions from the protein binding. The increase in plasma-free calcium decreases neuronal excitability, thus terminating not only the tetany but possibly also hiccupping. A more high-tech version of this is the induction of normoxic hypercapnia in ventilated patients.

Positive End-Expiratory Pressure

Also practicable only in intubated patients is the application of high positive end-expiratory pressure (PEEP), a high-tech version of the Valsalva maneuver.

Nasogastric Tube

Gastric decompression via a nasogastric tube can terminate hiccups.

Treatment

The treatment algorithm described is based on the assumption that correctable organic causes have been excluded or treated.

We start therapy with omeprazole (Prilosec)¹ 20 to 40 mg orally (PO) daily. If after 7 days no satisfactory change has occurred, baclofen (Lioresal)¹ is introduced. With baclofen, a “start low, go very slow” approach is indicated in order to avoid excessive drowsiness, weakness, and fatigue. The maximum daily dose is 45 mg. Quite often, patients are already on a proton pump inhibitor (PPI) when presenting. In these cases, immediate introduction of baclofen and continuation of the PPI are recommended. In our experience, the time of response to the combination therapy omeprazole plus baclofen is unpredictable; however, all changes that we observed happened within the first 6 months, and the vast majority within the first 6 weeks. If the desired result is achieved, we continue therapy for another 6 months, after which a very cautious weaning from baclofen is attempted. In cases where the combination therapy omeprazole plus baclofen is not (or not entirely) satisfactory, the addition of gabapentin (Neurontin)¹ “on the top” can be attempted. As with baclofen, with gabapentin a “start low, go slow” approach is indicated, the maximum dose of 400 mg three times daily used in such cases being reached after 3 weeks. An inverse approach with PPI plus gabapentin as initial combination is also possible.

In addition to any pharmacologic therapy, the practitioner must convey to the patient the feeling that he or she understands and appreciates the seriousness of the condition. Compliance with the treatment is required from the patient, who must understand that success can take time. Lifestyle and habit changes are also required. The hiccup patient must limit the size of meals and avoid carbonated beverages and “gas-forming” foods.

The approach presented here represents our experience in the treatment of chronic singultus. The views expressed are neither guidelines nor regulations.

¹Not FDA approved for this indication.

HOARSENESS AND LARYNGITIS

Method of
Lee Akst, MD

CURRENT DIAGNOSIS

- The general term to describe vocal difficulty is dysphonia. Hoarseness is a specific term for rough voice quality, which is one type of dysphonia. Laryngitis signifies laryngeal inflammation, which is one possible cause of dysphonia.
- An accurate history and physical examination guide the diagnosis of voice complaints. Although many portions of the examination for dysphonia can be done in a general setting, videostroboscopy is often necessary for diagnosis and may be available only in specialized laryngology offices.
- The most common cause of acute hoarseness is viral laryngitis. Symptoms are self-limited and usually resolve within 2 weeks.
- Dysphonia persisting for longer than 2 weeks suggests the possibility of another diagnosis, such as vocal cord paralysis, neoplasm, phonotraumatic lesion, or chronic laryngitis.
- Indications for referral of a patient with voice complaints to an otolaryngologist include dysphonia that persists for longer than 2 weeks, that is of acute onset during voicing, or that is accompanied by other symptoms such as otalgia, dysphagia, or difficulty breathing.

CURRENT THERAPY

- Appropriate treatment of voice complaints depends on accurate diagnosis.
- Supportive therapy is all that is necessary for most cases of acute laryngitis associated with viral upper respiratory tract infections.
- Laryngopharyngeal reflux is a common cause of chronic laryngitis, and appropriate therapy often requires twice-daily administration of proton pump inhibitors for at least 2 months.
- Microlaryngeal phonosurgery may be indicated for some patients with benign phonotraumatic lesions.
- Vocal cord medialization can rehabilitate the voice in a patient with unilateral vocal cord paralysis.
- Many patients with dysphonia benefit from voice therapy, alone or in combination with other treatment strategies.

Voice is an essential component of communication. Vocal difficulty is very distressing to patients and can have a negative impact on physical, social, and emotional qualities of life. To understand the pathophysiology, evaluation, and treatment of voice complaints, it is important to understand the anatomy and physiology of normal voice production. Looking first at how good voice quality is achieved makes it readily apparent how alterations in vocal fold vibration, symmetry, or closure can lead to various vocal difficulties.

To aid discussion of voice complaints, clarification of terminology is necessary. Although “hoarseness” is a term that most patients use to describe any type of voice complaint and “laryngitis” is the presumptive explanation that many patients provide for their symptoms, each of these terms has a more precise meaning. Dysphonia is the general term for vocal difficulty. Hoarseness implies a rough or raspy change in voice quality and is one type of dysphonia. Other categories include limited vocal projection, strained vocal effort, and change in pitch—each of which may occur with or without vocal roughness. The term “laryngitis” specifically describes inflammation of the larynx. This inflammation may be acute or chronic, and again it describes some but certainly

deterioration in respiratory function. More recently, diaphragmatic (phrenic) pacing has been described; however, experience is very limited.

Hypercapnia

Rebreathing in a paper bag is a well-known and reliable remedy for hyperventilation tetany. The increase in blood CO₂ levels (hypercapnia) thus induced leads to mild acidosis and thus to a liberation of calcium ions from the protein binding. The increase in plasma-free calcium decreases neuronal excitability, thus terminating not only the tetany but possibly also hiccupping. A more high-tech version of this is the induction of normoxic hypercapnia in ventilated patients.

Positive End-Expiratory Pressure

Also practicable only in intubated patients is the application of high positive end-expiratory pressure (PEEP), a high-tech version of the Valsalva maneuver.

Nasogastric Tube

Gastric decompression via a nasogastric tube can terminate hiccups.

Treatment

The treatment algorithm described is based on the assumption that correctable organic causes have been excluded or treated.

We start therapy with omeprazole (Prilosec)¹ 20 to 40 mg orally (PO) daily. If after 7 days no satisfactory change has occurred, baclofen (Lioresal)¹ is introduced. - Many patients with dysphonia benefit from voice therapy, alone or in combination with other treatment strategies.

Voice is an essential component of communication. Vocal difficulty is very distressing to patients and can have a negative impact on physical, social, and emotional qualities of life. To understand the pathophysiology, evaluation, and treatment of voice complaints, it is important to understand the anatomy and physiology of normal voice production. Looking first at how good voice quality is achieved makes it readily apparent how alterations in vocal fold vibration, symmetry, or closure can lead to various vocal difficulties.

To aid discussion of voice complaints, clarification of terminology is necessary. Although “hoarseness” is a term that most patients use to describe any type of voice complaint and “laryngitis” is the presumptive explanation that many patients provide for their symptoms, each of these terms has a more precise meaning. Dysphonia is the general term for vocal difficulty. Hoarseness implies a rough or raspy change in voice quality and is one type of dysphonia. Other categories include limited vocal projection, strained vocal effort, and change in pitch—each of which may occur with or without vocal roughness. The term “laryngitis” specifically describes inflammation of the larynx. This inflammation may be acute or chronic, and again it describes some but certainly

Figure 1 A, Normal vocal folds in abducted position for inspiration. B, Normal vocal folds in adducted position for phonation. C, Displacement of the vocal fold medial edges creates mucosal wave propagation during phonation and produces voice.

not all cases of dysphonia. This distinction will be made clear as the evaluation and management of dysphonia are described.

Normal Laryngeal Function

The larynx plays a central role in voice production by serving as a vibrating instrument that turns airflow from the lungs into sound. The sound is shaped into intelligible speech through the resonating and articulating functions of the pharynx and oral cavity. The ability of the larynx to create vibration and serve as a sound source is a function of its complex, layered microanatomy. The deeper layers of the vocal fold include the thyroarytenoid muscle and the vocal ligament, which position the more superficial layers of the superficial lamina propria and epithelium during phonation. Compared with the fibrous nature of the vocal ligament, the superficial lamina propria is a loose gelatinous layer whose pliability allows for voice production.

During inspiration (Figure 1A), the vocal folds are abducted so that air can move past the larynx without resistance. During phonation (Figure 1B), the vocal folds are held in an adducted position while the lungs drive air toward the larynx. Air pressure builds in the subglottis, beneath the vocal folds, until it overcomes the forces of vocal fold closure, pushes past the vocal folds, and generates negative pressure in its wake as it moves past the larynx. A combination of the vocal folds' intrinsic viscoelasticity and the negative pressure created through Bernoulli's effect draws the vocal fold edges back together, allowing subglottic pressure to rebuild and the cycle to repeat. Repeated cycles of opening and closing at the level of the vocal fold edges generate a so-called mucosal wave, which travels from the inferior edge of each vocal fold up across the medial and superior edges (Figure 1C). These waves may repeat hundreds of times each second, depending on pitch. This cycled opening and closing of the vocal folds during phonation imparts pressure waves to the air column that moves the vocal folds, generating sound. The ability of vocal folds to vibrate easily and symmetrically in this very rapid fashion allows for clear, smooth voicing.

Evaluation of Dysphonia

Central to the evaluation of dysphonia is the understanding that any disruption of vocal fold closure, symmetry, or vibration impairs the ability of the vocal folds to generate a clear sound source. Most voice complaints arise from anatomic or functional limitations in glottal closure or mucosal wave formation, although other parts of the respiratory tree are also responsible for components of the voice. General points concerning evaluation of dysphonia are discussed in this section, with specific causes discussed afterward.

History

A careful history can provide many clues that point toward the proper diagnosis in patients with dysphonia. Although many patients offer the complaint of "hoarseness" as a general term, a careful historian distinguishes between complaints related to voice quality, vocal projection, vocal effort or strain, vocal fatigue, and

so on. Two questions that can help a patient organize his or her own thoughts related to poor voice are "What abnormal things does your voice do now that it did not do before?" and "What normal things did your voice do before that it no longer can do?" The acuteness of onset, duration, severity, and progression of any complaint should be determined.

The history should also determine what other factors or events might have caused or exacerbated the dysphonia. Recent sources of laryngeal inflammation might include intubation, excessive voice use, or upper respiratory tract infection. Baseline conditions that foster chronic laryngeal inflammation include environmental allergies, rhinitis, and laryngopharyngeal reflux. Laryngopharyngeal reflux can exist in the absence of heartburn, with reflux-associated inflammation of the larynx and pharynx providing symptoms of globus pharyngeus, throat clearing, nonproductive cough, effortful swallowing, and even mild dysphagia in association with dysphonia.

Concerning the possibility of laryngeal malignancy, any patient with dysphonia should be asked about smoking and alcohol use, because these are risk factors for squamous cell carcinoma. Another important question in distinguishing inflammatory dysphonia from a mass lesion of the vocal fold concerns whether there are any periods of normal voice or the dysphonia is constant—inflammation may wax and wane, but dysphonia associated with mass lesions is usually progressive and unremitting. Finally, the history should elicit other possible head and neck complaints, including dyspnea, stridor, dysphagia, odynophagia, otalgia, sore throat, and pain with speaking (odynophonia). If hoarseness is associated with some of these symptoms for longer than 2 weeks, the suspicion of malignancy is increased.

Physical Examination

The physical examination for patients with dysphonia includes a complete head and neck evaluation with focus on the larynx and laryngeal function. Although much of the head and neck examination can be performed in a general setting, some portions of the laryngeal examination require specialized equipment found only in some otolaryngology offices that specialize in voice care. Routine head and neck evaluation should include systematic examination of the ears, nose, oral cavity, oropharynx, and neck.

Complaint of otalgia in the setting of an unremarkable ear examination suggests a possibility of referred pain from a lesion of the larynx or pharynx, and is concerning for possible malignancy. Edematous and erythematous nasal mucosa suggests rhinitis, with the possibility of postnasal drip contributing to laryngeal inflammation. Tremor of the tongue or palate might suggest neurologic disorder, whereas pharyngeal erythema and exudate suggest possible acute infection. Pachydermia (cobblestoning) of the posterior pharyngeal wall suggests the possibility of laryngopharyngeal reflux. Tenderness with manipulation of the hyoid bone suggests tension of the strap muscles and correlates closely with complaint of odynophonia and the possibility of muscle tension dysphonia. A neck mass might represent either metastatic lymphadenopathy from a laryngeal malignancy or a primary lesion which itself

compresses the recurrent laryngeal nerve and causes paralytic dysphonia. Surgical scarring along the neck suggests the possibility that prior thyroid surgery, carotid endarterectomy, or anterior approach to the cervical spine might have led to vocal fold paralysis.

Laryngeal Examination

Beyond a general examination of the head and neck, there should be directed evaluation of the larynx and laryngeal function. The examiner should listen to the voice carefully, because vocal characteristics such as roughness, breathiness, strain, vocal breaks, and diplophonia (pitch instability, with two different pitches present simultaneously) can help guide the differential diagnosis of dysphonia. Visual examination of the larynx has many forms, ranging from mirror examination to flexible fiberoptic laryngoscopy to videostrobolaryngoscopy.

Mirror examination offers an adequate view of the vocal folds in many patients but may be limited by patient tolerance, physician inexperience, and the inherently limited ability of this technique to brightly illuminate the larynx or record the examination for later review. Flexible laryngoscopy is routinely available in almost all otolaryngology offices, is well tolerated by patients, and offers good views of the larynx that can be recorded with appropriate equipment. Mirror examination and flexible laryngoscopy are limited to observation of vocal fold motion and anatomy but cannot observe laryngeal function because they do not visualize vibration of the vocal folds. To examine vocal fold vibration, videostroboscopy uses a strobe light to create the impression of slow-motion analysis of mucosal waves. Stroboscopy is typically available only in selected otolaryngology practices in which laryngologists specialize in the treatment of voice disorders.

Other Testing

Videostroboscopic evaluation, combined with a thorough history and routine physical examination, can establish the diagnosis for almost all patients with voice complaints, but further testing is sometimes indicated. For instance, electromyography is used by some laryngologists for further evaluation of vocal fold paralysis or paresis. More commonly, radiographic studies are used for further evaluation of some voice complaints. Computed tomography (CT) scans are ordered most often in the evaluation of suspected laryngeal neoplasms and for patients with vocal fold paralysis.

In the case of neoplasm, CT scanning is useful to assess the extent of the primary lesion and to evaluate possible metastatic cervical lymphadenopathy. In patients with laryngeal malignancy, chest radiography is also important to assess for pulmonary metastases. For patients with vocal fold paralysis who do not have a clear history of surgical injury of the recurrent laryngeal nerve, a CT scan from skull base to thoracic inlet identifies possible lesions along the course of the recurrent laryngeal nerve. Central problems are less likely, but if they are suspected as a cause of vocal fold paralysis, then magnetic resonance imaging of the brain may be indicated as well.

Types of Dysphonia

Although not comprehensive, the conditions discussed here account for the vast majority of voice complaints. Some patients with voice complaints have more than one condition, and not every patient will fit neatly into a single category. Nevertheless, understanding how each of these conditions creates dysphonia, and knowing which particular history and physical examination findings might be associated with each cause, can help a physician to appropriately diagnose and manage voice complaints.

Acute Laryngitis

Acute laryngitis is the most common cause of hoarseness and dysphonia. It is most often viral in nature, and onset of laryngeal symptoms may be associated with other symptoms of upper respiratory tract infection, including fever, myalgia, sore throat, and rhinorrhea. Viral inflammation of the vocal folds leads to diminished and more effortful vocal fold vibration, yielding a voice

characterized by increased effort and a harsh, strained quality with decreased projection. Characteristic findings on laryngoscopy include vocal fold edema and erythema with decreased amplitude of the mucosal wave. Treatment of acute viral laryngitis is supportive, with counseling for hydration, humidification, and mucolytics. Symptoms generally are self-limited and resolve within 2 weeks. During this time, patients should be instructed to use the voice in a comfortable fashion, rather than straining or pushing to get loudness, because pushing behaviors may lead to the development of persistent muscle tension dysphonia.

Bacterial or fungal infections also cause acute laryngitis in rare cases. With appropriate physical findings and in the right clinical setting, antibiotic or antifungal therapy may be used to treat these conditions. Amoxicillin-clavulanate (Augmentin) is often the antibiotic of choice, and fluconazole (Diflucan) is a commonly used antifungal agent.

Chronic Laryngitis

Chronic laryngitis is the nonspecific condition of prolonged laryngeal inflammation; the term itself does not indicate an etiology for the inflammation. Among the many possible sources for this inflammation are mechanical irritation from traumatic coughing or prolonged speaking, chemical irritation from environmental irritants (e.g., smoking, inhaled medications), and irritation from postnasal drip or laryngopharyngeal reflux. More than one cause may exist simultaneously. Issues related to cigarette use, excessive voice use, medication effect, and rhinitis can be identified with careful history taking. Laryngopharyngeal reflux is a very common source of chronic laryngitis. It may manifest with several nonspecific symptoms, such as throat irritation, globus pharyngeus, frequent throat clearing, and nonproductive cough, with or without accompanying heartburn. Because vocal fold inflammation increases with continued mechanical trauma, the hoarseness of chronic laryngitis typically gets worse with prolonged voice use and improves with voice rest. Examination findings in chronic laryngitis include generalized laryngeal edema and erythema, and careful inspection may also reveal interarytenoid hyperplasia, subglottic edema, laryngeal ventricular obliteration, and an increase in thick glottic secretions.

Treatment of chronic laryngitis is tailored to the cause of the inflammation. Vocal hygiene with moderate voice use and instructions to reduce throat clearing and coughing may diminish mechanical irritation, and smoking cessation is recommended to any smoker with laryngeal complaints. Several studies have suggested that an appropriate trial of proton pump inhibitors for treatment of laryngopharyngeal reflux includes twice-daily therapy for at least 2 months, in contrast to the once-daily dosing often used for typical heartburn complaints. Lifestyle counseling to limit consumption of caffeine, carbonation, alcohol, and acidic foods can improve reflux, and attention to hydration and humidification decreases the viscosity of glottic secretions. For patients who are troubled by vocal difficulties associated with chronic laryngitis, referral to a speech-language pathologist for voice therapy can improve compliance with suggested lifestyle changes and help foster vocal improvement.

Vocal Fold Paralysis

The dysphonia in cases of vocal fold paralysis usually relates to poor vocal fold closure (Figure 2). The result is a breathy voice with limited projection and increased vocal effort. The farther from midline the immobile vocal fold, the more air leaks through the incompetent glottal valve without being turned into sound. Patients whose immobile vocal fold sits in a lateral position may have severely weak and breathy voices, whereas patients whose immobile vocal fold sits near midline may have a perceptually near-normal conversational voice and complain only of mild increase in effort, vocal fatigue, or problems with loud projection. Because of their glottal insufficiency, patients may complain of “running out of air” with prolonged speech. Impaired glottal closure may also decrease airway protection during swallowing, so patients with vocal fold paralysis need to be questioned about aspiration

Figure 2 Vocal fold paralysis prevents the right vocal fold from closing to midline and creates dysphonia.

Figure 3 A large right hemorrhagic polyp, which can impair vocal fold vibration.

as well. Whereas rehabilitation of poor voice may be elective, patients with increased aspiration risk need prompt therapy.

Evaluation of vocal fold paralysis includes identification of the cause of paralysis. Surgical injury to the recurrent laryngeal nerve accounts for almost half of all cases of unilateral vocal fold paralysis, and cervical or thoracic neoplasm and idiopathic paralysis account for most of the remaining cases. In a patient without a clear surgical history explaining the paralysis, CT scanning from skull base to mediastinum can identify any possible lesions along the course of the recurrent laryngeal nerve. In those patients whose histories suggest other possible causes (e.g., central neurologic injury, Lyme disease), further investigations, such as magnetic resonance imaging of the brain or blood work may be indicated as well. Some physicians perform laryngeal electromyography to help with the prognosis of paralysis or to differentiate neurologic injury from cricoarytenoid joint fixation; however, this study is neither standardized nor routine in many practices. Although flexible laryngoscopy alone may be satisfactory to document vocal fold immobility, stroboscopy can be added to investigate the impact of glottal insufficiency on vocal cord vibration and possible vocal fold flutter.

Treatment of vocal fold paralysis might include any combination of voice therapy, injection laryngoplasty, transcervical medialization laryngoplasty, and laryngeal reinnervation. Depending on the cause of the paralysis, some patients experience gradual recovery with synkinetic reinnervation or recovery of purposeful vocal fold motion over a period of several months. Based on the degree of voice and swallowing handicap, treatment of patients with vocal fold paralysis may be optional rather than necessary. Voice therapy can help teach patients to produce a stronger voice despite the paralysis, but by itself will not help a paralyzed vocal cord to recover motion. Various medialization techniques have been developed to help reposition an immobile vocal fold in the midline, where the contralateral mobile vocal fold can provide for complete glottal closure and lead to improved voice and swallowing. Injection medialization can be performed in the office or in the operating room, with temporary or permanent materials; if recovery of vocal fold motion is thought possible, then temporary injection is preferred. Transcervical medialization is a permanent but reversible surgical technique performed by otolaryngologists that repositions an immobile vocal fold in the midline. Laryngeal reinnervation offers the possibility of midline positioning of the immobile vocal fold with restored tone and bulk of the vocal fold musculature; however, because results may not mature for several months, this technique is less commonly performed than either injection or transcervical medialization.

Phonotraumatic Lesions: Nodules, Polyps, and Cysts

During vibration, vocal folds are subject to the shearing stresses of vibration. Although vocal fold structure is designed to accommodate these stresses in most circumstances, patients with vocal abuse or excessive voice use are at risk for development of lesions

as the result of cumulative phonotrauma. Depending on the location and nature of these lesions, they are categorized as nodules, polyps, or cysts.

Vocal fold nodules are areas of fibrovascular scarring that are located just beneath the epithelium, at the level of the basement membrane and superficial lamina propria. They are typically bilateral and symmetrical, sitting at the junction of the anterior one third and the posterior two thirds of each vocal fold. Polyps are typically unilateral lesions that may be edematous or fibrous in nature and may contain hemorrhage (Figure 3). They usually are exophytic and extend outward from the vocal fold epithelium, although the fibrous base of a polyp may extend into the superficial lamina propria of a vocal fold. In contrast to an epithelial-based lesion such as a polyp, a vocal fold cyst is a subepithelial encapsulated lesion that sits entirely within the vocal fold; its size may exert a mass effect that deforms the medial edge of the involved vocal fold. These cysts are occasionally noted as congenital lesions in children, but in adults they are more often caused by traumatic occlusion of the ducts of the seromucinous glands within the larynx.

Nodules, polyps, and cysts cause dysphonia by disturbing vocal fold vibration, leading to rough voice quality. These lesions get larger as traumatic voice use accumulates, and vocal roughness usually becomes more severe and more constant as the lesions progress. Because vibration is more easily disturbed at high pitch, performers with these lesions may notice that high pitch is affected first. Effort of phonation often increases, but projection remains intact. Lesions large enough to limit vocal fold closure may also cause a slightly breathy voice quality. Because patients with excessive voice use are at risk for these lesions, a history of social and occupational voice demands is valuable in cases of suspected phonotrauma.

Treatment for these lesions always begins with voice therapy designed to modify the patient's voice use so as to diminish trauma. Voice therapy may be all that is necessary to allow resolution of some early traumatic changes, particularly in the case of edematous nodules. If dysphonia persists despite voice therapy and other conservative measures, surgery may be considered. Surgery with the goal of voice preservation and restoration (phonosurgery) is typically performed by otolaryngologists who specialize in the care of persons with vocal difficulties. The goal of phonosurgery for these lesions is to remove the lesion that impairs vibration while preserving as much of the remaining, pliable superficial lamina propria as possible, so that vocal fold vibration can be restored.

Reinke's Edema

Reinke's edema, also known as polypoid corditis, is a benign swelling of the vocal folds that is most commonly seen in patients with a long-term smoking history. The edema, a reaction to long-term irritation, accumulates within the superficial lamina propria. The edema is most often bilateral and occurs diffusely along the entire length of the vocal fold, rather than being limited to a more discrete

Figure 4 Symmetrical polypoid degeneration of the bilateral vocal folds, characteristic of Reinke's edema.

area, as is seen with phonotraumatic polyps (Figure 4). As vocal fold mass increases with disease progression, the pitch of the voice decreases, and this is the change in voice most associated with Reinke's edema. A classic presentation of this condition is a female in her fifth or sixth decade of life who provides a long history of smoking and progressive deepening of her voice. In rare circumstances, the vocal folds gradually accumulate enough edema to compromise the airway, so breathing complaints should be evaluated as well.

Because a significant smoking history is also a risk factor for vocal fold leukoplakia and malignancy, good visualization of the vocal folds is necessary to evaluate for other lesions in these patients. If benign edema of the vocal folds is truly the only lesion noted, management depends on the degree to which voice quality is disturbing to the patient or the degree to which the airway is narrowed. Smoking cessation can lead to stabilization of pitch at its current level, and phonosurgery to remove excess vocal fold mass can help lead to normalization of pitch and improve the airway. Phonosurgery may be performed with cold instruments or with the pulsed photoangiolytic lasers, an emerging therapy; in either case, there is a risk of creating a vocal fold scar that might limit vocal fold vibration even as vocal fold contours are improved.

Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis (Figure 5) is a benign laryngeal neoplasm that is caused by the human papilloma virus. It is the most common source of hoarseness in children, although adults also may be affected. As the lesions grow on the laryngeal epithelium, they create hoarseness and sometimes effortful voice by disrupting vocal fold vibration, particularly if the lesions are located along the medial edge of either vocal fold. Large and bulky lesions may lead to airway compromise, and advanced disease may spread

Figure 5 Recurrent respiratory papillomatosis, whose presence along each vocal fold medial edge disrupts sound production.

throughout the mucosa of the upper aerodigestive tract rather than being limited to the larynx. Although accurate diagnosis depends on histopathologic analysis, a diagnosis of benign papilloma can be suspected from the characteristic appearance of the vascular fronds, which can be seen under magnified visualization in the office or in the operating room.

Treatment of recurrent respiratory papillomatosis is surgery, which is performed with a carbon dioxide laser, microdebrider, cold instruments, or the emerging technology of pulsed potassium titanyl phosphate (KTP) laser. As its name implies, the condition is recurrent: Even though surgery may reduce or remove the papilloma temporarily, the tissue continues to harbor the papilloma virus, and the disease usually grows back. Because repeated surgeries are expected, the goal of any single procedure is to remove as much disease as possible while limiting surgical scarring of the vocal folds. Scarring created as a result of surgery is cumulative, and over time patients develop persistent dysphonia caused as much by repeated surgeries as by recurrence of the disease. An ability to treat epithelial lesions while limiting scarring at the level of the superficial lamina propria is one main advantage of pulsed laser photoangiolytic; that these pulsed laser procedures can be performed in the office as well as the operating room is another. To help limit the need for repeated surgical procedures, adjunct medical therapies such as interferon and cidofovir are sometimes used for treatment of advanced disease.

Vocal Cord Cancer

In 2008, an estimated 12,250 new cases of laryngeal cancer and 3,670 deaths attributable to laryngeal cancer occurred in the United States. The annual incidence of laryngeal cancer is 6.4 cases per 100,000 for men and 1.3 cases per 100,000 for women. Smoking is the single largest risk factor for laryngeal cancer, and excessive alcohol use has a synergistic effect as a risk factor as well. Survival rates for laryngeal cancer depend on the stage of the tumor at the time of diagnosis, which is a function of tumor size and possible tumor spread to the cervical lymph nodes or distant metastatic sites. Cancers that occur on the medial edge of the vocal fold produce dysphonia while still small, and many laryngeal cancers are diagnosed early.

The dysphonia associated with laryngeal cancer is constant, progressive, and unrelenting, without the intermittent vocal improvement that may occur in inflammatory conditions. The presence of dysphagia, odynophagia, otalgia, hemoptysis, or unexplained weight loss further increases the index of suspicion for malignancy. Cervical lymphadenopathy is associated with advanced tumors. Diagnosis may be suspected on the basis of laryngeal examination and is confirmed with biopsy. The presence or absence of mucosal waves on the involved vocal fold on videostroboscopic examination can help predict the depth of the lesion. Both a CT scan of the neck and chest radiographs are indicated to assess for tumor size and spread. Early cancers are treated with surgery or radiation therapy, with similar cure rates. Emerging technologies such as pulsed photoangiolytic lasers may allow for surgical treatment of early disease with better preservation of surrounding normal tissue. More advanced tumors are usually treated with a combination of radiation therapy and surgery or chemotherapy.

Leukoplakia, or a raised white plaque on the epithelial surface, is a visual marker for the likely presence of dysplasia or carcinoma in situ. As a very early lesion, vocal fold leukoplakia may manifest with mild dysphonia or may be found incidentally on head and neck examination performed for other reasons. This early disease may take many years before progressing to invasive carcinoma, and recognition of leukoplakia presents an opportunity for early treatment to prevent progression of disease. Pulsed laser photoangiolytic has emerged as a state-of-the-art therapy for treatment of this epithelial lesion with preservation of the underlying vocal fold pliability.

Neurologic Disorders and the Voice

Neurologic conditions that affect the voice usually do so by causing poor coordination of vocal fold motion. Spasmodic dysphonia, for

instance, leads to involuntary spasms that bring the vocal folds either tightly together (adductor spasmodic dysphonia) or apart (abductor spasmodic dysphonia) during phonation. These spasms lead to vocal breaks that are strained or breathy, respectively. Although the cause of spasmodic dysphonia is thought to lie within the central nervous system, the gold standard treatment of botulinum toxin is targeted at the end organ. Injection of botulinum toxin (Botox)¹ into appropriate laryngeal muscles can weaken these muscles and diminish the spasm.

Vocal fold tremor is a neurologic disorder that is distinct from spasmodic dysphonia. Its hallmark is tremulous voice quality caused by tremor of the larynx, which may occur both during phonation and at rest. Vocal fold tremor may exist alone or as part of systemic tremor. Botulinum toxin¹ can decrease the amplitude of the tremor but may exacerbate the loss of projection that many tremor patients also have as a complaint. Medications such as anxiolytics or β -blockers that are used to treat systemic tremor may also improve the voice in patients with vocal fold tremor without worsening hypophonia.

Functional Voice Disorders

Functional dysphonia may exist by itself or in combination with an anatomic or neurologic source of dysphonia. The most common form of functional voice disorder is muscle tension dysphonia, which describes inappropriate hyperfunction of the supraglottic muscles. This hyperfunction often occurs in response to another source of hoarseness, as the patient tries to force out a strained voice with improved projection rather than accept the limited voice quality that may accompany the other disorder. The hyperfunction may then become an entrenched habit separate from the original pathology. In this sense, a classic scenario for muscle tension dysphonia is a patient who strains to speak more loudly during an acute laryngitis episode and whose strained, squeezed voice pattern persists even after the acute laryngitis has resolved. Patients with muscle tension dysphonia may complain of odynophonia as tension in the involved supraglottic muscles leads to muscular pain with prolonged speaking. Once other lesions have been evaluated, the treatment of muscle tension dysphonia is expert voice therapy with an emphasis on decreased hyperfunction.

Presbylaryngis

Presbylaryngis is the term that is used to describe the aging voice. It typically manifests in the seventh or eighth decade but can develop earlier. Acoustically, presbylaryngis results in a characteristic thinned voice, often with decreased projection and increased vocal strain. The condition occurs as cumulative voice use leads to traumatic thinning of the superficial lamina propria, particularly at the mid-cord level. This loss of superficial lamina propria leads to deficiency at the medial edge of each vocal fold, and a spindle-shaped defect in glottal closure may be noticed with close evaluation. Many patients with a complaint of presbylaryngis find that appropriate voice therapy to address breath support and vocal projection leads to satisfactory improvement in the voice without altering the vocal fold anatomy. For those patients who remain unsatisfied with their voice after therapy, vocal fold medialization procedures can restore straight vocal cord edges and may lead to improved projection; however, currently available injectables and implants that address contour defects cannot restore pliability.

Conclusion

Understanding the anatomy and physiology of normal voice production provides a framework through which dysphonia can be evaluated. Application of this knowledge during the history and physical examination guides the diagnosis of hoarseness and allows clinicians to distinguish among conditions as varied as acute laryngitis, benign phonotraumatic lesions, vocal fold paralysis, and laryngeal cancer as part of a differential diagnosis. Videostrobolaryngoscopy allows evaluation of vocal fold function as well as structure and can confirm

diagnosis. As with any condition, accurate diagnosis directs appropriate therapy. Because no further evaluation or management is necessary for acute viral laryngitis, many patients with hoarseness require no more than a careful history and physical examination. However, if dysphonia persists for longer than 2 weeks or is accompanied by other laryngopharyngeal symptoms that are not thought to be related to an upper respiratory tract infection, referral should be made to an otolaryngologist for further evaluation.

PAIN

Method of

Steven A. House, MD

CURRENT DIAGNOSIS

- Always use history and physical examination and consider imaging or laboratory studies to rule out life- or function-threatening pathologies before merely providing symptomatic treatment.

Acute Pain

- Acute pain has a sudden onset, is usually nociceptive (somatic, visceral) in nature, and likely is due to apparent injury or medical condition.
- It can last up to 3 months and can demonstrate hypersympathetic signs of tachycardia, elevated blood pressure, dilated pupils, or diaphoresis.

Chronic Pain

- Chronic pain is usually gradual in onset, lasts more than 3 months, and rarely serves any purpose. It can manifest with hyperalgesia (hurts more than it should) or allodynia (hurts when it should not, e.g., light touch).
- Vegetative symptoms such as depression, fatigue, or anorexia may be present.
- A significant neuropathic component may be present.
- Psychiatric and social or socioeconomic issues may be exacerbating factors.
- Examples can include headaches, low back pain, osteoarthritis, and fibromyalgia.
- While opioids might be appropriate for some conditions / situations, in general they are proving to be neither as safe nor as effective for chronic, non-cancer pain as had been believed.

Quality

- Quality of the pain (e.g., sharp, dull, radiating, deep, superficial, lancinating, tingling, burning) is an important factor in determining the best management modalities.
- Quality plays a role in ruling in or ruling out severe disease that can require urgent surgical or other interventions rather than analgesics or adjunctive medications or therapies.

Severity

- Severity of the pain can be rated on a variety of scales such as numerical (0–5, 0–10), analogue (marked on a line with a range

¹Not FDA approved for this indication.

instance, leads to involuntary spasms that bring the vocal folds either tightly together (adductor spasmodic dysphonia) or apart (abductor spasmodic dysphonia) during phonation. These spasms lead to vocal breaks that are strained or breathy, respectively. Although the cause of spasmodic dysphonia is thought to lie within the central nervous system, the gold standard treatment of botulinum toxin is targeted at the end organ. Injection of botulinum toxin (Botox)¹ into appropriate laryngeal muscles can weaken these muscles and diminish the spasm.

Vocal fold tremor is a neurologic disorder that is distinct from spasmodic dysphonia. Its hallmark is tremulous voice quality caused by tremor of the larynx, which may occur both during phonation and at rest. Vocal fold tremor may exist alone or as part of systemic tremor. Botulinum toxin¹ can decrease the amplitude of the tremor but may exacerbate the loss of projection that many tremor patients also have as a complaint. Medications such as anxiolytics or β -blockers that are used to treat systemic tremor may also improve the voice in patients with vocal fold tremor without worsening hypophonia.

Functional Voice Disorders

Functional dysphonia may exist by itself or in combination with an anatomic or neurologic source of dysphonia. The most common form of functional voice disorder is muscle tension dysphonia, which describes inappropriate hyperfunction of the supraglottic muscles. This hyperfunction often occurs in response to another source of hoarseness, as the patient tries to force out a strained voice with improved projection rather than accept the limited voice quality that may accompany the other disorder. The hyperfunction may then become an entrenched habit separate from the original pathology. In this sense, a classic scenario for muscle tension dysphonia is a patient who strains to speak more loudly during an acute laryngitis episode and whose strained, squeezed voice pattern persists even after the acute laryngitis has resolved. Patients with muscle tension dysphonia may complain of odynophonia as tension in the involved supraglottic muscles leads to muscular pain with prolonged speaking. Once other lesions have been evaluated, the treatment of muscle tension dysphonia is expert voice therapy with an emphasis on decreased hyperfunction.

Presbylaryngis

Presbylaryngis is the term that is used to describe the aging voice. It typically manifests in the seventh or eighth decade but can develop earlier. Acoustically, presbylaryngis results in a characteristic thinned voice, often with decreased projection and increased vocal strain. The condition occurs as cumulative voice use leads to traumatic thinning of the superficial lamina propria, particularly at the mid-cord level. This loss of superficial lamina propria leads to deficiency at the medial edge of each vocal fold, and a spindle-shaped defect in glottal closure may be noticed with close evaluation. Many patients with a complaint of presbylaryngis find that appropriate voice therapy to address breath support and vocal projection leads to satisfactory improvement in the voice without altering the vocal fold anatomy. For those patients who remain unsatisfied with their voice after therapy, vocal fold medialization procedures can restore straight vocal cord edges and may lead to improved projection; however, currently available injectables and implants that address contour defects cannot restore pliability.

Conclusion

Understanding the anatomy and physiology of normal voice production provides a framework through which dysphonia can be evaluated. Application of this knowledge during the history and physical examination guides the diagnosis of hoarseness and allows clinicians to distinguish among conditions as varied as acute laryngitis, benign phonotraumatic lesions, vocal fold paralysis, and laryngeal cancer as part of a differential diagnosis. Videostrobolaryngoscopy allows evaluation of vocal fold function as well as structure and can confirm

diagnosis. As with any condition, accurate diagnosis directs appropriate therapy. Because no further evaluation or management is necessary for acute viral laryngitis, many patients with hoarseness require no more than a careful history and physical examination. However, if dysphonia persists for longer than 2 weeks or is accompanied by other laryngopharyngeal symptoms that are not thought to be related to an upper respiratory tract infection, referral should be made to an otolaryngologist for further evaluation.

PAIN

Method of

Steven A. House, MD

CURRENT DIAGNOSIS

- Always use history and physical examination and consider imaging or laboratory studies to rule out life- or function-threatening pathologies before merely providing symptomatic treatment.

Acute Pain

- Acute pain has a sudden onset, is usually nociceptive (somatic, visceral) in nature, and likely is due to apparent injury or medical condition.
- It can last up to 3 months and can demonstrate hypersympathetic signs of tachycardia, elevated blood pressure, dilated pupils, or diaphoresis.

Chronic Pain

- Chronic pain is usually gradual in onset, lasts more than 3 months, and rarely serves any purpose. It can manifest with hyperalgesia (hurts more than it should) or allodynia (hurts when it should not, e.g., light touch).
- Vegetative symptoms such as depression, fatigue, or anorexia may be present.
- A significant neuropathic component may be present.
- Psychiatric and social or socioeconomic issues may be exacerbating factors.
- Examples can include headaches, low back pain, osteoarthritis, and fibromyalgia.
- While opioids might be appropriate for some conditions / situations, in general they are proving to be neither as safe nor as effective for chronic, non-cancer pain as had been believed.

Quality

- Quality of the pain (e.g., sharp, dull, radiating, deep, superficial, lancinating, tingling, burning) is an important factor in determining the best management modalities.
- Quality plays a role in ruling in or ruling out severe disease that can require urgent surgical or other interventions rather than analgesics or adjunctive medications or therapies.

Severity

- Severity of the pain can be rated on a variety of scales such as numerical (0–5, 0–10), analogue (marked on a line with a range

¹Not FDA approved for this indication.

from no pain to the worst possible pain), or facial expression (smiles to grimaces, available for children and the elderly or patients with dementia).

- Functional scales (fully satisfactory function to debilitated) may be more helpful in determining the impact of the pain on the person's life.

CURRENT THERAPY

- Acute pain commonly responds to simple analgesics of the nonopioid, opioid, or combination varieties. Rest, ice, compression, and elevation (RICE) are helpful for acute inflammatory conditions and injuries.
- Chronic pain, because of its complexity, often requires multiple modalities. Pharmacologic options include nonopioid, opioid, adjuvant, or homeopathic medications. Nonpharmacologic options include physical therapy, chiropractic care, transcutaneous electrical nerve stimulation (TENS) unit, acupuncture, or surgical or anesthesia interventions.
- Adjuvant medications are drugs that are used for pain but do not have pain treatment as their primary indication, and they are often the most effective agents in neuropathic and/or chronic pain.
- Opioids are sometimes safer for long-term use, but the individual's risk for falls must be considered in the elderly, as opioids can increase this risk, and the risks of overdose and other adverse effects rise with increasing age and duration of exposure. For many chronic conditions such as low back pain, the evidence supporting the use of opioids is lacking, with efficacy often superseded by nonopioid medications. The risk of addiction MUST be considered before starting opioids on any patient. Since 1999, opioid overdose deaths as a proportion of all deaths has increased by 265% in men and 400% in women. Over 40% of opioid overdose deaths in the U.S. in 2016 involved prescription opioids, and the rates were highest in the 25–54-year-old age range. According to the CDC, nearly 2 million Americans above the age of 12 years abused or were dependent on opioids in 2014.
- NSAIDs carry a risk for GI and cardiac complications, especially in the elderly and those with a history of CAD or GI ulcers or gastritis.
- The patient *must* be involved in and cooperative with the treatment plan. Honesty and trust are necessary components of a therapeutic physician–patient relationship.
- Do not underestimate the placebo effect. If the patient feels that a harmless treatment is beneficial, take advantage of it.
- If the patient is not improving adequately, consult a surgeon if the source of pain is an operable condition, or consult a pain specialist if surgical intervention is not appropriate.

Epidemiology

Although estimates vary, approximately 50 million Americans experience chronic pain and incur costs and overall economic impact estimated as high as \$635 billion per year. Pain is the most common symptom that causes patients to pursue medical evaluation and management. The prevalence of several common pain syndromes including headaches, facial pain, abdominal pain, pelvic pain, and low back pain is slightly higher in women than in men because there are gender variations in the perception, coping, and reporting of pain. Pain tends to be undertreated in women, people of color, children, and the elderly, and it is underreported in nonverbal or cognitively impaired children and adults.

Risk Factors

Traumatic injury is a cause of acute pain and a risk factor for chronic pain. Patients who have mastectomy, laminectomy, thoracotomy, or amputations are at risk for pain syndromes. Chronic

musculoskeletal conditions such as arthritis, spinal stenosis, degenerative disk disease, or fibromyalgia; infectious diseases including HIV or varicella zoster; neuropathies from diagnoses such as diabetes, B₁₂ deficiency, or multiple sclerosis; treatment with certain chemotherapies or isoniazid (INH) without adequate vitamin B₆; psychiatric disorders such as depression, anxiety, or posttraumatic stress disorder (PTSD), especially as a consequence of domestic violence; or autoimmune disorders including lupus and rheumatoid arthritis can predispose the individual to chronic pain. Although the risk of pain increases with age, pain should not be considered a usual part of aging until it is appropriately evaluated. A motor vehicle accident or work-related injury or other condition where secondary gain is a possibility, especially if there is no apparent injury, raises the consideration of malingering.

Pathophysiology

Injury or potential injury is detected by nociceptors in the peripheral nervous system, and the signal is then transmitted through the dorsal horn of the spinal cord up to the brain for processing. The three primary classes of opioid receptors are the mu, kappa, and delta receptors, and they are located in areas throughout the central and peripheral nervous system. Upon binding these receptors, opioids block calcium channels and modulate the nociceptive pathways. The hyperstimulation of chronic pain (often via the NMDA receptor) and the resultant increase in intracellular calcium are neurotoxic due to lowering neuronal firing threshold and increasing firing frequency. This neurotoxicity can lead to ongoing pain in the absence of physical insult. Neuropathic pain can result from chronic pain or from physical or pathophysiologic injury or changes to the nerve, as in diabetic neuropathy or other neuropathies.

Prevention

The best prevention is a safe and healthy lifestyle. The combination of healthy diet and exercise has been demonstrated to improve pain in osteoarthritis better than either intervention alone, and maintaining a healthy weight can help prevent the arthritis in the first place. Smoking and obesity (odds ratio increasing with BMI) have been associated with chronic pain. Regarding safety, wearing seat belts while driving or using appropriate safety equipment at work and during recreational activities can help reduce the severity of injuries should they occur. Proper body mechanics are important as well.

Clinical Manifestations

Manifestations of pain depend on the location and underlying cause. In the acute setting, the patient can have tachycardia, elevated blood pressure, or diaphoresis, whereas chronic pain can manifest with vegetative symptoms of depression, fatigue, anorexia, or insomnia.

Diagnosis

Pain is most commonly a symptom rather than a disease in and of itself, so it behooves the provider to pursue treatable causes, especially red flag conditions, in addition to providing symptomatic treatment. The history regarding onset (shorter or longer than 3 months), exacerbating or remitting factors, quality, radiation, severity, and timing of the pain (constant vs. intermittent), in addition to any associated signs or symptoms such as fever, nausea, vomiting, or diarrhea, can help the provider in that regard. The physical examination is a key component in ruling out life- or function-threatening disorders. Is there tenderness, swelling, bruising, erythema, or deformity? Are strength, reflexes, and sensation intact? Does the patient demonstrate a consistent demeanor (grimace or other signs of pain) and gait (antalgic vs. normal) when moving from the waiting area to the examination room and out to the parking lot? The choice to use laboratory studies or imaging is determined by the location of the pain and the structures or organs that might be in that area. When determining severity, “What does the pain keep you from doing?” (which uses function as the measure of impairment and treatment efficacy rather than a

subjective pain score to guide therapy) may be a much more helpful question than “How bad is your pain?” If function is not improving, that could be considered a treatment failure, and medications and therapy should be adjusted rather than continuing the same regimen.

Differential Diagnosis

The differential diagnosis for all types of pain is far too extensive for the brevity of this chapter, but in addition to the plethora of physical diagnoses to be considered, the provider has to consider that chronic fatigue, depression, and domestic abuse can manifest as a chronic pain syndrome.

Treatment

Nonpharmacologic

Physical therapy (for chronic pain. For recent-onset low back pain, relief was statistically but not clinically significant as compared to usual care.), TENS units, chiropractic care, and regular exercise have shown benefit in certain conditions. Cognitive behavioral therapy and mindfulness training improve function more than pain, and CBT, acupuncture, and mind-body therapies (e.g., yoga, tai chi, mindfulness-based stress reduction, etc.) provide safer options that may be both beneficial and cost-effective. Surgery may be required, and interventions such as nerve blocks or epidural injections may also be of benefit. Kyphoplasty and vertebroplasty have fallen out of favor. Aerobic exercise and water therapy are helpful for fibromyalgia, but the patient must not overexert because this can exacerbate the pain.

Pharmacologic

Nonopioid Analgesics

Acetaminophen (Tylenol) is generally a safe and effective medication as long as the total daily dose for adults remains less than 3 g/day. For osteoarthritis of the hips and knees, acetaminophen provides

modest short-term benefit, and it is not generally effective for the management of low back pain. However, due to its relative safety as compared to other medications, it is certainly worth a try. Chronic use can increase the likelihood of transaminase elevations fourfold, so this is a consideration when patients are using other potentially hepatotoxic medications. There is an IV preparation available, but the only benefit of the IV over the oral preparations is shorter onset of action. Both the absorption and the action of acetaminophen are augmented by caffeine, so caffeine is utilized in multiple OTC and prescription medications, e.g., Excedrin or Fioricet.

Numerous NSAIDs are available, but none has been shown to be superior to another except for the convenience of dosing daily versus every 6 hours. All are generally safe in the acute setting but should be used with caution if needed long term, and they should be avoided altogether for long-term use in the elderly or patients with cardiovascular, renal, or peptic ulcer disease. This caution includes the cyclooxygenase (COX)-2-specific drugs. Naproxen seems to have the best cardiac profile while the COX-2 drugs tend to have the best GI profile. Misoprostol (Cytotec) or proton pump inhibitors can be used for GI prophylaxis.

Topical agents such as diclofenac (Flector 1.3% Patch, Voltaren 1% Gel), menthol, camphor, lidocaine, and capsaicin (Zostrix Cream, Qutenza 8% Patch) are effective in some patients.

Opioids (see Table 1)

For patients with inadequate response to the non-opioid analgesics, opioids are an option (Table 1). However, the proven efficacy for cancer pain and palliative care as well as some acute pain conditions cannot be extrapolated to chronic pain syndromes. The benefits of opioids in some conditions, e.g., chronic low back pain, and the overall safety of opioids have been called into question due to the dramatic increase in opioid abuse and opioid overdose deaths. Recent research has demonstrated a two-fold to threefold increase in all-cause mortality with chronic

TABLE 1 Opioid Analgesics

OPIOID	ADMINISTRATION		PROPERTIES
	PARENTERAL	ORAL	
Buprenorphine			
Butrans transdermal patch: 5, 10, 20 µg/h weekly patches Subutex* SL tab and film: 2, 8 mg Buprenex injection: 0.3 mg/mL	0.3 mg (IV) Patch: MED < 30 mg/day = 5 µg/h patch 30–80 mg/day = 10 µg/h patch; > 80 mg/day: do not use	Oral buprenorphine, with or without naloxone (Suboxone, Subutex) is limited to treatment of opiate addiction Requires training, approval, and new DEA number	Partial agonist Can cause QT prolongation C-III
Codeine			
Tablet: 15, 30, 60 mg Oral solution: 15 mg/5 mL	130 mg	180 mg	Prodrug converted by liver to morphine About 10% of population cannot convert, and some are rapid metabolizers, resulting in increased levels of morphine Ceiling dose is 60 mg/dose
Fentanyl			
Duragesic 72 h patch: 12.5, 25, 50, 75, 100 µg/h	~ 100 µg/h	—	Patch for those who cannot swallow Patient <i>must</i> have subcutaneous fat, because drug is lipophilic
Actiq or Oralet lozenge: 200, 400, 600, 800, 1200, 1600 µg Fentora buccal tab or Abstral SL tab: 100, 200, 300, 400, 600, 800 µg Subsys sublingual spray: 100, 200, 400, 600, 800 µg/spray.	No conversion for lozenges or buccal tabs; various formulations are not bioequivalent, so use caution when switching from one formulation to another; <i>must</i> start at lowest dose and titrate	~ ½ × daily morphine dose, disregarding units, e.g., 200 mg morphine PO/day = 100 µg/h patch	Lozenge or buccal tab for transmucosal use No cheap forms available Buccal formulations <i>only</i> indicated for breakthrough cancer pain in the opioid tolerant; can be rapidly fatal in opioid naïve patients.

opioid use, especially if using more than 200 mg/day morphine equivalent dose (MED) and/or sustained-release or long-acting (methadone) preparations. Additionally, risk of overdose death is increased to 3.7 to 4.6-fold at doses of 50–100 mg/day MED and as high as 9-fold increased risk for MED > 100 mg/day as compared to MED of less than 20 mg/day. After exceeding 200 mg/day MED, 1 in 32 dies. These risks are further escalated by co-administration of benzodiazepines or gabapentinoids. A prescription for naltrexone should be considered if the patient is using > 50 mg MED per day, and it is highly recommended if using > 100 mg MED per day. A useful calculator to calculate MED can be found at <http://www.agencymeddirectors.wa.gov/calculator/dosecalculator.htm>

According to the CDC, opioids were implicated in 71% of the pharmaceutical overdose deaths in 2013, and 60% were legally prescribed by a single provider. Opioids might be a safer option in the elderly as compared to NSAIDs, but they can increase fall risk. They should be avoided in patients with untreated sleep apnea because of increased risk for complications, especially in combination with benzodiazepines. This risk increases with age with as much as an eightfold increase for those older than 80 years of age. The risk of postoperative respiratory depression also increases with age. The risks of using chronic opioids likely outweigh the benefits in the management of headache, fibromyalgia, and chronic low back pain, according to a 2014 position paper from the American Academy of Neurology.

The risks and the adverse outcomes (abuse, addiction, overdose, and death) related to this class of medications culminated in the release of guidelines with twelve recommendations from the CDC in March 2016 for the prescribing of opioids for chronic pain. A brief summary of the author's recommendations: 1) Nonpharmacologic therapy and nonopioids are preferred for chronic pain. 2) Benefits of opioids on pain and function need to outweigh the risks. Screen for risk of dependence. 3) Establish treatment goals with the patient and discuss plan to discontinue opioids if treatment fails. 4) On initiation, use immediate release rather than ER/LA (extended release, long-acting) preparations. 5) Use the lowest effective dose, and reassess risks if dose is increased, especially if greater than 50 mg MED (morphine equivalent dose) per day. [See Table 1 for equivalent doses.]. 6) Acute pain should be treated acutely; less than 3 days usually but no more than 7 days. 7) Reassess within 1 to 4 weeks of initiation of treatment or dose escalation and at least every 3 months thereafter. Discontinue if benefits do not justify risk. 8) Consider prescribing naloxone

if there is concurrent benzodiazepine use, a history of overdose, or MED > 50 mg/day. 9) Use state drug monitoring programs at initiation and at least every 3 months. 10) Obtain a urine drug screen at initiation and at least annually. The prescribed medications and nothing else should be present. (Additionally, consider testing periodically for the presence of prescribed NSAIDs and adjunct medications to assess compliance with the whole treatment plan rather than just the opioid.). 11) Avoid concurrent with benzodiazepines. 12) Offer or arrange evidence-based treatment for patients with opioid use disorder.

In addition to these steps, multiple drugs have been formulated with “abuse-deterrent” properties. Preparations that meet the FDA's Guidance for Industry regarding abuse-deterrent opioids include: OxyContin (oxycodone), Targiniq ER (oxycodone/naloxone), Embeda (morphine / naltrexone), Hysingla ER (hydrocodone), MorphaBond ER (morphine), Xtampza ER (oxycodone), Troxyca ER (oxycodone / naltrexone), Arymo ER (morphine), Vantrela ER (hydrocodone), and RoxyBond (oxycodone). Unfortunately, there are no generic opioids with FDA-approved abuse-deterrent labeling.

Tramadol (Ultram, ConZip) is a weak mu agonist and an inhibitor of norepinephrine and serotonin uptake, a quality that gives it a niche in the treatment of neuropathic and radicular pain.¹ It is the only opioid studied for fibromyalgia in a randomized trial. A recent study has demonstrated an increased risk for hypoglycemia, notably in the first 30 days of treatment with tramadol.

Codeine is a prodrug that has to be converted to morphine to be effective, and about 10% of the population lacks the cytochrome P450 2D6 enzyme that makes the conversion, resulting in poor analgesic response. Owing to the need for conversion, doses exceeding 60 mg do not increase benefit because the enzyme system is saturated. Avoid prescribing codeine to children, as deaths have been reported, even with the use of age- and weight-appropriate dosages, as a result of the hypermetabolism of codeine to morphine.

Morphine is the prototype for the opioids. It is extremely versatile, it can be given via almost any route, and it is available in multiple dosages and preparations ranging from liquid to daily sustained release. Hydromorphone (Dilaudid, Exalgo) shares similar qualities but is more potent. Hydrocodone is only available in a sustained-release oral form (Zohydro ER, Hysingla ER), and in

¹Not FDA approved for this indication.

TABLE 2 Morphine and Methadone Equivalents

MORPHINE (DAILY REQUIREMENT)	METHADONE EQUIVALENT
<500 mg	5:1
500–1000 mg	10:1
>1000 mg	20:1

Acute pain: methadone = morphine (1:1). Chronic pain: The above conversion is for illustration of the complexity of methadone use. A more detailed table should be referenced before prescribing, and methadone should be used with extreme caution because of the risk for cardiac complications and respiratory depression.

combination with acetaminophen (Lortab, Norco, Vicodin). It was rescheduled by the DEA to schedule II in 2014. It had been the number-one prescribed medication in the US for several years until the rescheduling, which led to >20% reduction in prescriptions and >16% reduction in tablets dispensed.

Methadone (Dolophine) is the longest acting of the opioids at a half-life of 23 hours, although the duration of action can be variable. It is active as an *N*-methyl-D-aspartate (NMDA) receptor antagonist, inhibits norepinephrine and serotonin uptake, and is an agonist at the mu receptor. Therefore, methadone can be effective when other opioids fail, especially in the case of chronic or neuropathic pain, where the NMDA-receptor is more of a factor in pain control. It must be used with caution (Table 2) because it can prolong the QT interval and has an increased dose-dependent risk of respiratory depression as compared to other opioids.

Meperidine (Demerol) is relatively weak compared to morphine and others, and it is limited by poor oral bioavailability, a 48-hour acute pain indication, and the neurotoxicity of one of its metabolites, normeperidine (renally cleared, so it is contraindicated in renal patients). Other opioids are safer and more effective, so its use should be limited.

The mu agonists do not technically have a ceiling dose; however, the dose should be limited to the lowest effective dose. In the purely palliative or hospice patient, the dosage may be titrated to effect until the pain is relieved or side effects limit the dosage.

The mixed agonist-antagonists such as nalbuphine (Nubain), pentazocine (Talwin), and butorphanol (Stadol) tend to have a higher incidence of hallucination and confusion, and because they are agonists at kappa and delta receptors and antagonists at the mu receptor, they can produce withdrawal symptoms in patients who are routinely taking mu agonists. The partial agonist buprenorphine (Butrans patch, Subutex¹, Buprenex) is dose limited because it has a maximal effective dose as well as a potential to cause QT prolongation.

Patients who are taking opioids on a chronic basis should use a stimulant laxative such as senna with or without docusate, because fiber and dietary modification are usually inadequate for opioid-induced constipation, and fiber can aggravate the problem. Lubiprostone (Amitiza) can be used for opioid-induced constipation at the 24 mcg twice-daily dose. Naloxegol (Movantik), naldemedine (Symproic), and methylnaltrexone (Relistor) are peripheral rather than central mu antagonists, so they are indicated for managing opioid-induced constipation without negatively impacting pain control. Bisacodyl should not be used chronically due to its potential to damage the myenteric plexus of the gut and cause severe and permanent impairment of colonic motility.

Adjuvant Drugs

Adjuvant medications are drugs that are useful in the management of pain but do not have pain treatment as an indication. Some adjuvant medications such as duloxetine (Cymbalta) and pregabalin (Lyrica) have received an FDA indication for diabetic peripheral neuropathic pain. Tricyclic antidepressants are useful for chronic pain and they have the benefit, unlike duloxetine, of working at the lowest doses rather than having to titrate to the maximum dose to gain benefit.

Several anticonvulsants have demonstrated efficacy in the management of pain, most notably gabapentin (Neurontin)¹, pregabalin (Lyrica), and carbamazepine (Tegretol)¹. Others have been tested in trials, but these three have the most evidence to support their use. Gabapentin and pregabalin have the benefit of not requiring monitoring of blood levels or for marrow, liver, or renal toxicities. Gabapentin (Neurontin)¹ has been beneficial using a single dose of 1200 mg preoperatively, notably in combination with celecoxib (Celebrex)¹, in reducing postoperative opioid requirements in mastectomy, laminectomy, and thoracotomy patients. The benefits of the gabapentinoids, a.k.a., α -2- δ -ligand calcium channel blockers, in peripheral neuropathies have been inappropriately extrapolated to pain related to radiculopathy. Benefits in lumbar and cervical radiculopathy have not been successfully demonstrated in randomized trials.

Corticosteroids can be beneficial in inflammatory conditions, nerve or spinal cord compression, or increased intracranial pressure due to neoplasms. Any can help, but blood pressure elevations and fluid retention can be problematic in all but dexamethasone (Decadron)¹, which lacks mineralocorticoid activity. Steroids also have the downside of elevating blood glucose and, in long-term use, causing osteoporosis.

Muscle relaxants may be beneficial if muscle spasm is a source of pain, but there is insufficient evidence to determine relative efficacy or safety. Of these, two stand out: metaxalone (Skelaxin), which lacks the black-box warning for the operation of heavy equipment; and tizanidine (Zanaflex), which can antagonize α_1 receptors in the spinal cord to provide additional pain relief. In chronic use, the patient will need to be monitored for anemia and leukopenia with metaxalone and for liver abnormalities with tizanidine. Cyclobenzaprine (Flexeril) plus naproxen was not superior to naproxen alone for low back pain.

Calcitonin (Miacalcin)¹ has shown very modest benefit for pain due to osteoporotic vertebral compression fractures, but it shows no benefit for compression fractures due to bone metastasis.

Ziconotide (Prialt) has demonstrated benefit as well as safety for long-term pain management, but it is limited to only intrathecal use owing to gastrointestinal side effects.

Caffeine can modulate pain via action upon adenosine receptors that are involved in nociception. It is found in several over-the-counter analgesics, notably for migraine treatment. Regarding alternative medications, riboflavin⁷, butterbur⁷, and coenzyme Q10 (CoQ10)⁷ are effective for migraine prophylaxis. Glucosamine⁷, S-adenosylmethionine (SAM-e)⁷, methylsulfonylmethane (MSM)⁷, and willow bark⁷ are likely effective for arthritic and low-back pain.

Acetyl-L-carnitine (ALC)¹ had demonstrated efficacy in diabetic neuropathy at 2–3 gm/day. Capsaicin 0.075% cream (Zostrix) and 8% patch (Qutenza) have demonstrated benefit for peripheral neuropathy¹, post-herpetic neuralgia, and HIV-associated neuropathy¹.

Numerous medications in multiple drug classes have been studied for fibromyalgia, but many of the trials are small and/or of poor quality. Of these drugs, duloxetine (Cymbalta), pregabalin (Lyrica) and milnacipran (Savella) have received an FDA indication for fibromyalgia; and gabapentin (Neurontin)¹, ondansetron (Zofran)¹, and naltrexone (Depade, ReVia)¹ demonstrated modest benefit. The greatest benefit seems to be achieved by duloxetine and tricyclic antidepressants.

The use of cannabinoids has become legal in some states; however, their use for the management of pain is somewhat controversial as the studies evaluating these drugs are often of low to modest quality. A 2015 systematic review and meta-analysis showed mild reductions in pain, but the comparison groups were placebo rather than standard care. Additionally, cannabinoids are not without adverse effects, including impacts on cognition, motivation,

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

reaction time, and psychosis in a 2016 review. Negative impacts could be even greater as unintended consequences of medical and/or recreational use come to light. Isolation of the various compounds such as cannabidiol and β -caryophyllene from others like Δ 9-tetrahydrocannabinol (THC) could improve benefit, including oral administration, while limiting adverse physical and psychological effects.

Monitoring

Controlled-substance agreements are beneficial in setting the boundaries for the use of opioid pain relievers (Figure 1). Routine visits are necessary to document ongoing need for and adequate response to the prescribed regimen. Routine drug screening is beneficial for monitoring compliance with the opioid as well as nonopioid medications. However, the provider needs to be aware of the

Controlled Substances Agreement Template

1. This agreement is provided to prevent misunderstandings about policies regarding medications designated by the DEA as "controlled substances" that you will be taking for pain management or other medical conditions.
2. I understand that my provider is consenting to treat me based on this Agreement.
3. I understand that if I break this Agreement, my provider might stop prescribing these medications, whether by tapering my medication, discontinuing the medication and prescribing another medication to treat the withdrawal symptoms, or discontinuing the medication and referring me to a detoxification program.
4. I will communicate fully and honestly with my provider about the character and intensity of my pain, the effect that my pain has on my daily life and how well the medication is helping to relieve my pain. I will take the medication ONLY as prescribed and for the treatment of my physical pain as opposed to emotional or psychological distress (i.e., to get high).
5. My physician may prescribe other medications (adjuvant medications) or non-pharmacological therapies (physical therapy, TENS unit, etc.) to help with certain aspects of pain such as muscle spasm, burning, tingling or radiating pain. I will comply with this treatment with the same diligence as is expected for my controlled medication.
6. I will not use ANY illegal substances or any legal medication not prescribed to me. Additionally, I understand that alcohol, although legal, should not be used in conjunction with my medication as the combination could be fatal.
7. I will not share, sell or trade my medications with anyone.
8. I will use only one provider and one pharmacy for my medications unless otherwise agreed upon with my provider.
9. I am responsible for my own prescriptions and medications. I will safeguard my written prescription and medications from loss or theft, understanding they will not be replaced. I will secure my medication in a lock box or safe out of the reach of children at all times.
10. I understand that refills of my prescriptions will be made at the time of an office visit or during regular office hours and never during evenings or weekends when the office is closed.
11. I authorize my provider and my pharmacy to cooperate fully with any city, state and/or federal law enforcement agency in the investigation of any possible misuse, sale or other diversion of my medications.
12. I agree to submit to a blood or urine test, if requested by my provider, in order to determine my compliance with my medication program.
13. I understand that the use of these medications may adversely affect my ability to drive, operate machinery or perform certain tasks, and I agree not to attempt these tasks under the influence of medication. Additional risks include low testosterone, depression, sleep disturbances, constipation, respiratory depression, and death.
14. I understand that smoking cessation and a healthy lifestyle can be helpful in achieving control of pain. I will strive toward smoking cessation, a healthy diet, and exercise as my condition allows.
15. I agree to these guidelines, and they have been fully explained to me. All of my questions and concerns regarding treatment have been adequately answered.

I agree to use _____ pharmacy, *and only this pharmacy*, for my prescriptions for controlled substances.

This Agreement entered on this date: _____

Patient / Parent / Guardian signature: _____

Provider signature: _____

Figure 1 Controlled substances agreement.

metabolites of the different drugs. Hydromorphone (Dilaudid) and oxycodone (Opana) are metabolites of hydrocodone (Lortab, Norco) and oxycodone (Percocet, Endocet, OxyContin), respectively. All states except Missouri have prescription-monitoring programs that allow providers to monitor for the use of multiple providers and pharmacies to obtain controlled medications. Rules governing the prescribing and use of controlled substances vary among states, so the provider should be knowledgeable of local regulations as well as federal DEA requirements.

Complications

The Centers for Disease Control and Prevention (CDC) reported in 2011 that opioid pain relievers were involved in 73.8% of the 20,044 prescription drug overdose deaths, and this is believed to be an underestimate. Overdose death rates were three times greater in non-Hispanic whites and in American Indians and Alaska Natives than in blacks and Hispanic whites. The death rates were highest in the 35- to 54-years age range, producing a YPLL (years of potential life lost) comparable to that of motor vehicle accidents. Medicaid populations are at greater risk of opioid overdose than non-Medicaid populations, and prescription drug overdose death rates are higher in the more rural and impoverished counties.

In addition to the deaths, there is a significant cost burden of substance abuse treatment admissions, with the 2008 rates being six times the 1999 rate. Nonmedical use of opioids represents up to \$72.5 billion in health care costs. By 2010, opioids were sold in such a volume that every American adult could be treated for a month with hydrocodone 5 mg every 4 hours. Incidentally, 1999 is the year that several organizations began promoting “pain as the fifth vital sign,” with no secondary improvement in the quality of pain management. Drug addiction is very real, and about 15% of patients may be genetically predisposed to addiction; therefore clinicians should strongly consider this in their risk/benefit analysis before exposing a patient to these powerful medications. Using a tool such as the Opioid Risk Tool may be helpful in determining the risk of addiction in a particular individual.

Long-term safety of opioids has not been demonstrated, and chronic use has been associated with sleep disorders, adrenal suppression, and hypogonadism (and secondary erectile dysfunction and depression) among other problems.

PALLIATIVE AND END-OF-LIFE CARE

Method of

Steven A. House, MD

CURRENT DIAGNOSIS

- Any symptom can be in the realm of palliative care. Rapid identification and aggressive management of symptoms are important in maintaining the patient's quality of life.
- Palliative care is treatment that is focused on pain and symptom management as well as quality of life for patients and their families. It can be rendered at any point in the course or treatment of illness, whether that illness is life-limiting/threatening or not.
- Hospice is a philosophy and method of care that is completely focused on symptom management, quality of life for patients and families, and the transition at the end of life.

CURRENT THERAPY

- Recommend that all adult patients, regardless of current health status, execute advance directives (Living Will, Power of Attorney for Healthcare, Healthcare Surrogate, etc.) to help ensure that their treatment wishes and end-of-life care goals are met.
- For patients with life-threatening (e.g., progressing cancer) or life-limiting (e.g., patients with severe chronic obstructive pulmonary disease [COPD] or heart failure, requiring dialysis, or residing in a nursing home) illness, consider a Physician Order for Life-Sustaining Treatment (POLST) or Medical Order for Scope of Treatment (MOST) form (the name varies by state). These forms are used to convert the salient points of advance directives into medical orders so that they are immediately actionable by nurses or emergency medical services if the situation arises.
- Advance Care Planning discussions are billable under Medicare: 99497 for the first 30 minutes and 99498 for each additional 30 minutes.
- The best palliative care involves an interdisciplinary approach by physicians, nurses, counselors, chaplains, and others for the optimal management of symptoms (whether the suffering is physical, emotional, spiritual, existential, or practical) and family support.
- Early addition of palliative care to the overall treatment plan can improve survival and quality of life.
- Cancer pain is an indication for opioid therapy as opioids have proven efficacy in this scenario. For detailed information on opioids, please see Table 1 in the chapter in Section 1 on pain. Multiple modalities may be required for optimal pain control.
- For patients using opioids chronically, initiate a stimulant laxative like sennosides (Senokot, Ex-Lax) or lubiprostone (Amitiza) as the opioid's companion. Peripheral mu antagonists like methylnaltrexone (Relistor) or naloxegol (Movantik) are indicated for refractory opioid-induced constipation.
- Control nausea, as it can contribute to anorexia, weight loss, and functional decline. The antiseroenergic drugs, e.g., ondansetron (Zofran), granisetron (Kytril), palonosetron (Aloxi), or the combination netupitant/palonosetron (Akynzeo) are superior to the other classes of antiemetics in the settings of chemotherapy administration and postanesthesia. For

metabolites of the different drugs. Hydromorphone (Dilaudid) and oxycodone (Opana) are metabolites of hydrocodone (Lortab, Norco) and oxycodone (Percocet, Endocet, OxyContin), respectively. All states except Missouri have prescription-monitoring programs that allow providers to monitor for the use of multiple providers and pharmacies to obtain controlled medications. Rules governing the prescribing and use of controlled substances vary among states, so the provider should be knowledgeable of local regulations as well as federal DEA requirements.

Complications

The Centers for Disease Control and Prevention (CDC) reported in 2011 that opioid pain relievers were involved in 73.8% of the 20,044 prescription drug overdose deaths, and this is believed to be an underestimate. Overdose death rates were three times greater in non-Hispanic whites and in American Indians and Alaska Natives than in blacks and Hispanic whites. The death rates were highest in the 35- to 54-years age range, producing a YPLL (years of potential life lost) comparable to that of motor vehicle accidents. Medicaid populations are at greater risk of opioid overdose than non-Medicaid populations, and prescription drug overdose death rates are higher in the more rural and impoverished counties.

In addition to the deaths, there is a significant cost burden of substance abuse treatment admissions, with the 2008 rates being six times the 1999 rate. Nonmedical use of opioids represents up to \$72.5 billion in health care costs. By 2010, opioids were sold in such a volume that every American adult could be treated for a month with hydrocodone 5 mg every 4 hours. Incidentally, 1999 is the year that several organizations began promoting “pain as the fifth vital sign,” with no secondary improvement in the quality of pain management. Drug addiction is very real, and about 15% of patients may be genetically predisposed to addiction; therefore clinicians should strongly consider this in their risk/benefit analysis before exposing a patient to these powerful medications. Using a tool such as the Opioid Risk Tool may be helpful in determining the risk of addiction in a particular individual.

Long-term safety of opioids has not been demonstrated, and chronic use has been associated with sleep disorders, adrenal suppression, and hypogonadism (and secondary erectile dysfunction and depression) among other problems.

PALLIATIVE AND END-OF-LIFE CARE

Method of

Steven A. House, MD

CURRENT DIAGNOSIS

- Any symptom can be in the realm of palliative care. Rapid identification and aggressive management of symptoms are important in maintaining the patient's quality of life.
- Palliative care is treatment that is focused on pain and symptom management as well as quality of life for patients and their families. It can be rendered at any point in the course or treatment of illness, whether that illness is life-limiting/threatening or not.
- Hospice is a philosophy and method of care that is completely focused on symptom management, quality of life for patients and families, and the transition at the end of life.

CURRENT THERAPY

- Recommend that all adult patients, regardless of current health status, execute advance directives (Living Will, Power of Attorney for Healthcare, Healthcare Surrogate, etc.) to help ensure that their treatment wishes and end-of-life care goals are met.
- For patients with life-threatening (e.g., progressing cancer) or life-limiting (e.g., patients with severe chronic obstructive pulmonary disease [COPD] or heart failure, requiring dialysis, or residing in a nursing home) illness, consider a Physician Order for Life-Sustaining Treatment (POLST) or Medical Order for Scope of Treatment (MOST) form (the name varies by state). These forms are used to convert the salient points of advance directives into medical orders so that they are immediately actionable by nurses or emergency medical services if the situation arises.
- Advance Care Planning discussions are billable under Medicare: 99497 for the first 30 minutes and 99498 for each additional 30 minutes.
- The best palliative care involves an interdisciplinary approach by physicians, nurses, counselors, chaplains, and others for the optimal management of symptoms (whether the suffering is physical, emotional, spiritual, existential, or practical) and family support.
- Early addition of palliative care to the overall treatment plan can improve survival and quality of life.
- Cancer pain is an indication for opioid therapy as opioids have proven efficacy in this scenario. For detailed information on opioids, please see Table 1 in the chapter in Section 1 on pain. Multiple modalities may be required for optimal pain control.
- For patients using opioids chronically, initiate a stimulant laxative like sennosides (Senokot, Ex-Lax) or lubiprostone (Amitiza) as the opioid's companion. Peripheral mu antagonists like methylnaltrexone (Relistor) or naloxegol (Movantik) are indicated for refractory opioid-induced constipation.
- Control nausea, as it can contribute to anorexia, weight loss, and functional decline. The antiseroenergic drugs, e.g., ondansetron (Zofran), granisetron (Kytril), palonosetron (Aloxi), or the combination netupitant/palonosetron (Akynzeo) are superior to the other classes of antiemetics in the settings of chemotherapy administration and postanesthesia. For

uncomplicated nausea, prochlorperazine (Compazine) was found to be superior to promethazine (Phenergan).

- Dyspnea can be improved by providing a fan, a cooler room, and a view to the outside and avoiding confined spaces. Opioids, benzodiazepines, and/or other agents, depending on the situation, might be required. Thoracentesis can be palliative when an effusion is the source of dyspnea.
- Delirium must be evaluated for potential causes. Delirium with or without agitation can occur in up to 80% of patients, depending on the underlying condition. Medications are common causes, but pain and multiple other conditions can cause it as well. Medications such as haloperidol (Haldol)¹, chlorpromazine (Thorazine, brand discontinued)¹, or olanzapine (Zyprexa, Zyprexa Zydis)¹ can be helpful in many patients, but haloperidol is by far the cheapest alternative and a good place to start.
- Chlorpromazine is the only medication with the FDA indication for hiccups.
- Feeding tubes do not improve outcomes in late-stage dementia and can contribute to suffering.

¹Not FDA approved for this indication.

Epidemiology

There are over 2.5 million deaths in the United States annually. The most recent year for which mortality data are available is 2016, and cardiovascular disease is the top cause of death followed by all cancers combined, unintentional injuries, chronic obstructive pulmonary disease (COPD), congestive heart failure, cerebrovascular disease, chronic kidney disease, and chronic liver disease, among others. Any of these disease processes can have a significant symptom burden that worsens with disease progression.

Life has 100% mortality, so individuals should take the time to plan for it. The consequences of failing to plan for the transition to end-of-life care include increased psychological distress, medical treatments that are inconsistent with individual preferences, increased utilization of healthcare resources that have little therapeutic benefit while being very costly in dollars as well as quality of life, and a more difficult bereavement for survivors.

Cardiopulmonary resuscitation has poor outcomes under the best of circumstances (~ 15%), but it is even worse in patients with late-stage cancer, with only about 2% surviving to hospital discharge. Outcomes are also poor for the other noncardiac diseases listed above and decline further with age and comorbidities.

TABLE 1 Coanalgesic and Adjuvant Treatments for Pain: Adult Dosages

Nonsteroidal Antiinflammatory Drugs

Celecoxib (Celebrex) 200 mg PO daily or 100–200 mg PO bid; maximum: 400 mg/day
 Diclofenac sodium (Voltaren, Voltaren XR) 50–75 mg PO bid; injection (Dyloject) 37.5 mg IV q6h prn; maximum: 150 mg/day;
 Diclofenac epolamine topical (Flector patch 1.3%); apply 1 patch to most painful area bid
 Ibuprofen (Motrin, Advil) 400–800 mg PO tid; maximum: 3200 mg/day
 Ketorolac
 Nasal (Sprix) 15.75 mg/spray
 < 65 years old and < 50 kg: 1 spray in one nostril q6h prn. Maximum: 4 sprays/day × 5 days
 < 65 years old and ≥ 50 kg: 1 spray in each nostril q6h prn. Maximum: 8 sprays/day × 5 days
 (Toradol, brand discontinued)
 10 mg PO q4h prn. Maximum: 40 mg/day × 5 days
 Single dose: 30–60 mg IM or 15–30 mg IV
 Multiple dose: if < 65 years old and > 50 kg, 30 mg IM/IV q6h prn. Maximum: 120 mg/day × 5 days
 Or if > 65 years old or < 50 kg, 15 mg IM/IV q6h prn up to 60 mg/day × 5 days
 Naproxen (Naprosyn, EC-Naprosyn) 250–500 mg PO bid prn; maximum: 1500 mg/day
 Naproxen sodium (Aleve, Anaprox) 220–550 PO q12h prn; maximum: 1650 mg/day

Bisphosphonates—usually provide analgesia within a week and last up to 3 months

Pamidronate (Aredia)
 Malignant hypercalcemia: 60–90 mg (depending on the severity of hypercalcemia) IV × 1
 Osteolytic lesions (multiple myeloma) or bone metastases: 90 mg IV monthly
 Zoledronic acid (Zometa)
 Malignant hypercalcemia: 4 mg IV × 1
 Osteolytic lesions (multiple myeloma) or bone metastases: 4 mg IV q3–4 weeks

Radiopharmaceuticals—usually provide analgesia within 1–2 weeks and lasting 1–6 months. Dosing determined by radiation oncologist.

Antidepressants

Tricyclics
 Amitriptyline (Elavil)¹ 25–100 mg qhs. Can increase to 150 mg daily for pain.
 Nortriptyline (Pamelor)¹ 25–100 mg qhs. Up to 150 mg/day.
 Start low and titrate as needed. Use with caution in the elderly.
 Selective norepinephrine reuptake inhibitors—can be used to improve coexisting anxiety and/or depression.
 Duloxetine 60 mg/day; > 60 mg rarely more effective for pain, but can titrate higher for comorbid anxiety and/or depression if needed
 Venlafaxine (Effexor)¹ 37.5–225 mg daily. Start low and titrate.

Antiepileptic Drugs

Gabapentin (Neurontin)¹ 300–1200 mg tid. Maximum: 3600 mg/day. Start 300 mg qhs × 2–3 days, then bid × 2–3 days, then tid. May start with 100 mg qhs in the elderly.
 Pregabalin (Lyrica) 50–300 mg bid. Maximum: 600 mg/day. Start low and titrate for effect, using the lowest effective dose.

General Anesthesia/Sedation

Ketamine (Ketalar)¹ 0.1–0.2 mg/min IV (no bolus). This dosage is an adjunct to opioid therapy for severe uncontrolled pain and NOT intended to achieve general anesthesia. However, the clinician should seek assistance from anesthesiology or palliative care specialists. Hospital policies may vary.

¹Not FDA approved for this indication.

Risk Factors

Factors associated with worse pain or less symptom control are being female, elderly or a child, and race other than white. Historically, these groups have received less pain medication than Caucasian males for very similar diagnoses. These trends should be reversing. Lacking advance directives and failing to have such discussions with family members are related to receiving excessive and/or unbeneficial interventions/treatments.

Pathophysiology

A patient's symptoms can be caused by the underlying disease itself, mechanical encroachment on other organs and structures (e.g., bowel obstruction, neuropathic pain from nerve destruction, bone metastasis), becoming more sedentary or bedbound, medications, and/or tumor necrosis factor, neurokinin-1, and other inflammatory cytokines. Therefore symptoms may have different etiologies and pathophysiology depending on the underlying disease state. Such a review would be far too extensive for this section.

Prevention

Encourage all adult patients, regardless of current health status, to execute advance directives (Living Will, Power of Attorney for Healthcare, Healthcare Surrogate, etc.) to help ensure that their treatment wishes and end-of-life care goals are met. These discussions are billable under Medicare using CPT 99497 for the first 30 minutes face to face with patient, family members, and/or surrogate; and 99498 for each additional 30 minutes. For patients with life-threatening (e.g., progressing cancer) or life-limiting (e.g., severe COPD or heart failure, dialysis-dependent, or nursing home residents) illness, consider a Physician Order for Life-Sustaining Treatment (POLST) or a Medical Order for Scope of Treatment (MOST) form (forms vary by state). They are used to convert the salient points of advance directives into medical orders so that they are immediately actionable by nurses, emergency medical services, and others if the situation arises.

Ascertain the patient's/family's goals of care, and assess whether those goals are realistic under the circumstances. Evaluate whether a particular intervention will help achieve that goal. For example, if a patient's goal is to take a child on a special vacation, this cannot be achieved if the patient remains in the hospital receiving chemotherapy that is not working. Another example is a nursing home resident with dementia whose family just wants them "to be kept comfortable" but is considering feeding tube placement. Placing a feeding tube in advanced dementia does not improve outcomes and might require physical restraints to keep the patient from removing the tube. Therefore feeding tube placement will negatively impact the goal of comfort.

When maintaining comfort and improving quality of life become the primary goals, assist patients and their families with the transition to hospice care. Hospice is grossly underutilized, with median and average lengths of service of only 24 days and 71 days, respectively. Referrals are too often made excessively late, with 28% of patients having 7 or fewer days of service; therefore all of the benefits of hospice cannot always be fully realized in such a short time.

Palliative and end-of-life care, like all medical care, needs to be influenced by all four major aspects of medical ethics: autonomy (patient/surrogate has the right to pursue aggressive treatment as well as to refuse treatment, even if that treatment could be considered life-sustaining), beneficence (do "good" for the patient), non-maleficence ("do no harm"), and justice (appropriate distribution of finite resources to do the most good for the most people). These four ethics can come into conflict at times, especially with the emphasis on autonomy above the other three in the healthcare system in the United States. Hospitals and other medical facilities should have specific policies regarding medical futility, and ethics committees can be helpful in difficult or unusual cases.

Clinical Manifestations

Common symptoms in palliative care include pain, nausea with or without vomiting, dyspnea, delirium, constipation, dysphagia (cannot swallow food, fluids, or medications), and general

functional decline; that is, requiring more assistance with transfers, toileting, and self-care. Anorexia and lack of thirst are very common, notably in the last few hours to days of life, but anorexia can also be a side effect of medications. Intervening with IV fluids or nasogastric feeding can exacerbate symptoms (secretions, dyspnea, pain, nausea) and worsen outcomes. Weight loss is commonly observed. Medications for diabetes and other disorders can often be discontinued at this stage to help avoid side effects, drug interactions, and adverse reactions (e.g., hypoglycemia).

As patients enter the last hours of life, they might experience decreased level of consciousness, agitated delirium, mottling of the extremities beginning distally and moving proximally, changes in breathing (Cheyne-Stokes, rapid and shallow, Kussmaul, or apnoeal), decreased or absent oral intake, and/or skin cool to touch.

Diagnosis

Diagnosis and prognosis will vary widely depending on the underlying disease processes, but in palliative care, much of the diagnosis (symptom identification) is based on history. Any patient with symptom burden is a candidate for palliative care, whether the symptoms are physical, psychological, spiritual, or existential. The Edmonton Symptom Assessment Scale rates each of 11 different symptoms on a scale of 0 to 3 for a total score of 0 to 33. This scale gives an idea of overall symptom burden. The Karnofsky and Palliative Performance Scales range from 0% (deceased) to 100% (fully functional) rated on ambulation, activity and evidence of disease, self-care, oral intake, and level of consciousness. A score of about 40% is often associated with appropriateness for hospice. Hospice eligibility in the United States is solely based on a life expectancy of 6 months or less if the disease progresses on its expected course. The National Hospice and Palliative Care Organization (NHPCO) has devised some prognostic criteria for a variety of diagnoses including dementia, amyotrophic lateral sclerosis (ALS), acquired immune deficiency syndrome (AIDS), congestive heart failure, end-stage liver or kidney disease, COPD, and so on. Although not fully validated, the criteria can help guide the clinician in discussions with patients/families. "Hospice" is commonly associated with cancer; however, according to the NHPCO, only 27.2% of hospice patients in 2016 suffered from cancer (often referred late, as the median length of stay was only 19 days), followed by 18.7% cardiovascular and 18.0% dementia to round out the top three. There are various prognostic scoring systems for different disease states, and the Palliative Prognosis Score can help determine the prognosis for patients with terminal cancer. Additionally, the American Cancer Society has 5-year survival rates for various stages of numerous cancers on its website.

Differential Diagnosis

As this chapter discusses management of symptoms for a plethora of different diseases, the differential diagnosis of all symptomatic disease processes is far beyond its scope. However, when assessing various symptoms, treatment options can be selected based on the probable source. Is the pain new or in a new location, or is it in the same area, radiating, or worsening? Are the nausea/vomiting due to chemotherapy, anesthesia, metabolic disorders, bowel obstruction, anxiety, increased intracranial pressure, or something else? Is the constipation opioid-induced, due to poor intake, a result of using fiber without adequate fluid intake, or caused by another issue altogether? Is the dyspnea due to pleural effusion (may respond to thoracentesis far better than it would respond to medications), anxiety (could use selective serotonin reuptake inhibitors [SSRIs], hydroxyzine [Vistaril], benzodiazepine, cognitive behavioral therapy), airway obstruction (might use bronchoscopy, suction, or bronchodilators rather than other medications), excessive secretions (could treat with anticholinergic medications such as glycopyrrrolate [Robinul] or scopolamine), or other cause?

Therapy

To meet the needs of all forms of suffering (physical, emotional/psychological, spiritual, existential), an interdisciplinary approach using physicians, nurses, chaplains, counselors, social workers, and

others is essential. For all patients entering palliative care, and especially hospice care, all of their medications should be evaluated for risk and benefit and then prioritized based on the goals of care. In one study, patients with a life expectancy of less than 1 year taking a statin for primary or secondary prevention were randomized to continue or stop the statin. The average number of days until death was 229 after discontinuation versus 190 for continuation; thus survival and quality of life improved at a lower cost. Consider discontinuing statins, some oral hypoglycemic agents (notably sulfonylureas due to risk of hypoglycemia), or oral anticoagulants such as warfarin (Coumadin), apixaban (Eliquis), or dabigatran (Pradaxa) if risks now outweigh benefits. As the end of life approaches, discontinue other medications that are not essential for symptom control or quality of life, have more risks than benefits, or contribute to symptom burden (e.g., cholinesterase inhibitors) at this advanced stage of the disease.

Clinicians might withhold or withdraw treatments, but they should never withdraw “care.” Providers can change from “doing everything possible to cure a patient” to “doing everything possible to maintain comfort and quality of life.” This is more than semantics. Consider turning off the defibrillator component of a pacer-defibrillator to avoid unnecessary shocks. The pacer can remain on, as it can improve some symptoms while not prolonging life.

Pain

For a detailed review of medications used for pain, especially opioids, see the chapter on pain. This section will focus on cancer pain and end-of-life pain.

Pain of All Types

Opioids have demonstrated efficacy for cancer-related pain in numerous clinical trials. Methadone (Dolophine) can be effective when other opioids have failed, but it should be used with caution and by those familiar with its use.

Bone Pain

The bone pain due to metastatic lesions is partly due to prostaglandin release; thus coanalgesics like nonsteroidal antiinflammatory drugs or adjuvant medications such as corticosteroids, e.g., dexamethasone or prednisone, can be particularly helpful. Bisphosphonates such as zoledronic acid (Zometa) and pamidronate (Aredia) usually provide analgesia within a week that lasts up to 3 months. Monthly dosing may be required. Additionally, radiopharmaceuticals such as strontium-89 (Metastron), samarium-153 (Quadramet), and phosphorus-32 (Phosphocol P-32) may be helpful for cancer-related bone pain with analgesia usually beginning within 1 to 2 weeks and lasting 2 to 6 months. Their benefit is derived from significant uptake by areas of high bone turnover to provide internal, localized radiation. Radium-223 (Xofigo; indication limited to castration-resistant prostate cancer with bone metastasis) emits alpha radiation rather than the beta radiation of the three agents above, and it is more selective for metastatic lesions. External-beam radiation treatment (EBRT) achieves pain relief in over 75% of patients with analgesia beginning in 1 to 2 weeks and lasting 2 to 6 months. The appropriateness and dosing of radiopharmaceuticals and EBRT are determined by a radiation oncologist. The radiation oncologist might choose a single large fraction of EBRT rather than multiple small fractions if survival is expected to be greater than 3 months or if prolonged treatment will present too much hardship (transportation, increased suffering, time off work for caregivers, etc.) on the patient/family.

Neuropathic Pain

Neuropathic pain can have multiple causes, such as nerve invasion/compression, medication toxicities, human immunodeficiency virus (HIV), and complications of diabetes. Adjuvant medications that have proven efficacy, but not necessarily an indication for use by the Food and Drug Administration (FDA), include antidepressants such as amitriptyline (Elavil)¹, duloxetine (Cymbalta), and

venlafaxine (Effexor)¹, anticonvulsants like pregabalin (Lyrica) and gabapentin (Neurontin)¹, or, for highly refractory cases (due to significant risk, side effects, and/or legality), ketamine (Ketalar)¹ or cannabinoids. Topical agents like capsaicin (Capzasin-HP, Salonpas Gel Patch Hot) have evidence to support their use in diabetic neuropathy. Highly active antiretroviral therapy can decrease viral load and improve symptoms of AIDS, including those of HIV-related neuropathy.

Visceral Pain

Octreotide (Sandostatin) can be used for the severe abdominal cramping and diarrhea associated with carcinoid tumors or VIPomas or off-label for abdominal pain and other symptoms related to malignant bowel obstruction. See Table 1.

Dyspnea

Dyspnea is a sensation of breathlessness, and the only measure is a patient's self-report. It does not correlate well with respiratory rate, blood gas measurements, or pulse oximetry. The potential causes are many, and they should be considered before merely managing the symptom. The cause can determine the therapy. Anxiety can be managed with SSRIs or benzodiazepines. Airway obstruction could be relieved by suction or bronchoscopy. Hypoxemia has numerous causes that would have to be considered, but supplemental oxygen could help. Pleural or pericardial effusions could be drained. Pneumonia can be treated with antibiotics, pulmonary edema can be managed with diuretics and opioids, and pulmonary embolus can respond to anticoagulants. Transfusions can be helpful for dyspnea due to significant anemia (hemoglobin < 7 g/dL) resulting from hemorrhage or myelosuppression. Bronchospasm usually responds to inhaled β_2 agonists. If underlying causes are addressed, either by management or recognizing that treatment would not achieve the goals of care, symptom control is appropriate. Opioids can be helpful for symptom management. Nebulized morphine¹ is no better than saline. Excessive secretions can be managed with scopolamine or glycopyrrolate. The latter is preferred in the elderly, as it does not cross the blood-brain barrier. For nonpharmacologic interventions, see Box 1.

Nausea/Vomiting

The treatment of nausea and vomiting depends on the underlying cause. For chemotherapy-related nausea/vomiting, the 5HT₃ receptor antagonists are far more effective than other classes of antiemetics. The 5HT₃ class includes ondansetron (Zofran), granisetron (Sancuso, Sustol), dolasetron (Anzemet), and palonosetron (Aloxi). Additionally, there is a combination of netupitant/palonosetron (Akynzeo), which combines a 5HT₃ antagonist for acute-phase nausea/vomiting and a substance P/neurokinin 1 receptor antagonist (NK1RA) for the delayed phase, and it should be given with dexamethasone (Decadron)¹. Its only indication is for prophylaxis of chemotherapy-related nausea/vomiting, especially with highly emetogenic chemotherapy. The combination demonstrated superiority over palonosetron alone. Rolapitant (Varubi), another NK1RA, has a longer half-life than netupitant with fewer drug

¹Not FDA approved for this indication.

BOX 1 Nonpharmacologic Interventions for Dyspnea

- Reassure, work to manage anxiety.
- Behavioral approaches: relaxation, distraction, hypnosis.
- Limit the number of people in the room.
- Open window.
- Eliminate environmental irritants.
- Keep line of sight clear to outside.
- Reduce room temperature, but avoid chilling the patient.
- Introduce humidity.
- Reposition, elevate the head of the bed, keep patient turned.
- Educate and support the family.

¹Not FDA approved for this indication.

interactions. Aprepitant (Emend) is an NK1RA with fosaprepitant (Emend injection) as its IV alternative. Olanzapine (Zyprexa)¹ was more effective than aprepitant and noninferior to fosaprepitant in the setting of highly emetogenic chemotherapy, while it is far more cost-effective than either NK1RA and serves as a better acute antiemetic than metoclopramide (Reglan). Prochlorperazine (Compazine) was found to be superior to promethazine (Phenergan) for uncomplicated nausea/vomiting. See [Table 2](#).

Constipation

Constipation is quite common in palliative care, and it is easier to prevent than to treat. It is one of the primary side effects of opioids that does not attenuate with time. For routine constipation, almost any laxative will do. Polyethylene glycol 3350 (MiraLax, GlycoLax) daily with as-needed sennosides (Senokot) or bisacodyl (Dulcolax) is one example of a simple regimen. If the patient is taking medications that have constipation as a side effect, such as anticholinergic medications, calcium-channel blockers, they should be discontinued if possible. Opioid-induced constipation is due to the interaction of opioids with the mu receptors in the gut, thus leading to poor motility. It can be prevented for the most part if a stimulant laxative is initiated simultaneously with the opioid. Senna is safe for long-term use, but bisacodyl can damage the myenteric plexus over time. The chloride-channel activator lubiprostone (Amitiza) and the guanylate cyclase activator linaclotide (Linzess)¹ increase intestinal fluid secretion and motility, and the peripheral mu antagonists methylnaltrexone (Relistor) and naloxegol (Movantik)

are indicated for use by the FDA to treat refractory opioid-induced constipation. Alvimopan (Entereg)¹ is another peripheral mu antagonist, but its primary indication is for ileus, especially postoperatively. Fiber and bulking agents should be avoided, as they can worsen the problem. See [Table 3](#).

Anxiety

There are numerous reasons for patients receiving palliative care to be anxious, whether undergoing painful/unpleasant but curative interventions, suffering uncontrolled pain or dyspnea, or progressing toward hospice. Fear and uncertainty about the future are common causes, and they can be related to physical, psychological, social, spiritual, or practical (finances, managing home responsibilities) issues. Excessive alcohol or caffeine use can exacerbate anxiety, which may present with agitation, insomnia, restlessness, sweating, tachycardia, hyperventilation, panic disorder, worry, tension, and/or psychosomatic symptoms. For patients with expectation of cure or longer survival, SSRI or serotonin and norepinephrine reuptake inhibitor (SNRI) antidepressants can be beneficial. Venlafaxine (Effexor ER) has the shortest half-life, and steady state can be reached in 4 to 7 days. Benzodiazepines are helpful for shorter life expectancy, or they can be used until the antidepressants take effect. Diazepam (Valium) has a long duration of action due to numerous active metabolites, but it is slower in onset, as is clonazepam (Klonopin)¹. Alprazolam (Xanax) has very rapid onset but short duration of

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

TABLE 2 Antiemetics

Antipsychotics/Dopamine Antagonists

Chlorpromazine (Thorazine) 10–25 mg PO q4h prn. Can use 25–50 mg IM q3h prn, but change to PO as soon as possible.
 Haloperidol (Haldol)¹ 0.5–5 mg PO/IV bid–tid prn (off-label for nausea/vomiting); maximum 100 mg/day, but use lowest effective dose.
 Good choice when also managing delirium.
 Metoclopramide (Reglan) 5–10 mg PO/IV q6h prn
 Olanzapine (Zyprexa)¹ 5–10 mg PO daily–bid prn (off-label for nausea/vomiting)
 Prochlorperazine (Compazine) 5–10 mg PO/IM/IV q6h prn; maximum 10 mg/dose, 40 mg/day. Suppository, 25 mg PR q12h prn

Antihistamines

Hydroxyzine (Atarax, Vistaril) 25–100 mg PO q6h prn or IM q4h prn
 Meclizine (Antivert, Bonine)¹ 25–100 mg/day PO divided bid–tid prn (off-label)
 Promethazine (Phenergan) 12.5–25 mg PO/PR/IM/IV q4h prn. Use with caution IV: can cause necrosis and gangrene.

Antiserotonin (5HT3 Antagonists)

Dolasetron (Anzemet) 12.5 mg IV 15 minutes before ending anesthesia or at onset of postoperative nausea/vomiting; 100 mg PO × 1 within an hour before chemotherapy.
 Granisetron (Granisol, Sancuso [transdermal], Sustol [sustained release SC injection]) 2 mg PO × 1 or 1 mg PO q12h × 2 doses given within an hour before chemotherapy. If IV, 10 µg/kg IV × 1 within 30 minutes before chemotherapy. Transdermal, apply 1 patch (3.1 mg/24 h) × 1 24 hours before chemotherapy and leave on for up to 7 days. If SC, 10 mg SC q 7 days (give with dexamethasone [Decadron]¹).
 Ondansetron (Zuplenz, Zofran, Zofran ODT) 8 mg PO q8h for nausea/vomiting; 24 mg PO × 1 30 minutes before highly emetogenic chemotherapy.
 Palonosetron (Aloxi) 0.25 mg IV × 1 or 0.5 mg PO × 1 30 minutes before chemotherapy.

Antineurokinin (NK1 RA)

Aprepitant (Emend), fosaprepitant (Emend injection) 125 mg PO × 1 day 1 of chemotherapy, then 80 mg PO daily × 2 days. Or 150 mg IV × 1 30 minutes before chemotherapy.
 Netupitant/palonosetron (Akinzeo) 300/0.5 mg, 1 capsule 1 hour before highly emetogenic chemotherapy.
 Rolapitant (Varubi) 180 mg PO × 1, 1–2 hours before chemotherapy.
 Netupitant/palonosetron is already a combination, but all NK1RAs should be given with an HT3RA and dexamethasone before highly emetogenic chemotherapy.

Cannabinoid Receptor Agonists

Dronabinol (Marinol) 2.5–10 mg PO bid prn
 Nabilone (Cesamet) 1–2 mg PO bid prn; maximum: 2 mg PO tid
 Both drugs are indicated for chemotherapy-related nausea/vomiting refractory to other drugs. Significant psychiatric adverse events are possible.

Unknown Mechanism

Trimethobenzamide (Tigan) 300 mg PO or 200 mg IM q6h prn

¹Not FDA approved for this indication.

TABLE 3 Laxatives

Osmotic

Lactulose (Kristalose) 10–20 g in 4 oz. water PO daily. Maximum: 40 g/day
 Magnesium citrate (1.745 g/30 mL) 195–300 mL/day PO daily or divided bid; maximum: 300 mL/day
 Magnesium hydroxide (Milk of Magnesia), 400 mg tabs and 1200 mg/15 mL. 2400–4800 g PO daily or divided bid or qid
 Polyethylene glycol 3350 (MiraLax), 17 g in 8 oz. liquid PO daily

Stimulant

Bisacodyl (Dulcolax) 5 mg tabs 1–3 PO daily prn or 10 mg suppository PR daily prn
 Sennosides (Senna) 8.6 mg tabs; 2–4 tabs PO bid; maximum: 4 tabs PO bid

Secretory

Linaclotide (Linzess)¹ 145 µg PO daily. Stimulates cGMP production to increase intestinal fluid secretion and motility.
 Lubiprostone (Amitiza) 24 µg PO bid. Activates chloride channel to increase intestinal fluid secretion and motility.

Peripheral Mu-Receptor Antagonists

Methylnaltrexone (Relistor) 8–12 mg SC qod prn (or 0.15 mg/kg SC qod prn). Maximum: 1 dose/24 hours
 Naloxegol (Movantik) 25 mg PO daily

Avoid fiber and bulking agents in patients taking opioids or with limited fluid intake.

¹Not FDA approved for this indication.

action. Lorazepam (Ativan) strikes a happy medium between speed of onset and duration of action. Counseling and cognitive behavioral therapy are effective, especially in combination with medications.

Delirium

Delirium is a waxing/waning state of confusion that can be characterized by anxiety, disorientation, cognitive dysfunction, and hallucinations. There is also a catatonic variety of delirium. This condition can be caused by many things, but a short list would include constipation/impaction, hypoxemia, infection, electrolyte abnormalities, medications (including benzodiazepines and opioids), and pain. If a cause is identified and corrected but the patient is still symptomatic, haloperidol (Haldol)¹, chlorpromazine (Thorazine)¹, or olanzapine (Zyprexa)¹ can be helpful; however, haloperidol is by far the cheapest alternative and a good place to start. It can be given intravenously or orally, or it can be given subcutaneously (off-label).

Hiccups

Hiccups (singultus) is a common nuisance that can become quite distressing, especially if persistent (> 48 hours) or intractable (> 1 month). For patients with pain in the chest or abdominal regions, hiccups can make pain difficult to control in addition to being a bothersome symptom that can significantly decrease quality of life. Chlorpromazine, at 25 to 50 mg PO qid prn, is the only FDA-approved medication for hiccups, but haloperidol¹ is a viable and much cheaper alternative, as is metoclopramide (Reglan)¹. Gabapentin (Neurontin)¹ and phenytoin (Dilantin)¹ have been used with some success, notably in cases with a central nervous system etiology. Many other medications, including baclofen (Liorel)¹, have been tried without success. Nonpharmacologic methods, e.g., breath holding, hyperventilation, gargling, are worth trying, but evidence is lacking for any particular intervention.

Monitoring

Patients should be reevaluated routinely for the adequacy of pain and symptom control, as well as for their ability to cope with the underlying disease, symptom burden, and functional decline. The family needs to be assessed for additional stressors and coping mechanisms, as the family's adjustment, or lack thereof, can be detrimental to the patient's condition. If opioids or benzodiazepines are being used, the supply needs to be monitored for any signs

of aberrant use by the patient and/or the family and visitors. Additionally, patients can be monitored for excessive sedation or respiratory depression, especially when using methadone +/- a benzodiazepine. The FDA has issued a warning regarding coadministration of benzodiazepines and opioids as a cause of worsened respiratory depression, so these patients in particular should be monitored.

Palliative Sedation

For symptoms refractory to all other measures and with a life expectancy of under two weeks, palliative sedation can be considered, after informed consent, without hastening death according to one study.

Physician-Assisted Suicide (PAS)

Although this practice has been legalized in several states, the American Medical Association's Council on Ethical and Judicial Affairs has determined that PAS, as opposed to "aid in dying," is the most accurate description of the practice and that the AMA's current policy forbidding PAS should be upheld. Similarly, in 2017, the American College of Physicians also determined that PAS is contradictory to the physician's role in the physician-patient relationship.

Complications

Emergencies do exist within the palliative care and hospice settings. Spinal cord compression, hypercalcemia, superior vena cava syndrome, seizures, airway obstruction, hemorrhage, or acute worsening or crisis in pain or other symptom are examples. Management will depend on the patient's goals of care and stage of illness; however, uncontrolled symptoms should always be addressed. Having dark-colored linens and towels are good to have on hand for patients at risk for hemorrhage, as the blood does not appear as dramatic or traumatic for the patient and family as it would on white or light-colored materials.

PALPITATIONS

Method of

Rebecca Katzman, MD; and Justin Bailey, MD

CURRENT DIAGNOSIS

- History and physical examination
- Electrocardiogram
- Complete blood count (CBC)
- Thyroid-stimulating hormone (TSH)
- Complete metabolic panel

CURRENT THERAPY

- Dependent on underlying etiology. See Table 7.

Palpitations are the unpleasant sensation or awareness of one's own heartbeat. Patients may feel a racing heart, skipped heartbeats, or pounding in the chest or neck. Palpitations have been described as a “flip-flop” or “fluttering” in the chest. Palpitations may be due to cardiac arrhythmia, nonarrhythmic cardiac disease, drugs, other

medical conditions, or psychiatric disease. Cardiac arrhythmias and anxiety account for a majority of cases. Palpitations may be completely benign or a manifestation of a potentially fatal arrhythmia.

Epidemiology

Palpitations (ICD-9-CM 785.1, ICD-10-CM R00.2) are a common presenting complaint in a primary care office or the emergency department. They affect all genders and ages. Up to 16% of patients in general medical settings report palpitations, and up to 18% of cardiology outpatient visits are for cardiac arrhythmias. The most common etiologies are cardiac arrhythmias (43%) and anxiety/psychiatric (31%). In outpatient clinics psychiatric etiologies are slightly more common; in emergency department settings cardiac causes are increasingly likely. The underlying cause of palpitations in 15% of patients cannot be identified.

Nearly 90% of patients who have palpitations have recurrent symptoms of palpitations. Overall, 1-year mortality does not appear to be significantly increased, but patients report a moderate impact on their quality of life.

Although arrhythmias are frequently found to be the underlying cause of palpitations, it is important to note that many patients with arrhythmias do not have any symptoms.

Differential Diagnosis

The differential for palpitations is broad but can generally be broken down into cardiac versus noncardiac causes. Cardiac causes may be further divided into structural or arrhythmic causes. Noncardiac causes include medications and drugs, high-output states, and certain medical conditions. Gastroesophageal reflux or esophageal spasm may present as a brief intermittent episode of tightness or pounding in the chest. See Table 1 for a full listing of causes.

Psychiatric causes may account for up to one-third of presentations; however, it is important to note that psychiatric illness can coexist with cardiac or other medical causes, and palpitations can occur with panic attacks, generalized anxiety, depression, and somatization.

Cardiac arrhythmias often present as palpitations. Nearly any arrhythmia or change from a sinus rhythm can produce this sensation. A less common condition in otherwise healthy patients is inappropriate sinus tachycardia (IST), demonstrated by an elevated resting heart rate, an exaggerated heart rate response to exercise, or both. IST is thought to be due to abnormal autonomic control and response. Long QT syndrome, both congenital/familial and medication-induced, may predispose to ventricular tachyarrhythmias, including the often-fatal Torsades de pointes.

TABLE 1 Differential Diagnosis for Palpitations

Risk Factors

Structural cardiac disease, including valvular disease, may predispose patients to arrhythmias and palpitations. [Table 2](#) lists symptoms and risk factors that indicate an increased likelihood that palpitations are due to an underlying arrhythmia.

Pathophysiology

An arrhythmia is caused by the disruption of the normal electrical impulse that originates at the sinoatrial node and is conducted to the atrioventricular node, then through the His-Purkinje system to depolarize the ventricles. Disruption may occur anywhere along this pathway. Underlying structural disease, prior ischemia, congenital abnormalities in myocytes, or electrical pathways affect a normal electrical conduction pathway. Palpitations that are due to supraventricular or ventricular tachyarrhythmias often result from sympathetic stimulation and catecholamine surges.

Palpitations involving skipped or premature beats are often a sensation that results from the following episode of systole, when stroke volume is increased secondary to the prolonged length of the preceding diastole and increased ventricular inotropy.

Clinical Assessment

The keys to evaluation are a history and physical, a 12-lead electrocardiogram (ECG), and a basic laboratory evaluation including an evaluation of the thyroid gland. Clinicians must identify which patients are more likely to have underlying arrhythmia and require further evaluation. A good clinical history includes age of onset, description of palpitations, frequency, duration, timing, position, and associated symptoms, including dizziness, presyncope, and syncope. The clinical history should include a thorough medication review, including over-the-counter medications, alcohol and tobacco use, and illicit substance use. An increasing number of medications are being found to cause QT prolongation, especially when used in combination, and may predispose the patient to

ventricular arrhythmias (see [Tables 3](#) and [4](#)). A physical examination should be performed but may be limited, as clinicians rarely have the opportunity to examine a patient during an episode of palpitations.

Diagnostic Testing

A 12-lead ECG should be performed in all patients. It is appropriate to do limited laboratory evaluation with a complete blood count (CBC), thyroid-stimulating hormone (TSH), and complete metabolic panel (CMP or Chem-14) to identify anemia, thyroid disease, and electrolyte abnormalities that predispose to arrhythmias. Etiology can be determined in 40% of patients from this limited evaluation (see [Tables 5](#) and [6](#)).

Traditionally, ambulatory cardiac monitoring has been done via a Holter monitor. Patients keep a diary of the time and

TABLE 3 History and Physical Examination Clues to the Etiology of Palpitations

Cardiac Antiarrhythmics
Amiodarone (Cordarone)
Disopyramide (Norpace)
Procainamide
Quinidine
Sotalol (Betapace)
Diuretics
Sympathomimetics
Vasodilators
Antibiotics
Fluoroquinolones
Macrolides
Psychiatric
Phenothiazines
Chlorpromazine (Thorazine)
Promethazine (Phenergan)
Prochlorperazine (Compazine)
Fluphenazine (Prolixin)
Trifluoperazine (Stelazine)
Selective serotonin reuptake inhibitors
Tricyclic antidepressants
Haloperidol (Haldol)
Other
Amphetamines
Anticholinergics
Antihistamines
Protease inhibitors
Methadone (Dolophine)

TABLE 5 ECG Findings Suggestive of Diagnosis of Palpitations

ECG FINDINGS	SUGGESTED DIAGNOSIS
Irregularly irregular rhythm	Atrial fibrillation
Absent P waves	
Delta wave	Wolff Parkinson White
Short PR interval	
Widened QRS	
Short PR	AV nodal reentrant tachycardia
QT interval > 460 msec in women, > 440 msec in men	Predisposition to ventricular tachyarrhythmias, including Torsades de pointes
Left ventricular enlargement with left atrial abnormality	May be a focus for atrial fibrillation

TABLE 6 Diagnostic Considerations in the Evaluation of Palpitations

FINDINGS	FURTHER EVALUATION
Arrhythmia or predisposition to arrhythmia seen on ECG	Echocardiogram to look for structural heart disease
Palpitations brought on by exertion	Exercise stress test (avoid dobutamine if suspect arrhythmia)
Suspected arrhythmia, but none identified on ECG	Ambulatory cardiac monitoring – Holter monitor (24–48 h) – Continuous loop event recorder – Implantable loop recorder
Associated dizziness, syncope, presyncope	Referral to cardiologist for electrophysiology study
Known cardiac dysfunction, structural or valvular abnormality	Referral to cardiologist for electrophysiology study
Family history of sudden cardiac death	Referral to cardiologist for electrophysiology study

characteristics of their symptoms. This method is appropriate for patients who have daily palpitations. The monitor is worn for 24 to 48 hours. If symptoms are not present during the time the monitor is being worn, the test will be unrevealing. In addition, Holter monitoring may uncover arrhythmias (most commonly benign ectopy) that are unrelated to patient symptoms.

If arrhythmia is suspected in a patient but 24 to 48 hours is insufficient time to record an event, it is recommended that the patient be evaluated with a continuous loop event recorder for 2 weeks. These ambulatory monitors record continuously, but only save data from the specific interval when the patient activates the monitor (e.g., 2 min before and after an episode of palpitations). These monitors frequently send information transtelephonically rather than keeping data stored within the device itself. In patients with infrequent palpitations but known severe heart disease, an implantable loop recorder is an option. These monitors are implanted subcutaneously, typically in the left pectoral region, and usually left in place for 1 year. As with other loop event recorders, they save data when activated by the patient and can send information transtelephonically.

Panic disorder or anxiety is a diagnosis of exclusion. A patient with anxiety or other psychiatric illness may have a significant underlying arrhythmia. The catecholamine increase in patients with psychiatric disorder in times of stress or intense emotional experience may be proarrhythmogenic. These patients should undergo evaluation for arrhythmia, especially in the presence of risk factors, before having all of their symptoms attributed to their psychiatric illness.

Patients who have palpitations associated with dizziness, presyncope, or syncope in whom the diagnosis is not apparent should be referred for evaluation by a cardiologist. This sort of palpitation is the kind most likely to be associated with ventricular tachycardia or other serious arrhythmia.

Palpitations may occur more frequently during pregnancy, which is a high-output state. Postpartum cardiomyopathy is a structural disease that is unique to this population. Because pregnant women also have an increased risk of new arrhythmias, including atrial fibrillation, persistent palpitations should be evaluated thoroughly.

Treatment

Treatment should be focused toward the underlying cause of the palpitation.

Discussion of the management of specific causes of palpitations, including anemia, thyrotoxicosis, and hypoglycemia, can be found elsewhere. Chronic management of atrial fibrillation is also beyond the scope of this article.

Table 7 outlines the treatment of specific causes of palpitations.

Referral to a cardiologist is appropriate for patients with supraventricular tachyarrhythmias, long QT syndrome, or palpitations

TABLE 7 Treatment of Specific Causes of Palpitations

CAUSES OF PALPITATIONS	TREATMENT
Due to medication or drug	Stop offending agent
Premature atrial contractions	Decrease caffeine and alcohol/Tobacco cessation
Ectopy (PACs)	Beta blockers for prevention of ectopy – Metoprolol [Toprol XL] ^a 50 mg PO daily – Atenolol [Tenormin] ^a 50 mg PO daily
Narrow complex SVT	Vagal maneuvers (carotid massage, Valsalva, dive reflex) help during episode

Continued

TABLE 7 Treatment of Specific Causes of Palpitations—cont'd

CAUSES OF PALPITATIONS	TREATMENT
Hospitalized patient with prolonged SVT	<i>Adenosine</i> [Adenoscan] 6 mg IV bolus over 1 to 2 s, increased up to 12 mg IV every 1 to 2 min as needed for 2 doses
Atrial fibrillation with rapid ventricular response	<i>Metoprolol</i> [Lopressor] ^a 2.5 to 5 mg IV bolus over 2 min, repeated at 5 min intervals to a total of 15 mg <i>Esmolol</i> [Brevibloc] 0.5 mg/kg IV over 1 min, followed by 50 µg/kg/min continuous infusion with re-bolusing and increasing rate of infusion by 50 µg/kg/min every 4 min up to a maximum infusion rate of 200 µg/kg/min <i>Verapamil</i> [Isoptin] 5 to 10 mg IV over 2 to 3 min, repeated every 15 to 30 min as necessary <i>Diltiazem</i> [Cardizem], 0.25 mg/kg IV over 2 min with a second bolus of 0.35 mg/kg 15 min later if first dose is tolerated but does not produce desired reduction in heart rate. <i>Diltiazem</i> can then be run as a continuous infusion at a rate of 5 to 15 mg/h
Regular supraventricular tachyarrhythmias, such as WPW or AV nodal reentrant tachycardia	Radiofrequency ablation in electrophysiology laboratory

^aNot FDA approved for this indication.

associated with syncope/presyncope, as these are more likely to be ventricular arrhythmias.

Patients with potentially malignant ventricular tachyarrhythmias (e.g., frequent premature ventricular depolarizations, up to 3–10 per hour with some repetitive forms) are at increased risk for sudden cardiac death, but there is little evidence that treating with antiarrhythmics decreases mortality; in fact, some evidence suggests that these drugs actually increase mortality via proarrhythmic mechanisms. In these patients, consider a referral to a cardiologist for evaluation for an implantable cardiac defibrillator.

PHARYNGITIS

Method of

Ruth Weber, MD, MSED

CURRENT DIAGNOSIS

- Patients prioritize symptom relief over microbiologic cure.
- Most pharyngitis is viral; microbiologic confirmation is required for group A β -hemolytic streptococcus pharyngitis diagnosis.

- In adults, throat culture is not necessary if rapid antigen detection test is negative.
- Stop presumptive antibiotic therapy if throat culture results are negative for group A β -hemolytic streptococcus.

CURRENT THERAPY

- Penicillin is the drug of choice for group A β -hemolytic streptococcus pharyngitis. A first-generation cephalosporin or macrolide is indicated if the patient is allergic to penicillin.
- Treatment is necessary for 10 days to eradicate group A β -hemolytic streptococcus from the pharynx.
- Amoxicillin can be substituted for penicillin. Patients older than 12 years may be treated with once-daily amoxicillin (Moxatag).
- Patients are not infectious after 24 hours of appropriate antibiotic treatment.

Epidemiology

Pharyngitis is common and has substantial medical and societal costs. “Sore throat” accounts for more than 7 million outpatient visits by children annually. The estimated total cost of pharyngitis in children is \$540 million per year.

An estimated 30% of childhood pharyngitis is caused by group A β -hemolytic streptococcus (GABHS). In temperate climates, pharyngitis occurs in outbreaks during winter and early spring, predominantly involving children 5 to 15 years of age. GABHS is uncommon in preschool-aged children and in adults. Group C β -hemolytic streptococcus pharyngitis occurs mainly in college students and young adults.

Of other causes of pharyngitis (Table 1), gonococcal pharyngitis is most common in older adolescents and young adults. Transmission is by oral-genital contact. If gonococcal pharyngitis is diagnosed in a prepubertal child, sexual abuse must be considered.

TABLE 1 Pharyngitis: Distribution of Causative Organisms (All Age Groups)

<i>Neisseria gonorrhoeae</i>	< 1

Risk Factors

The major risk factors for GABHS pharyngitis are age and exposure such as in crowded schools or through household contacts. Oral sexual activity is implicated in gonococcal pharyngitis. Swimming pools have been implicated in transmission of group C and D β streptococcal pharyngitis.

Pathophysiology

Pathogenic strains of *Streptococcus pyogenes* can be differentiated by Lancefield antigens and by hemolysis on blood agar. The strain containing group A antigen and displaying β hemolysis causes pharyngitis (GABHS). The M protein is responsible for virulence. The M protein cross-reacts with cardiac myosin and laminin, potentially causing rheumatic heart disease. More than 100 M-protein serotypes have been identified. Some streptococcus strains produce erythrogenic toxins, causing the rash of scarlet fever. Patients develop lifelong immunity to one serotype after infection, but reinfection with a different serotype is possible.

Prevention

GABHS is transmitted by droplet spread. No evidence supports other forms of transmission. Patients and household/close contacts should be educated on minimizing droplet spread to reduce the transmission of GABHS.

Phase I trials have been completed on a multivalent vaccine targeting streptococcus M proteins that cause pharyngitis, invasive disease, and rheumatic fever.

Clinical Manifestations

The type of pharyngitis cannot be identified by history and clinical findings. Microbiologic confirmation is necessary to diagnose GABHS pharyngitis.

Group A β -Hemolytic Streptococcal Pharyngitis

In patients age 3 years to adult, sudden onset of sore throat, pain on swallowing, and fever (101°F–104°F) suggest GABHS pharyngitis. Nausea and vomiting can also occur in school-aged children. Clinical signs can include tonsillar erythema with or without exudate, anterior cervical lymphadenitis, soft palate petechiae, red swollen uvula, and scarletiform rash. Infants rarely present with exudative pharyngitis but have coryza with excoriation and crusting of the nares. Posttonsillectomy patients with GABHS can have milder symptoms and clinical signs.

Patients with suppurative complications of GABHS have unusually severe symptoms, with neck swelling, drooling, and “hot potato” voice. The clinician must look for peritonsillar abscess and infections in the parapharyngeal and submandibular spaces (Ludwig’s angina).

Scarlet Fever

Some strains of GABHS produce a pyogenic exotoxin that causes scarlet fever in susceptible patients. The clinical signs and symptoms are identical to GABHS pharyngitis plus development of the characteristic rash within 24 to 48 hours of symptom onset. The fine, papular, bright red rash blanches with pressure, begins on the neck, and spreads to the extremities and trunk. It is more pronounced in creases and feels rough, with a goose-pimple appearance. The punctate rash spares the face, but patients have flushed cheeks and forehead with pallor around the mouth. The rash fades in 3 to 4 days and is followed by desquamation. After desquamation of an initial white coating, the tongue has a classical strawberry appearance caused by edematous papillae.

Poststreptococcal Glomerulonephritis

Renal symptoms of hypertension, edema, and hematuria can occur 1 to 3 weeks after GABHS pharyngitis. Glomerulonephritis is an autoimmune response to M proteins. It is not preventable by antibiotics.

Viral Pharyngitis

Coryza, hoarseness, cough, diarrhea, viral exanthem, anterior stomatitis, and conjunctivitis can indicate a viral etiology for

pharyngitis. Adenovirus infections can cause fever for 7 days, and conjunctivitis can persist for 14 days. Adenoviral outbreaks are often associated with swimming pools.

Enterovirus pharyngitis (coxsackievirus, echovirus, enterovirus) occurs in summer and fall. Fever, cervical adenopathy, and erythema of the tonsils are common, but exudates are rare. Herpangina (Coxsackie virus A/B) manifests with fever and painful papulovesicular lesions in the posterior oropharynx that resolve in 7 days. Hand-foot-and-mouth disease (Coxsackie virus A-16) manifests with painful vesicles and ulcers in the mouth plus painful vesicles on the palms, soles, and occasionally trunk. Lesions resolve in 7 days.

Primary oral herpes simplex infection occurs in young children. It manifests as acute gingivostomatitis, with ulcerating vesicles on the anterior mouth and lips but not on the posterior pharynx. High fever with intense pain is common, and dehydration can occur. Symptoms last for 14 days.

Diagnosis

It is necessary to obtain microbiologic confirmation of infection before treating GABHS pharyngitis. If the clinical symptoms suggest GABHS pharyngitis, a throat culture or rapid antigen detection test (RADT) are indicated. If the clinical symptoms suggest viral pharyngitis, the pretest probability of GABHS infection is low, and a diagnostic test should not be performed.

Several methods for determining the probability of GABHS infection have been proposed. The Centor criteria (for adults) are widely accepted. A score of 1 is given for each of the following characteristics: tonsillar exudate, tender anterior cervical adenopathy, history of fever, and an absence of cough. A score of 3 or more indicates a positive predictive value for GABHS of 40% to 60%. A score of 0 to 1 indicates a positive predictive value for GABHS of 1% to 5%.

Throat culture is the gold standard for diagnosing GABHS infection. The tonsils and the posterior pharynx should be aggressively swabbed. Other areas of the mouth should not be touched when obtaining the culture. The culture should be obtained before beginning antibiotic therapy, because even a single dose of antibiotics can cause the culture to be negative. The swab is plated on a sheep’s blood agar plate and incubated. The plate must be read at both 24 and 48 hours of incubation. When done correctly, the throat culture has 90% to 95% sensitivity. Although throat culture is considered the gold standard for diagnosing GABHS infection, it does not differentiate a carrier state from clinical infection.

RADT has high specificity but low sensitivity. The many tests available have different performance characteristics. In children aged 5 to 15, a throat culture should be performed if the RADT test is negative to identify patients who have a false-negative RADT result. In adults, throat culture is not necessary after a negative RADT because of the low incidence of GABHS and extremely low risk of acute rheumatic fever. The use of RADT has allowed clinicians to begin antibiotic therapy early in those with a positive test. This decreases the risk of spread of GABHS, allows earlier return to school or work, and modestly improves clinical signs and symptoms.

Streptococcal antibody testing has no value in the acute diagnosis of GABHS pharyngitis. Testing has some value in confirming prior GABHS infection in patients in whom acute rheumatic fever or acute poststreptococcal glomerulonephritis is suspected. The two antibodies that can be identified are antistreptolysin O (ASO) and antideoxyribonuclease B (ARB). Positive, elevated, or increasing titers are confirmation of recent GABHS infection. ASO titers rise within a week of infection and peak 3 to 6 weeks after infection. ARB titers rise within 1 to 2 weeks of infection and peak at 6 to 8 weeks. In some patients titers remain elevated for prolonged periods; therefore a doubling of the titer in 6 weeks is necessary for diagnosing prior GABHS infection.

Differential Diagnosis

Infectious Mononucleosis

Classically a triad of severe sore throat, lymphadenopathy, and fever (up to 104°F) in 15- to 25-year-olds, mononucleosis begins

with a prodrome of chills, sweats, fever, and malaise. Clinical signs include enlarged tonsils; posterior and anterior cervical, axillary and inguinal adenopathy; and hepatosplenomegaly. Approximately 15% of patients present with jaundice and 5% with rash. Patients with mononucleosis who are treated with amoxicillin (Amoxil)¹ often develop a pruritic maculopapular rash. Complete blood count (CBC) shows an absolute lymphocytosis with greater than 10% atypical lymphocytes. Within 2 to 3 weeks, the heterophile antibody test (Mono Spot) becomes positive. The antibody test has a higher false-negative rate in children than in adults. If a false-negative test is suspected, an IgM antibody to viral capsid antigen is indicated to confirm the diagnosis.

Acute Retroviral Syndrome

Primary infection with HIV can manifest as a syndrome of fever, nonexudative pharyngitis, arthralgia, myalgia, and lymphadenopathy. Some 40% to 80% of patients develop a rash. HIV antibodies are negative. Assay for HIV type 1 RNA or p24 antigen is positive.

Neisseria gonorrhea

N. gonorrhea pharyngitis is usually asymptomatic and associated with oral sexual practices. The diagnosis is confirmed by isolating the organism on Thayer-Martin medium. All patients should be screened and treated for coinfection with chlamydia.

Lemierre's Syndrome

Lemierre's syndrome is a rare etiology of severe pharyngitis caused by *Fusobacterium necrophorum*. Infection spreads from the pharynx to include the surrounding tissues, with subsequent thrombophlebitis of the internal jugular vein.

Treatment

A major therapeutic decision is to determine if whether the patient needs an antibiotic in addition to symptomatic treatment.

The goal of treatment of viral pharyngitis is control of symptoms, especially relief of pain. Nonsteroidal antiinflammatory drugs are slightly superior to acetaminophen (Tylenol) for pain relief. No evidence supports the use of Chinese herbs for symptom relief. A single dose of corticosteroids (oral dexamethasone¹ 0.6 mg/kg—maximum dose 10 mg) may provide pain relief, for severe symptoms without serious side effects. The risk of recurrent dosing of corticosteroids has not been determined. Many patients mistakenly believe that antibiotic therapy relieves pain. Ancillary treatment options include rest, adequate fluid intake, and antipyretic medications.

The goals of antibiotic treatment of GABHS pharyngitis are to decrease infectivity and prevent suppurative and other complications, especially acute rheumatic fever. Symptoms generally improve within 3 to 4 days without treatment. Delay of treatment of GABHS pharyngitis for up to 9 days after symptoms begin does not appear to increase the risk of acute rheumatic fever, and a delay of 24 to 48 hours while awaiting culture results does not increase the risk of acute rheumatic fever. Early treatment of GABHS pharyngitis does reduce infectivity, lessens morbidity, and promotes early return to normal activities. Nevertheless, criteria for initiating antibiotics remain controversial.

The choice of antibiotic is determined by the bacteriology of GABHS, clinical efficacy, patient adherence to treatment regimen, adverse effects, and cost. It is not recommended to initiate antibiotics while awaiting throat culture results in children. However, if an antibiotic is started it must be discontinued if the culture is negative.

Penicillin remains the antibiotic of choice for GABHS pharyngitis. GABHS has never shown resistance to penicillin or cephalosporins. Amoxicillin¹ can replace penicillin for treatment. (Liquid amoxicillin has a better taste than liquid penicillin.) In the penicillin-allergic patient, a first-generation cephalosporin or macrolide may be substituted. In some areas of the United States

up to 8% of GABHS is resistant to macrolides and less than 1% is resistant to clindamycin (Cleocin). Antibiotics should be given for 10 days to eradicate GABHS from the pharynx. At this time, short-course (≤ 5 days) treatment cannot be recommended, except with azithromycin (Zithromax).

No clear evidence supports antibiotic treatment for group C or group G streptococcal pharyngitis. Treatment might shorten the course of infection. Treatment options are identical to those for GABHS pharyngitis.

Treatment Regimens

- Oral penicillin: PenicillinVK (Veetids)¹: 40 mg/kg/day (up to adult dose of 1000 mg/day) in divided doses two or three times daily for 10 days.
- Amoxicillin¹: 50 mg/kg/day (up to adult dose of 1000 mg/day) twice daily for 10 days; the FDA has approved amoxicillin ER tab (Moxatag) for patients older than 12 years at 775 mg once a day.
- Penicillin G benzathine (Bicillin-LA): Patients weighing less than 27 kg, 600,000 units IM; patients weighing 27 kg or more, 1.2 million units IM once. Penicillin G is used for patients who are unlikely to complete a full 10-day course of oral medication and for those with a personal or family history of rheumatic fever.
- First-generation oral cephalosporin: Cephalexin (Keflex) 25 to 50 mg/kg/day (up to adult dose of 1000 mg/day) twice daily for 10 days. This regimen should be used if the patient is allergic to penicillin; shorter courses are not FDA approved.
- Macrolides should be used if the patient is allergic to penicillin: Erythromycin 20 to 40 mg/kg/day (up to adult dose of 1000 mg/kg/day) in three or four doses for 10 days. Azithromycin (patients older than 6 months): Day 1: 10 mg/kg once (up to adult dose of 500 mg); days 2 to 5: 5 mg/kg once daily (up to adult dose of 250 mg/day). The dose of azithromycin is not established in infants younger than 6 months.

Tetracycline, sulfonamides, and older fluoroquinolones are not recommended because of high rates of resistance. All patients should be considered infectious until they have completed 24 hours of antibiotic therapy.

Monitoring

In general, follow-up throat cultures or RADT for patients successfully treated for GABHS pharyngitis (i.e., test for cure) are not necessary. An additional RADT or throat culture is required if symptoms do not abate, symptoms recur, or the patient had previous rheumatic fever.

Patients who have repeated symptomatic episodes of GABHS have either recurrent new infections or are carriers of GABHS, with repeated superimposed viral infections.

GABHS carriers have positive cultures for GABHS without clinical symptoms. Approximately 20% of school-aged children are carriers. GABHS carrier status is suspected if the clinical picture is of viral pharyngitis but the patient has positive RADT or cultures both when symptomatic and when asymptomatic. Carriers do not respond to antibiotics and have no serologic response to ASO and anti-DNA B. These patients do not need to be identified or treated. These patients do not develop rheumatic fever and are not important in the spread of GABHS to others.

Patients with repeated GABHS pharyngitis have a clinical picture of recurrent bacterial pharyngitis. They respond to antibiotics and have negative RADT and culture when they are asymptomatic. They have a serologic response to ASO and anti-DNA B. Prophylactic antibiotics are not recommended for these patients. Tonsillectomy may be considered when infection attack rates do not decrease over time and no other explanation of recurrent infection can be found. Meta-analyses have found inconclusive evidence of benefit from tonsillectomy compared to nonsurgical treatment.

Patients with GABHS pharyngitis who remain symptomatic and continue to have positive cultures should receive a second course of antibiotics, with either the same antimicrobial agent or intramuscular penicillin. If a patient experiences repeated infections and there is concern that the GABHS infection is being spread among

¹Not FDA approved for this indication.

close contacts, all close and family contacts should be cultured, and only those who are positive should be treated. Family pets are not reservoirs and do not spread disease.

Mass screening should be considered in outbreaks of GABHS in a closed or semiclosed community or in outbreaks of acute rheumatic fever or poststreptococcal glomerulonephritis.

Non-GABHS pharyngitis (i.e., group C or G β -hemolytic streptococcus) is not associated with rheumatic fever, and no evidence supports treatment or follow-up culture.

Complications

The complications of GABHS pharyngitis can be classified as suppurative and nonsuppurative.

Suppurative complications occur when the infection spreads to cause conditions such as lateral pharyngeal abscess, cervical lymphadenitis, sinusitis, otitis media, retropharyngeal abscess, Lemierre's syndrome, and mastoiditis. Appropriate treatment of GABHS with antibiotics decreases these complications.

Nonsuppurative complications include acute rheumatic fever, acute poststreptococcal glomerulonephritis, and poststreptococcal reactive arthritis. Acute rheumatic fever occurs 2 to 3 weeks after GABHS pharyngitis. It is not seen after GABHS skin infections. Starting antibiotics within 9 days of symptoms can prevent acute rheumatic fever. Acute poststreptococcal glomerulonephritis can occur 10 days after pharyngeal infection and 21 days after skin infection. Antibiotics do not alter the attack rate. Poststreptococcal reactive arthritis is similar to other reactive arthritis, and the attack rate is not altered by antibiotics.

Potential complications from treatment of GABHS pharyngitis include anaphylactic reaction to antibiotics and antibiotic resistance.

PRURITUS

Method of

Hassan Bencheqroun, MD

CURRENT DIAGNOSIS

- A careful history and physical examination will reveal a clear exposure, a sick contact, a recent travel, or clues to a systemic disease.
- Antihistamines are effective in treating histamine-mediated pruritus, but they are less effective in mechanisms involving serotonin, leukotrienes, etc.
- Initial testing in the absence of improvement with nonpharmacologic methods or antihistamine should include complete blood counts, thyroid-stimulating hormone, renal and liver panel, human immunodeficiency virus (HIV) test, and chest radiograph.
- Chronic pruritus may precede a systemic illness, especially in older adults. Hodgkin lymphoma is the malignant disease most strongly associated with pruritus and occurs in up to 30% of patients diagnosed with pruritus.

CURRENT THERAPY

- Acute and localized pruritus may resolve with nonpharmacologic methods, such as skin hydration with hypoallergenic, alcohol-free, and fragrance-free moisturizing creams; decreasing the length of showers and baths as well as the temperature of the water; identifying material that may irritate the skin either in jewelry or clothing items; and avoiding scratching.
- Wound care of scratch lesions includes any cellulitic portions.
- First-line pharmacologic treatments may include the use of antihistamine and antipruritic creams. Antipruritic agents may be used as second-line treatments.
- In the absence of improvement, the management of chronic pruritus should be directed at the underlying cause, or targets on the pruritic cascade—from blockade of intracellular and intercellular signaling pathways in the skin to the modulation of neurotransmission.

Pruritus is defined as an unpleasant sensory perception that causes the desire to scratch. While it shares similarities with pain, the neurophysiology of pruritus is distinct: pain causes withdrawal, whereas pruritus induces the reflex of reaching out and scratching.

Classification

Pruritus can be distinguished as acute or chronic, with the latter defined by the International Forum for the Study of Itch (IFSI) as lasting for 6 or more weeks.

Despite many classifications over the years, there is no uniform, clinically based classification of pruritic diseases to assist in the diagnosis and management of patients with pruritus. The classification chosen for this chapter focuses on clinical signs and distinguishes between the disease with and without primary or secondary skin lesions.

1. Group 1: Pruritus of primary diseased, inflamed skin
2. Group 2: Pruritus of primary nondiseased, noninflamed skin
3. Group 3: Pruritus with chronic secondary scratch lesions

Pathophysiology

The sensation of pruritus stems from a number of different causes. It is generally transmitted through slow-conducting unmyelinated C fibers and free pruriceptive cutaneous nerve endings located superficially in the skin, which appear to be more sensitive to pruritogenic substances than pain receptors. Histamine, neuropeptide substance P, interleukin 31 (mostly in atopic dermatitis), serotonin (a key component in several diseases), bradykinin, mast cell tryptase, and other unknown mediators (e.g., in uremic pruritus, cholestatic pruritus) may be involved in the genesis of pruritus. Impulses are transmitted from the dorsal root ganglion to the spinothalamic tract. Pruritus then generates a spinal reflex response, the scratch, which is as innate as a deep tendon reflex. Other pathogenic mechanisms include neuropathic (e.g., herpes zoster), acute traumatic stress (following burns and skin grafts), chronic pruritis increasingly seen in the elderly including paraneoplastic, and immune-mediated (atopic dermatitis). Lastly, opioids are known to modulate the sensation of pruritus, both peripherally and centrally.

Clinical Manifestations

Pruritus is among the most common symptoms in dermatology. While often overlooked, it is in fact rated by patients as the most quality-of-life–altering symptom of the underlying disease. Other associated symptoms depend on the etiology and may include urticarial skin lesions, dry skin, jaundice, and thyroid-related symptoms. Left untreated, itch and its associated scratching increase the risk of chronic skin changes and secondary infection.

Differential Diagnosis

The patient's workup further places him or her in one of the following categories:

close contacts, all close and family contacts should be cultured, and only those who are positive should be treated. Family pets are not reservoirs and do not spread disease.

Mass screening should be considered in outbreaks of GABHS in a closed or semiclosed community or in outbreaks of acute rheumatic fever or poststreptococcal glomerulonephritis.

Non-GABHS pharyngitis (i.e., group C or G β -hemolytic streptococcus) is not associated with rheumatic fever, and no evidence supports treatment or follow-up culture.

Complications

The complications of GABHS pharyngitis can be classified as suppurative and nonsuppurative.

Suppurative complications occur when the infection spreads to cause conditions such as lateral pharyngeal abscess, cervical lymphadenitis, sinusitis, otitis media, retropharyngeal abscess, Lemierre's syndrome, and mastoiditis. Appropriate treatment of GABHS with antibiotics decreases these complications.

Nonsuppurative complications include acute rheumatic fever, acute poststreptococcal glomerulonephritis, and poststreptococcal reactive arthritis. Acute rheumatic fever occurs 2 to 3 weeks after GABHS pharyngitis. It is not seen after GABHS skin infections. Starting antibiotics within 9 days of symptoms can prevent acute rheumatic fever. Acute poststreptococcal glomerulonephritis can occur 10 days after pharyngeal infection and 21 days after skin infection. Antibiotics do not alter the attack rate. Poststreptococcal reactive arthritis is similar to other reactive arthritis, and the attack rate is not altered by antibiotics.

Potential complications from treatment of GABHS pharyngitis include anaphylactic reaction to antibiotics and antibiotic resistance.

Pruritus is defined as an unpleasant sensory perception that causes the desire to scratch. While it shares similarities with pain, the neurophysiology of pruritus is distinct: pain causes withdrawal, whereas pruritus induces the reflex of reaching out and scratching.

Classification

Pruritus can be distinguished as acute or chronic, with the latter defined by the International Forum for the Study of Itch (IFSI) as lasting for 6 or more weeks.

Despite many classifications over the years, there is no uniform, clinically based classification of pruritic diseases to assist in the diagnosis and management of patients with pruritus. The classification chosen for this chapter focuses on clinical signs and distinguishes between the disease with and without primary or secondary skin lesions.

1. Group 1: Pruritus of primary diseased, inflamed skin
2. Group 2: Pruritus of primary nondiseased, noninflamed skin
3. Group 3: Pruritus with chronic secondary scratch lesions

Pathophysiology

The sensation of pruritus stems from a number of different causes. It is generally transmitted through slow-conducting unmyelinated C fibers and free pruriceptive cutaneous nerve endings located superficially in the skin, which appear to be more sensitive to pruritogenic substances than pain receptors. Histamine, neuropeptide substance P, interleukin 31 (mostly in atopic dermatitis), serotonin (a key component in several diseases), bradykinin, mast cell tryptase, and other unknown mediators (e.g., in uremic pruritus, cholestatic pruritus) may be involved in the genesis of pruritus. Impulses are transmitted from the dorsal root ganglion to the spinothalamic tract. Pruritus then generates a spinal reflex response, the scratch, which is as innate as a deep tendon reflex. Other pathogenic mechanisms include neuropathic (e.g., herpes zoster), acute traumatic stress (following burns and skin grafts), chronic pruritis increasingly seen in the elderly including paraneoplastic, and immune-mediated (atopic dermatitis). Lastly, opioids are known to modulate the sensation of pruritus, both peripherally and centrally.

Clinical Manifestations

Pruritus is among the most common symptoms in dermatology. While often overlooked, it is in fact rated by patients as the most quality-of-life-altering symptom of the underlying disease. Other associated symptoms depend on the etiology and may include urticarial skin lesions, dry skin, jaundice, and thyroid-related symptoms. Left untreated, itch and its associated scratching increase the risk of chronic skin changes and secondary infection.

Differential Diagnosis

The patient's workup further places him or her in one of the following categories:

1. Primary diseased, inflamed skin
 - **Inflammatory:** Atopic and contact dermatitis, psoriasis, dry skin, drug reactions
 - **Infectious:** Mycotic, bacterial and viral infections, folliculitis, scabies, pediculosis, arthropod reactions, and insect bites
 - **Autoimmune:** Bullous dermatoses, especially dermatitis herpetiformis, bullous pemphigoid, and dermatomyositis
 - **Dermatoses of pregnancy**
 - **Neoplasms:** Cutaneous T-cell-lymphoma (especially erythrodermic variants), cutaneous B-cell lymphoma, leukemic infiltrates of the skin
2. Primary nondiseased, noninflamed skin
 - Endocrine and metabolic diseases: Chronic renal failure, liver diseases/cholestasis, hyperthyroidism, malabsorption, perimenopausal pruritus
 - Infectious diseases: HIV infection, helminthosis, parasitosis
 - Hematologic and lymphoproliferative diseases, iron deficiency, polycythaemia vera, Hodgkin and non-Hodgkin lymphoma
 - Visceral neoplasms of the cervix, prostate, or colon, carcinoid syndrome
 - Pregnancy: Pruritus gravidarum with and without cholestasis
 - Drug-induced pruritus: Opioids, ACE-inhibitors, amiodarone, hydrochlorothiazide, estrogens, simvastatin, hydroxyethyl starch, allopurinol
3. Pruritus with chronic secondary scratch lesions (The underlying origin may be a systemic disease or a skin disease.)
 - Neurogenic origin (without neuronal damage), such as hepatic itch
 - Neuropathic diseases (neuronal damage causes itch)
 - Multiple sclerosis, neoplasms, abscesses, cerebral or spinal infarcts, brachioradial pruritus, postherpetic neuralgia, vulvodinia, small fiber neuropathy
 - Somatoform pruritus (e.g., obsessive-compulsive disorders)

Therapy

- Basic measures to lessen drying of skin: Limit bathing to short, cool showers with soap applied only to oily skin areas. A mild moisturizing cream is preferably applied immediately after bathing to lock in moisture. The patient's home should be humidified, especially during dry, cold winter months. Avoid contact irritants, such as wool, fiberglass, and detergents.
- Topical corticosteroids, oral melatonin⁷, and clonidine (Catapres)¹ showed some efficacy in reducing nocturnal itching or improving sleep quality in nocturnal pruritus.
- Many topical and systemic medications are available, but must be chosen according to existing comorbidities, possible interactions and side effects, and patient's compliance. Ultraviolet therapy may be administered in certain cases.
- Nonspecific therapy: A wheal and flare response is a marker of histamine-induced pruritus in patients with urticaria or an allergic dermatitis. These patients benefit from long-acting antihistamines. Concurrent H1 and H2 blockers increase therapeutic effectiveness. Also exercises focused on learning to disengage patient's attention away from pruritus or pain in chronic pruritus improves the symptoms.
- Specific antipruritic therapies target several points in the pruritic cascade—from blockade of intracellular and intercellular signaling pathways in the skin to the modulation of neurotransmission.
 - Nemolizumab⁵, an anti-IL-31 A receptor monoclonal antibody, was shown in a Phase II trial to induce a decrease of pruritus intensity in active treatment group when compared to placebo in atopic dermatitis patients.
 - Neurokinin 1 receptor antagonists such as Aprepitant (Emend)¹ showed potential activity in chronic pruritus. Novel

derivates with longer half-life time, such as serlopitant⁵ or trapidant⁵, are currently investigated in clinical trials.

- Future treatments also include bile acid transport inhibitors, phosphodiesterase-4 inhibitors, and nerve ion channels modulators.
- Treatment specific: Itching gradually recedes as the primary systemic condition improves.

Complications

Pruritus is accompanied by intense scratching. Skin may thicken, displaying lichen simplex chronicus: a localized skin thickening often appearing over the posterior neck, extremities, scrotum, vulva, anus, and buttocks. In prurigo nodularis, a variant of lichen simplex chronicus, some nodules develop over areas within easy scratching reach, such as the extensor arms and legs. Impetigo may result from superinfected excoriations in patients with atopic dermatitis.

⁵Investigational drug in the United States.

RHINITIS

Method of
Sheryl Beard, MD

CURRENT DIAGNOSIS

- Rhinitis presents as nasal congestion, sneezing, itching, rhinorrhea, and postnasal drainage.
- Patients with palatal and nasal itching should be considered for allergic disease.
- Allergic rhinitis is confirmed by positive skin-prick testing and IgE reactivity.
- Nonallergic rhinitis patients lack allergic evidence for disease.
- Nonallergic rhinitis conditions have multiple presentations.

CURRENT THERAPY

- Avoidance therapy should be first-line treatment for all forms of rhinitis.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

⁷Available as a dietary supplement.

1. Primary diseased, inflamed skin
 - **Inflammatory:** Atopic and contact dermatitis, psoriasis, dry skin, drug reactions

CURRENT THERAPY

- Avoidance therapy should be first-line treatment for all forms of rhinitis.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

⁷Available as a dietary supplement.

- Second generation oral antihistamines have good therapeutic efficacy for allergic rhinitis.
- Intranasal corticosteroids are the mainstay of treatment for nonallergic rhinitis and moderate-to-severe allergic rhinitis.
- Consultation with an allergy specialist should be considered in cases with multiple treatment failures.
- Patients whose allergic rhinitis is uncontrolled on multiple therapies should be considered for immunotherapy.

Introduction

Rhinitis is defined as inflammation of the nasal mucous membranes. Rhinitis presents as nasal congestion, sneezing, itching, rhinorrhea, and postnasal drainage; it can be divided into allergic and nonallergic rhinitis. Mixed rhinitis has components of both allergic and nonallergic disease. Allergic rhinitis is nasal inflammation that is mediated by IgE to environmental allergens. Nonallergic rhinitis is defined by non-IgE-mediated perennial symptoms. Nonallergic rhinitis shares symptoms with allergic rhinitis, but is only distinguishable by negative allergy tests. Nonallergic rhinitis is also known as perennial nonallergic rhinitis, idiopathic rhinitis, and vasomotor rhinitis.

Most research still classifies allergic rhinitis according to its seasonality or its perennial nature. Seasonal allergic rhinitis is commonly caused by pollen allergens; perennial allergic rhinitis is mainly caused by dust mites and animal dander. Allergic rhinitis can be further classified as mild, moderate, or severe. Mild rhinitis is rhinitis that does not impair work, school, daily functioning, or sleep. Moderate to severe rhinitis interferes with activities of daily living, quality of life, and/or sleep. Severe rhinitis is so marked that normal functioning cannot take place without treatment. Episodic allergic rhinitis occurs with sporadic inhaled aeroallergen exposure not typically encountered by the patient's usual indoor and outdoor environments. An example of episodic allergic rhinitis is a child who is allergic to cats but is not normally exposed, but then visits a household with cats and develops symptoms.

The Allergic Rhinitis and its Impact on Asthma Guidelines: Revised 2010 (ARIA) discouraged the use of the terms seasonal and perennial rhinitis in favor of intermittent and persistent rhinitis. Intermittent rhinitis can be defined as nasal symptoms lasting less than 4 weeks' duration and fewer than 4 days per week. Persistent rhinitis is rhinitis lasting more than 4 weeks' duration or more than 4 days per week.

No standard classification exists for nonallergic rhinitis. A variety of conditions present with similar symptoms and are called nonallergic rhinitis. Nonallergic rhinitis includes vasomotor rhinitis, gustatory rhinitis, nonallergic rhinitis with eosinophilia syndrome (NARES), occupational rhinitis, hormonal rhinitis, drug-induced rhinitis, and atrophic rhinitis. Another entity classified in or out of nonallergic rhinitis is infectious rhinitis.

Local allergic rhinitis is a newly defined entity found in nonatopic patients. Local allergic rhinitis is characterized by local inflammatory reactions including local eosinophils and localized IgE in response to aeroallergens. Local allergic rhinitis does not show significant skin-prick testing reactions, and patients have negative systemic IgE reactions to aeroallergens.

Rhinitis may be viewed by some as a trivial disease, but it places a significant financial burden on society. The estimated direct and indirect costs to society of rhinitis were around \$11.58 billion in 2002.

Epidemiology/Risk Factors

The National Health and Nutrition Survey (NHANES II and III) suggests that the overall prevalence of IgE sensitivity might be increasing. Of the patients evaluated for rhinitis in the United States, 43% (58 million people) have allergic disease, 23% (19 million people) have nonallergic disease, and 34% (26 million people) have mixed rhinitis. Seventy percent of allergic patients develop the disease in childhood (20 years and younger) as opposed to nonallergic rhinitis patients, 70% of whom develop disease in adulthood.

Approximately two thirds of nonallergic rhinitis patients have vasomotor rhinitis, and one-third have NARES. Nonallergic rhinitis has a female predominance.

The prevalence of local allergic rhinitis is largely unknown. In a small study of rhinitis patients, the prevalence of local allergic rhinitis was 25.7%, nonallergic rhinitis was 11.2%, and allergic rhinitis was 63.1%. Local allergic rhinitis is associated with asthma and conjunctivitis, and commonly begins in childhood.

Pathophysiology

Allergic

Allergic rhinitis is the result of an IgE mediated, type I hypersensitivity allergic reaction in response to an inhaled allergen. Allergens are proteins derived from airborne particulate matter, including dust-mite feces, pollens, animal dander, and cockroach particles. Antigen-presenting cells (APCs) engulf allergens in the nose and break them into antigenic peptides. APCs present these peptides to naïve T cells (T_H0). T_H0 cells differentiate once activated, into the T_H2 subtype. The T_H2 lymphocytes generate cytokines that regulate B-lymphocytes and sequester inflammatory cells (including eosinophils).

B-lymphocytes produce IgE. IgE attaches to mast cells and basophils and renders them sensitized. Once sensitized and cells are exposed to allergen, the mast cells and basophils degranulate. Degranulation of these cells releases a host of mediators including histamine and prostaglandin. Histamine stimulates histamine type I ($H1$) receptors on nerve endings that cause pruritus, sneezing and increased secretions. These symptoms constitute the early-phase response of allergic rhinitis. The early-phase response occurs within minutes of allergen exposure and dissipates within 1 hour.

Eosinophils produce IL-5, which acts to promote activation and survival of other eosinophils. Eosinophils also produce toxic products that damage local mucosal cells. The damage done by these cells is what constitutes the late-phase reaction. The late-phase reaction occurs several hours after allergen exposure and is characterized by nasal congestion.

Nonallergic Rhinitis

The nasal mucosa has two major functions; one is trapping inhaled particles through mucus production and the second is humidifying inhaled air through a complex vascular system. The mucus glands and the vascular system are regulated by the parasympathetic and the adrenergic nervous systems. Sensory nerves are stimulated by irritants in the nose through the use of a sensory receptor called a *nociceptor*. The nociceptive signal generates a neural reflex in the central nervous system (CNS) controlling sympathetic and parasympathetic tone in the nasal mucosa. Parasympathetic stimulation results in mucus production. Sympathetic stimulation causes vasoconstriction, which empties venous cavities. Lack of sympathetic tone causes venous engorgement and nasal congestion.

Symptomatic nonallergic rhinitis is an exaggeration of a normal defensive mechanism. Inflammation in the nose causes an upregulation of this neural activity, resulting in the exaggerated response (also known as neural hyperresponsiveness). Hyperresponsive parasympathetic efferent nerves trigger glandular activation in the nasal mucosa, leading to vasodilation and mucus production. Excessive mucus production anteriorly causes rhinorrhea and posteriorly causes postnasal drip. This hyperresponsiveness can be due to structural or functional components of the nasal mucosa altered through genetic or pathologic factors. The exact mechanisms of nonallergic rhinitis conditions are poorly understood because of their multiple presentations.

Infectious Rhinitis/Rhinosinusitis

Acute sinusitis (rhinosinusitis) most commonly occurs as a complication of viral upper-respiratory infections (URIs). Viral URIs cause nasal mucosal edema, which leads to obstruction of the sinus openings and ciliary impairment. Bacteria proliferate in the stagnant mucus as well as the low-oxygen-tension environment of the sinus cavities. Chronic rhinosinusitis is the result of long-term obstruction and/or dysfunction of the sinuses. Chronic inflammation leads to chronic low-grade infections.

Prevention

Environmental control of allergens can improve the severity of allergic rhinitis and can reduce the need for medications. Environmental control should be thorough if treatment is sought, but the full beneficial effects of the change may take weeks to months. Mild disease can usually be managed with avoidance measures. Complete avoidance of allergen, particularly pollen, is usually not feasible.

Reduction of dust mite allergen exposure can be done in the following ways: remove carpets and soft toys, use covers impermeable to allergen for mattresses and pillows, vacuum beds weekly, and wash bedding at 60 degrees Celsius (140 degrees Fahrenheit). Pet dander avoidance can only be effectively managed by removing the pet and carefully cleaning all carpets, furniture and mattresses.

Clinical Manifestations

If the patient presents with symptoms of palatal itching, nasal itching, ocular symptoms, or sneezing, consideration should be given to an allergic cause.

The presentation of nonallergic rhinitis is dependent on the type of nonallergic rhinitis. Overall, patients with nonallergic rhinitis lack other allergic conditions.

The vasomotor rhinitis patient will present with predominantly nasal obstruction and rhinorrhea. Typically, symptoms are triggered by temperature, exercise, and environmental stimuli (odors, smoke, and dust).

NARES patients generally have more intense symptoms than vasomotor rhinitis or allergic disease patients. NARES patients present with paroxysms of flares to include sneezing, watery rhinorrhea, nasal itching, congestion, and some anosmia. NARES patients have eosinophils on a nasal smear, but lack other allergic evidence by skin-prick testing.

Gustatory rhinitis sufferers complain of nasal congestion and rhinorrhea associated with ingestion of foods and, sometimes, alcoholic beverages.

Nasal crusting, dryness, and fetor are the characteristics of atrophic rhinitis. These findings are due to glandular cell atrophy. Patients will have abnormally wide nasal cavities and may have squamous metaplasia.

Occupational rhinitis patients have components of allergic and nonallergic disease. Patients present with nasal congestion and rhinorrhea triggered by an occupational exposure. Symptoms are present during duty and generally improve away from the work environment. Substances leading to symptoms include irritating chemicals, grain dust, ozone, lab animal antigens, and wood. Often occupational rhinitis co-exists with occupational asthma.

Hormonal rhinitis manifests as nasal congestion during pregnancy or the menstrual cycle. Pregnant women are six times more likely to have rhinitis and sinusitis than nonpregnant women. Rhinitis usually resolves two weeks postdelivery.

Drug-induced rhinitis occurs with certain medications. ACE inhibitors, phosphodiesterase-5 selective inhibitors, alpha-receptor antagonists, and phenolamine are common triggers. Patients present with rhinorrhea and nasal congestion.

Rhinitis medicamentosa is a condition that presents with severe congestion. It is caused by prolonged and repetitive use of topical nasal decongestants. It can also be associated with cocaine use.

Anatomic rhinitis is more likely in patients who present with unilateral nasal symptoms.

Infectious rhinitis presents with sinus tenderness, erythema to the mucosa, postnasal drainage and sometimes periorbital edema.

Diagnosis

The diagnosis of allergic rhinitis, nonallergic rhinitis, and infectious rhinitis is based largely on history and physical examination. Other diagnostic testing can be performed to aid in providing a more definitive diagnosis or to rule out other causes.

Allergic rhinitis is confirmed by IgE reactivity to environmental allergen sensitivity through skin-prick testing. When skin-prick testing is difficult to interpret or if it is not feasible, serum-allergen-specific IgE testing can be used. Nasal smears looking for

eosinophils are not recommended for routine use in the diagnosis of allergic rhinitis.

Other testing available for evaluation of rhinitis includes nasal endoscopy, rhinomanometry, and radiologic imaging. Fiberoptic nasal endoscopy is reserved for those with atypical symptoms or an inadequate response to treatment. Rhinomanometry measures airflow obstruction in the upper airway. Rhinomanometry provides an objective measurement of nasal congestion. Rhinomanometry is used to evaluate clinical response to interventions and assess anatomic severity, such as in patients with obstructive sleep apnea. Radiologic imaging, such as computerized tomography (CT) and magnetic resonance imaging (MRI), is used to evaluate anatomic structure. Imaging may not correlate well with nasal function and is expensive.

If a provider suspects a cerebrospinal fluid (CSF) leak, the rhinorrhea can be evaluated for beta transferrin protein, which is present only in CSF.

History

The best diagnostic tool in the evaluation of rhinitis is the history. Information regarding previous evaluation and treatment should be elicited. A positive family history of rhinitis points towards allergic disease. The history of symptoms should include questions regarding congestion; sneezing; rhinorrhea; sore throat; dry throat; cough; itchy, red, or tearing eyes; voice changes; sinus symptoms of drainage; pressure or pain; snoring; ear pain or loss of hearing; and smelling difficulty.

When gathering the details of each symptom, evaluate the onset (such as those in childhood), frequency (episodic versus continual), pattern (seasonality), characteristics of secretions, triggers, severity (to include quality of life evaluation), and associated geographic location or environment (home versus work). Once a trigger is identified, history needs to be gathered even further to evaluate the possibility of modifying the exposure.

Physical Examination

As with any disease process, the physical examination provides clues into the diagnosis. Although the physical examination in rhinitis patients should focus on the nasal mucosa, other body areas should be examined to rule out other processes. For example, the tympanic membranes should be examined for mobility, retraction, erythema, and Eustachian tube dysfunction.

Examination of the eyes in allergic rhinitis might show that the conjunctiva have edema, erythema, and/or cobblestoning. Excessive lacrimation could be another finding. Darkening of the skin of the lower eyelids is prevalent in allergic disease and is also called "allergic shiners."

Allergic and nonallergic nasal mucosa may have a similar appearance. The nasal mucosa may appear boggy with a bluish appearance or be erythematous. Excessive watery-clear mucus might be present. Turbinate hypertrophy is another physical examination finding in rhinitis. Other nasal mucosa findings to look for are nasal polyps, sinusitis, septal deviation, septal perforation, and crusting.

Looking for elongated facies, mouth breathing, and a high arch in the palate may provide a clue to the severity of the nasal obstruction. The tonsils and adenoids should be examined for enlargement. Posterior nasal drainage and cobblestoning in the oropharynx are common findings in rhinitis patients.

The skin examination provides useful information in the patient with rhinitis. Atopic dermatitis or urticaria may be findings associated with allergic disease. The skin should be evaluated for dermatographism. Patients with dermatographism cannot be evaluated for allergic disease using skin-prick testing.

Differential Diagnosis

Many different pathologic conditions can present similarly to rhinitis. Conditions to keep in mind while evaluating and treating a patient for rhinitis include: nasal polyps, ciliary dyskinesia syndrome, anatomic abnormalities such as deviated septum or tumors, nasal turbinate hypertrophy, cerebrospinal fluid rhinorrhea,

pharyngonasal reflux, systemic disorders such as Wegener's disease, aspirin intolerance, and other medication side effects.

Treatment

Overall

Current guidelines in treatment of rhinitis do not take cost into consideration. However, the individual treatment goals should be based on factors such as age, route of administration preference (i.e., nasal versus oral), severity, seasonality, side effects, cost, benefit to comorbid conditions, and onset of action. For example, onset of action is an important consideration for an individual who has more episodic symptoms. Also, individual patients respond differently to treatment regimens within a given group.

Avoidance

Due to the lack of high-quality evidence, implementation of avoidance measures is largely based on panel recommendations. In addition, the ubiquitous nature of allergens may limit the effectiveness of the avoidance measures. For dust mites, encasing pillows and bedding in dust mite resistant materials may be beneficial. Pollen is seasonal and can be minimized by keeping the windows closed, using air conditioning, and limiting outdoor exposure. Using particulate filters in the home can also assist in reducing overall allergen load of pollens and dust. Avoiding basements and lowering household humidity may reduce the amount of mold exposure patients receive. Pet avoidance can only be reached by ridding the house of the pet altogether. Other, less-effective measures include limiting exposure of the pet to the house and/or bedroom.

Intranasal Corticosteroid (INS)

Intranasal corticosteroids are first-line treatment for moderate to severe allergic rhinitis and most nonallergic rhinitis conditions. All allergic rhinitis symptoms can be treated with INS. The intranasal corticosteroids budesonide aerosol (Rhinocort Aqua), fluticasone propionate aqueous (Flonase), and beclomethasone aqueous (Beconase AQ) preparations all have a Federal Drug Administration (FDA) treatment indication of nonallergic rhinitis. Intranasal corticosteroid side effects include irritation, bleeding, and perforation of the nasal septum; rarely, local candidiasis is seen with INS use. They are safe to use in pregnancy. No single INS preparation is more efficacious than, or has any relevant difference from, any other. INS has negligible hypothalamic-pituitary-adrenal axis suppression, and systemic burden is clinically insignificant.

Intranasal Anticholinergic (IP)

Ipratropium bromide (Atrovent), a specific intranasal anticholinergic, inhibits parasympathetic function in the nasal mucosa. The parasympathetic blockade reduces the output of secretions from seromucous glands in the nose. Ipratropium can be used in treatment of anterior watery rhinorrhea but has a very limited role in reducing postnasal drip, nasal congestion, or sneezing. Topical ipratropium prior to ingestion of food can be used as pretreatment of gustatory rhinitis and is effective in treatment of the common cold and skier's nose. Side effects of IP include nasal dryness, burning, irritation, stuffy nose, headache, and dry mouth.

Intranasal Antihistamine (INA)

Azelastine (Astelin) is a nasal spray approved by the FDA for allergic and vasomotor rhinitis. Olopatadine (Patanase) intranasal spray has been approved for seasonal allergic rhinitis. INA has faster onset of action than intranasal corticosteroids. INA should be taken twice per day for maximum clinical benefit and may benefit those with nasal congestion. INA does not produce a significant amount of sedation, but side effects include headache, epistaxis, bitter taste, and nasal irritation.

Nasal Cromolyn

Cromolyn (NasalCrom) should be considered for early mild rhinitis, but should not be considered a first-line treatment in allergic rhinitis. Nasal cromolyn can be used prior to allergen exposure

for prophylaxis of episodic allergic rhinitis. Cromolyn is mostly void of side effects. Cromolyn inhibits mast cell degranulation and is administered three to four times a day. Cromolyn has very limited usefulness for nonallergic rhinitis conditions.

Nasal Saline

Using nasal saline to irrigate the nasal cavities may remove mucus, enhance ciliary movement, improve sinus opening, and remove allergic and irritant particles. Several devices exist including: the neti pot, a nasally adapted plastic bottle, and a pulse irrigator. Evidence suggests that hypertonic saline provides modest benefit over isotonic saline, although it might be more irritating.

Topical Decongestants

Topical decongestants reduce congestion, but have no effect on itching, sneezing, or rhinorrhea. Oxymetazoline (Afrin), a common topical decongestant, causes nasal vasoconstriction. Vasoconstriction can cause tissue hypoxemia and inflammation, leading to severe rebound nasal congestion. Topical decongestants are not recommended for continued use because they can cause rhinitis medicamentosa.

Oral Antihistamines

Oral antihistamines block H1 receptors, thereby reducing nasal and palatal itching, rhinorrhea, sneezing, conjunctivitis, and urticaria. Nasal congestion is not treated well with oral antihistamines. First-generation oral antihistamines are poorly selective for H1 receptors. The sedative effects of these antihistamines result from crossing the blood-brain barrier; they have been linked to industrial accidents and contribute to loss of function at work and school. For these reasons, first-generation antihistamines have limited usefulness. Second generation H1 antagonists have excellent evidence for therapeutic efficacy. These medications may have some role in the treatment of nonallergic rhinitis because of their anticholinergic properties, but consideration must be given to these systemic properties, including dry mucous membranes, blurry vision, constipation, tachycardia, and urinary retention. A combination of intranasal corticosteroid treatment with oral antihistamines may be effective for sneezing and rhinorrhea in NARES.

Leukotriene Receptor Antagonists (LTRA)

Leukotriene receptor antagonists were originally studied in the treatment of asthma. The only LTRA approved by the FDA for treatment of allergic rhinitis is montelukast (Singulair). Montelukast is clinically efficacious in both perennial and seasonal allergic rhinitis. Montelukast is approved for children 6 months and older and has a pregnancy category B rating. The oral antihistamine loratadine (Claritin) and montelukast have similar efficacy, and can have additional benefit when used together. Although rare, montelukast has been associated with adverse psychiatric behavior, including suicidality. LTRA have no role in nonallergic rhinitis.

Oral Decongestants

Oral decongestants such as pseudoephedrine reduce nasal congestion. Oral decongestants have a sales restriction in many states. Side effects include insomnia, anorexia, irritability, and palpitations. Blood pressure elevation is rarely a concern in controlled hypertensive patients or in normotensive patients. Oral decongestants should be considered last-line treatment for nonallergic rhinitis conditions.

Systemic Corticosteroids

Few studies are available to support the use of systemic steroids in the treatment of rhinitis. Oral corticosteroids may have a role for severe resistive rhinitis, but not as first-line treatment. Short-term use of 5 to 7 days of oral corticosteroids is the standard, but they should not be used for longer than 3 weeks because of the risk for adverse effects. Oral steroids should be used as first-line treatment for severe nasal polyposis, a subset of anatomic rhinitis. Systemic steroids should not be used in children or pregnant women. Intranasal injections of corticosteroids have no role in the treatment

of rhinitis. Parenteral corticosteroids are contraindicated because of long-term effects.

Surgery

Surgery can reduce nasal obstruction caused by septal deviation, turbinate hypertrophy, or adenoid hypertrophy. Procedures that can be performed include nasal polypectomy, septoplasty, reductive hypertrophic turbinate surgery, adenoidectomy, and endoscopic sinus surgery. Two nerves can be transected to decrease the parasympathetic nerve supply to the nasal mucosa: the vidian nerve, through endoscopic resection; and the anterior ethmoid nerve, through electrocoagulation, which leads to reduced nasal secretions.

Anti IgE

Omalizumab (Xolair) is a monoclonal antibody available for the treatment of poorly controlled asthma, but it might have a role in the treatment of allergic rhinitis.¹ Omalizumab binds to IgE, hindering its relationship with inflammatory cells. Omalizumab only binds to circulating IgE and not bound IgE. Due to its high cost, reports of anaphylaxis, and its injectable only formulation, omalizumab has a limited role in allergic rhinitis treatment.

Immunotherapy

Allergen extract immunotherapy has been used in the treatment of respiratory allergic disease since 1911, and its efficacy has been documented since the 1970s. The amount of allergen in each immunotherapy dose is slowly increased with each dose until a maintenance phase is reached. Immunotherapy is an effective treatment for allergic rhinitis and is the only treatment proven to alter the course of allergic disease. Debate exists regarding which form of immunotherapy is superior. Contraindications to immunotherapy include beta-blocker use, due to complications in treating anaphylaxis, and uncontrolled underlying diseases, such as uncontrolled asthma.

Subcutaneous immunotherapy uses the injectable form of allergen extract. Adequate treatment usually consists of a 3- to 5-year course of immunotherapy. Subcutaneous immunotherapy is indicated in those patients for whom medications and avoidance measures are inadequate, as well as those with only a few relevant allergens. The inherent risk of subcutaneous immunotherapy is systemic anaphylaxis, therefore it is dosed in the physician's office. The rate of local reactions in subcutaneous immunotherapy is 0.6-58% and systemic reactions is 0.06 to 0.9%. The risk of death is 1 per 2.5 million injections. Subcutaneous immunotherapy is covered by most insurance plans.

Studies for local-route immunotherapy (noninjected), many of which were carried out in Europe, have only been undertaken in adults. Local routes of immunotherapy include sublingual, local nasal, oral, and bronchial. Indications for local-route immunotherapy are the same as those for subcutaneous immunotherapy.

Sublingual immunotherapy was approved by the FDA in April 2014. Sublingual immunotherapy formulations in the United States are low dose compared to those used in Europe, but have limited allergens available. The risk profile is low and therefore can be dosed at home. The rate of local reactions with sublingual immunotherapy is 0.2-97% and systemic reactions is 0.056%. No deaths have been reported with sublingual immunotherapy use. Some medical allergy providers use subcutaneous extracts (aqueous) as sublingual therapy, but this is an off-label use.

Use of local nasal immunotherapy is used mostly in Europe. Oral and bronchial immunotherapy are not supported by evidence.

Monitoring

The provider should consider stepping down treatment when the patients' symptoms have been controlled. The Total Nasal Symptoms Score [TNSS] is a subjective assessment of the patient's specific symptoms, including rhinorrhea, nasal congestion, sneezing,

and pruritus, and can be used to assess effectiveness of medications. The Rhinoconjunctivitis Quality of Life Questionnaire can also be used. Consideration for referral to an allergist might be extended to patients who have had a prolonged course, secondary infections, polyps, or other comorbid conditions including chronic sinusitis and asthma, or if immunotherapy is a consideration.

Complications

Rhinitis is associated with multiple complications including fatigue, decline in cognitive function, loss of productivity, headache, and disturbance of sleep. Patients with mild disease may experience these in mild form. Patients with moderate to severe disease may experience these complications in addition to impairment of activities, leisure, and work or school functioning.

SPINE PAIN

Method of

David Borenstein, MD; and Federico Balagué, MD

CURRENT DIAGNOSIS

- Most spine pain is mechanical in origin in 95% or more of patients.
- Symptoms of mechanical acute spine pain resolve in most patients in 1 to 8 weeks.
- Most patients with spine pain do not require laboratory tests or radiographs to achieve resolution of their symptom of spine pain.

CURRENT THERAPY

- Localized neck or low back pain
 - Encouragement to remain active out of bed
 - Patient education about the natural history to improvement
 - Reassurance about the incidence of resolution
 - Effective oral drug therapy: NSAIDs, analgesics, muscle relaxants
 - Physical therapy with exercise program
- Radicular pain
 - Encouragement to remain active out of bed

¹Not FDA approved for this indication.

of rhinitis. Parenteral corticosteroids are contraindicated because of long-term effects.

Surgery

Surgery can reduce nasal obstruction caused by septal deviation, turbinate hypertrophy, or adenoid hypertrophy. - Most patients with spine pain do not require laboratory tests or radiographs to achieve resolution of their symptom of spine pain.

CURRENT THERAPY

- Localized neck or low back pain
 - Encouragement to remain active out of bed
 - Patient education about the natural history to improvement
 - Reassurance about the incidence of resolution
 - Effective oral drug therapy: NSAIDs, analgesics, muscle relaxants
 - Physical therapy with exercise program
- Radicular pain
 - Encouragement to remain active out of bed

¹Not FDA approved for this indication.

- Patient education about the potential for improvement
- Efficacy of oral drug therapy: NSAIDs, analgesics, muscle relaxants, corticosteroids, antiseizure medication, epidural corticosteroid injections
- Physical therapy: Mackenzie exercises for disk herniation
- Surgical decompression for cauda equina, motor weakness, or intractable pain

Abbreviation: NSAID = nonsteroidal antiinflammatory drug.

Spine pain is a common symptom that is diagnosed and treated by a wide variety of health care professionals. The interest in this medical problem is not limited to its incidence as a patient problem but also stems from the likelihood of spine pain being experienced by the treating physician as well. The good news about spine pain is that the vast majority of patients (about 90%) improve over 2 months with minimal intervention, but relapses are frequent. The bad news is that the smaller number of patients who develop chronic spine pain use more than the majority of health resources expended on this expensive medical problem. The goal of therapy is to relieve spine pain while it is acute so that chronic pain does not develop.

The axial skeleton may be divided into cervical, thoracic, lumbar, sacral, and coccygeal locations. The lumbar and cervical areas are the most mobile and at greatest risk for damage. These two areas will be the primary subjects of this article.

Epidemiology

Spine pain is the most common musculoskeletal complaint worldwide and produces direct and indirect costs of hundreds of billions of dollars each year in the United States. More than 80% of the world's population at some time during their lives will have an episode of low back pain. An estimated 20% of the US population has back pain every year. Neck pain occurs at a variable rate ranging from 0.055/1000 person-years (disk herniation with radiculopathy) to 213/1000 person-years (self-reported neck pain). Thoracic spine pain is relatively rare compared with the incidence of pain in the other two locations in the axial skeleton.

Persons of all ages develop spine pain. Younger people are at risk for developmental problems (idiopathic scoliosis, spondylolysis, spondylolisthesis), and older patients develop disorders associated with degeneration of spinal structures (osteoarthritis, spinal stenosis).

Risk Factors

Psychosocial factors are stronger predictors of incident low back pain than mechanical factors in adolescent populations. In adults, psychosocial difficulties are risk factors for chronicity more strongly related to outcome than any clinical or mechanical variables. Previous episodes of spine pain are strong predictors of future ones.

Studies of cohorts of twins have shown that nonspecific low back pain is more than 60% genetically determined, and work and leisure-time physical activities play a minor role. Other environmental factors, such as smoking and obesity, have not been shown to be a predictor of the development of spine pain on a consistent basis.

Pathophysiology

Most of the structures of the axial skeleton receive sensory input. The presence of anatomic alterations in these structures is not sufficient to predict the presence of pain. In general, spine pain is referred to as nonspecific because no definite pain generator can be identified. The nociceptive inputs generated by musculoskeletal structures is referred to as *somatic pain*.

In the first few decades of life, muscular sprains and strains of the paraspinal muscles in the lumbar and cervical regions are the most likely source of spinal pain. These muscular injuries occur when lifting in a position that places stress on paraspinal

structures. Often the spine is in an awkward position and is mechanically disadvantaged. The subsequent muscle injury results in reflexive muscular contraction that can recruit muscles in the same myotome. Tonic contraction approximates the damaged components of the muscle but results in relative anoxia that causes the production of anaerobic metabolites that stimulate nociceptors. The number of recruited muscles may be extensive, manifested by severe spinal stiffness and limitation of motion. Most of these soft-tissue injuries to the muscle heal spontaneously without any long-term structural alterations.

Simultaneously, as people age, intervertebral disks become flatter as the nucleus pulposus loses its absorbency and the annulus fibrosus fissures and degenerates. The process results in the loss of disk integrity. Degeneration of normal biomechanical and biochemical disk properties results. Biomechanical insufficiency inevitably results in a transfer of stresses posterior to the facet joints and ligaments that are ill suited to assume compressive, tensile, and shear loads. Osteophytes form in response to these abnormal pressures, compromising the space for the neural elements. Disk degeneration itself might not be a painful process until alterations in facet joint alignment result in the onset of articular pain.

Spondylolysis is a developmental abnormality associated with a stress fracture in the growth plate of the pars interarticularis. This abnormality may be discovered as a radiographic abnormality in an asymptomatic patient. An increased risk of low back pain occurs with spondylolisthesis, the abnormality associated with instability of spinal elements in the setting of spondylolysis.

Pain generation in the axial skeleton may be somatic or neuropathic in origin. The joints, ligaments, muscles, fascia, blood vessels, and disks can be the source of localized somatic spine pain. Somatic pain, when it does radiate, tends to be less focused in distribution and exacerbated by specific positions of the spine.

Neuropathic or radicular pain is the sensation generated by damage of neural elements. Intervertebral disk herniation with compression of spinal nerve roots causes neural inflammation resulting in neuropathic and radicular pain. Radicular pain follows the path of the corresponding spinal nerve root. In addition to pain, sensory deficits and muscle weakness can occur, depending on the intensity of the nerve compression. In the setting of chronic low back pain, the role of the central nervous system in mediating persistent symptoms has been highlighted increasingly in the medical literature.

Prevention

Since the turn of the century, adolescents have reported nonspecific spine pain at an incidence similar to that in adult populations. This finding suggests that primary prevention must be given at a very early age to have any chance of efficacy.

Among papers reporting on primary prevention, only exercise has shown effectiveness, with effect sizes ranging from 0.39 to 0.69. Other techniques, such as stress management, shoe inserts, back supports, education, and reduced lifting, were found ineffective.

Clinical Manifestations

The most common symptoms of spinal disorders are regional pain and decreased range of motion associated in a minority of patients with radiating pain. For the majority of patients, pain has mechanical characteristics: Its intensity increases with physical activity, movements, or some postures and decreases with rest. However, it has been demonstrated that nocturnal pain is not uncommon in the absence of serious, specific spinal disorders. The precise topography of pain is often difficult for the patient to describe, and its interpretation is difficult owing to the overlap of the cutaneous projections between adjacent spinal levels and the similarities between dermatomes, myotomes, and sclerotomes.

Diagnosis

The diagnosis of spine pain is based upon the patient's history and physical examination. The history and physical examination should include a description of the pain that is as detailed as

possible (e.g., past episodes, precise location, beginning of symptoms, factors increasing or decreasing pain intensity, radiating pain, neurologic symptoms, systemic symptoms), patient's medical history (e.g., past spinal surgery, neoplasia, corticosteroid treatments), and a limited physical examination focused on the posture of the spine, range of motion, muscle contraction, pain on palpation or percussion, and a brief neurologic examination.

Besides the high rate of false-positive results and financial costs, imaging studies have a negative effect on a patient's quality of life. Therefore, unless there is a clear-cut surgical indication or a suspicion of an underlying life-threatening disorder, no imaging studies should be ordered on the first encounter for a patient with acute nonspecific low back or neck pain. Similarly, laboratory testing is not required unless a patient presents with clinical symptoms that suggest a systemic illness (e.g., fever, weight loss).

Differential Diagnosis

A number of guidelines are available in the literature to help a clinician in the diagnosis and treatment of patients with spine pain. The purpose of these approaches is to differentiate the vast majority of patients with mechanical disorders who will improve with noninvasive therapy without the need for radiographic or laboratory investigation from the small minority with a specific cause of spinal pain.

Traditionally, red flags have been used to identify patients with a systemic disorder causing spine pain. The red flags have included questions regarding prior history of cancer, weight loss, prolonged morning stiffness, bladder dysfunction, and bowel

dysfunction. The presence of these findings suggests a diagnosis of malignancy, infection, spondyloarthropathy, or cauda equina syndrome, respectively. A study has reported that red-flag disorders occur so infrequently and have so many false-positive findings as not to be helpful in the primary care setting at the initial visit. The one exception was spine pain associated with osteoporotic vertebral compression fractures.

Despite the findings of this one report, clinicians need to be mindful of patients who would be harmed to a significant degree by delayed therapy. The disorders that require expeditious evaluation and treatment are intraabdominal vascular disorders with tearing pain and hemodynamic instability (expanding aortic aneurysm); cauda equina syndrome with bilateral sciatica; saddle anesthesia; bladder or bowel incontinence (lumbar space-occupying compressive lesions); and cervical myelopathy with balance difficulties, autonomic dysfunction, and hyperreflexia with spasticity and Babinski's sign (cervical space-occupying compressive lesions). These disorders require expeditious vessel repair or decompression surgery.

The differential diagnosis of mechanical low back pain (Table 1) and mechanical neck pain (Table 2) includes disorders ranging from muscle strain and herniated disk to scoliosis and whiplash injuries. The age of patients, pain pattern with exacerbating and mitigating factors, tension signs, and findings of plain radiographs can help differentiate among these common causes of spine pain.

Nonspecific is a term used commonly to describe the pain associated with mechanical disorders. On occasion, physicians have confused the use of "nonspecific" as meaning an absence of

BOX 1 Management of Low Back Pain**Acute (3–6 weeks)**

First consultation: gather information on core outcome domains
 Rule out pain of nonspinal origin
 Rule out specific causes (red flags)
 No routine imaging
 Inform and reassure the patient. Advise to stay active and continue daily activities, if possible, including work
 Prescribe analgesia, if necessary. First choice: acetaminophen; second choice: NSAIDs
 Consider adding muscle relaxants (short course) or referring for spinal manipulation
 Avoid overmedicalizing, especially in patients with favorable outcome
 Be aware of yellow flags: inappropriate attitudes and beliefs about back pain, inappropriate pain behavior, emotional problems

Subacute (6–12 weeks)

Reassessment
 Bear in mind minimum clinically important difference of core outcome tools

Consider patients' expectations
 Consider yellow flags if outcome is not favorable
 Reassess regularly by valid outcome tools to evaluate response to treatment
 Focus on function
 Give priority to active treatments
 Consider multidisciplinary program in occupational setting for workers with subacute low back pain and sick leave (>4–8 weeks)

Chronic (3–12 weeks)

Repeat thorough clinical examination
 In cases of low impairment and disability, simple evidence-based therapies (e.g., exercises, medication, brief interventions) might be sufficient
 In cases of more-severe disability or chronicity, give priority to multidisciplinary approaches (biopsychosocial)

Abbreviation: NSAID = Nonsteroidal antiinflammatory drug.

From Balagué F, Mannion AF, Pellisé F, Cedraschi C. Clinical update: low back pain. *Lancet* 2007;369(9563):726–728.

pathology causing pain associated with mechanical disorders. The “nonspecific” designation refers to the inability to identify the specific pain-generating anatomic structure, not the absence of somatic pain.

Therapy

Many mechanical disorders of the spine are self-limited in duration, with a vast majority of patients improving gradually over time (Box 1). This progression to “natural healing” makes placebo look efficacious in many clinical trials investigating therapies for spine pain. This situation results in evidence-based reviews of spine pain therapies revealing very few categories that have a clinically significant impact on improvement. Nonetheless, physicians need to make therapeutic choices for their patients despite this relative paucity of evidence. Therapy for spine pain includes controlled physical activity, nonsteroidal antiinflammatory drugs (NSAIDs), skeletal muscle relaxants, local and epidural corticosteroid injections, and long-term pain therapy. Surgical intervention is reserved for patients who have surgically correctable abnormalities and who have cauda equina syndrome, increasing motor weakness, spasticity, or intractable pain.

The treatment of an individual patient has to be tailored based on the patient's expectations and preferences. Goals of the treatment should be clearly defined, and the patient should be informed about the expected benefits and side effects of the treatment at the first encounter. A short trial limited to a few days may be a good start.

Self-management with education of the patient about maintaining physical activities as tolerated has been encouraged for neck and low back pain. Information on nonpharmacologic pain-management strategies and daily life activities may be provided by health care providers, but patients adhere more to the former than to the latter.

Exercises are slightly effective for pain and function in patients with chronic low back pain. No specific form of exercise is clearly better than others.

The use of manipulative physical techniques in the care of patients with spine pain remains controversial. The absence of clear-cut distinctions between manipulative techniques with or without thrust adds to the confusion when one analyzes the efficacy of manual therapy treatments. Overall there is some clinical trial evidence in favor of spinal manipulation for acute low back pain.

NSAIDs have short-term efficacy for both acute and chronic low back pain; however, the effect sizes are not very large. The efficacy of these drugs for patients with radicular pain has not been

evaluated well enough to make general recommendations. No single class of NSAIDs has superiority to another. Cyclooxygenase 2 (COX-2) inhibitors have a better gastrointestinal (GI) safety profile but no greater efficacy. A patient's response cannot be predicted, and a trial-and-error approach is often necessary.

Opiates have not demonstrated any favorable influence in the outcome of low back pain patients. Side effects are quite common and the risk of addiction is real. When these kinds of drugs are effective, the improvement is more important in pain intensity than in terms of function. Muscle relaxants do have some efficacy for acute and chronic low back pain, but the effect size is limited.

Antidepressants are not generally prescribed owing to an inconsistent improvement of patients. For patients with chronic low back pain and depression, an optimized antidepressant treatment shows a better effect on depression than on pain and functional capacity. Duloxetine (Cymbalta), a serotonin and norepinephrine reuptake inhibitor, is approved by the U.S. Food and Drug Administration for the indication of chronic low back pain.

Evidence is lacking to support the prescription of systemic corticosteroids. However, corticosteroids have the advantage of not being toxic to the kidneys. Oral corticosteroids may be considered in patients with radicular pain from a herniated disk or spinal stenosis where epidural injections are relatively contraindicated (chronic warfarin therapy).

Some patients will have persistent neuropathic pain despite surgical decompression or as a result of postsurgical fibrosis. Opioid therapy is ineffective in many patients with chronic neuropathic pain. Antiepileptic medicines, such as gabapentin (Neurontin)¹ and pregabalin (Lyrica), have efficacy in peripheral neuropathic pain. These same medicines are prescribed in patients with chronic neuropathic radicular pain with the hope that the mechanisms that work with peripheral neuropathy will also work for spine pain patients. Other medicines including antidepressants (duloxetine [Cymbalta], tricyclic antidepressants) have been tried when other drugs have been ineffective.

Epidural, selective nerve root, or facet joint injections have not shown adequate efficacy to be recommended on a regular basis. However, a limited number (2 or 3) of spinal injections may be attempted for patients with radicular pain who do not improve with oral medication.

¹Not FDA approved for this indication.

Spinal surgery is indicated for disk herniation with radicular compromise, cervical or lumbar spinal stenosis with myelopathy or neurogenic claudication, and unstable spondylolisthesis. Controversy remains, however, concerning the relative benefit of surgical versus medical therapy for radiculopathy. Discectomy significantly shortens (by about 8 weeks) the acute phase of pain associated with radiculopathy. However, studies with longer follow-up periods have never shown a clear difference between conservative and surgical therapies. Some studies have shown that intensive, multidisciplinary, conservative programs can be compared with surgical fusion procedures for patients with spinal instability.

For the most chronically disabled spine pain patients only, intensive multidisciplinary programs including, among others, physical reconditioning and cognitive-behavioral methods, have shown effectiveness.

Monitoring

From the standpoint of monitoring the efficacy of the treatment, five main dimensions have been recommended to evaluate the outcome of patients with spine pain. The intensity of pain is relevant, but so is the perceived functional capacity, generic health status, work disability, and satisfaction with treatment. Many tools are available for the evaluation of each specific dimension. The clinician who decides to start using any specific tool needs to know, among other information, the minimal clinically meaningful changes for each tool, because differences that may be statistically significant when comparing two groups of patients may be irrelevant at the individual patient level. For example, in terms of intensity of pain, the threshold usually accepted is 3.5 to 4.7 and 2.5 to 4.5 out of 10 for patients with acute and chronic pain, respectively.

Precisely evaluating several domains with specific tools is rather time consuming. However, for busy clinicians, there are brief instruments (core set of measures) with roughly 7 or 8 questions that include all the previously mentioned dimensions and that have been properly validated.

Complications

The clinician should inform the patient about the possible side effects of therapies as they are initiated. At subsequent visits, specific questions regarding the potential side effects are asked. For example, the presence of hypertension, peripheral edema, and hepatic and renal dysfunction need to be evaluated in patients who are taking chronic NSAID therapy.

In addition, a majority of NSAIDs have potential GI toxicity including mild mucosal irritation, ulcers, and perforations. Hematologic and neurologic toxicity are quite variable depending on the prescribed drug. Cardiovascular toxicity may clearly be an issue, particularly for long-term treatments. The benefit of persistent use of NSAIDs for patients with chronic spine pain needs to be weighed against the increased risk of toxicities.

The use of opiates induces constipation and urinary retention that may be a serious problem for some patients. These drugs can also produce drowsiness, headache, nausea, or vomiting.

Antidepressants also produce drowsiness and anticholinergic symptoms during the first couple of weeks of use. These drugs have specific side effects including tachycardia, weight gain, or sexual problems.

TINNITUS

Method of

Richard Sadovsky, MD; and Abraham Shulman, MD

CURRENT DIAGNOSIS

- Tinnitus is common among those exposed to loud noise, among veterans, and among older adults.
- Tinnitus severity can range from very mild occasional noise awareness to a disruptive sound that can result in depression, cognitive impairment, and even suicide.
- Many people who complain of tinnitus also have a moderate to severe hearing loss.
- Pulsatile and/or unilateral tinnitus may be a sign of cardiovascular disease.
- Children also can have tinnitus, but are even less likely than adults to complain.

CURRENT THERAPY

- No cure exists for tinnitus, although proper diagnosis and management using a team approach can result in some relief.
- Tinnitus intensity and bother are affected by many individual factors beyond the actual volume and frequency of noise, such as patient affect and mental state.
- Cognitive-behavioral therapy and a hearing aid or masking device are the most common successful management tools for tinnitus, although combined treatment including medication offers the best success for patients with severe idiopathic tinnitus.
- Protection should be worn when exposed to loud noise.
- Successful management of troublesome complications, including insomnia, anxiety, and depression, will decrease tinnitus-associated symptom severity in most patients.

Spinal surgery is indicated for disk herniation with radicular compromise, cervical or lumbar spinal stenosis with myelopathy or neurogenic claudication, and unstable spondylolisthesis. Controversy remains, however, concerning the relative benefit of surgical versus medical therapy for radiculopathy. - Tinnitus severity can range from very mild occasional noise awareness to a disruptive sound that can result in depression, cognitive impairment, and even suicide.
- Many people who complain of tinnitus also have a moderate to severe hearing loss.
- Pulsatile and/or unilateral tinnitus may be a sign of cardiovascular disease.
- Children also can have tinnitus, but are even less likely than adults to complain.

CURRENT THERAPY

- No cure exists for tinnitus, although proper diagnosis and management using a team approach can result in some relief.
- Tinnitus intensity and bother are affected by many individual factors beyond the actual volume and frequency of noise, such as patient affect and mental state.
- Cognitive-behavioral therapy and a hearing aid or masking device are the most common successful management tools for tinnitus, although combined treatment including medication offers the best success for patients with severe idiopathic tinnitus.
- Protection should be worn when exposed to loud noise.
- Successful management of troublesome complications, including insomnia, anxiety, and depression, will decrease tinnitus-associated symptom severity in most patients.

Definition and Epidemiology

Tinnitus is a symptom defined as perception of an internally generated sound that usually cannot be heard by others. Modern definitions include the dynamic advances in underlying neurophysiology noting a clinically conscious awareness of aberrant activity in synaptic circuitry that can manifest as an aberrant auditory perception that may increase with time, causing severe disabling symptoms. Perception can be a tonal sensation or ringing or noise-like sound, but can also include more complex sounds (crickets buzzing, pulsing noise), may fluctuate over time, and can be perceived in one or both ears or heard diffusely in the head. Thirty million people in the United States, or 10% of the entire population, note the presence of tinnitus at some time during their lives, with the incidence as high as 26.7% for people 65 to 84 years of age and a peak from ages 60 to 69. There appears to be no gender difference in tinnitus prevalence, although a few studies report a higher incidence among men. Some estimates of tinnitus incidence among older adults are even higher because fear of serious causes of tinnitus can discourage them from mentioning it. Wartime veterans often suffer from tinnitus, making it one of the major causes of disability among veterans. The incidence of tinnitus among children is 13%, with a higher rate among those who have had severe hearing loss.

Half of sufferers are bothered whereas others report no impact on life. Nearly 40% experience tinnitus more than 80% of the time. There is a wide variety of loudness, pitch, temporal variability, and family history of tinnitus among sufferers.

Some experts believe that the severity of tinnitus appears to be correlated with exposure to noise. Forty-four percent report no hearing loss, although it is agreed that most people with tinnitus have hearing loss. Among some, the hearing loss is mild and not noticed, but others report moderate and even profound hearing loss. Most tinnitus is *subjective*, heard only by the patient. *Objective tinnitus* can be heard by the examiner, by a careful stethoscope examination near the patient's ear, head, and/or neck.

Risk Factors/Etiologies (Subjective and Objective Tinnitus)

The most common risk factors for subjective tinnitus include (1) older age and/or hearing loss (presbycusis) and (2) exposure to loud noises (e.g., wartime veterans). Others include the following:

1. Conductive local causes of hearing loss such as cerumen impaction, obstruction of the external auditory canal, middle ear effusion, otosclerosis
2. Sensorineural and neurovascular causes/associated disorders such as loud sounds, Ménière's disease, acoustic neuroma, multiple sclerosis, head trauma, cerebral infarctions, seizures
3. Cardiovascular and hematologic disorders, including hypertension and blood pressure fluctuations, heart disease, arrhythmias, anemia
4. Metabolic disorders, including diabetes, dyslipidemia, hypertriglyceridemia, hypothyroidism or hyperthyroidism, obesity, vitamin B₁₂ or zinc deficiency
5. Ototoxic medications such as salicylates, NSAIDs, aminoglycosides, erythromycin, methotrexate, loop diuretics, chloroquine (Aralen), quinine (Qualaquin)
6. Temporomandibular joint disorder
7. Trigger factors, including anxiety, bad news, upper respiratory infections, and any other activities/disorders causing increased arousal mediated by the autonomic nervous system

The most common risk factors for objective tinnitus include (1) vascular abnormalities (e.g., arterial bruits, venous hums, heart murmurs), (2) neurologic disease, and (3) eustachian tube dysfunction (e.g., patulous eustachian tube causing blowing sounds with breathing). Others include glomus tumor and palatomyoclonus (stapedial muscle spasm).

Pathophysiology

The mechanism that produces tinnitus remains unclear. Subjective tinnitus is considered to be sensorineurophysiologic in origin, whereas objective tinnitus is thought to arise from vascular,

muscular, or respiratory origins, as well as the temporomandibular joint. Tinnitus may originate peripherally or centrally at any location along the auditory pathway from the cochlear nucleus to the auditory cortex, as well as from other nonauditory central brain structures. Leading theories for auditory pathway tinnitus include the following: (1) sequential injury to outer, then inner cochlear hair cells; (2) repetitive discharge in auditory nerve fibers in the dorsal cochlear nucleus that are stimulated in a continuous cycle; (3) hyperactive spontaneous activity in the auditory nuclei in the inferior colliculus of the brainstem; and (4) less than the usual suppressive activity of the central auditory cortex on peripheral auditory nerve activity. Pathologic changes in neural patterns create a subjective perception of sounds that resembles the pattern of actual sounds. Recent research is demonstrating a common pathway involving three separate neuroanatomic substrates in the central nervous system that are activated in severe idiopathic tinnitus, including sensory, affective (emotion and behavior), and psychomotor centers, meaning that multiple symptoms may occur at the same time.

The reorganization of edge frequencies in the cortical tonotopic map, in which cortical neurons begin to respond preferentially to sound frequencies at the edge of normal hearing, has recently been detected in tinnitus sufferers by neuromagnetic brain imaging. Other researchers using functional magnetic resonance imaging have recently implicated auditory-limbic interactions to explain the etiology of chronic tinnitus. They found moderate hyperactivity on MRI in the primary and posterior auditory cortices of tinnitus patients. However, the greatest degree of hyperactivity was noted in two limbic structures, the nucleus accumbens and the ventromedial prefrontal cortex.

Positron emission tomography (PET) studies predominantly show increased blood flow in several auditory structures, including the medial geniculate nucleus, the primary and secondary auditory cortex, the auditory brainstem, and temporal-parietal association areas. Brain changes can also be seen in nonauditory areas, including the hippocampus, amygdala, and cingulate gyrus.

Prevention

- Limit or avoid exposure to loud noises.
- Wear earplugs or ear defenders. (Tissues and cotton balls are not sufficient because they may become lodged in the ear canal).
- Cut back on alcohol and caffeine.
- Do not smoke (nicotine reduces blood flow to the ear structures).
- Exercise regularly to improve blood flow.
- Maintain healthy weight (tinnitus is more common in obese people).
- Take care of cardiovascular health.
- Avoid ototoxic medications (see Risk Factors above), especially among patients predisposed to ototoxicity such as advanced or very young age, pregnancy, renal or hepatic disease, or history of hearing loss. Monitor hearing when these medications must be used.

Clinical Manifestations

Patients with the symptom of tinnitus may complain of a mild inconsequential ringing, buzzing, hissing, roaring, clicking, or rough sounds, heard from time to time and for short periods of time, to an unbearable, constant noise, which can seriously degrade the patient's ability to function and enjoy life. Tinnitus can be acute or chronic in nature, unilateral or bilateral, nonpulsatile or pulsatile: arterial, venous, or nonvascular. The great majority of patients experience tinnitus without significant associated symptoms, but more than one-fourth of persons with tinnitus are distressed by it. Associated anxiety or depression often leads to more severe tinnitus-associated symptoms and to a greater negative impact on the patient's life. Various questionnaires, including the Tinnitus Handicap Questionnaire and the Tinnitus Severity Index, quantify the effect that tinnitus has on multiple areas in a patient's life.

The potential adverse effects of tinnitus are noted under Complications.

Diagnosis

The primary care office is an appropriate place to initiate the management of tinnitus.

History

Complete medical and psychological history

Tinnitus components

Sensory

Affect

Psychomotor

Any factors that worsen or relieve symptoms

Prior treatment history

Complete physical examination

Concentrate on the following:

Audiologic

Neurologic

Cardiovascular

Metabolic

Psychological

Laboratory tests

Thyroid function tests

Vitamin B₁₂

Complete blood count

Fasting glucose

Lipids, including triglycerides

Zinc

The evaluation of the patient with tinnitus begins with a thorough patient history, which involves an attempt to determine the etiologic and/or contributing factors causing ear noise. Certain parameters of the sounds heard can help identify potential etiologies and determine the need for further evaluation and treatment as seen in [Box 1](#). Besides identifying the (sensation) of tinnitus, a review of the patient's affect and psychomotor functioning is an important part of strategizing the total management plan.

BOX 1

Useful Tinnitus Parameters for Primary Care Clinicians

1. Sensory perception—directs evaluation
 - Subjective
 - Objective
2. Level of distress—directs degree of evaluation and management
 - Mild (not bothersome)
 - Moderate (noticeable)
 - Severe (bothersome)
3. Etiology/contributors—directs precision vs general management choices
 - Identifiable
 - Idiopathic
4. Tinnitus origin (pathways)—directs evaluation and management
 - Central (nonauditory system)
 - Peripheral (auditory system)
5. Components of tinnitus sensation—directs priority and types of management strategies
 - Sensory
 - Affective (emotion and behavior)
 - Psychomotor
6. Sensory characteristics requiring early consultation with an appropriate specialist
 - Unilateral
 - Objective
 - Sudden onset
 - Pulsatile

In the primary care office, the tinnitus patient should undergo a thorough physical examination with special attention to audiologic (including vertigo), cardiovascular, neurologic, and metabolic systems. A basic otologic examination includes (1) using a stethoscope to identify objective tinnitus, (2) examination of the external canal, (3) basic hearing testing, and (4) specific testing for sensorineural or conductive hearing loss using the Weber and Rinne tests. Thyroid studies, a hematocrit determination, complete blood chemistry, vitamin B₁₂, and lipid profile should be obtained if the patient has any suggestion of a metabolic abnormality. Primary care clinicians can identify many of the parameters that will determine further evaluation and management plans (see [Box 1](#)).

The management team evaluation continues with diagnostic audiologic testing, including audio testing, speech discrimination testing, and tympanometry. Other audiologic measurements of tinnitus may include pitch masking, loudness masking, minimum masking level, and residual inhibition.

Further investigation should be dictated by team discussion of potential etiologic/exacerbating factors for the individual patient. Patients with unilateral or pulsatile tinnitus are more likely to have serious underlying disease, such as vascular middle ear tumors, and should be evaluated by an otolaryngologist and possibly a cardiologist or neurologist. Many of these patients also require accompanying computed tomography (CT) angiogram, magnetic resonance imaging (MRI), carotid ultrasound, and perhaps standard angiography.

Differential Diagnosis

Not all sounds of internal origin perceived by the patient are those defined as tinnitus. Patients can also have ear noise caused by auditory hallucinations, as well as benign “transient noise.”

Auditory hallucinations can occur in both psychotic and nonpsychotic patients. In a patient who by appropriate evaluation is considered to be psychotic, and more likely schizophrenic, hearing voices or other sounds may be auditory hallucinations. Stress or sleep deprivation can also cause auditory hallucinations in nonpsychotic patients. In a patient who is not sleep deprived or stressed, or drinking large amounts of caffeine-containing beverages, ear noise is more likely to be tinnitus.

Transient noise is defined as a whistling sound accompanied by a sensation of sudden temporary hearing loss. These episodes generally disappear in seconds and occur rarely, whereas tinnitus is generally defined as lasting over 5 minutes and occurring at least twice weekly. They are usually not related to any specific event or activity, often unilateral, and sometimes accompanied by a feeling of ear blockage. Usually, no treatment is necessary beyond patient education.

Management

There is no cure for tinnitus, although a multidisciplinary approach (tinnitus-targeted therapy) with a medico-audiologic approach can partially alleviate associated symptoms. The goal is “control” rather than “treatment.” In expert hands, a majority of severely disabled tinnitus patients can get long-term relief with targeted medication and instrumentation.

Tinnitus management includes the following:

1. Eliminate potentially ototoxic medications and/or any precipitating active diseases/disorders (see [Risk Factors/Etiologies](#) above).
2. Administer targeted medication based on contributory medical conditions, severity of distress, tinnitus type (cochlear-peripheral or central), and tinnitus components involved (sensory, affective, and/or psychomotor).
3. Use instrumentation such as hearing aids, tinnitus masks, tinnitus retraining including low noise generators, and/or relaxing external sound stimulation with silence avoidance.
4. Provide mental health support, including stress management, biofeedback, reassurance, and relaxation techniques.

¹Not FDA approved for this indication.

No medications have been found to consistently reduce tinnitus symptoms, probably because of the heterogeneity of clinical tinnitus types. Pharmacologic treatment should deal specifically with the component(s) of severe tinnitus being targeted and uses drugs for their FDA-approved purposes to logically manage an individual's tinnitus presentation. The sensory component symptoms among patients with predominantly cochlear-type severe tinnitus (peripheral) can be treated with pentoxifylline (Trental),¹ which can enhance the oxygen-carrying capacity of the blood. If response is poor, intratympanic drug therapy with a steroid and/or instrumentation can be considered. Sensory symptoms among patients with predominantly central-type severe tinnitus can be offered trial instrumentation or brain scanning. If scanning is positive, neuroprotection using medications such as gabapentin (Neurontin)¹ and clonazepam (Klonopin)¹ may be helpful. The affective component of tinnitus can be pharmacologically managed with psychiatric consultation and may also include gabapentin and/or clonazepam (useful for anxiolytic and antiepileptic effects) or some other anxiolytic. The psychomotor component can sometimes be improved with medications such as papaverine¹ or clopidogrel (Plavix)¹ for cerebrovascular insufficiency and antiseizure drugs for epilepsy. Medications can be used continuously or as needed. There are no set regimens for the pharmacologic management of tinnitus. Because anxiolytics and antidepressants can sometimes cause or worsen tinnitus, close follow-up is important for treatment success. Other potentially contributing conditions and/or distressing symptoms should be appropriately treated.

Patients with severe tinnitus not responding to initial therapies or who are in significant distress should be referred to audiology, dentistry, neurology, physical therapy, and a mental health expert. Audiologist recommendations about masking devices to cover up the constant ringing may be helpful. Pleasant sounds such as TVs, radios, or fans can provide distractions. Sound generators can be worn in the ear to produce stable signal (white noise) and are most effective alone in patients with normal or near-normal hearing. This therapy can be combined with a hearing aid, which is most effective when done by a professional hearing expert with strict protocols. The amplification of ambient sound may also reduce tinnitus. Surgical cochlear implant in the profoundly hard-of-hearing patient can help with hearing issues but can also cause tinnitus for the first time.

Dentists can be helpful by evaluating for temporomandibular joint problems and other habits and recommending dental orthotics and home exercises to reduce clenching and grinding when appropriate. Neurologists can evaluate for vestibular symptoms, pain syndromes, and other cranial disorders. Physical therapists can evaluate the head and neck for biomechanical and posture problems and teach useful exercise techniques. Psychological counseling can improve levels of distress with greater improvement shown in combined cognitive strategies/education interventions. Patients can be taught to pay less attention to symptoms, overcome fear, accept tinnitus as part of life, and keep busy with happy activities. Acceptance and commitment therapy to better understand tinnitus and to look at it more objectively than emotionally may be useful. Careful choices and titrations of anxiolytic, antidepressant, and hypnotic medications reduce some of the affective components of tinnitus. Herbs and dietary supplements are commonly used, but there is no evidence to support their efficacy.

Experimental treatments include transcranial magnetic stimulation, low-level laser therapy, phase-out treatment (individualized sound developed to cancel out tinnitus), neuromonics (customized sound therapy), and tinnitus retraining therapy (remove perception from consciousness). The relationship between the auditory and limbic systems may offer a route of management via limbic stimulation and/or external limbic activation associated with emotional stress or depression. These areas are all under active study.

¹Not FDA approved for this indication.

BOX 2 Complications and/or Comorbid Conditions

Affective

Stress

Sleep problems/insomnia—trouble falling asleep, waking up in the middle of the night, worries about getting enough sleep

Depression—restlessness, lack of energy, change in appetite

Anxiety and irritability—worrying, muscle tension and headaches, shortness of breath, rapid pulse, difficulty concentrating

Headaches

Psychomotor

Fatigue

Trouble concentrating, memory problems

Major negative effect on work performance

Monitoring

Patients with tinnitus should be monitored for (1) distress symptoms, (2) adverse effects of symptoms, (3) effectiveness of management plan, and (4) hearing. This can be done using direct questions and annual hearing tests. Scales that have been shown to be particularly useful in monitoring patients with tinnitus include the Tinnitus Handicap Inventory—Screening Version (THI-S), the Patient Health Questionnaire (PHQ-9), the Tinnitus Treatment Monitoring Interview (TOMI), and the Generalized Anxiety Disorder 7 (GAD-7). Although the causal relationship is unclear, suicide risk must be monitored, especially among persons who were at high suicide risk before they developed tinnitus.

Recent data using nuclear imaging hint that patients with severe subjective idiopathic tinnitus may be at high risk for brain ischemia and neurodegenerative central nervous system disease consistent with senile dementia of the Alzheimer's type. Monitoring mental status in chronic severe tinnitus sufferers may be useful.

Complications

Different people are affected by tinnitus in different ways. For some, it may be simply irritating. For others, it may be more disruptive. Tinnitus primarily affects the ability to concentrate and sleep. Newer theories pointing out the central nervous substrate activation with tinnitus of sensory, affect, and psychomotor centers help explain the complexity and variability of tinnitus comorbidities (Box 2).

ALLERGIC REACTIONS TO INSECT STINGS

Method of

Theodore M. Freeman, MD

CURRENT DIAGNOSIS

- Determine the insect involved by recording circumstances of sting event.
- Determine the type of reaction: usual (expected), large local, or systemic (anaphylaxis).

CURRENT THERAPY

- Treatment for usual reactions
 - H₁-antihistamines, analgesics, cold compresses
 - Discussion of avoidance measures
- Treatment of large local reactions
 - H₁-antihistamines, analgesics, cold compresses
 - Discussion of avoidance measures and possible prescription of epinephrine autoinjectors (e.g., Auvi-Q, EpiPen)
- Treatment of systemic reactions
 - Epinephrine
 - Supplemental therapy, including antihistamines, β -adrenergics, oxygen, intravenous fluids, and perhaps vasopressors
 - Patients on β -blockers may require glucagon (e.g., Glucagon Emergency Kit, GlucaGen HypoKit)
 - Discussion of avoidance measures, medical alert accessories, prescription for epinephrine autoinjectors
 - Referral to allergist-immunologist to evaluate for specific IgE and possible institution of immunotherapy

Most stinging insects belong to the order Hymenoptera. They include species of bees (genus *Apis*, including honey bees and bumblebees), wasps (genus *Polistes*), yellow jackets (genus *Vespula*), hornets (genus *Dolichovespula*), and fire ants (genus *Solenopsis*).

Diagnosis

There are two important historical points to ascertain when seeing a patient with an allergic reaction to a stinging insect. The first is the type of insect that caused the sting. The physician may not rely on the patient's identification. Clues about the type of insect can be obtained from the circumstances of the sting.

Bees are herbivores and not aggressive. Stings from these insects often occur in fields with flowering plants when a barefoot patient steps or accidentally sits on them. Bees have a barbed stinger and attached venom sac, which may be left in place after a sting. These should be removed immediately with a scraping motion; any pinching of the sac may inject additional venom.

Yellow jackets are aggressive scavengers and are found wherever food is left in the open. Stings from these insects usually occur in

picnic areas or around open garbage containers. Like bees, yellow jackets occasionally leave a stinger in place, so this historical feature is not definitive. Wasps usually are not aggressive, except in defense of their nests. However, they tend to build these nests under the eaves and overhangs of our homes, and people stung by wasps are usually entering or exiting their homes.

Hornets are not as aggressive, except in defense of their nest. Because the nests are built in trees, stings by these insects are rarer.

Fire ants are very aggressive in defense of their nests, which are low mounds built above ground with extensive tunnels beneath the surface. In endemic areas (mostly the southeastern United States), they swarm and attack as a group when disturbed. Patients stung by fire ants are usually outdoors and accidentally stand in a mound or disturb a mound while working or playing in their yard or garden. Fire ant workers do not fly. They bite only to get a grip and then sting from the abdomen and inject a toxic alkaloid venom. Because they attack as a group, they are usually seen and clearly identified by the patient. The size of the fire ants means their venom is injected less deeply than that of other hymenoptera, which leads to the usual development of a pseudopustule about 24 hours after a sting. These pseudopustules contain necrotic cellular material but are sterile because fire ant venom has antibiotic properties that can kill bacteria and fungi. The pseudopustules should be left alone; opening and draining them only increases the risk of secondary infection.

The second historical point is the type of reaction by the patient to the sting. The active venom components produce immediate swelling, redness, and tenderness with fairly intense pain at the site of the sting that slowly resolves over several hours. Sometimes, the immediate reaction progresses, and swelling (>10 cm) continues for 1 to 2 days and extends across several contiguous joints away from the site of the sting. This large local reaction may take 5 to 10 days to fully resolve, and it may be difficult to differentiate this from a secondary infection. Large local reactions peak in 1 to 2 days and then slowly recede, whereas secondary infections continue to get worse. Large local reactions do not cause systemic fever or lymphangitis, which should be treated with antibiotics if they occur.

The reaction of most concern is anaphylaxis. Unfortunately, many of the symptoms are similar to those of anxiety, which also may occur in a concerned patient: feelings of impending doom, a rapid heartbeat, shortness of breath, and nausea. Other symptoms that should not be seen in anxiety include a metallic taste, pruritus, and abdominal or uterine cramping. Signs of anaphylaxis include flushing, urticaria, angioedema, vomiting, diarrhea, bronchospasm, hypotension, and shock. Diagnosis of anaphylaxis requires involvement of 2 organ systems out of cutaneous, pulmonary, gastrointestinal or cardiovascular or a drop in blood pressure after a known allergen exposure. Involvement of the upper airway and cardiopulmonary systems is associated with death, and hymenoptera stings are the cause of about 40 deaths per year in the United States. Documentation of the type of reaction is essential for future risk assessment and determination of whether prophylactic therapy should be offered.

The risk for a systemic reaction after hymenoptera sting in the general population is estimated to be 3% to 5%. In patients who have a documented large local reaction to an insect sting or a generalized cutaneous reaction (hives angioedema without other organ

system involvement), the risk of systemic reactions increases slightly to about 10%. Patients suffering large local reactions or generalized cutaneous reactions, may be referred to a specialist for specific IgE testing. For patients who have suffered anaphylaxis, the risk of systemic reactions after a sting is 50% to 60%. If a patient has suffered an anaphylactic event after a hymenoptera sting and has specific IgE to that hymenoptera as determined by in vivo (skin testing) or in vitro methods and is then placed on immunotherapy for that insect, the risk of systemic reaction after another sting is only 2% to 3%. Immunotherapy entails the use of specific venom products for each species, with the exception of fire ants. Because of the difficulty in extracting venom from fire ants, the only commercially available product for fire ants is the whole-body extract. Although whole-body extract is not effective therapy for other hymenoptera, it has been shown to be effective for fire ants.

Treatment

Immediate therapy for insect stings depends on the type of reaction. For the expected short-duration local reaction, treatment includes cold compresses; antihistamines, such as diphenhydramine (Benadryl 25–50 mg for adults; 1 mg/kg [up to 50 mg] for children) or cetirizine (Zyrtec 10 mg for adults and children older than 6 years; 5 mg for children younger than 6 years); and analgesics, such as acetaminophen (Tylenol) or ibuprofen (Motrin). Avoidance of future stings may be discussed with the patient. Recommendations include the following:

- Remove wasps' nests from around the home, especially near doorways.
- Avoid areas near open garbage.
- Do not leave open food or drinks during outdoor eating.
- Wear shoes, socks, and work gloves when working in the yard or garden.

Large local reactions may be treated as described for short-duration local reactions, with the addition of a short course (5–7 days) of oral steroids (e.g., Medrol dose pack), especially if there is significant morbidity associated with the site of the reaction. For instance, if a hand or foot is involved, a patient may not be able to write, work, or walk for up to a week. Avoidance measures should be discussed. Epinephrine auto-injectors (e.g., EpiPen, EpiPen Jr, Adrenaclick, Auvi-Q) may be given, depending on the patient's anxiety about future stings. Epinephrine auto-injectors are simple devices with instructions clearly printed on them, but mistakes in usage do occur. The most common include "bouncing" the injector off the leg, which ejects the epinephrine onto the leg instead of delivering it intramuscularly, and putting the thumb over the end of the injector, which if the injector is reversed leads to no delivery of epinephrine and thumb trauma. The auto-injector Auvi-Q provides audible instructions to the user. Demonstration pens and videos of proper technique may be obtained from the manufacturers (e.g., Amedra, Mylan, Sanofi).

The primary treatment of anaphylaxis is epinephrine (1:1000 concentration), with 0.3 to 0.5 mL given intramuscularly in adults or 0.01 mL/kg in children (less than 30 kg) every 5 to 15 minutes as needed. The patient should be placed in a recumbent position with the feet elevated. Supplemental therapy includes antihistamines (i.e., H₁-receptor antagonists); H₂-blockers (e.g., ranitidine [Zantac¹] 150 mg PO) for cutaneous signs and symptoms; β-adrenergics (e.g., albuterol [Proventil, AccuNeb]) administered by metered-dose inhaler or nebulizer for bronchoconstriction; oxygen for hypoxia; intravenous fluids and possibly vasopressors for hypotension; and intubation for compromise of the upper airway.

In patients who have suffered prior anaphylaxis physicians must avoid the tendency to treat the initial cutaneous-only symptoms with antihistamines alone, because cutaneous signs and symptoms often develop rapidly into life-threatening events. When a patient has a prior history of anaphylaxis to insect stings, the appropriate therapy is epinephrine even if the initial presenting symptoms are

cutaneous only. Most anaphylaxis responds quickly to a single dose of epinephrine, although up to 30% of anaphylaxis cases require two or more doses. Because anaphylaxis may be prolonged and last hours and epinephrine has a short duration of action (1 hour), patients should be observed for 4 to 6 hours after the last epinephrine dose. They should remain symptom free during that time before being released from the clinic or emergency department. In 3% to 20% of patients, a biphasic reaction occurs with recurrence of signs and symptoms 4–6 hours (range, 1–72 hours) after the initial reaction. For patients with prolonged or severe reactions, which are more often associated with a recurrence, overnight admission for observation should be considered.

Oral (prednisone 1 mg/kg up to 50 mg daily) or intravenous (methylprednisolone [Solu-Medrol] 1–2 mg/kg every 6 hours) steroids are sometimes given to minimize recurrences. Many patients are on β-blocking agents, which may make patients suffering anaphylaxis refractory to treatment with epinephrine. In this case, glucagon (e.g., GlucaGen HypoKit, Glucagon Emergency Kit¹) at a dose of 1 to 5 mg (20–30 µg/kg [maximum 1 mg] in children)³ may be tried intravenously over 5 minutes, followed by infusions (5–15 µg/min)³ titrated to clinical response. Patients who have suffered anaphylaxis must be given instructions on avoidance of future stings, epinephrine pen autoinjectors (EpiPen), and information on medical alert accessories (e.g., necklaces, bracelets). They should also be referred to an allergist-immunologist to evaluate them for the presence of specific IgE, counseling, and consideration of immunotherapy, which may significantly reduce their future risk.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

ANAPHYLAXIS AND SERUM SICKNESS

Method of

Stephen F. Kemp, MD

CURRENT DIAGNOSIS

- Cutaneous: urticaria, angioedema, diffuse erythema, generalized pruritus
- Respiratory: tachypnea, bronchospasm, laryngeal or tongue edema, dysphonia
- Cardiovascular: tachycardia, bradycardia, hypotension, angina, cardiac arrhythmias
- Gastrointestinal: nausea, emesis, diarrhea, abdominal cramps, dysphagia
- Other: rhinitis, conjunctivitis, uterine cramps, headache, dizziness, syncope, blurred vision, seizure

Anaphylaxis

Anaphylaxis, an acute and potentially lethal multisystem allergic reaction, is virtually unavoidable in medical practice. Health care professionals must be able to recognize the signs of anaphylaxis,

¹Not FDA approved for this indication.

system involvement), the risk of systemic reactions increases slightly to about 10%. Patients suffering large local reactions or generalized cutaneous reactions, may be referred to a specialist for specific IgE testing. For patients who have suffered anaphylaxis, the risk of systemic reactions after a sting is 50% to 60%. If a patient has suffered an anaphylactic event after a hymenoptera sting and has specific IgE to that hymenoptera as determined by in vivo (skin testing) or in vitro methods and is then placed on immunotherapy for that insect, the risk of systemic reaction after another sting is only 2% to 3%. Immunotherapy entails the use of specific venom products for each species, with the exception of fire ants. Because of the difficulty in extracting venom from fire ants, the only commercially available product for fire ants is the whole-body extract. Although whole-body extract is not effective therapy for other hymenoptera, it has been shown to be effective for fire ants.

Treatment

Immediate therapy for insect stings depends on the type of reaction. For the expected short-duration local reaction, treatment includes cold compresses; antihistamines, such as diphenhydramine (Benadryl 25–50 mg for adults; 1 mg/kg [up to 50 mg] for children) or cetirizine (Zyrtec 10 mg for adults and children older than 6 years; 5 mg for children younger than 6 years); and analgesics, such as acetaminophen (Tylenol) or ibuprofen (Motrin). Avoidance of future stings may be discussed with the patient. Recommendations include the following:

- Remove wasps' nests from around the home, especially near doorways.
- Avoid areas near open garbage.
- Do not leave open food or drinks during outdoor eating.
- Wear shoes, socks, and work gloves when working in the yard or garden.

Large local reactions may be treated as described for short-duration local reactions, with the addition of a short course (5–7 days) of oral steroids (e.g., Medrol dose pack), especially if there is significant morbidity associated with the site of the reaction. For instance, if a hand or foot is involved, a patient may not be able to write, work, or walk for up to a week. Avoidance measures should be discussed. Epinephrine auto-injectors (e.g., EpiPen, EpiPen Jr, Adrenaclick, Auvi-Q) may be given, depending on the patient's anxiety about future stings. Epinephrine auto-injectors are simple devices with instructions clearly printed on them, but mistakes in usage do occur. The most common include "bouncing" the injector off the leg, which ejects the epinephrine onto the leg instead of delivering it intramuscularly, and putting the thumb over the end of the injector, which if the injector is reversed leads to no delivery of epinephrine and thumb trauma. The auto-injector Auvi-Q provides audible instructions to the user. Demonstration pens and videos of proper technique may be obtained from the manufacturers (e.g., Amedra, Mylan, Sanofi).

The primary treatment of anaphylaxis is epinephrine (1:1000 concentration), with 0.3 to 0.5 mL given intramuscularly in adults or 0.01 mL/kg in children (less than 30 kg) every 5 to 15 minutes as needed. The patient should be placed in a recumbent position with the feet elevated. ANAPHYLAXIS AND SERUM SICKNESS

Method of

Stephen F. Kemp, MD

CURRENT DIAGNOSIS

- Cutaneous: urticaria, angioedema, diffuse erythema, generalized pruritus
- Respiratory: tachypnea, bronchospasm, laryngeal or tongue edema, dysphonia
- Cardiovascular: tachycardia, bradycardia, hypotension, angina, cardiac arrhythmias
- Gastrointestinal: nausea, emesis, diarrhea, abdominal cramps, dysphagia
- Other: rhinitis, conjunctivitis, uterine cramps, headache, dizziness, syncope, blurred vision, seizure

Anaphylaxis

Anaphylaxis, an acute and potentially lethal multisystem allergic reaction, is virtually unavoidable in medical practice. Health care professionals must be able to recognize the signs of anaphylaxis,

¹Not FDA approved for this indication.

treat an episode promptly and appropriately, and be able to provide preventive recommendations. Epinephrine, which should be administered immediately, is the drug of choice for acute anaphylaxis.

Anaphylaxis is not a reportable disease, and both its morbidity and mortality are probably underestimated. A variety of statistics on the epidemiology of anaphylaxis have been published, but the lifetime risk per person in the United States is presumed to be 1% to 3%, with a mortality rate of 1%.

There is no universally accepted definition of anaphylaxis. An international and interdisciplinary group of representatives and experts from thirteen professional, governmental, and lay organizations proposed the following working definition: "Anaphylaxis is a serious allergic reaction that is rapid in onset and may cause death." Clinically, anaphylaxis is considered likely to be present if any one of the following three criteria is satisfied within minutes to hours:

- Acute onset of illness with involvement of skin, mucosal surface, or both, and at least one of the following: respiratory compromise, hypotension, or end-organ dysfunction;
- Two or more of the following occurring rapidly after exposure to a likely allergen: involvement of skin or mucosal surface, respiratory compromise, hypotension, or persistent gastrointestinal symptoms;
- Hypotension develops after exposure to a known allergen for that patient: age-specific low blood pressure or decline of systolic blood pressure of greater than 30% compared with baseline.

In clinical practice, however, waiting until the development of multiorgan symptoms is risky because the ultimate severity of anaphylactic reaction is difficult to predict from the outset.

Anaphylaxis has varied clinical presentations, but respiratory compromise and cardiovascular collapse cause the most concern because they are the most frequent causes of fatalities. Urticaria and angioedema are the most common manifestations (more than 90% in retrospective series) but may be delayed or absent in rapidly progressive anaphylaxis. The previous severity of anaphylaxis is not predictive of the severity of a future reaction. The more rapidly anaphylaxis occurs after exposure to an offending stimulus, the more likely the reaction is to be severe and potentially life threatening. Anaphylaxis often produces signs and symptoms within 5 to 30 minutes, but reactions sometimes may not develop for several hours.

Pathophysiology

The chemical mediators that cause anaphylaxis are preformed and released from granules (histamine, tryptase, and others) or are generated from membrane lipids (prostaglandin D₂, leukotrienes, and platelet-activating factor) by the activated mast cell or basophil.

Tryptase is concentrated selectively in the secretory granules of all human mast cells. Its plasma levels during mast cell degranulation correlate with the clinical severity of anaphylaxis but need not be elevated in all forms of anaphylaxis (e.g., food-associated anaphylaxis).

Histamine exerts its pathophysiological effects via both H₁ and H₂ receptors. Erythema (flushing), hypotension, and headache are mediated by both H₁ and H₂ receptors, whereas tachycardia, pruritus, bronchospasm, and rhinorrhea are associated with H₁ receptors alone.

PAF and PAF acetylhydrolase, the enzyme that inactivates PAF, appear to be important in human anaphylaxis. Serum PAF levels directly correlate with anaphylaxis severity, more so than tryptase or histamine levels. PAF acetylhydrolase levels inversely correlate with anaphylaxis severity.

Increased vascular permeability during anaphylaxis can produce a shift of 35% of intravascular fluid to the extravascular space within 10 minutes. This shift of effective blood volume causes compensatory catecholamine release, activates the renin-angiotensin-aldosterone system, and stimulates production of endothelin-1.

Mast cells accumulate at sites of coronary plaque erosion and rupture, and they may contribute to coronary artery thrombosis. Because antibodies attached to mast cells can trigger mast cell degranulation, some investigators suggest that anaphylaxis may promote plaque rupture.

TABLE 1 Representative Agents That Cause Anaphylaxis

IgE dependent:
• Foods (such as peanuts, tree nuts, and crustaceans)
• Medications (such as antibiotics)
• Venoms (fire ants, yellow jackets, others)
• Allergen extracts
• Latex
• Exercise (where food or medication dependent)
• Hormones
IgE independent:
• Nonspecific degranulation of mast cells and basophils
• Opioids
• Muscle relaxants
• Idiopathic
• Physical factors
• Exercise
• Cold, heat
• Disturbance of arachidonic acid metabolism
• Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs)
• Immune aggregates
• Intravenous immunoglobulin
• Cytotoxic
• Transfusion reactions to cellular elements (IgM, IgG)
• Multimediator complement activation/activation of contact system
• Radiocontrast media
• Angiotensin-converting enzyme (ACE) inhibitor administered during renal dialysis with selected dialysis membranes
• Protamine (possibly)
• Other
• c-kit mutation (D816V)

Modified and updated from Kemp SF, Lockey RF. Anaphylaxis: A review of causes and mechanisms. *J Allergy Clin Immunol* 2002;110:341–8.

Agents That Cause Anaphylaxis

Cause and effect often is confirmed historically in subjects who experience recurrent, objective findings of anaphylaxis on inadvertent reexposure to the offending agent. Diagnostic testing, where appropriate, may confirm the presence of specific IgE or the degranulation of mast cells and basophils.

Virtually any agent capable of activating mast cells or basophils may potentially precipitate anaphylactic or anaphylactoid reactions. **Table 1** lists common causes of anaphylaxis classified by pathophysiologic mechanism. Idiopathic anaphylaxis, anaphylaxis with no identifiable cause, has accounted for approximately a third of cases in most retrospective studies of anaphylaxis. However, of 601 patients evaluated for more than two decades in a university-affiliated practice (the largest retrospective series), 59% of subjects were deemed to have idiopathic anaphylaxis.

Idiopathic anaphylaxis remains a diagnosis of exclusion, however. Serial histories and diagnostic tests for foods, spices, and vegetable gums occasionally identify a specific culprit in subjects previously presumed to have idiopathic anaphylaxis. The most common identifiable causes of anaphylaxis are foods, medications, insect stings, and immunotherapy injections. Anaphylaxis to peanuts or tree nuts causes the greatest concern because of its life-threatening severity, especially in subjects with asthma, and the tendency for subjects to develop lifelong allergic responsiveness to these foods.

Recurrent Anaphylaxis

Depending on the report, recurrent (biphasic) anaphylaxis occurs in 1% to 20% of subjects who experience anaphylaxis. Signs and symptoms experienced during the recurrent phase of anaphylaxis may be equivalent to or worse than those observed in the initial reaction and may occur 1 to 72 hours (most within 8 hours) after apparent remission. Thus it may be necessary to monitor subjects up to 24 hours after apparent recovery from the initial phase. Observation periods after apparent recovery from the initial phase should be individualized and based on such factors as comorbid conditions and distance from the patient's home to the closest emergency facility, particularly because there are no reliable predictors of biphasic anaphylaxis.

Differential Diagnosis

Several systemic disorders share clinical features with anaphylaxis. The vasodepressor (vasovagal) reaction probably is the condition most commonly confused with anaphylactic reactions. In vasodepressor reactions, however, urticaria is absent, dyspnea is generally absent, the blood pressure is usually normal or elevated, and the skin is typically cool and pale. Tachycardia is the rule in anaphylaxis. Bradycardia may be underrecognized in anaphylaxis, however. Brown and others conducted sting challenges in 19 subjects known to be allergic to jack jumper ants (*Myrmecia*). All eight subjects who became hypotensive developed bradycardia after an initial tachycardia.

Systemic mastocytosis, a disease characterized by mast cell proliferation in multiple organs, usually features urticaria pigmentosa (brownish macules that transform into wheals on stroking them) and recurrent episodes of pruritus, flushing, tachycardia, abdominal pain, diarrhea, syncope, or headache. Other diagnostic considerations include myocardial dysfunction, pulmonary embolism, foreign body aspiration, acute poisoning, seizure disorder, and psychogenic manifestations (no objective findings observed or documented).

Management of Anaphylaxis

Systematic reviews have noted the lack of optimal, randomized controlled trials of epinephrine, antihistamines, and corticosteroids in anaphylaxis. Pending a stronger evidence base for the treatment of anaphylaxis, current practice parameters and consensus emergency management guidelines afford the best options. Table 2 outlines a sequential approach to management. Assessment and maintenance of airway, breathing, circulation, and mentation are necessary before proceeding to other management steps. Subjects are monitored continuously to facilitate prompt detection of any treatment complications. The recumbent position is strongly recommended. In a retrospective review of prehospital anaphylactic fatalities in the United Kingdom, the postural history was known for 10 individuals. Four of the 10 were associated with assumption of an upright or sitting posture and postmortem findings consistent with “empty heart” and pulseless electrical activity.

Epinephrine is the treatment of choice for acute anaphylaxis. Aqueous epinephrine 1:1000 dilution, 0.2 to 0.5 mL (0.01 mg/kg in children; maximum dose, 0.3 mg) administered intramuscularly every 5 minutes, as necessary, should be used to control symptoms and sustain or increase blood pressure. Comparisons of intramuscular injections to subcutaneous injections during acute anaphylaxis are not available. However, absorption is more rapid, and plasma levels are higher in symptom-free individuals who receive epinephrine intramuscularly in the anterolateral thigh.

All subsequent therapeutic interventions depend on the initial response to epinephrine and the severity of the reaction. Development of toxicity or inadequate response to epinephrine injections indicates that additional therapeutic modalities are necessary.

The α -adrenergic effect of epinephrine reverses peripheral vasodilation, which alleviates hypotension and also reduces angioedema and urticaria. It may also minimize further absorption of antigen from a sting or injection. The β -adrenergic properties of epinephrine increase myocardial output and contractility, cause bronchodilation, and suppress further mediator release from mast cells and basophils.

Fatalities during witnessed anaphylaxis usually result from delayed administration of epinephrine and from severe respiratory and/or cardiovascular complications. *There is no absolute contraindication to epinephrine administration in anaphylaxis.*

Oxygen should be administered to subjects with anaphylaxis who require multiple doses of epinephrine, receive inhaled β_2 agonists, have protracted anaphylaxis, or have preexisting hypoxemia or myocardial dysfunction.

H₁ and H₂ antihistamines might support the treatment of anaphylaxis. However, these agents act much slower than epinephrine and should never be administered alone as treatment for anaphylaxis. They do, however, attenuate cutaneous symptoms (e.g., urticaria or pruritus). Authors of systematic reviews have concluded

TABLE 2 Management of Anaphylaxis

Immediate intervention:

- Assess airway, breathing, circulation, and adequacy of mentation.
- Administer aqueous epinephrine 1:1000 dilution, 0.2–0.5 mL (0.01 mg/kg in children; maximum dose, 0.3 mg) intramuscularly q5 min, as necessary, to control symptoms and blood pressure.
- Place subject in recumbent position and elevate lower extremities.

Possibly appropriate, subsequent measures depending on response to epinephrine:

- Consider call for assistance and transportation to an emergency department or intensive care facility.
- Establish and maintain airway.
- Administer oxygen.
- Establish venous access.
- Use crystalloid (e.g., lactated Ringer’s or normal saline) IV (IO) for fluid replacement.

Specific measures to consider after epinephrine injections, where appropriate:

- An epinephrine infusion might be prepared. Continuous hemodynamic monitoring is essential (see reference for specific details).
- Diphenhydramine (Benadryl). Note: In the management of anaphylaxis, a combination of diphenhydramine and ranitidine (Zantac)¹ is superior to diphenhydramine alone in urticarial suppression.
- For bronchospasm resistant to epinephrine, use nebulized albuterol (Proventil).
- For refractory hypotension, consider dopamine (Intropin), 400 mg in 500 mL D₅W, or normal saline administered IV (IO)¹ at 2–20 μ g/kg/min titrated to maintain adequate blood pressure. Continuous hemodynamic monitoring is essential.
- Where use of β -blockers complicates therapy, consider glucagon,¹ 1–5 mg (20–30 μ g/kg; maximum: 1 mg in children), administered IV (IO)¹ over 5 min followed by an infusion of 5–15 μ g/min. Aspiration precautions should be observed.
- For patients with a history of asthma and for those who experience severe or prolonged anaphylaxis, consider methylprednisolone (Solu-Medrol) (1.0–2.0 mg/kg/d).

Observation and subsequent outpatient follow-up:

- Observation periods after apparent resolution must be individualized and based on such factors as the clinical scenario, comorbid conditions, and distance from the patient’s home to the closest emergency department. After recovery from the acute episode, patients should receive epinephrine auto-injectors (EpiPen, Adrenaclick or Auvi Q) and be instructed in proper technique. Everyone post-anaphylaxis requires a careful diagnostic evaluation in consultation with an allergist-immunologist.

¹Not FDA approved for this indication.

Abbreviations: IV = intravenous, IO = intraosseous.

Modified from Lieberman P, Nicklas RA, Randolph C, et al. Anaphylaxis—a practice parameter update 2015. *Ann Allergy Asthma Immunol* 2015;115:341–384.

they were unable to make any evidence-based recommendations for use of H₁ or H₂ antihistamines in the treatment of anaphylaxis. Antihistamines thus should be considered as *second-line* treatment.

Systemic corticosteroids have no role in the acute management of anaphylaxis because even intravenous administration of these agents may have no effect for 4 to 6 hours after administration. Although corticosteroids traditionally are used in the management of anaphylaxis, their effect has never been evaluated in placebo-controlled trials. Corticosteroids administered during anaphylaxis might provide additional benefit for patients with asthma or other conditions recently treated with corticosteroids. However, no definite recommendations can be made because the data concerning possible preventive benefits are conflicting and limited.

Numerous cases of unusually severe or refractory anaphylaxis are reported in subjects receiving β -blocking agents. Usual doses of epinephrine administered during anaphylaxis to subjects taking β -blockers may not produce the desired clinical response. In such situations, both isotonic volume expansion and glucagon¹

¹Not FDA approved for this indication.

administration are recommended. Case reports demonstrate glucagon may potentially reverse refractory hypotension and bronchospasm because it bypasses the β -adrenergic receptor and directly activates adenylyl cyclase.

Persistent hypotension despite epinephrine injections should first be treated with intravenous crystalloid solutions (e.g., lactated Ringer's or normal saline). One to 2 L of crystalloid might need to be administered to adults at a rate of 5 to 10 mL/kg in the first 5 minutes. Children should receive up to 30 mL/kg in the first hour. Large volumes (e.g., 7 L) are often required.

Vasopressors should be administered if epinephrine injections and volume expansion fail to alleviate hypotension. Dopamine (Intropin) frequently increases blood pressure while maintaining or enhancing renal and splanchnic perfusion. These agents would not be expected to work as well in patients already maximally vasoconstricted by their internal compensatory response to anaphylaxis.

Prevention of Anaphylaxis

Table 3 outlines the basic principles for the prevention of future anaphylactic episodes in high-risk individuals. An allergist-immunologist can provide comprehensive professional advice on these matters.

All subjects at high risk for recurrent anaphylaxis should carry epinephrine delivery devices and know how to administer them. An EpiPen (Mylan Specialty US) is a spring-loaded, pressure-activated syringe (auto-injector) with a single 0.3-mg dose (1:1000 dilution) of epinephrine. It is easy to use and inject through clothing. An EpiPen Jr, which delivers 0.15 mg (1:2000 dilution) epinephrine, is appropriate for children weighing less than 30 kg. Adrenaclick (Amedra) is available as a single-dose autoinjector of either 0.15 mg or 0.3 mg. Authorized generic epinephrine USP products are also available for EpiPen, EpiPen Jr, and Adrenaclick. Auvi-Q (Kaléo) is an autoinjector device that is available in 0.1-mg, 0.15-mg, or 0.3-mg single dose. Approximately the size of a credit card, it is equipped with blinking lights at the needle end and a voice recording that guides the user throughout administration.

TABLE 3 Preventive Measures for Subjects with Anaphylaxis

General measures:

- Obtain thorough history to diagnose life-threatening food or drug allergy.
- Identify cause of anaphylaxis and those individuals at risk for future attacks.
- Provide instruction on proper reading of food and medication labels, where appropriate.
- Patient should avoid exposure to antigens and cross-reactive substances.
- Manage asthma and coronary artery disease optimally.
- Use a waiting period of 30 minutes after injections.
- Consider office waiting period of 2 hours for oral medication patient has not taken previously.

Specific measures for high-risk subjects:

- Individuals at high risk for anaphylaxis should carry self-injectable epinephrine (EpiPen or Adrenaclick) at all times and receive instruction in proper use with placebo trainer.
- Individuals should wear a Medic Alert bracelet or chain.
- Other agents for β -adrenergic antagonists, angiotensin-converting enzyme (ACE) inhibitors, tricyclic antidepressants, and monoamine oxidase inhibitors should be substituted whenever possible.
- Agents suspected of causing anaphylaxis should be administered slowly, under supervision, and orally if possible.
- Where appropriate, use specific preventive strategies, including pharmacologic prophylaxis, short-term challenge and desensitization and long-term desensitization.

Modified from Kemp SF. Office approach to anaphylaxis: sooner better than later. *Am J Med* 2007;120:664–668.

Serum Sickness

Serum sickness is a clinical syndrome of fever, malaise, and urticarial or morbilliform cutaneous eruption that is often preceded by generalized erythema and pruritus. Arthralgias or arthritis (mainly large joints), neuropathy, lymphadenopathy, nephritis, abdominal pain (emesis or melena are possible), or vasculitis (cutaneous or systemic) may occur in some cases. Cutaneous vasculitis, also known as *hypersensitivity vasculitis*, is often manifested by palpable purpura, which most commonly are found on the lower extremities of ambulatory individuals or on the sacral or gluteal region of patients with restricted mobility. These purpura reflect vascular leakage from inflamed postcapillary venules. Systemic vasculitis may occur in association with autoimmune diseases, infection, or malignancy.

Many agents may produce serum sickness or serum sickness-like reactions (Table 4). *Serum sickness* classically refers to the immune complex syndrome caused by immunization with heterologous serum proteins (often equine or murine). The most frequent cause is immune complex-mediated drug hypersensitivity. A serum sickness-like drug reaction generally develops 6 to 21 days after the culprit medication is started, but it can occur within 12 to 48 hours in previously sensitized individuals.

Pathogenesis and Laboratory Abnormalities

Healthy individuals regularly generate low levels of circulating immune complexes, which are either excreted by the kidneys or extracted in the liver and spleen by monocytes and macrophages. It is hypothesized that serum sickness results when a drug (hapten) binds to plasma protein and antibodies are generated in response to the drug-protein complex. Complement activation occurs when large quantities of soluble antigen-antibody (immune) complexes fix to vascular endothelial receptors. Complement fragments attract and activate neutrophils, which release proteases that induce tissue injury. The urticaria in serum sickness probably results from immune complex necrotizing vasculitis and complement activation that induces mast cell degranulation. IgE-dependent mechanisms likely are also contributory in some individuals. Laboratory abnormalities include elevated erythrocyte sedimentation rate, leukopenia (acute phase), occasional plasmacytosis, and decreased total hemolytic complement (CH50), C3, and C4. Slight albuminuria, hyaline casts, and microscopic hematuria may also occur.

Treatment

Stoppage of the culprit agent, when identified, is recommended. Serum sickness is usually self-limited and rarely life threatening when the offending drug or protein is stopped or removed. Symptoms generally improve over 2 to 4 weeks as patients clear their immune complexes, although rarely symptoms can last as long as 2 to 3 months. Evidence-based treatment recommendations for serum sickness are very limited. Long-acting, less-sedating H_1 antihistamines such as cetirizine (Zyrtec), desloratadine (Clarinet),

TABLE 4 Representative Agents That Cause Serum Sickness

Medications: β -lactam antibiotics, sulfonamides, ciprofloxacin (Cipro), metronidazole (Flagyl), rifampin (Rifadin), allopurinol (Zyloprim), carbamazepine (Tegretol), phenytoin (Dilantin), fluoxetine (Prozac), bupropion (Wellbutrin), methimazole (Tapazole), propylthiouracil, thiazide diuretics, captopril (Capoten), propranolol (Inderal), verapamil (Calan), streptokinase (Streptase), others.

Heterologous (animal-derived) antisera:

- Horse: snake and spider venom, tetanus, botulism, diphtheria
- Horse or rabbit: anti-lymphocyte globulin
- Mouse: monoclonal antibodies (muromonab-CD3 [Orthoclone OKT3])
- Mouse/human monoclonal antibody chimerisms: rituximab (Rituxan), infliximab (Remicade)

Homologous (human-derived) antisera: cytomegalovirus, hepatitis B, rabies, tetanus, perinatal $RH_0(D)$

fenofenadine (Allegra), or loratadine (Claritin) generally control urticaria. Systemic corticosteroids (e.g., prednisone, 0.5 to 1.0 mg/kg/day) may help severe symptoms (e.g., temperature > 38.5° C, severe arthralgias, or extensive dermatitis). Fever and arthralgias typically resolve within 48 to 72 hours of treatment, and the formation of new cutaneous eruptions usually ceases within the same time frame. Antihistamine therapy is continued for 1 week after apparent resolution of symptoms and then slowly discontinued. Corticosteroids often can be stopped in less than one week.

Diagnostic testing is presently unable to predict future episodes of serum sickness. If no therapeutic alternative is available and repeat treatment with a culprit drug is considered essential, concurrent treatment with antihistamines and possibly corticosteroids might help to prevent a future episode of serum sickness due to the drug.

DRUG HYPERSENSITIVITY REACTIONS

Method of

Miriam Chan, PharmD; Kristen Rundell, MS, MD; and Ann M. Aring, MD

CURRENT DIAGNOSIS

- Detailed history should include past medical history; current diagnosis; previous and current medication use, including over-the-counter drugs and herbals; duration of the medication use; any similar reactions in the past.
- Physical examination should include vitals, temperature, and skin examination for rash.
- Laboratory testing should be conducted based on symptoms that may include complete blood count (CBC) with differential, eosinophils, sedimentation rate, liver enzymes, international normalized ratio (INR), and diagnostic skin biopsy or testing.

CURRENT THERAPY

- For life-threatening anaphylaxis reaction, start basic life support using mnemonic ACB (airway, compression, breathing) and give epinephrine immediately.
- Discontinue the offending drug if medically possible. Try drug substitution if warranted.
- An alternative option is to reduce the dose or frequency of the drug.

- Start symptomatic treatment based on the type of reaction and the offending medication.
- Some reactions may respond to treatment with antihistamines, H₂ blockers, or steroids.

Epidemiology

Drug hypersensitivity reactions are one of the many different types of adverse drug reactions (ADRs). ADRs are common, yet the more severe reactions have been estimated to cause 3% to 6% of hospital admissions. More than 100,000 deaths annually are caused by serious ADRs, making these reactions one of the leading causes of death in the United States. Early detection of all ADRs can potentially improve patient outcomes and lower health care costs.

Classifications

An ADR is a broad term that refers to any predictable or unpredictable reaction to a medication. A predictable (type A) reaction is dose dependent and is related to the known pharmacologic properties of the drug. Predictable reactions account for about 80% of all ADRs. An example of a type A reaction is gastritis that results from taking nonsteroidal antiinflammatory drugs (NSAIDs). The remaining 20% of ADRs are caused by unpredictable (type B) reactions. Type B reactions occur in susceptible individuals. These are hypersensitivity reactions that are different from the pharmacologic actions of the drug; they are results of interactions between the drug and the individual human immune system. Type B reactions can be further divided into drug intolerance, drug idiosyncrasy, drug allergy (immunologically mediated), and pseudoallergic reactions (anaphylactoid reactions). This chapter will focus on these type B drug hypersensitivity reactions.

Pathophysiology

Several mechanisms may play a role in the underlying etiology of immunologic drug reactions. The Gell and Coombs classification system was the original system to describe four predominant immune mechanisms. These four reaction types are listed as type I reactions (IgE mediated), type II reactions (cytotoxic), type III reactions (immune complex), and type IV reactions (delayed, cell mediated). Table 1 provides a detailed description of this classification. Type I and IV reactions are more common than type II and III reactions. Most drugs cause one type of reaction, whereas certain drugs, such as penicillin, can induce all four types of reactions.

The Gell and Coombs classification has recently been revised to reflect the functional heterogeneity of T cells. Under the new system, type IV reactions are further subclassified into four categories: IVa (macrophage activation), IVb (eosinophils), IVc (CD4⁺ or CD8⁺ T cells), and IVd (neutrophils). Nevertheless, many common hypersensitivity reactions cannot be classified in this system because of the lack of knowledge of their immune mechanism or a mixed mechanism.

A new concept of drug interaction with immune receptors has recently been developed by Pichler and colleagues. It is called the *p-i concept* (pharmacologic interaction with immune receptors). In this concept, a drug binds noncovalently to a T-cell receptor and stimulates an immune response, which can cause inflammatory reactions of different types. The stimulation of the T cell is enhanced by the additional interaction with the major histocompatibility complex molecule. This is direct stimulation of memory and effector T cells, and no sensitization is required. The skin has a high concentration of effector memory T cells, which can be rapidly stimulated by antigen penetration. The skin also possesses a dense network of dendritic cells that act as antigen-presenting cells and increase hypersensitivity reactions. As a result, clinical symptoms by p-i drugs may appear more rapidly. Some severe reactions—such as Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), the drug rash with eosinophilia and systemic symptoms (DRESS) syndrome, or hypersensitivity syndrome—are believed to be p-i related. Examples are abacavir (Ziagen) hypersensitivity syndrome and SJS/TEN from carbamazepine (Tegretol).

fenofenadine (Allegra), or loratadine (Claritin) generally control urticaria. Systemic corticosteroids (e.g., prednisone, 0.5 to 1.0 mg/kg/day) may help severe symptoms (e.g., temperature $> 38.5^{\circ}\text{C}$, severe arthralgias, or extensive dermatitis). Fever and arthralgias typically resolve within 48 to 72 hours of treatment, and the formation of new cutaneous eruptions usually ceases within the same time frame. Antihistamine therapy is continued for 1 week after apparent resolution of symptoms and then slowly discontinued. Corticosteroids often can be stopped in less than one week.

Diagnostic testing is presently unable to predict future episodes of serum sickness. If no therapeutic alternative is available and repeat treatment with a culprit drug is considered essential, concurrent treatment with antihistamines and possibly corticosteroids might help to prevent a future episode of serum sickness due to the drug.

Epidemiology

Drug hypersensitivity reactions are one of the many different types of adverse drug reactions (ADRs). ADRs are common, yet the more severe reactions have been estimated to cause 3% to 6% of hospital admissions. More than 100,000 deaths annually are caused by serious ADRs, making these reactions one of the leading causes of death in the United States. Early detection of all ADRs can potentially improve patient outcomes and lower health care costs.

Classifications

An ADR is a broad term that refers to any predictable or unpredictable reaction to a medication. A predictable (type A) reaction is dose dependent and is related to the known pharmacologic properties of the drug. Predictable reactions account for about 80% of all ADRs. An example of a type A reaction is gastritis that results from taking nonsteroidal antiinflammatory drugs (NSAIDs). The remaining 20% of ADRs are caused by unpredictable (type B) reactions. Type B reactions occur in susceptible individuals. These are hypersensitivity reactions that are different from the pharmacologic actions of the drug; they are results of interactions between the drug and the individual human immune system. Type B reactions can be further divided into drug intolerance, drug idiosyncrasy, drug allergy (immunologically mediated), and pseudoallergic reactions (anaphylactoid reactions). This chapter will focus on these type B drug hypersensitivity reactions.

Pathophysiology

Several mechanisms may play a role in the underlying etiology of immunologic drug reactions. The Gell and Coombs classification system was the original system to describe four predominant immune mechanisms. These four reaction types are listed as type I reactions (IgE mediated), type II reactions (cytotoxic), type III reactions (immune complex), and type IV reactions (delayed, cell mediated). Table 1 provides a detailed description of this classification. Type I and IV reactions are more common than type II and III reactions. Most drugs cause one type of reaction, whereas certain drugs, such as penicillin, can induce all four types of reactions.

The Gell and Coombs classification has recently been revised to reflect the functional heterogeneity of T cells. Under the new system, type IV reactions are further subclassified into four categories: IVa (macrophage activation), IVb (eosinophils), IVc (CD4^+ or CD8^+ T cells), and IVd (neutrophils). Nevertheless, many common hypersensitivity reactions cannot be classified in this system because of the lack of knowledge of their immune mechanism or a mixed mechanism.

A new concept of drug interaction with immune receptors has recently been developed by Pichler and colleagues. It is called the *p-i concept* (pharmacologic interaction with immune receptors). In this concept, a drug binds noncovalently to a T-cell receptor and stimulates an immune response, which can cause inflammatory reactions of different types. The stimulation of the T cell is enhanced by the additional interaction with the major histocompatibility complex molecule. This is direct stimulation of memory and effector T cells, and no sensitization is required. The skin has a high concentration of effector memory T cells, which can be rapidly stimulated by antigen penetration. The skin also possesses a dense network of dendritic cells that act as antigen-presenting cells and increase hypersensitivity reactions. As a result, clinical symptoms by p-i drugs may appear more rapidly. Some severe reactions—such as Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), the drug rash with eosinophilia and systemic symptoms (DRESS) syndrome, or hypersensitivity syndrome—are believed to be p-i related. Examples are abacavir (Ziagen) hypersensitivity syndrome and SJS/TEN from carbamazepine (Tegretol).

TABLE 1 Classification of Drug Hypersensitivity Reactions

TYPE	MECHANISM	CLINICAL FEATURES	TIMING OF REACTIONS	EXAMPLES
Type I (IgE mediated)	Drug-IgE complex binds to mast cells	Urticaria, angioedema, bronchospasm, pruritus, GI symptoms, anaphylaxis	Immediate (minutes to hours after drug exposure, depending on the route of administration)	β -lactam antibiotic
Type II (cytotoxic)	Specific IgG or IgM antibodies directed at drug-hapten-coated cells	Hemolytic anemia, neutropenia, thrombocytopenia	Variable	Penicillin (hemolytic anemia), heparin (thrombocytopenia)
Type III (immune complex)	Antigen-antibody complexes	Serum sickness, vasculitis, drug fever	1–3 weeks after drug exposure	Penicillin (serum sickness), sulfonamides (vasculitis), azathioprine (drug fever)
Type IV (delayed, cell mediated)	Activation and expansion of drug-specific T cell	Prominent skin findings: Contact dermatitis, morbilliform eruptions	2–7 days after exposure	Topical antihistamine, penicillin, sulfonamides

Risk Factors for Hypersensitivity Drug Reactions

The chemical structure and molecular weight of the drug may help predict the type of hypersensitivity reaction. Larger drugs with greater structural complexity are more likely to be immunogenic. However, drugs with small molecular weight (< 1000 Da) can elicit hypersensitivity reactions by coupling with carrier proteins to form hapten-carrier complexes. Other drug-related factors include the dose, route of administration, duration of treatment, repetitive exposure to the drug, and concurrent illness. Topical and intravenous drug administrations are more likely to cause hypersensitivity reactions than are oral medications.

Patient risk factors include age, female gender, infection with human immunodeficiency virus, atopy, specific genetic polymorphisms, previous drug hypersensitivity reactions, and inherent predisposition to react to multiple unrelated drugs.

Clinical Manifestations

Drug hypersensitivity reactions can manifest in a great variety of clinical symptoms and diseases. While some reactions are mild and often unnoticed, others, such as anaphylaxis, can be severe and even fatal. Dermatologic symptoms are the most common physical manifestation of allergic drug reactions. Drug hypersensitivity reactions can also affect various internal organs, causing diseases such as hepatitis, nephritis, and pneumonitis. The non-cutaneous physical findings are generally nonspecific and may not be helpful and even delay the diagnosis and management decisions.

Dermatologic Symptoms

The most common allergic drug reactions affect the skin and can cause a variety of different exanthems. The most common skin reaction is the classic “drug rash,” which is a morbilliform eruption originating on the trunk. Other dermatologic symptoms include urticaria, angioedema, acne, bullous eruptions, fixed drug eruptions, erythema multiforme, lupus erythematosus, photosensitivity, psoriasis, purpura, vasculitis, and pruritus. The most severe forms of cutaneous drug reactions are Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug rash with eosinophilia and systemic symptoms (DRESS) syndrome.

Stevens-Johnson Syndrome

SJS is a systemic disorder that has cutaneous manifestations. SJS was previously thought to be synonymous with erythema multiforme major. There are now criteria that separate the two disorders. In contrast to erythema multiforme, the target lesions associated with SJS have only two rings. The inner ring may have urticaria, pustules, or necrotic lesions surrounded by macular erythema. It is a T-cell-mediated toxic reaction to the basement membrane of the epidermal cells. There is massive and widespread apoptosis, for which there are several associated cytokines. The

recent theories suggest that there are two pathways, one that consists of granule-mediated exocytosis (perforin and granzyme B), and one that consists of Fas-Fas ligand interaction associated apoptosis for the keratinocytes. More recent data suggest that granulysin, which is a cationic cytolytic protein released by T lymphocytes, may play a role as well.

Interestingly, HLA genotype may predispose patients to SJS or TEN. Those patients with the HLA-B1502 found among the Han Chinese population may be associated with increased risk for developing SJS/TEN and use of carbamazepine.

SJS and TEN are on the same continuum. The definition of epidermal detachment and desquamation of epidermal cells is less than 10% of the body surface area for SJS and more than 30% for TEN. There is an overlapping diagnosis of SJS/TEN for the 10% to 30% category. To help differentiate from other ADRs, there is often a prodromal period in which a patient may have a cough and a fever. The lesions may occur up to 4 weeks after exposure to the drug. In addition, the lesions may be limited to the trunk; however, they more commonly involve the palmar surface of the hands and the dorsum of the feet, as well as the mucous membranes.

The most common drug classes associated with SJS and TENs are sulfonamides, cephalosporins, imidazole agents, and oxycam derivatives. Drugs such as carbamazepine, phenytoin (Dilantin), valproic acid (Depakote), lamotrigine (Lamictal), allopurinol (Zyloprim), nevirapine (Viramune), peramivir (Rapivab), and quinolones have been reported to cause SJS/TEN. In a retrospective chart review of 64 patients who had a diagnosis of SJS/TEN, Mili-szewski et al. identified allopurinol as the single most common offending agent (20% of cases). According to the US Food and Drug Administration (FDA) Safety Alerts in 2013, acetaminophen has been associated with SJS, TEN, and acute generalized exanthematous pustulosis (AGEP). The evidence supporting causality primarily comes from a small number of cases reported in the medical literature.

The treatment is immediate cessation of the culprit drug and symptomatic treatment. Glucocorticoids are controversial and depend on the course and extent of the disease.

Toxic Epidermal Necrolysis

As previously stated, TEN is the cell-mediated disorder that involves more than 30% of the body surface. This is the more-severe form of the ADR: the mortality rates may be as high as 50%, mostly from sepsis. Patients are usually admitted to the burn unit for electrolyte and infection management. Glucocorticoids are contraindicated. There have been mixed results using IV immunoglobulin (IVIG)¹ in these patients. The IVIG is believed to inhibit

¹Not FDA approved for this indication.

the Fas-Fas ligand, which is the underlying mechanism for the basement membrane separation.

Drug Rash with Eosinophilia and Systemic Symptoms

DRESS syndrome or drug-induced hypersensitivity syndrome (DIHS) is a rare, life-threatening drug-induced reaction with a mortality rate of 10%. Therefore it is important to recognize the signs and symptoms early to initiate treatment. Most patients will have fever, lymphadenopathy (75%), eosinophilia, and an erythematous morbilliform rash on the face and body in addition to liver and multiorgan damage. The symptoms can occur 2 to 6 weeks after the drug administration. There are many drugs that can cause DRESS syndrome such as allopurinol, sulfonamides, and psychotropic medications. Based on literature review, DRESS syndrome is increasingly being recognized by psychiatrists. Carbamazepine is the most frequently reported etiology; however, DRESS syndrome is also seen with lamotrigine, phenytoin, valproate, and phenobarbital. The treatment is drug withdrawal, systemic corticosteroids, topical treatment for lesions, and supportive care, often in the ICU or burn unit.

Acute Generalized Exanthematous Pustulosis

Acute generalized exanthematous pustulosis (AGEP) is a rare ADR that presents as a fever and small nonfollicular pustules on a widespread erythematous background. AGEP may closely mimic pustular psoriasis clinically. The presence of acanthuses and papillomatosis and a personal or family history of psoriasis favor a diagnosis of pustular psoriasis. Exposure to medication, especially antibiotics with a short latency from the initiation of the drug, favors AGEP. The eruption usually occurs within 24 hours of the initiation of the drug, and healing occurs quickly after the discontinuation of the drug. Lesions heal within 2 weeks of discontinuation without scarring. The exact mechanism of drug-specific T lymphocytes is unknown, yet IL-3 and IL-8 may be the trigger for neutrophil-activating cytokines in the skin.

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is an important cause of acute kidney injury (AKI). More than two thirds of AIN cases are caused by drug hypersensitivity reactions. Drugs most commonly associated with AIN include antibiotics (particularly β -lactam, fluoroquinolones, and rifampicin), NSAIDs, proton pump inhibitors, phenytoin, allopurinol, and 5-aminosalicylates.

The clinical presentation of drug-induced AIN is highly variable and depends on the class of drug involved. Patients with AIN may be asymptomatic with elevation in creatinine or blood urea nitrogen or abnormal urinary sediment. When present, symptoms are nonspecific. The "classic" triad of fever, rash, and eosinophilia is present in less than 5% to 10% of patients. Each individual component of the triad also occurs at various rates.

A diagnosis of AIN should be considered in any patients with unexplained AKI, clinical manifestations of a hypersensitivity reaction, and a history of exposure to any drug associated with AIN. A definitive diagnosis of AIN is established by kidney biopsy. AIN is characterized by interstitial inflammation, tubulitis, edema, and, in some cases, eventual interstitial fibrosis. The precise disease mechanism is unclear, but the presence of T lymphocytes in the inflammatory infiltrate suggests a type IV hypersensitivity response.

Early recognition is crucial as patients can ultimately develop chronic kidney disease. The mainstay of therapy is timely discontinuation of the causative agent. If AIN persists, corticosteroids may be used to improve kidney function. However, available data on corticosteroids are inconclusive, and randomized controlled trials are needed to confirm the benefits of corticosteroids in the treatment of AIN.

Evaluation

Because the history is essential for determining whether a patient is experiencing a drug hypersensitivity reaction, it is important to review all medications and the timeline of exposure. This includes any over-the-counter medications, herbal supplements, or

occasional-use medications. Occasional-use medications may include NSAIDs, acetaminophen, cold medications, and so forth. It is important to establish a temporal relationship to the onset of the medication and the initiation of the symptoms. Oftentimes, the medication may have been discontinued before the appearance of the first symptom, so a review of medications from several weeks before the symptoms is also important. In addition, because the host immune response plays a role in some of the IgE-mediated reactions, it is important to review any immunocompromising chronic or acute illnesses or states that the patient may have or is currently experiencing. This includes HIV, chronic obstructive pulmonary disease (COPD), asthma, chemotherapy, and pregnancy. For some ADRs, HLA type may be important. A patient's known genetic predisposition needs to be taken into account as well. A thorough history will also need to include any organ system or symptom that may be related to the suspected ADR.

A physical examination should augment and help to establish the working diagnosis of the type of ADR and the potentially offending drug. This should include vital signs of temperature, respiratory, and hydration status. The skin examination is important, as are appropriate evaluation and documentation of the type of lesion or lesions present. An examination of the oral mucosa and the conjunctiva of the eye should be done. Any lymphadenopathy, petechiae, or pallor should be noted.

Laboratory testing may be obtained to confirm or rule out a diagnosis. This may include a chest x-ray, CBC with differential, possible skin biopsy, liver function testing, creatinine, and electrolyte testing. A sedimentation rate and CRP testing may also be useful. Although additional autoimmune or antibody testing may be done, caution is suggested. There may not be a high yield on these tests, and they can be quite costly for patients.

Management

Anaphylaxis

Anaphylaxis can be a fatal drug hypersensitivity reaction because of its rapid onset. It is often underrecognized and undertreated because it can mimic other conditions and is variable in its presentation. However, respiratory compromise and cardiovascular collapse are of greatest concern, because they are the most common causes of death. Urticaria and angioedema are the most common manifestations but may be delayed or absent. The more quickly anaphylaxis occurs after exposure to the offending agent, the more likely the reaction is to be severe and potentially life threatening.

Most anaphylaxis episodes are IgE-mediated reactions resulting in a sudden mast cell and basophil degranulation. This sudden release of mediators affects the cutaneous, pulmonary, cardiac, GI, vascular, and neurologic systems. Medications are a common trigger of anaphylaxis in adults. Most cases of IgE-mediated drug anaphylaxis in the United States are due to penicillins and cephalosporins. Antibiotics are also the most common cause of perioperative anaphylaxis because skin eruptions may be missed in patients who are draped during surgery. Some anaphylaxis reactions involve other immunologic mechanisms. Administration of blood products (e.g., IVIG, animal antiserum) can cause an anaphylactoid reaction due, at least in part, to complement activation. Activation of the complement cascade can cause mast cell/basophil degranulation. Anaphylaxis episodes can also occur independently of any immunologic mechanism. Certain drugs, such as opioids, dextrans, and protamine, can cause a direct release of histamine and other mediators from mast cells and basophils. Finally, there are acute systemic reactions without any obvious triggers or mechanisms (idiopathic anaphylaxis).

Anaphylaxis is a clinical diagnosis with a short window of treatment time available. Therefore laboratory testing is limited and may not be of much value. Initially, the patient will describe flushing, pruritus, and a sense of impending doom. Some patients will have dyspnea, dizziness, syncope, or GI symptoms of diarrhea and abdominal cramping. Most patients will have cutaneous symptoms of flushing, urticaria, or angioedema. Some patients will progress to respiratory or cardiovascular complications.

The goal of therapy should be early recognition and treatment with epinephrine to prevent a progression to life-threatening respiratory or cardiovascular failure. The immediate intervention should include stopping the offending drug if possible, epinephrine injection, basic life support, high-flow oxygen, cardiac monitoring, and IV access. Epinephrine is the drug of choice for anaphylaxis. The therapeutic actions of epinephrine include α -1-adrenergic vasoconstrictor effects (decreases mucosal edema, thereby relieving upper airway obstruction, and increases blood pressure to prevent shock), β -1 adrenergic effects (increases rate and force of cardiac contractions), and β -2 effects (increases bronchodilation and decreases the release of mediators of inflammation from mast cells/basophils). Delayed epinephrine administration has been associated with fatalities. Intramuscular epinephrine in the thigh results in high-plasma concentrations and is preferred in the setting of anaphylaxis. The recommended dose of epinephrine is 0.3 mg (1 mg/mL) IM every 5 minutes. Typically, only one or two additional doses are needed. Patients in shock should receive epinephrine by slow IV infusion at 2 to 10 mcg/min with the rate titrated according to response and the presence of continuous hemodynamic monitoring. Patients taking beta-blockers may be resistant to treatment with epinephrine. In this case, glucagon¹ 1 to 5 mg IV over 5 minutes should be administered because its cardiac effects are not mediated through beta-receptors.

Adjunctive therapies for the treatment of anaphylaxis include antihistamines and corticosteroids. Consider an inhaled beta-agonist if wheezing. Diphenhydramine (Benadryl), an H₁ antihistamine, may be given intravenously at the dose of 25 to 50 mg. If an H₂ blocker is considered, give ranitidine (Zantac)¹ 50 mg/20 mL as an IV infusion over 5 minutes. Use of both diphenhydramine and ranitidine is superior to diphenhydramine alone. Corticosteroids are used to prevent a potential late-phase reaction that may occur in up to 23% of adults with anaphylaxis. There is no proven best dose or route of steroid therapy. The most common dosage is prednisone 20 to 60 mg daily for 3 to 5 days.

Angioedema

Angioedema is characterized by a deep dermal, subcutaneous, mucosal swelling. Many patients present with both urticaria and angioedema. Angioedema can progress rapidly from a mild swelling of the oral mucosal to a life-threatening laryngeal edema. With this rapid sequence of events, the most important part of treatment is obtaining and maintaining a patent airway. Epinephrine 0.3 mg IM every 10 minutes should be administered to patients who present with anaphylaxis, respiratory distress, or severe laryngeal edema. Once the airway is patent, the patient should be treated with H₁ antihistamines, H₂ blockers, and steroids. The milder cases may be treated similarly to other allergic reactions. H₁ antihistamines such as diphenhydramine and hydroxyzine (Atarax) are effective in relieving pruritus but can cause significant sedation. Therefore second-generation H₁ antihistamines¹ (loratadine [Claritin], cetirizine [Zyrtec], desloratadine [Clarinex], fexofenadine [Allegra]) are often chosen for outpatient therapy. Doxepin (Sinequan),¹ a tricyclic antidepressant with potent H₁ and H₂ blocker activities, can be used as an alternative to H₁ antihistamines. However, it should not be used as first-line treatment for acute urticaria and angioedema because of its significant side effects of severe sedation, dry mouth, and weight gain. Corticosteroids are used in patients who are not responsive to antihistamines. For most patients, a short course of oral prednisone is adequate.

In drug-induced angioedema, the offending drug should be stopped and avoided. Further trial of the medication is not recommended, because the patient will respond more quickly and with more severe symptoms on reintroduction. The patient should be counseled, and epinephrine 0.3 mg in an auto-injectable device (EpiPen, Auvi-Q) may be prescribed in case of recurrence in the future.

¹Not FDA approved for this indication.

Specific Drugs

Almost all drugs can cause a drug hypersensitivity reaction. However, certain drugs are more frequently associated with specific types of reactions. Some of the more commonly used drugs are discussed here in more detail.

Antibiotics

Penicillin

Penicillin allergy is the most well-known drug allergy and also the most costly ADR. Although most drugs usually have type I and type IV reactions, penicillin may cause all four types of allergic drug reactions. The rate of penicillin-induced anaphylaxis after intravenous administration is approximately 1 to 2 per 10,000 treated patients.

Only about 10% of patients who report a penicillin drug allergy actually have a true immunologic response. The other 90% are actually able to tolerate penicillin or a cephalosporin. Because of this overreporting, there are several patient safety concerns. These include the antibiotic coverage of an organism not being optimal and an increase in drug resistance, which results in higher health care costs. Therefore it is important to evaluate a patient for true penicillin allergy.

Penicillin skin testing is the best method for diagnosing an IgE-mediated penicillin allergy. A commercially available product, PrePen, contains benzylpenicilloyl polylysine (PPL), which is a major antigenic determinant of penicillin. Minor determinants are metabolic derivatives of penicillin that may also produce an immune response. The current recommendations for penicillin skin testing are to administer both the major determinant (PPL) and the minor determinants (penicillin G). These two tests identify approximately 90% to 97% of the currently allergic patients. Patients with a history of penicillin allergy but negative skin testing to PPL and the minor determinants rarely experience allergic reactions on reexposure. If they should occur, the reactions are mild and self-limiting.

In general, patients who report symptoms consistent with an immediate or type I reaction or are skin-test positive to penicillin should not receive penicillin. Desensitization should be considered if penicillin is the treatment of choice for an infection and no acceptable nonpenicillin alternatives are available. Patients should be desensitized in a hospital setting. Desensitization involves administering incremental doses of oral penicillin every 15 minutes for a total of 4 to 12 hours, after which time the first dose of penicillin is given. An example of a penicillin desensitization protocol is available in the Morbidity and Mortality Weekly Report at <https://www.cdc.gov/std/tg2015/pen-allergy.htm>.

Penicillin and Cephalosporin Cross-Reactivity

The rate of cross-reactivity between penicillin and cephalosporins has been historically cited to be as high as 10%. Recent data suggest that the rate may be much lower. The degree of cross-reactivity is highest between penicillins and first-generation cephalosporins, which have identical R-group side chains. In this case amoxicillin would be cross-reactive with cefadroxil (Duricef) and cefprozil (Cefzil), whereas ampicillin would be with cefaclor and cephalexin. Because of the differences in the chemical structures, second- and third-generation cephalosporins (cefdinir [Omnicef], cefuroxime [Ceftin], cefpodoxime [Vantin], and ceftriaxone [Rocephin]) are unlikely to be associated with cross-reactivity with penicillin. According to the latest guidelines for acute otitis media from the American Academy of Pediatrics and American Academy of Family Physicians, alternative initial antibiotics in patients with penicillin allergy include cefdinir, cefuroxime, cefpodoxime, or ceftriaxone.

Patients with penicillin allergy who have a negative skin-test result to penicillin (major and minor determinants) may safely receive cephalosporins. Cephalosporin treatment of patients with penicillin allergy who did not have a severe or recent penicillin reaction history shows a reaction rate of 0.1%. Use cephalosporin with caution in patients who report an immediate or accelerated penicillin allergy or those with a positive skin test to penicillin.

Sulfonamides (Sulfa Drugs)

Beside penicillins, sulfonamide antibiotics are the second most common cause of drug-induced allergic reactions. They commonly cause a delayed maculopapular/morbilliform eruption. Acute urticarial reactions (IgE mediated) to sulfamethoxazole (SMX) or trimethoprim (TMP) are relatively infrequent; the incidence of skin rash resulting from SMX-TMP (Bactrim) in healthy subjects is estimated to be 3%. Sulfonamides are also the most common cause of SJS and TEN.

Patients with HIV have the greatest risk of sulfonamide-induced allergic reactions. The typical reaction to SMX-TMP in patients with HIV is a generalized maculopapular eruption that occurs during the second week of treatment and is usually accompanied by pruritus and fever. Because SMX-TMP is the drug of choice for a number of HIV-associated infections such as *Pneumocystis carinii* pneumonia and spontaneous bacterial peritonitis, several methods of desensitization have been devised to administer SMX-TMP to patients with HIV with a history of allergic reaction to the drug.

There are three classes of sulfonamides based on chemical structure: sulfonfylarylamines (including sulfa antibiotics), nonsulfonfylarylamines, and sulfonamide-moiety-containing drugs. A sulfonfylarylamine has a sulfonamide moiety directly attached to a benzene ring with an amine ($-NH_2$) moiety at the N4 position. A nonsulfonfylarylamine also has a sulfonamide moiety attached to a benzene ring, but it does not have an amine group at the N4 position. A sulfonamide-moiety-containing drug has a sulfonamide group that is not connected to a benzene ring. Table 2 presents a list of sulfonamide-containing drugs based on their chemical structure.

The N4 amine is critical for the development of delayed reactions to sulfa antibiotics. Given the important chemical differences

between drugs containing sulfa antibiotics and sulfa in nonantibiotics, the risk of cross-reactivity is extremely unlikely. A retrospective cohort study by Strom and colleagues showed that approximately 90% of patients with sulfa antibiotic allergy did not have a reaction to a sulfonamide nonantibiotic. Patients with allergic reactions to sulfa antibiotics are also more likely to experience allergic reactions to the other types of sulfonamides, but this is not because of cross-sensitivity. There is no reliable skin test to rule out or confirm sulfa allergy. Some experts recommend avoiding all classes of sulfonamides in patients with serious reactions such as SJS, TEN, or anaphylaxis to any one sulfonamide.

Most diuretics are sulfonamide derivatives. The only diuretics that are not in this group are the potassium-sparing diuretics (triamterene [Dyrenium], spironolactone [Aldactone], amiloride [Midamor]) and ethacrynic acid (Edecrin). Dapsone is a sulfone that is chemically unrelated to sulfonamides. *It should also be noted that sulfates, sulfur, and sulfites are chemically unrelated to sulfonamides and do not cross-react.*

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACEIs) have two major adverse effects: cough and angioedema. The cough is typically dry and nonproductive. The incidence of ACEI-induced cough has been reported to be 5% to 35%. Cough occurs more commonly in women, African-Americans, and Asians. The onset of cough ranges from within hours of the first dose to months after the initiation of therapy. The diagnosis is confirmed by the resolution of cough, usually within 1 to 4 weeks after discontinuation of the ACEI; however, the cough can linger for up to 3 months. The cause for ACEI-induced cough is unclear but might be related to bradykinin, substance P, or another mechanism. Angiotensin II receptor blockers (ARBs) are not associated with an increased incidence of cough and can be used as an alternative to ACEIs. Because the cough may persist for several months after stopping the ACEI, starting the ARB is not a contraindication at this time, yet the cough may persist through the initiation of the new drug.

The incidence of angioedema with ACEIs is approximately 0.1% to 0.7%. With the widespread use of ACEIs, angioedema has become a growing problem. ACEI-induced angioedema is more common in patients who are over age 65, black, or female. Angioedema frequently involves swelling of the face or upper airway and can be life threatening or fatal. It can occur within days, months, or even years after the start of treatment. However, nearly 60% of cases occur within the first week of therapy. ACEIs cause angioedema by direct interference with the degradation of bradykinin, thereby increasing bradykinin levels and leading to increased vascular permeability, inflammation, and activation of nociceptors. Bradykinin is also a prominent mediator in hereditary angioedema. Therefore ACEIs are contraindicated in patients with hereditary angioedema.

ARBs directly inhibit the angiotensin receptor and do not interfere with bradykinin degradation. Theoretically, they can be relatively safe alternatives for patients with a previous history of ACEI-associated angioedema. However, some reports of ARB-induced angioedema have recently been published. The mechanism of how ARBs cause angioedema is unclear. A meta-analysis suggests that for patients who developed angioedema when taking an ACEI, the risk of persistent angioedema when subsequently switched to an ARB is less than 10%. Therefore ARBs may be an alternative only for patients with a high therapeutic need for angiotensin inhibition. ARB treatment should be started with observation. Patients should be educated on the signs of angioedema and provided with proper emergency instructions on how to proceed if angioedema should occur.

The direct renin inhibitor aliskiren (Tekturna) does not alter local or circulating bradykinin and is believed to be an alternative in patients with ACEI- and ARB-related angioedema. However, cases of angioedema have been reported with aliskiren. As with ARBs, renin inhibitors should be used with caution in patients who previously experienced angioedema to ACEIs.

TABLE 2 Classification of Sulfonamides Based on Chemical Structure

Drug

Sulfonfylarylamines

Antibiotics:	Antiinflammatory:
Sulfadiazine	Sulfasalazine (Azulfidine)
Sulfamethoxazole	Protease Inhibitors:
Sulfisoxazole	Darunavir (Prezista)
Sulfapyridine	Fosamprenavir (Lexiva)

Nonsulfonfylarylamines

Carbonic Anhydrase Inhibitors:	Sulfonfylureas:
Acetazolamide (Diamox)	Chlorpropamide
Brinzolamide (Azopt)	Glimepiride (Amaryl)
Dorzolamide (Trusopt)	Glipizide (Glucotrol)
Methazolamide (Neptazane)	Glyburide (Diabeta)
Cyclooxygenase 2 (COX-2) Inhibitors:	Tolbutamide
Celecoxib (Celebrex)	Tolazamide (Tolinase)
Loop Diuretics:	Other Agents:
Bumetanide (Bumex)	Mafenide (Sulfamylon)
Furosemide (Lasix)	Probenecid
Torsemide (Demax)	Tamsulosin (Flomax)
Thiazides Diuretics:	Tipranavir (Aptivus)
Chlorothiazide (Diuril)	
Chlorthalidone	
Hydrochlorothiazide	
Indapamide (Lozol)	
Metolazone (Zaroxolyn)	

Sulfonamide-Moiety-Containing Drugs

5-HT Agonists:	Other Agents:
Naratriptan (Amerge)	Ibutilide (Corvert)
Sumatriptan (Imitrex)	Simeprevir (Olysio)
	Sotalol (Betapace)
	Topiramate (Topamax)
	Zonisamide (Zonegran)

Aspirin and NSAIDs

Aspirin (ASA) and NSAIDs can cause several types of hypersensitivity reactions. The four most-common types of reactions are based on the drug pathways. Aspirin-exacerbated respiratory disease (AERD) is a serious reaction induced by ASA and NSAIDs in patients with asthma and chronic rhinosinusitis. AERD does not fit precisely into a specific type of ADR and is often referred to as a type of pseudoallergic reaction. AERD affects up to 20% of adults with asthma. It is more common in women. The usual age of onset is around 30 years. The pathophysiology of AERD is related to aberrant arachidonic acid metabolism. Patients with AERD also have increased respiratory tract expression of cysteinyl leukotriene 1 receptor and heightened responsiveness to inhaled leukotriene E₄. Administration of aspirin or an NSAID to these patients leads to inhibition of cyclooxygenase 1 (COX-1), resulting in a decrease in prostaglandin E₂ levels. Prostaglandin E₂ normally inhibits 5-lipoxygenase. As a result of decreased prostaglandin E₂ levels, arachidonic acid is preferentially metabolized in the 5-lipoxygenase pathway, leading to increased production of cysteinyl leukotrienes.

Patients with AERD typically have both rhinoconjunctivitis and bronchospasm within minutes of ingestion of a dose of ASA or NSAID. The bronchospasm can be severe and result in respiratory failure, which may require intubation and mechanical ventilation. Management of patients with AERD involves treatment of the patient's asthma and chronic rhinosinusitis and avoidance of aspirin and NSAIDs. Desensitization is available in cases when the patient has a specific therapeutic need for regular ASA or NSAID therapy. Selective COX-2 inhibitors very rarely cause reactions in patients with AERD and can be taken safely.

The second type of ASA and NSAID hypersensitivity reaction is an exacerbation of urticaria or angioedema in patients with chronic idiopathic urticaria. Approximately 20% to 40% of patients with chronic urticaria may have this drug-induced reaction. The mechanism of this reaction is related to COX-1 inhibition. The exacerbating effects are usually dose dependent. All drugs that inhibit COX-1 cross-react to cause this reaction. Selective COX-2 inhibitors are generally considered safe to take in patients with chronic idiopathic urticaria.

The third type of hypersensitivity reaction is an anaphylactic or immediate urticarial reaction or angioedema appearing soon after the intake of a specific NSAID. Other NSAIDs from other groups or even an NSAID from the same group with a slightly different chemical structure is tolerated by the patient. An IgE-mediated mechanism is implicated only in some instances. The diagnosis is made mainly by exclusion. Further research is needed in this topic.

The fourth type of hypersensitivity reaction is urticaria or angioedema caused by ASA or any NSAID that inhibits COX-1 in patients without chronic urticaria. These reactions may be either drug specific or cross-reactive to other NSAIDs. Rarely, patients may have combined respiratory and cutaneous reactions that cannot be classified into one of the four reaction types described.

Corticosteroids

Corticosteroids are the most frequently used drugs for the treatment of allergic conditions, yet they can also induce hypersensitivity reactions. Most hypersensitivity reactions to steroids can be classified into type I (immediate, IgE-mediated) and type IV (delayed, cell-mediated) mechanisms. Type I reactions are characterized by the presence of urticaria and anaphylaxis. Type IV reactions can be presented as maculopapular exanthema and delayed urticaria.

Allergic contact dermatitis (type IV reaction) caused by topical administration of steroids is the most common type of allergic reaction induced by this class of drugs, occurring at the rate of 3% to 6%. Usually this is seen as a failure to improve or a worsening of an existing dermatitis that is being treated with topical steroid. Keep in mind that the reaction can also be due to other constituents of the creams, such as neomycin or cetostearyl alcohol. The diagnosis can be done using patch testing, which detects more than 90% of

allergic patients. The topical steroids most frequently involved are nonfluorinated, such as hydrocortisone and budesonide.

Inhaled and intranasal steroids can induce both local and systemic reactions. Local reactions include contact dermatitis, pruritus, nasal congestion, erythema, and dry cough and are quite often irritant in nature. Systemic reactions include eczematous lesions, particularly on the face, exanthema, and urticaria. The most frequently involved steroid is budesonide. The actual mechanism of this reaction is not clear, but it may be a T-cell-mediated reaction.

Hypersensitivity reactions to systemically administered steroids seldom occur. Most of the data come from case reports. Both immediate and delayed reactions have been described, ranging from urticaria to sudden cardiovascular collapse and death. Most immediate reactions are caused by intravenous methylprednisolone and hydrocortisone. In a few cases, the reactions can be induced by salts, such as succinate, or rarely by certain diluents such as carboxymethylcellulose or metabisulfite. Nonimmediate reactions are mainly mild, such as delayed urticaria or maculopapular exanthema. The drug involved most often is betamethasone.

Cross-reactivity between steroids is difficult to assess. Based on corticosteroid patch test results and their chemical structure, Coopman and colleagues divided the steroids into four groups: A (hydrocortisone type), B (triamcinolone acetonide type), C (betamethasone type), and D (hydrocortisone-17-butyrate type). Group D can be subdivided into D1 and D2 depending on the presence or absence of a C16 methyl substitution and/or halogenations on the C9 of the B ring. Table 3 provides the listing of the

TABLE 3 Coopman Classification of Cross-Reactivity in Corticosteroids

GROUP	TYPE	DRUGS
A	Hydrocortisone	Hydrocortisone (acetate, succinate, phosphate) Methylprednisolone (acetate, succinate, phosphate) Prednisolone, prednisolone acetate Tixocortol pivalate*
B	Triamcinolone acetonide	Amcinonide (Cyclocort) Budesonide (Pulmicort, Rhinocort, Entocort) Desonide (Desonate, DesOwen) Flunisolide Fluocinolone acetonide (Synalar) Fluocinolone Halcinonide (Halog) Triamcinolone Triamcinolone acetonide (Kenalog)
C	Betamethasone	Betamethasone (Celestone) Desoxymethasone Dexamethasone Paramethasone* Fluocortolone*
D1	Hydrocortisone-17-butyrate	Beclomethasone dipropionate (QVAR) Betamethasone valerate Betamethasone dipropionate Clobetasone 17-butyrate* Clobetasol 17-propionate (Clobex)
D2	Hydrocortisone-17-butyrate	Fluticasone (Flonase) Mometasone Prednicarbate (Dermatop) Hydrocortisone 17-butyrate (Locoid) Hydrocortisone 17-propionate* Methylprednisolone aceponate*

*Not available in the United States.
From Torres and Canto (2010).

four groups. High cross-reactivity exists between corticosteroids in each group, as well as between group D2 and groups A and B, with group D1 exhibiting quite low cross-reactivity with the other groups.

Local Anesthetics

The most common immunologic reaction to local anesthetic is allergic contact dermatitis (type IV). IgE-mediated reactions (type I) to local anesthetics are very rare. Most adverse reactions are due to nonallergic factors such as vasovagal response, anxiety, dysrhythmias, and toxic reactions resulting from inadvertent IV epinephrine effects.

Any patient who presents with a history of an allergic reaction to local anesthetics should be carefully evaluated. Skin testing and graded challenge can be performed in patients who present with a history suggestive of a possible IgE-mediated allergic reaction to these drugs. A local anesthetic that does not contain epinephrine or other additives, such as parabens or sulfites, is preferred in this situation.

It is necessary to identify the type of local anesthetics to be used. Local anesthetics are classified as esters or amides based on their chemical structure. Drugs in the esters group include benzocaine (Americaine, Dermoplast, Lanacane, Hurracaine), chloroprocaine, cocaine, procaine (Novocaine), proparacaine (Alcaine, Opthaine), and tetracaine (Tetacaine). Most allergic reactions reported in the literature have been caused by agents in the esters group, which are derivatives of para-aminobenzoic acid (PABA), a known allergen. Cross-reactivity occurs among members of the ester group, but the esters do not cross-react with the amides. Agents in the amides group include bupivacaine (Marcaine), lidocaine, mepivacaine (Polocaine), prilocaine (Citanest), and ropivacaine (Naropin). Amide local anesthetics generally do not cross-react with other amides or with the esters.

Radiocontrast Media

There are two types of radiocontrast media (RCM): ionic high osmolality and nonionic low osmolality. Both of these agents contain iodine. The nonionic RCMs are much more widely used today than the ionic agents.

Allergic reactions to RCM are common and can range from mild to life threatening. Anaphylactoid reactions and severe life-threatening reactions occur in 1% to 3% and 0.22% of patients who receive ionic RCM, respectively. Less than 0.5% and 0.04% of patients who receive nonionic agents have anaphylactoid reactions and severe reactions, respectively. The fatality rate is approximately 1 to 2 per 100,000 procedures, and it is similar for both ionic and nonionic agents. RCM reactions are typically not mediated by IgE antibodies. RCM acts directly on mast cells and basophils, resulting in the release of histamine and other systemic mediators, which cause the anaphylactoid reactions. Patients at greater risk for more serious anaphylactoid reactions include females; those with asthma, heart disease, and a history of previous anaphylactoid reaction to RCM; and those taking beta-blockers. People who have seafood allergy are not at increased risk for reactions to RCM compared with the general population. The pathogenesis of anaphylactoid reactions is also not related to iodine.

Management of patients with previous RCM reactions include the use of a nonionic, low-osmolality agent and a pretreatment regimen. One common regimen consists of prednisone (50 mg PO at 13, 7, and 1 hour before the procedure), diphenhydramine (50 mg at 1 hour before the procedure), and a histamine H₂-receptor antagonist (1 hour before the procedure). This will significantly reduce the risk for anaphylactoid reaction with reexposure to RCM.

Delayed reactions to RCM occur 1 hour to 1 week after RCM administration. Approximately 2% of patients have delayed reactions to RCM. These reactions are generally mild, self-limited cutaneous eruptions. The mechanism is usually T-cell mediated. Rarely, more serious and life-threatening delayed reactions such as SJS, TEN, and DRESS syndrome have been reported.

Chlorhexidine

Chlorhexidine gluconate is an antiseptic agent. It is commonly available in OTC products as a skin and wound disinfectant (e.g., Betasept, Hibiclens). Hypersensitivity reactions to chlorhexidine include contact dermatitis, pruritus, urticaria, dyspnea, and anaphylaxis. Prescription chlorhexidine gluconate mouthwashes and oral chips used for gum disease contain a warning about the rare but serious allergic reactions in their labels. According to a recent FDA Drug Safety Communication, the number of reports of serious allergic reactions to chlorhexidine-containing products has increased over the last several years. As a result, an anaphylaxis warning is now added to the OTC product labels under Drug Facts.

Several case reports have suggested that some patients with prior exposure to chlorhexidine and patients with chlorhexidine-induced contact dermatitis may be susceptible to anaphylaxis caused by chlorhexidine sensitization. Since chlorhexidine is the standard skin disinfectant used before surgery or invasive procedures, the exposure to the agent becomes more widespread. Even though severe anaphylaxis to chlorhexidine has been estimated to be rare, the actual rate may be higher than reported. Such reports remind clinicians to be vigilant about chlorhexidine as a hidden allergen, especially in surgical patients.

Herbal Supplements

There is a perception that herbal supplements are “natural” and therefore safe. In fact, severe allergic reactions including asthma and anaphylaxis have been well documented in patients using bee pollen products and echinacea. Echinacea is an herb belonging to a group of flowering plants known as Asteraceae. Asteraceae-derived pollens are an important cause of hay fever and asthma. Asteraceae may cause contact allergic dermatitis. Cross-reactivity exists between members of the Asteraceae family, such as ragweed, dandelion, daisy, chamomile, echinacea, feverfew, and milk thistle.

A lack of quality control has been a major concern in the herbal supplement industry. Chinese herbal products may be adulterated with synthetic medications not listed on the label. Contaminated supplements may be a potential risk for systemic contact dermatitis in nickel- and mercury-allergic patients. Because of the widespread use of herbal supplements and the underreporting of adverse events to herbs, all patients should be questioned about the use of herbal supplements when being evaluated for hypersensitivity reactions.

Conclusion

Drug hypersensitivity reactions are common; fortunately, severe and often fatal reactions are not. It is important for the clinician to have a working knowledge of common drug-induced hypersensitive reactions as well as the ability to identify and document common dermatologic findings. With that background knowledge, a thorough history and physical examination should enable the clinician to diagnose the majority of these types of reactions. A timely and appropriate management plan can then be implemented. As always, it is important to educate patients regarding their drug hypersensitivity history and the potential for future reactions.

ACUTE MYOCARDIAL INFARCTION: FOCUS ON ST-ELEVATION MYOCARDIAL INFARCTION

Method of

Kuang-Yuh Chyu, MD, PhD; and Prediman K. Shah, MD, MACC

Coronary heart disease (CHD) results from atherosclerotic coronary artery disease (CAD), and its acute manifestation is acute coronary syndrome (ACS). Based on the presenting symptoms, characteristic ECG changes, and cardiac biomarkers, ACS can be further subdivided into unstable angina (USA), non-ST-elevation myocardial infarction (NSTEMI), or ST-elevation myocardial infarction (STEMI). The majority of patients with ACS have similar underlying pathophysiology: atherosclerotic plaque formation leading to narrowing of coronary arteries with plaque rupture or erosion and superimposed thrombus formation resulting in an acute presentation. A small portion of ACS cases can be due to conditions such as coronary artery spasm, spontaneous coronary artery dissection, coronary embolization, or cocaine use. Stress-induced acute cardiomyopathy, without angiographic signs of severely occlusive disease, can closely simulate atherothrombotic STEMI.

Although the three ACS entities share similar pathophysiology, their presentations vary widely. The initial recognition, diagnostic testing, and management strategies for these entities are similar and applicable to all patients with ACS. Diagnostically, patients with STEMI as a whole reflect a more homogenous group of patients when compared with patients with USA or NSTEMI, and patients with STEMI carry the highest risk regarding acute morbidity and mortality. The major difference in managing these three groups of patients lies in the decision for and timing of acute reperfusion of occluded culprit coronary arteries.

In the past three decades, there has been a steady decline in the incidence of STEMI and significant improvement in the outcomes of patients with STEMI with the introduction of early coronary reperfusion strategies; improved adjunctive pharmacologic therapies; adoption of guideline-directed treatments such as lipid lowering, blood pressure control, and diabetes mellitus control; and cigarette smoking cessation to effectively modify risk factors. Currently the in-hospital mortality of STEMI has reached as low as 7%.

Diagnosis

Electrocardiogram

ECG is the most important diagnostic test to detect STEMI because clinical features, physical examination, and CAD risk factor profile only have modest sensitivity and specificity in diagnosing STEMI. Current guidelines define ST elevation at the J point in at least two continuous leads of 2 mm or greater in men or 1.5 mm or greater in women in leads V2 to V3 and/or 1 mm or greater in other contiguous chest leads or the limb leads in the absence of left ventricular hypertrophy or left bundle branch block (LBBB). Other ECG abnormalities such as paced rhythm, drug or electrolyte (hyperkalemia) effects, or Brugada syndrome also reduce the sensitivity and specificity of STEMI ECG interpretation.

Some patients present with ECG changes, although not with typical ST elevation, indicating equivalent clinical risk to STEMI, and should be treated as having a true STEMI. These STEMI-equivalent ECG patterns include (1) isolated ST depression in two or more precordial

leads (V1 to V4), indicating true posterior wall MI; (2) ST depression in multiple leads with ST elevation in aVR, indicating left main or triple-vessel CAD; (3) Wellens sign with symmetrical deep T-wave inversions in anterior precordial leads; (4) hyperacute T wave; and (5) de Winter sign showing ST depression and peaked T waves in the precordial leads. Occasionally patients with left circumflex artery occlusion can present with a normal or near-normal ECG.

Serum Biomarkers

Serum biomarkers of myocardial necrosis such as cardiac-specific troponins T and I are complementary to diagnosing STEMI. In clinical practice, STEMI is often diagnosed with ECG alone, whereas the laboratory result of biomarkers is not yet available. The troponin level typically rises 4 to 6 hours after the onset of symptoms and peaks within 12 to 24 hours if reperfusion therapy succeeds in reperfusing the occluded coronary artery and patients present early in the course of STEMI; its level tends to peak after 24 hours if reperfusion therapy fails or in patients who receive no reperfusion therapy. After STEMI, successfully reperfused or not, the troponin level remains elevated for 7 to 10 days. For patients suspected of having recurrent ACS within a week after the index STEMI, given the troponin level remaining elevated, creatine kinase (CK) and the MB isoform of CK (CK-MB) levels can be used as biomarkers to establish additional myocardial necrosis from a recurrent event because CK and CK-MB levels usually return to normal 48 to 72 hours after the initial index event.

Imaging

STEMI is commonly accompanied with wall motion abnormalities on echocardiogram, but echocardiogram is not essential to diagnose STEMI. Echocardiogram is extremely useful in managing patients with STEMI, especially when they present with acute complications from STEMI such as acute congestive heart failure, acute mitral regurgitation, free wall or ventricular septal rupture, pericardial effusion, cardiogenic shock, or left ventricular thrombus.

Management of STEMI

The principal concept of managing STEMI is “time is muscle”; hence, it is important for patients to recognize symptoms for early presentation and for the medical community to administer suitable reperfusion therapy in a timely manner.

Prehospital Phase

Current guidelines recommend that patients with STEMI receive reperfusion therapy as soon as possible but within 12 hours of symptom onset to achieve optimal myocardial salvage to reduce mortality and morbidity. In daily clinical practice, a substantial number of patients still present late and miss the golden window of reperfusion. Common reasons for late presentation include (1) patients’ lack of knowledge to recognize symptoms, (2) patients’ inertia to seek medical care, (3) patients’ lack of access to medical care, and (4) atypical symptoms that mislead patients or medical care providers to consider noncardiac problems.

Patients with suspicious myocardial ischemic symptoms are encouraged to call emergency medical services (EMS) immediately for help; this has the following benefits: (1) patients can receive early treatment, (2) patients can receive immediate resuscitation should STEMI complications such as cardiac arrest occur en route to the hospital, and (3) an early prehospital ECG and communication with

a hospital capable of percutaneous intervention (PCI) by EMS significantly reduce reperfusion time and improve outcome. However, currently only a fraction of such patients are transported by EMS. Improving this requires public education to enhance recognition of symptoms, implementation of an efficient EMS system, and infrastructures with standardized treatment algorithms for STEMI.

Initial management by EMS usually includes pain relief by morphine, administration of nitroglycerin,¹ oxygen, and non-enteric-coated aspirin (162 to 325 mg) unless contraindicated. The role of routine oxygen supplementation to patients with STEMI has recently been questioned. A recent randomized clinical trial (Air Versus Oxygen in Myocardial Infarction [AVOID] trial) suggests that supplemental oxygen therapy (8 L/min via face mask) in patients with STEMI without hypoxia (oxygen saturation >94%) may increase early myocardial injury and is associated with larger myocardial infarction size at 6 months.

Once STEMI is identified by a prehospital ECG performed by EMS, an assessment of candidacy for and availability of reperfusion therapy is an important next step of management to ensure immediate reperfusion and administration of its adjunctive therapy to maintain culprit coronary artery patency, limit infarct size and adverse left ventricular (LV) remodeling, and improve outcome. To achieve the best outcome from reperfusion therapy, patients with STEMI should receive suitable reperfusion therapy within 12 hours of symptom onset—the earlier the better. Current reperfusion therapy options for STEMI include primary percutaneous coronary intervention (PPCI) or fibrinolysis. PPCI is the treatment of choice for STEMI because it confers a beneficial reduction in mortality and recurrent ischemia when compared with fibrinolysis. Hence current guidelines recommend EMS to transport patients to a PCI-capable hospital and PPCI as the preferred method of reperfusion therapy with a system goal of less than 90 minutes from first medical contact (FMC) to device time.

Not every hospital is PCI capable. Based on the Nationwide Inpatient Sample database, only 33.7% of hospitals in the United States provided STEMI-related PCI in 2011. If a patient is sent to or arrives at a non-PCI-capable hospital, guidelines recommend transferring that patient to a PCI-capable hospital for PPCI with a system goal of less than 120 minutes from FMC to device time. If there is an anticipated delay of FMC to device time of 120 minutes or more, a fibrinolytic agent can be given within 30 minutes of hospital arrival if the patient has no contraindications for fibrinolysis (Table 1). Prehospital fibrinolysis, administered by EMS with physician supervision, has been shown to be feasible and safe, with a shortened reperfusion time and reduced mortality. Such strategy, however, is not used in the United States.

In clinical practice sometimes it is not possible to achieve strict time goals because of uncertainty of the initial diagnosis, necessity to treat concomitant comorbidities or complications, patient preference or consent issues, and local factors delaying transport. Therefore emphasis should be to deliver reperfusion therapy to eligible patients as rapidly as possible.

In-Hospital Reperfusion Strategy

Primary Percutaneous Coronary Intervention

PPCI performed in a high-volume hospital by experienced operators achieves a higher patency rate of infarct-related artery (IRA) and lower rate of recurrent ischemia, reinfarction, hemorrhagic stroke, and death when compared with fibrinolysis. In particular, PPCI has the greatest benefit in high-risk patients such as those with cardiogenic shock. Hence, PPCI is the preferred method of reperfusion whenever possible with the system goal of 90 to 120 minutes.

The reperfusion technique used in PPCI has evolved greatly in the past few decades, from balloon angioplasty, bare-metal stent (BMS), and drug-eluting stent (DES) to bioresorbable vascular scaffolds (BVSs). Compared with balloon angioplasty, BMS used in PPCI confers reduced risk for subsequent target-vessel revascularization but

TABLE 1 Contraindications and Cautions for Fibrinolytic Therapy in STEMI*

Absolute Contraindications

- Any prior ICH
- Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 mos
- EXCEPT acute ischemic stroke within 4.5 h
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head or facial trauma within 3 mos
- Intracranial or intraspinal surgery within 2 mos
- Severe uncontrolled hypertension (unresponsive to emergency therapy)
- For streptokinase, prior treatment within the previous 6 mos

Relative Contraindications

- History of chronic, severe, poorly controlled hypertension
- Significant hypertension on presentation (SBP > 180 mm Hg or DBP > 110 mmHg)
- History of prior ischemic stroke >3 mos
- Dementia
- Known intracranial pathology not covered in absolute contraindications
- Traumatic or prolonged (>10 mm) CPR
- Major surgery (<3 wk)
- Recent (within 2 to 4 wk) internal bleeding
- Noncompressible vascular punctures
- Pregnancy
- Active peptic ulcer
- Oral anticoagulant therapy

CPR indicates cardiopulmonary resuscitation; DBP, diastolic blood pressure; ICH, intracranial hemorrhage; SBP, systolic blood pressure; and STEMI, ST-elevation myocardial infarction.

*Viewed as advisory for clinical decision making and may not be all-inclusive or definitive.

does not reduce the mortality rate. Compared with BMS, DES used in PPCI decreases the restenosis rate and need for reintervention without reduction in reinfarction and death. BVS is a new stent technology, but its role in PPCI has not been well established because data concerning using BVSs in STEMI are insufficient and because of its association with a higher rate of stent thrombosis, especially in the first 30 days after implantation, and late lumen loss when compared with DES.

Fibrinolysis

The currently available intravenous fibrinolytic agents are tenecteplase (TNKase), reteplase (Retavase), and alteplase (Activase) (Table 2). A fibrinolytic agent should be administered to eligible patients without contraindication within 30 minutes of arrival at the emergency department. It is important to evaluate the risk/benefit ratio for each individual patient before administering fibrinolytic therapy because it carries a small but fatal risk of hemorrhage stroke (about 1%). The ideal patient to receive a fibrinolytic agent would be with symptom onset within 1 to 2 hours, low bleeding risk, and age younger than 65 years.

Although fibrinolysis achieves a reasonable patency rate of IRA (Table 2), a substantial portion of patients fail to achieve successful reperfusion as defined by the following clinical criteria: (1) resolution of chest pain, (2) reduction of >50% of the initial ST-segment elevation pattern on follow-up ECG 60 to 90 minutes after initiation of fibrinolysis, and (3) occurrence of reperfusion arrhythmia (accelerated idioventricular rhythm [AIVR]). If fibrinolysis does not achieve resolution of ST elevation by at least 50% in the worst lead at 60 to 90 minutes, rescue PCI (transfer to PCI-capable hospital if necessary) should be strongly considered.

Percutaneous Intervention After Fibrinolysis

Approximately 40% of STEMI patients who receive fibrinolysis fail to achieve successful reperfusion and require emergency rescue PCI. Other indications for rescue PCI include severe heart failure, cardiogenic shock, persistent chest pain, or electrical instability.

¹Not FDA approved for this indication.

TABLE 2 Comparison of Fibrinolytic Agents

	ALTEPLASE (T-PA) (ACTIVASE)	RETEPLASE (R-PA) (RETAVASE)	TENECTEPLASE (TNK-TPA) (TNKASE)
Dose	Up to 100 mg in 90 min (weight based)	10 U + 10 U IV boluses given 30 min apart	30–50 mg based on weight
Bolus administration	No	Yes	Yes
Antigenic	No	No	No
Allergic reaction	No	No	No
Fibrin specificity	++	++	++++
90 min TIMI 2 or 3 patency rate (%)	73–84	84	85
TIMI 3 flow (%)	54	60	63

Modified from 2013 ACCF/AHA STEMI guideline.

Hence, these patients should be transferred to a PCI-capable hospital immediately if fibrinolysis has been administered in a non-PCI capable hospital.

Otherwise, stable patients after successful fibrinolysis can undergo coronary angiography with an intent to revascularize as soon as logistically feasible, ideally between 3 and 24 hours after fibrinolysis (so-called *pharmaco-invasive strategy*). In patients older than 75 years, if a pharmaco-invasive strategy is chosen as the reperfusion strategy, a fibrinolytic agent at half dose (such as the half dose of tenecteplase used in the STREAM trial) should be used to reduce bleeding risks because patients will receive concomitant antiplatelets and anticoagulants for PCI. A recent EARLY-MYO trial confirmed the efficacy of a pharmaco-invasive strategy using half dose alteplase followed by PCI within 3 to 24 hours was non-inferior to primary PCI in 30-day rates of total death, reinfarction, heart failure or major bleeding but with higher rate of minor bleeding. Very early PCI after successful fibrinolysis (<2 to 3 hours) is not recommended.

Facilitated Percutaneous Intervention

This strategy refers to a full dose or partial dose of fibrinolysis plus a glycoprotein IIb/IIIa antagonist or antithrombotic followed by immediate PCI if there is no evidence of reperfusion failure. Current guidelines do not recommend this strategy owing to potential harms such as an increase in ischemic events, bleeding, and mortality.

Patients with STEMI and Multivessel Coronary Artery Disease

About 40% to 65% of patients with STEMI undergoing PPCI for culprit IRA have multivessel CAD. Significant multivessel CAD, if left unrevascularized, is associated with a worse clinical prognosis. For patients with STEMI with cardiogenic shock, conventional paradigm deemed it reasonable to perform multivessel PPCI (or emergency coronary artery bypass grafting [CABG] in selected patients) to achieve as complete a revascularization as possible. However, this is now being challenged by a recent CULPRIT-SHOCK trial that showed that initial revascularization of the culprit lesion only by PCI in patients with acute MI, with multivessel ACD, and cardiogenic shock resulted in a lower 30-day risk of death or renal-replacement therapy when compared with a strategy of immediate multivessel PCI.

For stable patients, randomized clinical trials have demonstrated the feasibility of performing multivessel PPCI in acute settings. This approach has the following advantages: complete revascularization leading to improved left ventricular function and prognosis,

decreased vascular complications from repeated procedures, and reduced length of stay and medical costs. However, the procedure will be longer with potentially higher radiation exposure, higher risk for contrast nephropathy owing to a higher contrast load, risk of compromising viable myocardium supplied by the nonculprit coronary artery owing to procedure complications, and unnecessary stenting to the nonculprit artery without objective evidence of ischemia. The 2015 American College of Cardiology (ACC)/AHA/Society for Cardiovascular Angiography and Interventions (SCAI) focused update on PPCI for patients with STEMI supports multivessel PCI, either at the time of PCI to the STEMI culprit vessel or as a staged procedure in selected hemodynamically stable patients. Interventional cardiologists should integrate clinical data, characteristics of lesions and procedures, clinical risks, and complications from procedures to determine the best timing and strategy to achieve the optimal benefit. The guideline does not endorse routine multivessel PPCI in patients with STEMI and multivessel CAD.

Patients with STEMI Who Present Later Than 12 Hours After Symptom Onset

Patients with STEMI who present between 12 hours and 2 days after symptom onset without unstable symptoms or signs are no longer eligible for fibrinolysis but are still eligible for PPCI to salvage myocardium, which confers the benefit of reduced infarct size when compared with conventional therapy guided by a pre-discharge symptom-limited exercise test or unplanned PCI guided by clinical instability as demonstrated in the Beyond 12 Hours Reperfusion Alternative Evaluation (BRAVE-2) trial. For patients with STEMI who present more than 48 hours after symptom onset without clinical instability, a strategy of symptom-limited stress test first or coronary angiography first to delineate high-risk features of coronary anatomy is reasonable with an intent to revascularize high-risk coronary anatomy. If patients are clinically stable without high-risk coronary anatomy noted by angiography and present between 3 and 28 days after symptom onset, PCI to open the occluded IRA does not confer a clinical benefit in reducing mortality, congestive heart failure, or nonfatal myocardial infarction when compared with medical therapy as demonstrated in the Occluded Artery Trial (OAT). Irrespective of time of presentation, patients with STEMI who present with hemodynamic or electrical instability should undergo coronary angiography with an intent to revascularize the jeopardized myocardium as soon as possible.

Figure 1 summarizes current pathways of managing patients with STEMI based on their time of presentation, their clinical status, and availability of reperfusion therapy.

Adjunct therapy

Antiplatelet Therapy

Aspirin

Unless contraindicated, 162 to 325 mg of aspirin should be administered as a loading dose immediately and continued indefinitely at a dose of at least 81 to 325 mg daily in all patients with STEMI, with 81 mg being the preferred maintenance dose. Patients with a history of aspirin allergy can be given clopidogrel (Plavix) instead.

P2Y₁₂ Receptor Inhibitors

Clopidogrel is a second-generation thienopyridine and irreversibly blocks the platelet P2Y₁₂ receptor to inhibit platelet activation and aggregation. Current guidelines support the use of clopidogrel during fibrinolysis or PPCI. For patients undergoing fibrinolytic therapy, a loading dose of 300 mg followed by a maintenance dose of 75 mg daily has been recommended for patients younger than 75 years. For patients older than 75 years, only the maintenance dose of 75 mg should be given. Prasugrel (Effient) and ticagrelor (Brilinta) have not been studied and, hence, are not recommended in the setting of fibrinolysis as reperfusion therapy. For patients undergoing PPCI, depending on whether they are receiving a fibrinolytic agent and the timing of subsequent PCI, a different dosing regimen of clopidogrel may be recommended (Figure 2).

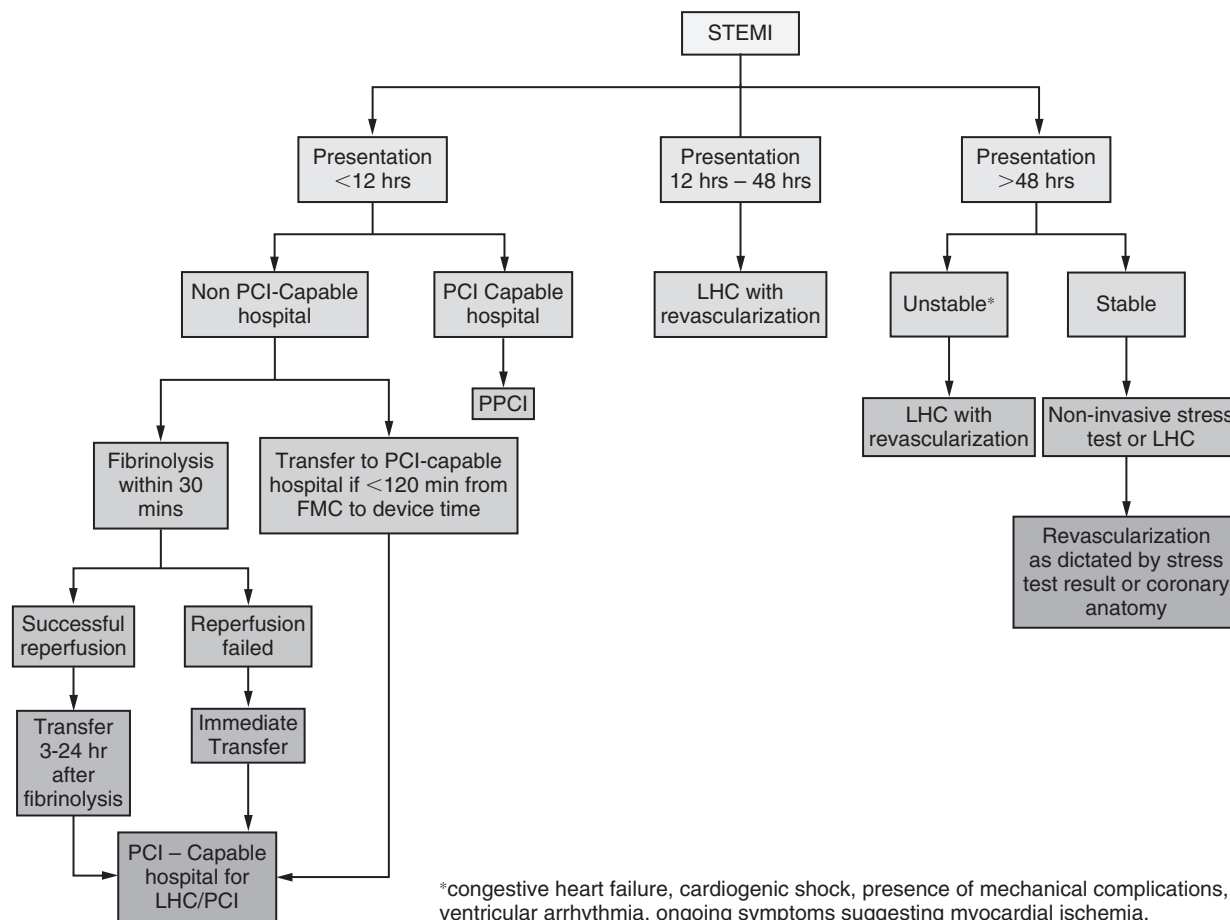

Figure 1 Pathways of managing ST-elevation myocardial infarction (STEMI).

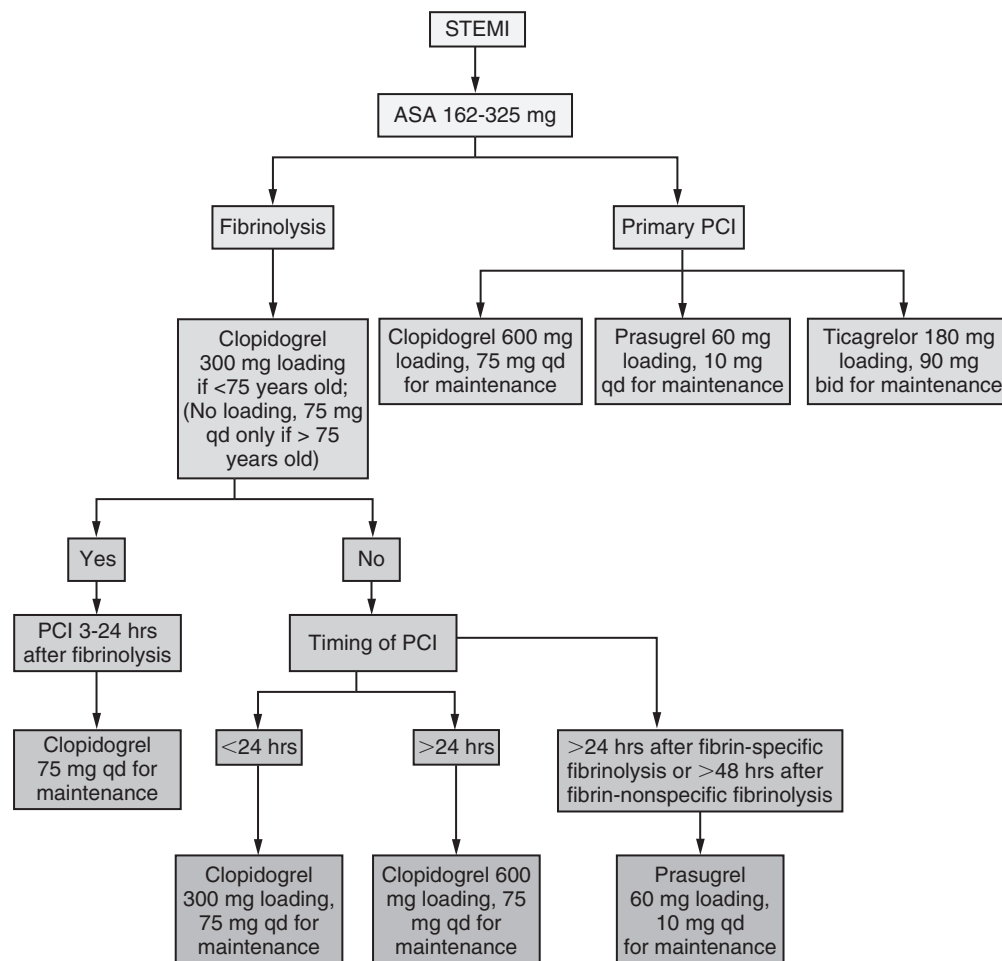

Figure 2 Oral regimen of different P2Y₁₂ receptor inhibitors based on reperfusion strategies. Modified from 2013 ACCF/AHA STEMI guideline.

Prasugrel is a third-generation thienopyridine P2Y₁₂ receptor inhibitor. It is metabolized to its active form more quickly than clopidogrel and hence confers a more potent effect. In a subset of patients with STEMI in the TRITON-TIMI 38 trial, prasugrel was more efficacious in preventing composite endpoints of cardiovascular (CV) death, myocardial infarction, and stroke when compared to clopidogrel, but it had a higher major bleeding rate. Prasugrel is also contraindicated in patients older than 75 years, with body weight less than 60 kg, or with prior history of stroke or transient ischemic attack.

Ticagrelor is a direct reversible P2Y₁₂ receptor inhibitor with a more potent, faster-acting property when compared with clopidogrel or prasugrel. In the pivotal Platelet Inhibition and Patient Outcomes (PLATO) trial ticagrelor lowered composite CV death, myocardial infarction, and stroke when compared with clopidogrel but with an increase in non-procedure-related bleeding.

Clopidogrel, prasugrel, and ticagrelor require several hours to achieve maximal platelet inhibition. Additionally, in the setting of STEMI, the bioavailability of these oral agents may be hampered by clinical factors such as nausea, vomiting, and cardiogenic shock, leading to poor GI absorption and leaving patients not adequately protected by platelet inhibition during immediate PPCI. Cangrelor (Kengreal) is a fast-acting, reversible adenosine diphosphate (ADP) receptor inhibitor that is administered intravenously to achieve P2Y₁₂ inhibition within 2 minutes. Its plasma half-life is 3 to 6 minutes, and platelet function returns to normal within 60 minutes after discontinuation of infusion. The US Food and Drug Administration (FDA) has approved cangrelor to be used as an adjunct therapy during PCI to reduce repeat coronary revascularization and stent thrombosis in patients who have not been pretreated with an oral P2Y₁₂ inhibitor and are not receiving a glycoprotein IIb/IIIa receptor antagonist. How to transition from cangrelor to an oral P2Y₁₂ inhibitor after PCI depends on which oral P2Y₁₂ inhibitor a patient is being transitioned to. Based on the CHAMPION PHOENIX trial, to transition to clopidogrel, 600 mg clopidogrel loading is necessary immediately after discontinuation of cangrelor infusion. Based on pharmacodynamic data, prasugrel 60 mg should be administered

immediately after stopping cangrelor infusion, whereas ticagrelor 180 mg can be given anytime during cangrelor infusion or immediately after infusion ends.

The 2016 ACC/AHA-focused update on duration of dual antiplatelet therapy (DAPT) in patients with CAD recommends at least 12 months of DAPT in patients with ACS (STEMI or NSTEMI) after BMS or DES implantation. Continuation of DAPT beyond 12 months is reasonable in patients who tolerate DAPT, do not have bleeding complications, and are not at high bleeding risk (prior bleeding on DAPT, coagulopathy, or oral anticoagulant use).

Glycoprotein IIb/IIIa Receptor Antagonists

Glycoprotein (GP) IIb/IIIa receptor antagonists include abciximab (ReoPro, a chimeric monoclonal antibody), eptifibatide (Integrilin, a synthetic peptidic inhibitor), and tirofiban (Aggrastat, a nonpeptidic inhibitor). The benefit of intravenous GP IIb/IIIa receptor antagonists in patients with STEMI was largely established before the era of oral DAPT. With current use of DAPT, contemporary trials fail to show benefit with upstream administration of GP IIb/IIIa receptor antagonists before PPCI with either unfractionated heparin¹ or bivalirudin (Angiomax). Current US and European guidelines recommend using GP IIb/IIIa receptor antagonists for bailout situations after a large thrombus burden, no reflow or slow flow, or inadequate P2Y₁₂ receptor antagonist loading during PCI.

Anticoagulants

Unfractionated heparin (UFH)¹, low-molecular-weight heparin with enoxaparin (Lovenox) as prototype, fondaparinux (Arixtra)¹, and bivalirudin (Angiomax) are widely used in reperfusion therapy to limit thrombus propagation, reduce reocclusion and reinfarction, and improve vessel patency unless contraindicated. The choice of individual agent and its dose and duration of use depends on the choice of reperfusion therapy, concomitant use of other antiplatelet agents, and renal function (Table 3).

¹Not FDA approved for this indication.

TABLE 3 Dosage of Anticoagulants in Reperfusion Therapy for STEMI

	REPERFUSION THERAPY	
	FIBRINOLYSIS	PRIMARY PCI
Unfractionated Heparin ¹	<ul style="list-style-type: none"> IV bolus of 60 U/kg (maximum 4000 U) followed by an infusion of 12 U/kg per h (maximum 1000 U) initially, adjusted to maintain aPTT at 1.5 to 2.0 times control (approximately 50–70 s) for 48 h or until revascularization 	<ul style="list-style-type: none"> With GPI planned, 50–70 U/kg IV bolus, to achieve ACT 200–250 s Without GPI planned, 70–100 U/kg IV bolus to achieve ACT 250–300 s with HemoTec or 300–350 s with Hemochron
Low-Molecular-Weight Heparin (enoxaparin [Lovenox])	<ul style="list-style-type: none"> If age < 75 y: 30-mg IV bolus, followed in 15 min by 1 mg/kg subcutaneously every 12 h (maximum 100 mg for the first 2 doses) If age ≥ 75 y: no bolus, 0.75 mg/kg subcutaneously every 12 h (maximum 75 mg for the first 2 doses) Regardless of age, if CrCl < 30 mL/min: 1 mg/kg subcutaneously every 24 h Duration: For the index hospitalization, up to 8 d or until revascularization 	No information
Bivalirudin (Angiomax)	No information	<ul style="list-style-type: none"> With or without prior heparin: 0.75 mg/kg bolus, 1.75 mg/kg per h infusion to the end of PCI. Additional bolus of 0.3 mg/kg if needed Reduce infusion to 1 mg/kg per h if estimated CrCl < 30 mL/min Prefer over heparin and GPI in high-risk cases of bleeding
Fondaparinux (Arixtra) ¹	<ul style="list-style-type: none"> Initial dose 2.5 mg IV, then 2.5 mg subcutaneously daily starting the following day, for the index hospitalization up to 8 d or until revascularization Contraindicated if CrCl < 30 mL/min 	Not recommended as sole anticoagulant

Abbreviations: ACT = activated clotting time; aPTT = activated partial thromboplastin time; CrCl = creatinine clearance; GPI = glycoprotein IIb/IIIa inhibitors; PCI = percutaneous intervention; STEMI = ST-elevation myocardial infarction.

¹Not FDA approved for this indication.

Modified from 2013 ACCF/AHA STEMI guideline.

Given that PPCI is the preferred method of reperfusion and occurs early after presentation, and given physicians' familiarity with UFH, intravenous UFH is the preferred anticoagulant agent for PPCI. In patients with high bleeding risk, bivalirudin with DAPT is a reasonable alternative to UFH (whether the patient was pretreated with UFH) when avoidance of GP IIb/IIIa receptor antagonists is desired during PPCI.

For patients with STEMI who receive fibrinolysis as initial reperfusion therapy, UFH, enoxaparin, and fondaparinux all receive a class I recommendation based on ACC/AHA guidelines. UFH is preferred since a pharmaco-invasive strategy is common or for patients who may need rescue PCI. Bivalirudin may be used after fibrinolysis in patients who develop heparin-induced thrombocytopenia and require continued anticoagulation.

Guideline-Directed Medical Therapy

Beta-Blocker

Beta-blocker therapy decreases myocardial oxygen demand and improves myocardial remodeling with the benefits of reducing angina, infarct size, and mortality. Current guidelines recommend initiating oral beta-blockers in the first 24 hours in patients with STEMI who are without contraindications such as congestive heart failure, evidence of a low output state, increased risk for cardiogenic shock, heart block, or reactive airway disease. If not given in the first 24 hours owing to contraindications, physicians need to reevaluate patients to determine their subsequent eligibility. Oral beta-blockers should be continued for 3 years after MI as recommended by the ACC/AHA secondary prevention guideline, and longer if there are other indications (such as systolic LV dysfunction). Commonly used beta-blocker regimens are (1) metoprolol tartrate (Lopressor) 25 to 50 mg every 6 to 12 hours orally, transitioned over the next 2 to 3 days to twice-daily dosing of metoprolol tartrate or to daily metoprolol succinate (Toprol XL), and then titrated to a daily dose of 200 mg as tolerated, and (2) carvedilol (Coreg)¹ 6.25 mg twice daily, titrated to 25 mg twice daily as tolerated.

Current guidelines recommend intravenous beta-blocker only for patients with refractory hypertension or ongoing ischemia without contraindications. Several small randomized clinical trials have suggested that early use of intravenous metoprolol tartrate in selected patients with STEMI with Killip class I to II and no atrioventricular (AV) block before PPCI may reduce infarct size with a higher LV ejection fraction or reduce the incidence of malignant arrhythmia in the acute phase without an excess of adverse events.

Angiotensin-Converting Enzyme Inhibitors or Angiotensin II Receptor Blockers

Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) reduce afterload and decrease myocardial remodeling. Either ACEIs or ARBs should be started within 24 hours if there are no contraindications such as worsening renal function, advanced kidney disease, bilateral renal artery stenosis, hyperkalemia, or hypotension. These agents have the largest benefit in patients with anterior STEMI, congestive heart failure, or LV ejection fraction (LVEF) less than 40%. ACEIs may be given routinely to all patients without contraindication, whereas ARBs are an alternative for patients intolerant to ACEIs. There is no additional benefit, only more harm if ACEIs and ARBs are given concomitantly.

Commonly used ACEI regimens are (1) captopril 6.25 to 12.5 mg three times per day to start, titrated to 25 to 50 mg three times per day as tolerated; (2) lisinopril (Prinivil) 2.5 to 5 mg/day to start, titrated to 10 mg/day or higher as tolerated; (3) ramipril (Altace) 2.5 mg twice daily to start, titrated to 5 mg twice daily as tolerated; and (4) trandolapril (Mavik) test dose 0.5 mg, titrated up to 4 mg daily as tolerated. A commonly used ARB regimen is valsartan (Diovan) 20 mg twice daily to start, titrated to 160 mg twice daily as tolerated.

HMG CoA Reductase Inhibitors (Statins)

Treatment with statins after ACS lowers the risk of CV mortality, recurrent MI, stroke, and the need for coronary revascularization. Without contraindications, all patients should receive high-intensity statins as early as possible to improve compliance. Although current guidelines do not endorse a particular low-density lipoprotein (LDL) level as a treatment goal, it is recommended to obtain a fasting lipid panel within 24 hours of presentation. A commonly used high-intensity statin regimen is atorvastatin (Lipitor)¹ 80 mg daily as tolerated. Statins need to be used cautiously with drugs metabolized via CYP3A4 and fibrates, with frequent monitoring for myopathy and hepatic toxicity. Statin use needs to be combined with diet and therapeutic lifestyle therapies.

Aldosterone Antagonists

Eplerenone (Inspra) improves myocardial remodeling and may reduce all-cause and CV mortality and rehospitalization. The 2013 ACC/AHA STEMI guideline recommends starting this medication 3 to 14 days after STEMI in eligible patients (creatinine ≤ 2.5 mg/dL in men and ≤ 2.0 mg/dL in women, potassium ≤ 5.0 mEq/L) with heart failure, with LVEF less than 35% to 40%, and already on adequate doses of beta-blockers and ACEIs or ARBs. However, earlier administration (< 7 days) is preferable to achieve mortality and rehospitalization benefits as suggested by a post hoc analysis of the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) trial.

Implantable Cardioverter-Defibrillator

Patients who develop ventricular tachycardia or fibrillation more than 48 hours after STEMI have the highest risk of sudden cardiac death (SCD) and, hence, are eligible for an implantable cardioverter-defibrillator (ICD) as a secondary prevention measure for SCD. For primary prevention, multiple trials have established the efficacy of prevention of sudden cardiac death by ICD implantation in patients with LVEF less than 35% and New York Heart Association (NYHA) class II or III symptoms (or LVEF $< 30\%$ with NYHA class I symptoms) despite optimal medical therapy 40 days after index STEMI and expectation of at least 1-year survival.

Other Medical Therapy

Morphine

Morphine is a time-honored medication used to reduce pain and anxiety, especially in patients with pulmonary edema during acute presentation of STEMI. However, analysis of results from several clinical trials suggests that a morphine/P2Y₁₂ inhibitor interaction exists, which could lead to adverse clinical consequences. Several recent pharmacokinetic studies in healthy volunteers have shown that intravenous morphine administration can reduce the level of active metabolites of clopidogrel and delay the maximal inhibition of platelet aggregation. A similar effect of morphine on ticagrelor was also reported. Given the current trend of using oral P2Y₁₂ receptor inhibitors before PPCI for STEMI, administration of morphine with P2Y₁₂ receptor inhibitors deserves careful consideration. However, routine avoidance of morphine has not been recommended.

Nitrate

Nitroglycerin reduces LV preload, increases coronary blood flow, and relieves chest pain symptoms. However, it plays no role in decreasing myocardial injury from coronary artery occlusion in STEMI. Its use in STEMI is mostly for congestive heart failure, hypertension, or rare cases of coronary spasm. It is contraindicated in patients with hypotension (systolic blood pressure [SBP] < 90 mm Hg or SBP > 30 mm Hg below baseline), right

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

ventricular infarction from right coronary artery occlusion, or use of 5'-phosphodiesterase inhibitors within 24 to 48 hours.

Complications of STEMI

Cardiogenic Shock

Cardiogenic shock is defined as an SBP less than 90 mm Hg for longer than 1 hour that is (1) not responsive to fluid administration alone, (2) secondary to cardiac dysfunction, or (3) associated with signs of hypoperfusion or cardiac index less than 2.2 L/min per m² and pulmonary capillary wedge pressure greater than 18 mm Hg. It occurs in fewer than 10% of STEMI patients (2.4% in 1986 GISSI-1 trial; 6.5% in Germany ALKK-PCI registry as reported in 2013).

Almost 75% to 80% of cases of cardiogenic shock are due to severe LV systolic dysfunction; right ventricular infarction, mechanical complications from ventricular septal rupture, acute mitral regurgitation, and free wall rupture leading to tamponade account for the rest. Other uncommon causes of non-cardiogenic shock after STEMI are bleeding, systemic inflammatory response syndrome, infection, bowel ischemia, or iatrogenic (such as due to medication).

Cardiogenic shock due to mechanical complications after STEMI occurs in a bimodal fashion, with the majority of cases occurring within 24 hours. An early echocardiogram is extremely helpful to delineate the etiology of cardiogenic shock to guide subsequent definitive treatment. Cardiogenic shock carries a high in-hospital mortality, approaching 50%, and is higher in patients older than 75 years. These high-mortality patients require immediate stabilization to prevent end-stage organ damage followed by emergency coronary angiography and revascularization (Table 4).

Electrical Complications

Ventricular Arrhythmia

Lethal ventricular arrhythmia, ventricular tachycardia (VT) or ventricular fibrillation (VF), is the most common cause of out-of-hospital cardiac arrest in STEMI. For hospitalized patients, VT/VF occurs in fewer than 10% of cases in the era of reperfusion therapy, and most cases occur within 48 hours of presentation. VT/VF is often associated with congestive heart failure, cardiogenic shock, or failed reperfusion of an occluded coronary artery. Hence, correction of electrolyte and acid-base disturbance, adequate reperfusion to reduce myocardial ischemia, and treatment of heart failure or shock are important preventive measures. Early administration of beta-blockers within 24 hours to patients without contraindications reduces the incidence of VF. If VT/VF occurs, treatment

includes immediate defibrillation or cardioversion and an antiarrhythmic agent such as amiodarone (Cordarone). Isolated premature ventricular contractions, nonsustained VT without hemodynamic instability, and AIVR do not generally require specific treatment.

Supraventricular Arrhythmia

Common supraventricular arrhythmias after STEMI include atrial fibrillation, atrial flutter, and sinus tachycardia. They are usually the consequence of or triggered by congestive heart failure, atrial infarction, pericarditis, hypoxia, or other underlying systemic problems (such as chronic obstructive pulmonary disease, bleeding, anemia, or infection). Treatment is directed to the underlying causes. For atrial fibrillation/flutter, physicians should pay special attention to anticoagulation use given the frequent concomitant use of DAPT and antithrombotics and the rate versus rhythm control strategy.

Bradycardia and Heart Block

Sinus bradycardia may occur after inferior STEMI. Because it is generally mediated through increased vagal tone, close monitoring usually suffices. High-grade AV block (second or third degree) can occur after inferior or anterior STEMI, with a worse prognosis after anterior STEMI owing to a greater degree of myocardial injury. High-grade AV block after inferior STEMI usually is transient and with a narrow complex escape rhythm, which subsides within 2 weeks. Occasionally temporary pacemaker placement may be necessary if bradycardia causes hemodynamic instability. High-grade AV block from anterior STEMI usually requires placement of a prophylactic temporary pacing system because it is commonly associated with hemodynamic instability.

TABLE 4 Management Measures for Cardiogenic Shock

Immediate stabilization of patients to prevent end-stage organ damage

Maintain adequate mean arterial blood pressure with norepinephrine (Levophed), dopamine, or dobutamine with intraarterial pressure monitoring; norepinephrine preferred over dopamine for less arrhythmogenic effect

Hemodynamic monitoring with Swan-Ganz catheter to guide inotrope or fluid management

Selective use of mechanical circulatory support* if patient cannot be stabilized by previous measures

Early echocardiography to define etiology of cardiogenic shock

Early mechanical ventilation

Management of hemodynamically significant arrhythmia

Fibrinolysis in STEMI if delay to PCI > 2 h

Early coronary angiography and revascularization

Early transfer to regional tertiary care hospital for revascularization

Prophylactic IABP placement before transfer

PCI often the treatment of choice

CABG (with correction of mechanical complications if present) in cardiogenic shock if feasible

Abbreviations: CABG = coronary artery bypass grafting; IABP = intraaortic balloon pump; LV = left ventricular; PCI = percutaneous intervention; STEMI = ST-elevation myocardial infarction.

*IABP is more readily available; limited experience with other LV assist devices such as Impella and TandemHeart device.

ANGINA PECTORIS

Method of

Kenneth Tobin, DO; and Kim Eagle, MD

CURRENT DIAGNOSIS

- The clinical diagnosis of angina depends largely on the accurate assessment of a patient's risk factor profile for coronary artery disease and the typicality of the symptom complex.
- The most common symptom of angina pectoris is left-sided chest pain or pressure, with or without associated radiation of pain or pressure to the jaw or left arm, occurring with exertion and relieved with rest or sublingual nitroglycerin.
- Women may present with atypical symptoms such as sharp, nonexertional chest pain; generalized fatigue; or right-sided chest pain.
- Basic screening tests (e.g., 12-lead electrocardiogram, laboratory data, chest radiograph) are normal in most cases.
- For an initial diagnosis, appropriate noninvasive testing or coronary angiography, or both, is important to define the amount of ischemic myocardium and an overall treatment plan.
- Even when invasive procedures are clinically indicated, aggressive medical therapy with high-dose statins, attainment of appropriate blood pressure levels, smoking cessation, and use of antiplatelet therapy is of paramount importance.
- Patients who have clinical evidence of unstable angina and laboratory evidence of myocardial ischemia most often benefit from early invasive treatment strategies.

CURRENT THERAPY

Stable Angina Pectoris

- Treatment includes β -blockers, nitrates, and calcium channel blockers for symptom control.
- Consider the addition of ranolazine (Ranexa) if symptoms are not adequately controlled.

Aggressive Cholesterol Treatment Based on the ACC-AHA Blood Cholesterol Guidelines

- Blood pressure management
- Antiplatelet therapy
- Lifestyle modifications:
 - Smoking cessation
 - Exercise prescription
 - Dietary guidelines
 - Depression assessment

Unstable Angina

- With positive biomarkers for myocardial ischemia, consider coronary angiography.
- With negative biomarkers for myocardial ischemia, consider noninvasive assessment once symptoms are controlled.
- With a substantial ischemic burden identified, consider coronary angiography.
- With no or minimal ischemia identified, consider increasing medical therapy.
- With persistent symptoms, consider other treatment modalities.

Angina pectoris is defined as cardiac-induced pain that is a direct result of a mismatch between myocardial oxygen supply and demand. The initial presentation of ischemic heart disease is chronic stable angina in approximately 50% of patients; it is estimated that 16.5 million Americans have this diagnosis. Ischemic heart disease is the leading cause of death in the United States.

Stable angina refers to predictable chest discomfort during various levels of exertional activity that is predictably resolved with rest or administration of sublingual nitroglycerin (Nitrostat). Unstable angina is an acute ischemic event; this diagnosis includes patients with new-onset cardiac chest pain, angina at rest, post-myocardial infarction angina, or an accelerating pattern of previously stable angina. The terms unstable angina and non-Q wave myocardial infarction are often used interchangeably and should be further defined on the basis of myocardial necrosis as measured by serum biomarkers.

The clinical sensation of angina pectoris is caused by stimulation of chemosensitive and mechanosensitive receptors of unmyelinated nerve cells found within cardiac muscle fibers and around the coronary vessels. This stimulation cascade is thought to occur when lactate, serotonin, bradykinin, histamine, reactive oxygen species, and adenosine are released into the coronary circulation during periods of lactic acidosis. Nerve stimulation via the sympathetic ganglia occurs most commonly between the seventh cervical and fourth thoracic portions of the spinal cord. This explains from an anatomic standpoint why the most commonly recognized pain patterns for angina pectoris involve discomfort in the chest, neck, jaw, and left arm.

The most common cause of angina pectoris is coronary atherosclerosis. As plaque is initially deposited within a coronary vessel, there may be no significant internal luminal compromise during the early positive remodeling phase. However, at the point at which this compensatory mechanism fails, internal luminal compromise ensues. As long as the coronary artery segment distal to the stenosis retains the ability to vasodilate in response to increasing blood flow demands, coronary homeostasis is maintained. Once the critical threshold is passed, the blood supply cannot accommodate this demand, and angina may occur. The four major factors that determine myocardial oxygen demand are heart rate, systolic blood pressure, myocardial wall tension, and myocardial contractility.

Clinical Features

For patients with documented coronary artery disease (CAD) who have predictable episodes of classic symptoms, the diagnosis of angina pectoris is straightforward. Most patients are aware of the levels of exertion that typically induce angina symptoms. Most describe a pain or heaviness across their middle chest that may or may not radiate to the jaw or left arm. Some patients deny chest pain symptoms altogether and instead complain of exertional dyspnea or diaphoresis. Environmental situations such as cold exposure, emotional stress, or heavy meals can induce angina. The Canadian Cardiovascular Society and the New York Heart Association classification systems are used to define angina severity. Both systems use a I through IV scale, with mild angina (class I) referring to episodes that occur with extreme exertion and severe angina (class IV) to episodes that occur with minimal or no exertion. These classification systems are useful for risk stratification and for assessing medical therapy efficacy.

There are clear gender differences in the clinical presentations of angina. Pleuritic, musculoskeletal-type pain, nonexertional pain, and nocturnal pains have been reported as anginal equivalents in women. Fatigue is one of the most common presenting symptoms for CAD in women. The key to the diagnosis in men and women lies in a thorough history, which should always include the quality, location, provoking activities, and duration of pain and factors that relieve the pain. Based on a detailed clinical history, the many diagnoses that can masquerade as angina may be eliminated (Table 1).

Diagnostic Testing

A baseline electrocardiogram (ECG) is often one of the initial tests obtained in a patient with the complaint of chest pain. A normal

- Women may present with atypical symptoms such as sharp, nonexertional chest pain; generalized fatigue; or right-sided chest pain.
- Basic screening tests (e.g., 12-lead electrocardiogram, laboratory data, chest radiograph) are normal in most cases.
- For an initial diagnosis, appropriate noninvasive testing or coronary angiography, or both, is important to define the amount of ischemic myocardium and an overall treatment plan.
- Even when invasive procedures are clinically indicated, aggressive medical therapy with high-dose statins, attainment of appropriate blood pressure levels, smoking cessation, and use of antiplatelet therapy is of paramount importance.
- Patients who have clinical evidence of unstable angina and laboratory evidence of myocardial ischemia most often benefit from early invasive treatment strategies.

CURRENT THERAPY

Stable Angina Pectoris

- Treatment includes β -blockers, nitrates, and calcium channel blockers for symptom control.
- Consider the addition of ranolazine (Ranexa) if symptoms are not adequately controlled.

Aggressive Cholesterol Treatment Based on the ACC-AHA Blood Cholesterol Guidelines

- Blood pressure management
- Antiplatelet therapy
- Lifestyle modifications:
 - Smoking cessation
 - Exercise prescription
 - Dietary guidelines
 - Depression assessment

Unstable Angina

- With positive biomarkers for myocardial ischemia, consider coronary angiography.
- With negative biomarkers for myocardial ischemia, consider noninvasive assessment once symptoms are controlled.
- With a substantial ischemic burden identified, consider coronary angiography.
- With no or minimal ischemia identified, consider increasing medical therapy.
- With persistent symptoms, consider other treatment modalities.

Angina pectoris is defined as cardiac-induced pain that is a direct result of a mismatch between myocardial oxygen supply and demand. The initial presentation of ischemic heart disease is chronic stable angina in approximately 50% of patients; it is estimated that 16.5 million Americans have this diagnosis. Ischemic heart disease is the leading cause of death in the United States.

Stable angina refers to predictable chest discomfort during various levels of exertional activity that is predictably resolved with rest or administration of sublingual nitroglycerin (Nitrostat). Unstable angina is an acute ischemic event; this diagnosis includes patients with new-onset cardiac chest pain, angina at rest, post-myocardial infarction angina, or an accelerating pattern of previously stable angina. The terms unstable angina and non-Q wave myocardial infarction are often used interchangeably and should be further defined on the basis of myocardial necrosis as measured by serum biomarkers.

The clinical sensation of angina pectoris is caused by stimulation of chemosensitive and mechanosensitive receptors of unmyelinated nerve cells found within cardiac muscle fibers and around the coronary vessels. This stimulation cascade is thought to occur when lactate, serotonin, bradykinin, histamine, reactive oxygen species, and adenosine are released into the coronary circulation during periods of lactic acidosis. Nerve stimulation via the sympathetic ganglia occurs most commonly between the seventh cervical and fourth thoracic portions of the spinal cord. This explains from an anatomic standpoint why the most commonly recognized pain patterns for angina pectoris involve discomfort in the chest, neck, jaw, and left arm.

The most common cause of angina pectoris is coronary atherosclerosis. As plaque is initially deposited within a coronary vessel, there may be no significant internal luminal compromise during the early positive remodeling phase. However, at the point at which this compensatory mechanism fails, internal luminal compromise ensues. As long as the coronary artery segment distal to the stenosis retains the ability to vasodilate in response to increasing blood flow demands, coronary homeostasis is maintained. Once the critical threshold is passed, the blood supply cannot accommodate this demand, and angina may occur. The four major factors that determine myocardial oxygen demand are heart rate, systolic blood pressure, myocardial wall tension, and myocardial contractility.

Clinical Features

For patients with documented coronary artery disease (CAD) who have predictable episodes of classic symptoms, the diagnosis of angina pectoris is straightforward. Most patients are aware of the levels of exertion that typically induce angina symptoms. Most describe a pain or heaviness across their middle chest that may or may not radiate to the jaw or left arm. Some patients deny chest pain symptoms altogether and instead complain of exertional dyspnea or diaphoresis. Environmental situations such as cold exposure, emotional stress, or heavy meals can induce angina. The Canadian Cardiovascular Society and the New York Heart Association classification systems are used to define angina severity. Both systems use a I through IV scale, with mild angina (class I) referring to episodes that occur with extreme exertion and severe angina (class IV) to episodes that occur with minimal or no exertion. These classification systems are useful for risk stratification and for assessing medical therapy efficacy.

There are clear gender differences in the clinical presentations of angina. Pleuritic, musculoskeletal-type pain, nonexertional pain, and nocturnal pains have been reported as anginal equivalents in women. Fatigue is one of the most common presenting symptoms for CAD in women. The key to the diagnosis in men and women lies in a thorough history, which should always include the quality, location, provoking activities, and duration of pain and factors that relieve the pain. Based on a detailed clinical history, the many diagnoses that can masquerade as angina may be eliminated (Table 1).

Diagnostic Testing

A baseline electrocardiogram (ECG) is often one of the initial tests obtained in a patient with the complaint of chest pain. A normal

TABLE 1 Differential Diagnosis of Chest Pain

Cardiac ischemia
Angina
Myocardial infarction
Vasospastic angina
Pericarditis
Aortic dissection (new-onset chest pain and new aortic insufficiency noted on auscultation is an aortic dissection until proven otherwise)
Pulmonary embolism
Esophageal spasm
Gastroesophageal reflux disease
Musculoskeletal pain
Biliary colic
Acute pneumonia

tracing does not exclude the diagnosis of ischemic heart disease. More than 50% of patients with diagnosed angina have a normal ECG at rest. The baseline ECG may, however, show evidence of pathologic Q waves or left ventricular hypertrophy, either of which increases the statistical probability of significant CAD. Baseline laboratory data should include a fasting lipid panel to help define the patient's risk factor profile.

Stress testing is an appropriate screening tool for the initial diagnosis of CAD, risk stratification after acute ischemic syndrome, and assessment of treatment efficacy. Whenever feasible, it is more advantageous to obtain an exercise stress test rather than a pharmacologically based study. The additional prognostic data obtained through exercise include blood pressure response, heart rate response, heart rate recovery, metabolic equivalent level attained, and ECG assessment of the ST segment. There are several validated exercise protocols that add additional risk stratification measures to the test results.

The predictive value of exercise treadmill stress testing ranges from 40% for single-vessel disease to 90% for three-vessel disease. A baseline left bundle branch block, paced rhythm, poorly controlled atrial arrhythmia, or left ventricular hypertrophy with secondary ischemic changes often renders the test inconclusive when assessing for ischemic changes. However, if stress testing is being performed for attainment of hemodynamic responses and achievable metabolic equivalent levels, these baseline ECG abnormalities may be overlooked.

Stress test accuracy is markedly improved by the addition of an imaging modality such as echocardiography or nuclear perfusion scanning. The sensitivity and specificity of stress echocardiography and stress nuclear imaging are 85% to 90%. Stress echocardiography is believed to be somewhat more specific, and stress nuclear imaging is thought to be more sensitive. A stress echocardiogram also allows assessment of left ventricular systolic function and valvular function and prediction of right ventricular pressure. In deciding on which stress test to perform, one should rely on the expertise of the testing facility and the individual patient's circumstance.

Risk Factor Management

Hypertension

Hypertension is a commonly occurring, well-established, major cardiovascular risk factor. Initial treatment of hypertension in patients with ischemic heart disease should always include lifestyle management. Appropriate weight loss with a goal of achieving a body mass index $<25 \text{ kg/m}^2$ can improve hypertension control. A reduction in dietary salt intake can also have positive effects on a patient's blood pressure.

Discord has resulted from the publication of recent hypertension guidelines by various medical societies, as well as the 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults Report from the Panel Members Appointed to the Eighth Joint National Committee. It has been shown that cardiovascular risk progressively increases at blood pressures greater than 115/75 mm Hg. A meta-analysis of 61 prospective observational trials of hypertension involving 1 million adults with no known vascular disease at baseline revealed several interesting findings. Patient outcomes were related per decade of age to the usual blood pressure at the start of that decade. For example, from ages 40 to 69, for each increase in 20 mm Hg systolic blood pressure, a twofold increase in cardiovascular death rate occurred. These findings were much more pronounced in patients who were between 80 and 89 years old than in the youngest cohort, 40 to 49 years old. Although the relative risk was much higher in the younger group, the absolute risk was greatest among the octogenarians. These increased cardiovascular risks were not confined to subjects with blood pressures greater than 140/90 mm Hg; rather, there was a threshold of risk shown all the way down to 115/75 mm Hg. Even small reductions in blood pressure can have a significant positive impact on cardiovascular disease. Blood pressure reductions of 4 mm Hg systolic and 3 mm Hg diastolic were shown to reduce cardiovascular events by 15% in a cohort of 20,888 patients.

The Heart Outcomes Prevention Evaluation study asked the question whether all patients with atherosclerosis, regardless of blood pressure, should be treated with an angiotensin-converting enzyme inhibitor. Although many subsequent editorials implied that all patients with CAD could benefit from this therapy, a closer look at the data suggests a different interpretation. The mean blood pressure was 139/79 mm Hg, suggesting that a significant portion of the 9297 participants had a baseline blood pressure higher than this value. Compared with placebo, the treatment group had a 22% reduction in the primary outcome composite of myocardial infarction, stroke, or cardiovascular death. A small substudy using 24-hour ambulatory blood pressure monitoring showed blood pressure differences of 11 mm Hg systolic and 4 mm Hg diastolic in the treatment group compared with the placebo group, which may explain the cardiovascular event reductions reported.

The blood pressure goal for treatment of hypertension in patients with established ischemic heart disease should be $<130/80 \text{ mm Hg}$. One must be careful with aggressive diastolic blood pressure management, as some studies have shown a J-shaped curve relationship between diastolic blood pressures and coronary events.

Hyperlipidemia

Dyslipidemia is an important risk factor for atherosclerotic cardiovascular disease, and the lowering of LDL-cholesterol has been shown to correlate with reductions in cardiovascular disease event rates. Previously published cholesterol treatment guidelines recommended achieving less than 70 mg/dL LDL-cholesterol levels in CAD patients. The current guidelines published by the ACC-AHA depart from these specific values, and instead recommend using high-intensity 3-hydroxy-3-methylglutaryl coenzyme reductase inhibitors (statins) to reduce the LDL-cholesterol levels by more than 50%. These agents have been shown to be well tolerated and have positive nonlipid pleiotropic effects, as well as the ability to dramatically lower LDL levels.

Observational evidence suggests that regardless of how cholesterol is lowered, a reduction in atherosclerotic cardiovascular disease will result. However, to achieve meaningful reductions in cardiovascular mortality, the recommended choice for lowering LDL-cholesterol levels among the currently available pharmacologic agents are the statins. These agents have been studied exclusively using fixed dose combinations and not dose titrated to achieve various LDL-c levels; therefore currently available data do not support specific LDL target goals.

The Cholesterol Treatment Trialists' meta-analysis, including 90,056 subjects from 14 trials, showed a 12% reduction in all-cause mortality per 38.6 mg/dL (1 mmol/L) reduction in

LDL-cholesterol, with a 19% reduction in coronary mortality, a 24% reduction in need for revascularization, a 17% reduction in stroke incidence, and a 21% reduction in any major vascular event during a mean follow-up period of 5 years. These benefits were observed in different age groups, across genders, at different baseline cholesterol levels, and equally among those with and without prior CAD and cardiovascular risk factors.

The Heart Protection Study showed that in patients with established CAD, other atherosclerotic vascular disease, or diabetes, statin therapy reduced cardiovascular events regardless of the baseline LDL-cholesterol level. The trial, which enrolled 20,536 patients aged 40 to 80 years, showed a 24% reduction in major cardiovascular events, a 25% reduction in stroke, and a 13% reduction in overall mortality with statin therapy.

Patients with a recent acute ischemic syndrome were enrolled in the Pravastatin or Atorvastatin Evaluation and Infection Therapy trial, known as Thrombolysis in Myocardial Infarction 22, which compared 80 mg atorvastatin (Lipitor) with 40 mg of pravastatin (Pravachol). The atorvastatin group achieved a median LDL level of 62 mg/dL, compared with 96 mg/dL in the pravastatin group. The relative risk reduction for this reduced LDL level was 16%. A substudy looking at the LDL-cholesterol levels achieved with atorvastatin showed that those subjects achieving a level of 40 to 60 mg/dL had a 22% reduction in events, compared with those achieving a level of 80 to 100 mg/dL. Therefore it appears that high-dose statin therapy and aggressive LDL-lowering in this patient population lead to reduced cardiovascular events.

The Treating to New Targets trial was the first to compare a more intensely treated group with a less intensely treated group using the same agent. The design of this 10,000-patient study eliminated concerns that outcome differences were induced by dissimilar statin preparations. The mean LDL level achieved was 101 mg/dL with 10 mg atorvastatin, and 77 mg/dL with the 80 mg dose. This LDL reduction was associated with a relative risk reduction of 27% for the primary endpoint of the first major cardiovascular event.

There is an increased risk of myopathy and rhabdomyolysis in patients taking 80 mg simvastatin (Zocor), according to the Study of the Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH). The FDA has subsequently restricted high-dose simvastatin to patients who have been on this dose for longer than 12 months without evidence of myopathy, and the agency has recommended that new patients should not be started on this particular dose.

To effectively achieve a greater than 50% LDL-cholesterol reduction in CAD patients utilizing currently available pharmacologic agents, the most recent treatment guidelines suggest either atorvastatin 40 to 80 mg or rosuvastatin (Crestor) 20 to 40 mg. In other patient populations that require moderate-intensity statin therapy, there are several statin choices. Because there is no currently available evidence to suggest that non-statin lipid-altering agents effectively reduce cardiovascular mortality, these medications should not be routinely prescribed.

It is apparent from both primary and secondary prevention lipid trials that achieving lower LDL levels reduces cardiovascular event rates. Because there is no high-quality clinical evidence to support achieving specific LDL levels in patients with diagnosed CAD, high-dose statin therapy should be the mainstay of pharmacologically based therapy, if tolerated.

Metabolic Syndrome

The combined presence of insulin resistance, hypertension, dyslipidemia, and abdominal obesity define metabolic syndrome. There is debate about whether this is a true syndrome or simply a clustering of cardiovascular risk factors in a particular individual. The key concept is that the concomitant presence of these particular cardiovascular risk factors markedly increases a patient's chances of developing diabetes mellitus and coronary atherosclerosis. The approach to treatment for this syndrome is no different from that for the individual components. Recognition of the components is key to the treatment of this disorder.

Smoking

Cigarette smoking is probably the most important of the identified modifiable cardiovascular risk factors. The incidence of CAD is two to four times higher in smokers than in nonsmokers. The pathophysiological process that leads to atherosclerosis from smoking stems from induced platelet dysfunction, endothelial dysfunction, smooth muscle cell proliferation, and attenuated high-density lipoprotein-cholesterol levels. Smoking cessation must be sought for every CAD patient.

Diet

Lifestyle changes for patients with CAD must incorporate healthy eating habits. The Mediterranean diet has been shown to positively affect cardiovascular disease, and conversely, a diet high in saturated fats has been shown to negatively influence multiple cardiac risk factors. Patients should be encouraged to incorporate high proportions of fruits and vegetables into their diet, along with olive oil and regular servings of fish coupled with a reduced amount of red meats.

Other Lifestyle Changes

Exercise should be encouraged in patients with stable angina, once all appropriate invasive and noninvasive tests have been completed and a stable medical regimen has been established.

Increasing a patient's aerobic capacity can lower the body's oxygen requirement for a given workload, which can lead to increased exercise tolerance and reduced anginal symptoms. Aerobic exercise can improve endothelial function and positively affect baroreflex sensitivity and heart rate variability in patients with CAD.

Endorphins released during exercise are thought to be mood enhancers, as well as effective muscle relaxants. Exercise itself improves sleep patterns. Cortisol levels are reduced with regular exercise, which may attenuate the body's sensation of stress and anxiety. For these reasons, appropriate exercise programs for patients with stable angina have far-reaching positive benefits. Exercise guidelines for CAD patients have been published and should be reviewed before patients begin aggressive secondary prevention efforts.

Major depression affects approximately 25% of people recovering from a myocardial infarction, and another 40% suffer from mild depression. In any given year, one of every three long-term acute ischemic syndrome survivors will develop depression. The Heart and Soul Study examined 1017 patients with stable CAD over a period of 4.8 years. Patients identified with depression were twice as likely to experience recurrent cardiovascular events. Physical inactivity was associated with a 44% greater rate of cardiovascular events. Patients with symptoms of depression were less likely to follow dietary, exercise, and medication recommendations.

Approach to Treatment

Medical Therapy

Medications used to treat angina pectoris and typical dosages are listed in [Table 2](#).

Nitrates

Nitrates provide an exogenous source of nitric oxide, which serves to relax smooth muscle and inhibit platelet aggregation. Nitrates exert their antianginal effect by reducing myocardial oxygen demand through coronary and systemic vasodilatation. Nitrates are strong venodilators, and in higher doses they can also induce arterial dilatation. Reducing the preload through venodilatation reduces myocardial oxygen demand. Coronary artery dilatation of stenotic vessels and intracoronary collaterals directly increases myocardial oxygen delivery. Through these mechanisms, nitrates have been shown to prevent recurrent episodes of angina and to increase exercise tolerance.

There are several nitrate preparations; they differ mainly in route of administration, onset of action, and effective half-life. Nitrate tolerance can occur with long-term use of any nitrate preparation

TABLE 2 Medications Used for the Treatment of Angina Pectoris

NAME	DOSAGE
β-Blockers	
Atenolol (Tenormin)	25–200 mg PO qd
Metoprolol tartrate (Lopressor)	25–200 mg bid
Metoprolol succinate (Toprol XL)	25–200 mg qd
Carvedilol (Coreg) ¹	6.25–25 mg PO bid
Carvedilol phosphate (Coreg CR) ¹	20–80 mg PO qd
Propranolol (Inderal)	80–320 mg/d, divided bid or tid
Propranolol (Inderal LA)	80–160 mg PO qd
Labetalol (Trandate, Normodyne) ¹	200–800 mg bid
Nitrates	
Isosorbide dinitrate (Isordil)	10–40 mg PO bid or tid
Isosorbide mononitrate (Imdur)	30–240 mg PO qd
Nitroglycerin (Nitrostat)	0.4 mg SL q5min
Nitroglycerin transdermal (Nitro-Dur)	0.2–0.8 mg/h 12–14 h patch
Calcium Channel Blockers	
Dihydropyridines	
Amlodipine (Norvasc)	2.5–10 mg PO qd
Felodipine (Plendil) ¹	2.5–10 mg PO qd
Nifedipine (Procardia XL)	30–90 mg PO qd
Nondihydropyridines	
Verapamil (Calan)	80–120 mg PO tid
Verapamil (Calan SR)	120–480 mg PO qd
Diltiazem (Cardizem)	360 mg/d PO, divided tid or qid
Diltiazem (Cardizem LA)	180–360 mg PO qd
Other	
Ranexa	500 mg twice daily and increase to 1000 mg twice daily as needed, based on clinical symptoms

¹Not FDA approved for this indication.

and can be avoided by providing a 10- to 12-hour nitrate-free interval. “Nitrates should be used with caution in patients with a diagnosis of hypertrophic obstructive cardiomyopathy.”

β -Blockers

β -Blockers competitively inhibit catecholamines from binding to β -receptors. Over time, β -blocker therapy leads to an increase in β -receptor density. Because of receptor upregulation, acute β -blocker withdrawal may lead to a transient supersensitivity to catecholamines and subsequent angina or even myocardial infarction. There are three classes of β -receptors. Some β -blockers are receptor specific, and some exert an effect over all three receptors. However, at higher doses, even β -selective agents have cross-reactivity for all β -receptors. β -Blockers reduce myocardial oxygen demand through a negative inotropic effect, a chronotropic effect, and a reduction in left ventricular wall stress.

Several cardioselective β -blockers, including atenolol (Tenormin) and metoprolol (Lopressor), have been shown to be effective

antianginals that are fairly well tolerated in patients with underlying bronchospastic disease. Dosing is important for β -blocker efficacy. A study comparing atenolol with placebo showed that all doses from 25 through 200 mg/day were effective in reducing angina, but only the two highest doses led to an increase in exercise tolerance. Certain β -blockers have intrinsic sympathomimetic activity, including pindolol (Visken)¹ and acebutolol (Sectral).¹ Although they may be effective in reducing angina, they should be used with caution in patients with a prior history of myocardial infarction and in those with left ventricular dysfunction, because they may not reduce heart rate or blood pressure at rest.

When β -blockers are used to treat angina, a goal resting heart rate should be between 55 and 60 beats/minute. Caution should be used in patients with resting bradycardia and in those with known reactive airway disease. Atenolol is renally excreted and should be used with caution in the elderly and in those with known renal dysfunction.

Calcium Channel Blockers

Calcium channel blockers are classified as either dihydropyridines or nondihydropyridines. The former group includes amlodipine (Norvasc), felodipine (Plendil),¹ nifedipine (Procardia), and nifedipine (Cardene); the latter includes diltiazem (Cardizem) and verapamil (Calan). There are differences among the two subclasses in regard to chronotropic, dromotropic, and inotropic effects.

Calcium channel blockers positively alter myocardial oxygen supply and demand, mainly through direct arterial vasodilatation. The nondihydropyridines also exhibit negative chronotropic and inotropic effects, thus further lowering myocardial oxygen demands.

One of the early quick-release preparations of a dihydropyridine calcium channel blocker, nifedipine, was reported to potentially induce myocardial infarction when used to treat angina. This was most likely due to a rapid drop in afterload leading to reflex adrenergic activation. Sustained-release preparations of nifedipine (Procardia XL), as well as the other dihydropyridines, have been proven safe and effective in patients with cardiovascular disease. Although amlodipine and felodipine are tolerated in patients with left ventricular systolic dysfunction, other calcium channel blockers should be avoided in this patient subset.

Ranolazine (Ranexa)

Ranolazine (Ranexa) is a new and unique antianginal drug approved for the treatment of stable angina. It is a sustained-release preparation that has been approved for patients who remain symptomatic while on standard angina pharmacotherapy. Its mechanism of action may be through reduction of fatty acid oxidation or effects on sodium shifts and intracellular calcium levels. QT prolongation has been reported, but a significant increase in arrhythmias has not been seen. Side effects include dizziness, constipation, and nausea. Dosing is 500 or 1000 mg twice daily, and the major route of metabolism is the cytochrome P-450 system. Ranolazine should be used cautiously in patients who are taking other pharmacologic agents that have the potential to prolong the QT interval, “and in patients with liver cirrhosis.”

Medication Combinations

Many patients with chronic stable angina require more than one antianginal medication to control their symptoms. “Current guidelines recommend β -blockers or calcium channel blockers as initial therapy unless otherwise contraindicated, with the addition of nitrates as symptoms dictate. Further medications may be added and individualized to each patient based on their degree of angina and overall clinical response.”

However, it is important to recognize medication side effects when deciding which agents to combine. β -Blockers block the atrioventricular (AV) node and exert a portion of their effectiveness through this mechanism. The nondihydropyridine calcium channel blockers also have AV-nodal blocking properties and therefore

¹Not FDA approved for this indication.

should be used cautiously with β -blockers, especially in patients with preexisting conduction system disease. The dihydropyridine agents do not have AV-nodal blocking effects and may be a safer choice when used in combination with β -blockers. Nitrates do not have a side-effect profile that raises concerns when they are used with β -blockers or with calcium channel blockers.

Antiplatelet Therapy

The common etiology leading to an acute ischemic syndrome is a platelet-rich clot occurring at the site of a significant coronary artery stenosis, often after a plaque rupture. Antiplatelet medications have been shown to consistently decrease morbidity and mortality in a wide array of cardiovascular disease patients. A meta-analysis suggested that for patients with stable cardiovascular disease, low-dose aspirin therapy (50–100 mg daily) is as effective as higher doses (>300 mg). In this patient population, aspirin therapy resulted in a 26% reduction in myocardial infarction; the number of patients needed to treat to prevent a myocardial infarction was 83.

The Antiplatelet Trialists' Collaboration study demonstrated a reduction in myocardial infarction, stroke, and death in high-risk cardiovascular patients treated with antiplatelet therapy. Consensus guidelines recommend indefinite oral aspirin for the secondary prevention of cardiovascular events in all angina patients.

Clopidogrel (Plavix)¹ is an effective alternative to aspirin for the treatment of stable cardiovascular disease in those patients with a true aspirin allergy. However, there are no compelling data to indicate that clopidogrel (or newer agents, such as prasugrel [Effient]¹ and ticagrelor [Brilinta]¹) are superior to aspirin in this particular patient population. In patients with unstable angina, dual antiplatelet therapy with aspirin and clopidogrel is recommended.

Invasive Assessment

The decision to pursue an invasive treatment approach differs significantly in patients with chronic stable angina and in those with acute coronary syndromes. Within both groups, accurate risk stratification is the key consideration in choosing who will benefit from coronary angiography and subsequent percutaneous coronary intervention. An invasive strategy in unstable angina patients has been shown to reduce recurrent acute coronary syndrome events consistently in many trials. A routine invasive strategy is recommended for patients with non-ST-segment acute ischemic syndromes who have refractory ischemia, elevated cardiac biomarkers suggesting myocardial necrosis, or new ST-segment depression on ECG monitoring.

In patients with unstable angina, there are significant gender differences in outcomes related to the use of invasive therapy. Both men and women with elevated biomarkers from myocardial necrosis have comparable reductions in rates of death, myocardial infarction, and rehospitalization with invasive treatment strategies. However, in the absence of positive biomarkers, women appear to have potentially negative outcomes with an invasive approach. The current American College of Cardiology and American Heart Association guidelines recommend a conservative approach in such women.

Patients diagnosed with stable angina comprise a vast array of clinical presentations. The two most heated debates in this arena concern the initial choice of medical therapy versus an invasive approach, and when to cross over from a medical treatment plan to an invasive one. The Atorvastatin Versus Revascularization Treatment (AVERT) trial studied the effects of intensive lipid-lowering therapy on ischemic events in a relatively low-risk population of patients with single- or two-vessel disease compared with percutaneous transluminal coronary angioplasty. AVERT randomized 341 patients to medical therapy plus atorvastatin 80 mg or to angioplasty followed by usual medical care (which included the option of statin therapy at the choice of the treating physician). The medical treatment group experienced a 36% reduction in the

composite endpoint of ischemic events compared with the angioplasty group. This difference was due primarily to repeated angioplasty, coronary artery bypass grafting, or hospitalization for worsening angina. The primary outcome of this trial from a practical standpoint was that high-dose statin therapy was safe in this patient population and did not increase cardiovascular events, compared with an angioplasty-based treatment plan.

One of the keys in interpreting the available data is recognizing that by the time many of these trials are published, the percutaneous treatment choices are often outdated. Early trials used mainly balloon angioplasty; later trials used early-generation bare metal stents. Equally as important is to determine what the background medical treatment plans were for any particular trial on this subject. Often, lipid therapy was not aggressive, hypertension management was not confirmed to be adequate, and intravenous glycoprotein IIb/IIIa antagonists were either not available or not used as a standard protocol when indicated.

The Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial was designed to address the potential advantages of current medical therapy over a percutaneous approach in patients with demonstrable ischemia but stable CAD. Of the 35,000 patients screened, only 2287 met the study inclusion criteria. All participants of the COURAGE trial underwent a coronary angiography, and patients with high-risk anatomic findings such as severe left main coronary artery stenosis were excluded. The biggest difference in this trial compared with previous studies was that strict guideline-based medical therapy was followed in both groups. In the entire cohort, 85% of subjects were taking a β -blocker, 93% were taking a statin, and 85% were taking aspirin. The final interpretation of the COURAGE trial results was not that medical therapy is superior for all patients with CAD, but that in selected cohorts, aggressive medical therapy is an appropriate first step in the treatment of ischemic heart disease.

Novel Therapies

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization is an invasive treatment that can be performed as an open-heart procedure or percutaneously. The mechanism was originally thought to be the creation of myocardial channels leading to collateral circulation to ischemic zones, but this concept has been called into question. Current theories suggest cardiac denervation, laser-induced angiogenesis, or placebo effect. Likely selection bias within trials has also limited published outcomes data. In a randomized trial involving patients with class III or IV angina and percutaneously untreatable CAD, there was no reduction in angina, no improvement in exercise tolerance, and no decrease in adverse cardiac events after percutaneous transmyocardial laser revascularization, compared with maximal medical therapy. In this trial, the placebo effect was dramatically reduced through extensive blinding protocols for patients and treating physicians.

Angiogenesis leading to the induction of newly formed coronary vessels has been an active area of research for many years. Three main angiogenic growth factors have been studied: fibroblastic growth factors, vascular endothelial growth factor, and platelet-derived growth factor. Major research limitations for these agents are that they do not act independently, and their biologic properties are poorly understood. Potential complications such as aberrant vascular proliferation, tumor development or proliferation, and proatherogenic effects have made patient enrollment difficult. Although there are some trial results suggesting that the ischemic burden shown on perfusion imaging may be reduced, no firm positive outcome data have yet been published.

External Counterpulsation

External counterpulsation is a noninvasive method of increasing coronary blood flow through diastolic augmentation. Large blood pressure cuffs are placed on both legs and thighs and are inflated to a pressure of 300 mm Hg in early diastole (triggered by the patient's ECG), promoting venous return to the heart. The mechanism is unclear but may be related to enhanced endothelial

¹Not FDA approved for this indication.

function, improved myocardial perfusion, and possibly placebo effect. Several small studies have suggested “a clinical reduction in angina episodes, but no positive mortality benefit has yet been published. A meta-analysis that included 13 observational studies and followed 949 patients’ angina class using the CCS classification scheme noted at least a one-class improvement in 86%” of the study population. Contraindications to this treatment include certain aortic valvular diseases, aortic aneurysm, and peripheral vascular disease.

Spinal Cord Stimulation

For patients whose angina is refractory to medical therapy and who are not candidates for revascularization, spinal cord stimulation may be considered. Little intermediate or long-term data are available, but many short-term studies suggest reduced angina episodes. Placement of the device and subsequent stimulation at the C7-T1 level suggests that the mechanism of action is reduced pain sensation.

Acupuncture

Acupuncture has been shown to be of benefit for the relief of both acute and chronic pain in various medical conditions. With respect to patients with documented CAD and symptomatic angina, there is insufficient data currently available to recommend this modality. The difficulty in devising a true blinded study may limit randomized data from being effectively obtained in the future.

Other Causes of Angina

Syndrome X

The cardiac syndrome X refers to patients who have normal or near-normal epicardial coronary arteries and episodic chest pain. This disorder is much more common in women and is often seen in patients younger than 50 years of age. The chest pain episodes may last longer than 30 minutes and may have a variable response to sublingual nitrates. Patients with syndrome X often describe typical stress-induced angina. Risk factors include hypertension, diabetes, and hyperlipidemia. Female patients are typically postmenopausal and frequently have stress-induced symptoms and ischemia on stress imaging. They often respond to standard angina medications and typically have a better prognosis than patients with significant epicardial plaque.

Vasospastic or Prinzmetal’s Angina

The classic definition of Prinzmetal’s angina is chest pain with documented ST-segment elevation during symptoms or during exercise in the face of angiographically normal or near-normal coronary arteries. Over the years, the definition has expanded to include patients who have classic angina symptoms commonly relieved with nitrates or calcium channel blockers and minimal or no CAD. It has been shown that patients with nonobstructive CAD may be prone to focal artery spasm at the stenosis site; therefore the previous requirement of normal coronary arteries is not an absolute necessity. Other disease states (e.g., Raynaud’s phenomenon) can increase a patient’s development of coronary artery spasm, as can illicit drug usage (e.g., cocaine). Vasospasm is more common in active smokers. β -Blockers should be used cautiously in these patients because they may exacerbate coronary spasm. Patients with angiographically documented intramyocardial bridging may be prone to focal coronary spasm and subsequent angina pectoris.

Newer Imaging Techniques

Calcium Scoring

Coronary artery calcium scoring is a well-studied imaging modality used to assess a patient’s pretest probability of CAD. With respect to evaluation for angina, one must remember that electron-beam computed tomographic (CT) scanning does not offer physiologic data and therefore does not allow determination of myocardial ischemia. This study is most useful in the work-up of a low-risk patient with an atypical chest pain syndrome. If such a patient has an elevated calcium score, other studies may be reasonable “and further assessment of the patients’ cholesterol values should be performed.”

CT Coronary Angiography

CT coronary angiography is a noninvasive way to image the coronary arteries. Like electron-beam CT, it does not provide physiological data regarding coronary artery perfusion, but it does provide anatomic information such as the presence and percentage of coronary artery stenosis. Although selected patients with stable or unstable angina may be considered candidates for CT angiography, its main utility is to evaluate patients for chest pain who are otherwise at low risk and have a low pretest probability. Because of the volume of intravenous contrast required by CT angiography, the risk of contrast nephropathy must be considered when contemplating this study.

Summary

The approach to the patient with angina should be based on a global assessment and intensive treatment of all identified cardiovascular risk factors. “It is recommended that all patients receive the appropriate dose of statin and antiplatelet therapy.” Noninvasive testing is helpful for an initial diagnosis and to guide the decision for a more invasive approach. Familiarity and adherence to current treatment guidelines is of paramount importance. There are important gender differences that should not be overlooked in the clinical presentation of angina and in the approach to optimal therapy.

AORTIC DISEASE: ANEURYSM AND DISSECTION

Method of

David G. Neschis, MD

CURRENT DIAGNOSIS

- Because the majority of patients with abdominal aortic aneurysms are asymptomatic, the majority of abdominal aortic aneurysms are detected on imaging studies performed for other indications.
- Patients older than 50 years who present with abdominal or back pain of unclear etiology should be considered for evaluation of possible abdominal aortic aneurysm.
- Asymptomatic men older than 65 years who have ever smoked are eligible for abdominal aortic aneurysm screening.
- All patients older than 60 years who have a strong family history of abdominal aortic aneurysms should be considered for screening.
- Patients presenting with sudden onset of chest or back pain without clear etiology should be evaluated for dissection.
- Dissection can mimic numerous other conditions.

CURRENT THERAPY

Indications for Repair of Aneurysm

- Fusiform abdominal aortic aneurysms greater than 5.5 cm in maximum diameter
- Most saccular aneurysms and pseudoaneurysms
- Thoracic and thoracoabdominal aortic aneurysms of greater than 6 cm in maximal diameter
- Aneurysms that are symptomatic or are rapidly enlarging

Indications for Repair of Aortic Dissection

- Dissections involving the ascending aorta
- Dissections involving only the descending aorta are usually managed medically unless complicated by the following: unrelenting pain, end organ ischemia, or significant aneurysmal degeneration to greater than 6 cm in maximal diameter

Abdominal Aortic Aneurysms

Epidemiology

A ruptured abdominal aortic aneurysm is a devastating event leading to approximately 15,000 deaths per year, and it is the 13th leading cause of death in the United States. It is the 10th leading cause of death in men. Once rupture occurs, there is an 85% chance of death overall and approximately 50% mortality in the patients who make it to the hospital alive. Clearly, the goal is to identify this life-threatening lesion and repair prior to rupture. Abdominal aortic aneurysms are approximately four times more prevalent in men than in women. The overall incidence in persons older than 60 years is approximately 3% to 4%, with incidence as high as 10% to 12% in an elderly hypertensive population.

Risk Factors

Men are approximately 4 times more likely than women to develop an abdominal aortic aneurysm. Clearly, older persons, particularly those older than 60 years, are at higher risk. Tobacco use is probably the strongest preventable risk factor, with tobacco users being approximately eight times more likely to be affected than nonsmokers. Hypertension is present in approximately 40% of patients with abdominal aortic aneurysms. Family history also plays a significant role. In fact, men who have first-degree female relatives who had aneurysms are approximately 18 times more likely than the general population to develop an abdominal aortic aneurysm. There is also a strong correlation between abdominal aortic aneurysms and other peripheral artery aneurysms. Patients with bilateral popliteal artery aneurysms have an approximately 50% to 60% risk of having an abdominal aortic aneurysm.

Pathophysiology

An aneurysm is a dilatation of a blood vessel that could occur in any blood vessel in the body, even in the veins. Most commonly it is defined as a dilatation of approximately 1.5 to 2 times at that diameter of the adjacent normal vessel.

The definition of a pseudoaneurysm is often misunderstood. The attempt to describe a pseudoaneurysm in terms of the number of layers of the artery wall involved does nothing to help resolve this confusion. A pseudoaneurysm is a walled-off defect in the artery wall. A circular shell of adventitial and surrounding connective tissue contains the blood, preventing free hemorrhage. However, there remains continued flow out and back into the arterial lumen, resulting in a classic to-and-fro pattern on duplex ultrasound. The most common cause of a pseudoaneurysm is iatrogenic, from needle puncture, but it also can be caused by trauma or focal rupture of the artery at the site of an atherosclerotic ulcer.

The etiology of true aneurysms is not clear, although in the past these have been attributed to atherosclerosis. However, it is well known that the majority of patients with abdominal aortic aneurysms do not have associated significant occlusive disease. Biochemical studies have demonstrated decreased quantities of elastin and collagen in the walls of aneurysmal aortas. It is believed that a family of enzymes known as matrix metalloproteinase (MMP), particularly those that have collagenase and elastase activity, are likely involved in development of arterial aneurysms. The propensity for growth and rupture is based on Laplace's law, $T = PR$, where T represents wall tension (or in other words the propensity to rupture), P is the transmitted pressure, and R is the radius. This explains why patients with hypertension and those with larger aneurysms are at higher risk for aortic rupture.

Prevention

Currently the most effective means to prevent aneurysm rupture is early detection and elective repair. Avoidance of smoking and aggressive control of blood pressure would likely be helpful in preventing aneurysmal development and growth. Patients with known abdominal aortic aneurysms that are relatively small and at low risk for rupture are generally serially followed with imaging studies over time. These patients are advised to avoid straining (e.g., heavy lifting), avoid smoking, and keep their blood pressure well controlled.

Investigation is ongoing in efforts to develop a medication that may be helpful in slowing the growth of abdominal aortic aneurysms. It has been known since 1985 that tetracycline antibiotics have activity against MMPs. There had been several animal studies and at least one small human study suggesting that doxycycline (Vibramycin)¹ may be effective at slowing the growth of abdominal aortic aneurysms. Currently, larger human studies are ongoing. At this point, there are no formal recommendations regarding the use of doxycycline for the purpose of slowing aneurysmal growth.

Clinical Manifestations

Approximately 75% of abdominal aortic aneurysms are asymptomatic and discovered incidentally. Unfortunately, physical

¹Not FDA approved for this indication.

Risk Factors

Men are approximately 4 times more likely than women to develop an abdominal aortic aneurysm. Clearly, older persons, particularly those older than 60 years, are at higher risk. Tobacco use is probably the strongest preventable risk factor, with tobacco users being approximately eight times more likely to be affected than nonsmokers. Hypertension is present in approximately 40% of patients with abdominal aortic aneurysms. Family history also plays a significant role. In fact, men who have first-degree female relatives who had aneurysms are approximately 18 times more likely than the general population to develop an abdominal aortic aneurysm. There is also a strong correlation between abdominal aortic aneurysms and other peripheral artery aneurysms. Patients with bilateral popliteal artery aneurysms have an approximately 50% to 60% risk of having an abdominal aortic aneurysm.

Pathophysiology

An aneurysm is a dilatation of a blood vessel that could occur in any blood vessel in the body, even in the veins. Most commonly it is defined as a dilatation of approximately 1.5 to 2 times at that diameter of the adjacent normal vessel.

The definition of a pseudoaneurysm is often misunderstood. The attempt to describe a pseudoaneurysm in terms of the number of layers of the artery wall involved does nothing to help resolve this confusion. A pseudoaneurysm is a walled-off defect in the artery wall. A circular shell of adventitial and surrounding connective tissue contains the blood, preventing free hemorrhage. However, there remains continued flow out and back into the arterial lumen, resulting in a classic to-and-fro pattern on duplex ultrasound. The most common cause of a pseudoaneurysm is iatrogenic, from needle puncture, but it also can be caused by trauma or focal rupture of the artery at the site of an atherosclerotic ulcer.

The etiology of true aneurysms is not clear, although in the past these have been attributed to atherosclerosis. However, it is well known that the majority of patients with abdominal aortic aneurysms do not have associated significant occlusive disease. Biochemical studies have demonstrated decreased quantities of elastin and collagen in the walls of aneurysmal aortas. It is believed that a family of enzymes known as matrix metalloproteinase (MMP), particularly those that have collagenase and elastase activity, are likely involved in development of arterial aneurysms. The propensity for growth and rupture is based on Laplace's law, $T = PR$, where T represents wall tension (or in other words the propensity to rupture), P is the transmitted pressure, and R is the radius. This explains why patients with hypertension and those with larger aneurysms are at higher risk for aortic rupture.

Prevention

Currently the most effective means to prevent aneurysm rupture is early detection and elective repair. Avoidance of smoking and aggressive control of blood pressure would likely be helpful in preventing aneurysmal development and growth. Patients with known abdominal aortic aneurysms that are relatively small and at low risk for rupture are generally serially followed with imaging studies over time. These patients are advised to avoid straining (e.g., heavy lifting), avoid smoking, and keep their blood pressure well controlled.

Investigation is ongoing in efforts to develop a medication that may be helpful in slowing the growth of abdominal aortic aneurysms. It has been known since 1985 that tetracycline antibiotics have activity against MMPs. There had been several animal studies and at least one small human study suggesting that doxycycline (Vibramycin)¹ may be effective at slowing the growth of abdominal aortic aneurysms. Currently, larger human studies are ongoing. At this point, there are no formal recommendations regarding the use of doxycycline for the purpose of slowing aneurysmal growth.

Clinical Manifestations

Approximately 75% of abdominal aortic aneurysms are asymptomatic and discovered incidentally. Unfortunately, physical

¹Not FDA approved for this indication.

examination is an unreliable method for detecting aneurysms or determining aneurysm size. In heavier patients it may be simply impossible to adequately palpate the aorta. The majority of aneurysms are incidental findings identified on imaging studies performed for other reasons. Occasionally, an aneurysm is first detected upon operation for another condition.

Unfortunately, when an aneurysm becomes symptomatic, this is usually a sign of impending rupture. Symptoms related to abdominal aortic aneurysms can include abdominal or back pain. The classic triad of findings in the setting of abdominal aortic aneurysm rupture includes abdominal pain, hypotension, and a pulsatile abdominal mass. This triad, however, occurs in only approximately 20% of the patients. Often a high index of suspicion needs to be maintained.

The episode of hypotension associated with aneurysm rupture may be manifested as an episode of syncope or near-syncope before the patient arrives at the hospital. It is quite possible for the patient to have a contained rupture of the abdominal aorta and appear quite stable with a normal blood pressure in the emergency department. Although uncommon, a primary fistula between the aneurysm and gastrointestinal tract can occur and manifest as gastrointestinal bleeding.

Diagnosis

Several imaging modalities are available that can accurately diagnose and measure abdominal aortic aneurysms. Real-time B-mode ultrasound scanning has the advantage of being almost universally available, relatively inexpensive, and essentially risk free. The major disadvantage, however, is that it is technician dependent. Computed tomography (CT) scans can provide a very accurate representation of the aorta in a very short study time (Figures 1 and 2). The use of iodinated contrast is not necessary to obtain a gross size measurement of the aorta. The contrast, however, helps delineate the flow lumen more clearly, and it is quite valuable in planning repair. Disadvantages include the use of ionizing radiation and the use of iodinated contrast material. MRI is also accurate in determining the size of the aneurysm; however, study times are longer, equipment is less widely available, and the expense is considerable. Angiography, while excellent for evaluating the status of important aortic branches and for evaluating occlusive disease, is not an accurate study for the purpose of determining maximal diameter of the aneurysm. Often aneurysms are filled with laminated thrombus, and the flow lumen, which was seen on aortography, is not representative of the true aneurysm size.

Treatment

The decision on when to intervene in an abdominal aortic aneurysm is based on a careful analysis of the patient's risk for rupture

Figure 1 Large abdominal aortic aneurysm. Notice how the majority of this aneurysm is filled with laminated thrombus. The flow lumen is only mildly dilated, and this aneurysm could be missed on angiography alone.

Figure 2 Classic image of a ruptured abdominal aortic aneurysm, which in this case can be seen even without the use of intravascular contrast. Note the lack of symmetry and obliteration of tissue planes in the retroperitoneum on the left.

versus the risk of operative repair. Historically, open repair can be performed with less than 5% in-hospital mortality. Based on historical studies it was estimated that the risk of rupture for an approximately 5-cm aneurysm was about 1% per year, which increased dramatically to 6.6% for aneurysms between 6 and 7 cm. It has been fairly well established for years that aneurysms larger than 5.5 cm are generally recommended for repair and those less than 4 cm are generally observed over time. There remains a gray area for moderate aneurysms in the 4- to 5.5-cm category.

Two large prospective randomized trials were developed to answer this question. These include the United Kingdom Small Aneurysm Trial and the Department of Veterans Affairs Aneurysm Detection and Management (ADAM) trial. Both these studies randomized patients with moderately sized aneurysms to observation versus open repair. Results of both trials were fairly similar. The rupture rate for aneurysms under observation was 0.5% to 1% per year, and neither trial showed a difference in long-term survival. Both studies concluded that it was relatively safe to observe patients with aneurysms less than 5.5 cm in diameter, particularly in men who would be compliant with the follow-up regimen. The diameter of the aneurysm, however, should not be the only data point used for a decision on whether to repair.

Women seem to have a higher rupture rate for a particular aneurysm diameter than men, perhaps because they are starting with smaller aortas to begin with. Patients with COPD may be at higher risk for rupture as well. Saccular or eccentric-shaped aneurysms may also have a higher propensity to rupture and should not be subject to diameter recommendations for fusiform aneurysms (Figures 3 and 4). Additionally, rapidly growing aneurysms—growing at a rate faster than approximately 0.5 cm per year—should be considered for repair.

Once it has been determined that repair is indicated, a number of options are available. Traditional open repair involves a relatively large abdominal incision, cross clamping of the aorta, and replacement of the aneurysmal segment with a graft of polyethylene terephthalate (Dacron) or polytetrafluoroethylene (PTFE; Teflon). Often the iliac arteries are involved, and in these cases a bifurcated graft is placed. Open repair is quite durable and very effective at preventing aneurysm-related deaths. Long-term complications are rare, and patients following open repair generally enjoy 95% freedom from issues related to the repair over the course of their lifetime. Disadvantages, however, include the large incision and an approximate 1-week hospital stay. Recovery to a relatively normal level of function occasionally takes months. In the past, many patients were deemed too old or frail to be expected to undergo open surgery.

Figure 3 Axial CT slice and reconstructed images of a saccular abdominal aortic aneurysm. This lesion could also be described as a pseudoaneurysm. For these, treatment is recommended because it is thought that the risk of rupture is higher than for a similarly sized fusiform abdominal aortic aneurysm.

Figure 4 Angiogram of patient in Figure 3, demonstrating aneurysm before and after deployment of an endograft, which successfully excluded the lesion from the circulation.

Endograft repair has revolutionized the practice of vascular surgery. Using small incisions placed at the groin and performing the procedure under fluoroscopic guidance, devices can now be advanced into the aorta from the femoral artery. Using angiography as a guide, the graft typically is deployed below the renal arteries and effectively excludes the aneurysm from the circulation. Advantages include small incisions and very short hospital stays. Patients are typically discharged on the first or second day after aneurysm repair. Recovery to normal activity is also quite rapid, taking approximately 1 to 2 weeks. Use of this modality

has allowed treatment of older and frailer patients who previously were denied treatment due to concerns of operative risk.

Endograft repair, however, is clearly not without its disadvantages. Currently, the durability of endograft repair is unknown, and these patients are subject to frequent serial imaging. Also, there is a higher incidence of graft-related complications, which can occur in up to 35% of patients. These include the development of leaks of blood into the aneurysm sac outside the graft device, issues related to graft failure and migration, and graft limb thrombosis. These grafts are also quite expensive.

Two major prospective randomized trials studying traditional open versus endograft repair are often cited. These include the United Kingdom–based EVAR-1 trial (first Endovascular Aneurysm Repair trial) and the Dutch-based DREAM trial (Diabetes REduction Assessment with ramipril and rosiglitazone Medication trial). Both studies randomized patients who were believed to be good risks for open repair to endograft versus traditional open repair. The results of both of these studies were relatively similar in that both studies demonstrated a clear early survival benefit for patients in the endograft group. However, this came at a cost of an increased incidence of graft-related complications in the endograft group and a higher cost for the endograft group. Additionally, at 2 to 4 years, there was no clear difference in long-term survival in either group.

Ultimately, the decision about whether to proceed with open or endograft repair is a decision between surgeon and patient based on the patient's aortic anatomy, overall health, and the patient's and physician's preference. It would appear, however, that older and frail patients with good anatomy should be strongly considered for endograft repair.

Monitoring

Patients with abdominal aortic aneurysms should be evaluated for the presence of femoral and popliteal aneurysms (particularly in men) and for thoracic aortic aneurysms. After open repair, a follow-up CT scan with contrast should be considered approximately 5 years out to evaluate for the integrity of the graft (i.e., pseudoaneurysms), as well as development of new aneurysms. Patients who have undergone endograft repair require more-intensive monitoring. Typical regimens include a contrast-enhanced CT scan approximately 2 weeks after repair, then 6 months after repair, and then based on the perceived stability of the graft, approximately yearly thereafter. Some centers have used duplex ultrasonography for evaluating patients after endograft repair in efforts to reduce the amount of ionizing radiation the patients receive. However, it should be remembered that duplex ultrasound is highly technician dependent, and follow-up of patients with endograft repairs using only duplex ultrasound should be performed in experienced centers.

Thoracic Aortic Aneurysms

Thoracic aortic aneurysms (TAAs) are limited to the chest cavity. Although they are less common than infrarenal abdominal aortic aneurysms, they share similar risk factors. The male-to-female ratio incidence of the TAA is approximately 1:1.

In the past, the threshold for repair was at a diameter greater than 6 cm. This threshold was chosen due to the higher operative risks associated with repair of the thoracic aorta. Now with the availability of endograft, patients with good anatomy are generally recommended for repair at a diameter similar to those for the infrarenal aorta.

Open repair involves performing a thoracotomy and cross-clamping the aorta. Repair in this location is often performed with the addition of extracorporeal bypass to maintain perfusion to the viscera and spinal cord drain performance of the repair. Although the risk of paraplegia in the treatment of infrarenal aortic is exceedingly low, the risk of paraplegia from a repair of an isolated TAA is approximately 6%. Endograft devices for repair of TAA are now widely available and have reduced the incidence of paraplegia to approximately 3%.

Thoracoabdominal Aortic Aneurysms

By definition, thoracoabdominal aortic aneurysms require entrance to both the thoracic and abdominal cavity to perform repair. These lesions are usually true aneurysms of the aorta and should not be confused with dissection. Repair of thoracoabdominal aortic aneurysms is quite complex and carries risks of death and paraplegia as high as 20% in some settings. These procedures are generally performed at larger institutions with considerable experience with this condition. Unfortunately, endograft devices for the repair of thoracoabdominal aortic aneurysms are limited to a handful of centers in the United States.

Thoracic Aortic Dissection

Thoracic aortic dissection is the most common aortic emergency, even more common than ruptured abdominal aortic aneurysm. This potentially fatal condition is rare in patients younger than 50 years and is approximately two times more common in men than women. Patients at risk include patients with a history of connective tissue disorders and patients with severe, poorly controlled hypertension.

An aortic dissection occurs when there is loss of integrity of the intima and blood dissects into the media. Once in the media, there is a natural plane through which dissection is quite easy.

Although there are various classification systems for aortic dissection, the Stanford classification is perhaps the most widely used and the most useful. In this classification, any dissection that involves the ascending aorta, whether it involves the ascending aorta alone or both the ascending and descending thoracoabdominal aorta, are classified as type A. Dissections that do not involve the ascending aorta are classified as type B. This classification is useful because type A dissections require urgent surgery. Type B dissections are typically managed medically unless they are associated with complications such as unremitting pain, aneurysmal expansion, and end-organ ischemia. By convention, aortic dissections that are evaluated within 14 days after the onset of symptoms are considered acute, and those evaluated beyond 14 days are considered chronic.

Helical CAT scanners with the use of contrast are excellent at defining the location and extent of aortic dissection. However, being alert to the potential for this diagnosis requires a high index of suspicion. Aortic dissection can mimic a variety of common conditions based on the extent of the dissection and the aortic branches involved (Table 1). Uncomplicated type B dissections are typically managed medically. This is usually performed in an intensive care setting with the use of intravenous medications to control contractility and, if necessary, hypertension.

In the past, due to the friability of dissected aortic tissue, the results of operative repair for type B dissections have been particularly poor. Currently, endograft repair with the purpose of excluding the entry point of dissection and reestablishing flow to the true lumen is gaining popularity in the treatment of complex dissection. This at times may be supplemented by stenting of affected aortic side branches and fenestration to establish a connection between the true and false lumen to restore perfusion to certain organs. Once the acute phase has passed and medically treated patients are under good hypertensive control, these patients are then converted to an oral medication regimen and transferred out of the intensive care setting. Patients need to be followed up with serial CT imaging after discharge to evaluate for aneurysmal

TABLE 1 Dissection: The Great Mimic

TERRITORY INVOLVED OR AFFECTED BY DISSECTION	MIMICS
Rupture into pericardial sac	Cardiac tamponade
Dissection through aortic valve	Acute aortic insufficiency
Dissection occluding coronary arteries	Myocardial infarction
Involvement of cerebral vessels	Stroke
Involvement of subclavian arteries	Upper extremity ischemia (cold arm)
Dissection running down descending thoracic aorta	Severe back pain and paralysis
Mesenteric artery obstruction	Mesenteric ischemia
Renal artery obstruction	Oliguria and acute renal failure
Iliac artery occlusion	Lower extremity ischemia (cold leg)

degeneration of the false lumen. This evaluation should occur every 6 months until the patient is stable and then yearly thereafter.

In cases where the total aortic diameter grows to greater than 6 cm, repair for the purpose of preventing rupture is indicated, although this is often technically more complicated than treating a fusiform aneurysm in the absence of a previous dissection. Patients should strictly adhere to their blood pressure medication regimen for life.

ATRIAL FIBRILLATION

Method of

Lin Yee Chen, MD, MS; and Samuel C. Dudley, Jr., MD, PhD

CURRENT DIAGNOSIS

- History taking and physical examination for atrial fibrillation (AF) should be focused on determining symptom severity (to decide on treatment strategy), risk of thromboembolic stroke, and associated cardiovascular risk factors.
- Symptoms include palpitations, chest discomfort, shortness of breath, and reduced exercise capacity. Some patients are symptom free.
- Investigations include 12-lead electrocardiogram (ECG) for confirmation, transthoracic echocardiogram to evaluate left atrial size, left ventricular ejection fraction, and rule out valvular abnormalities, and blood tests for thyroid, renal, and hepatic function.

CURRENT THERAPY

- Rate control: Achieve average ventricular rate of less than 110 beats/min by using atrioventricular node (AVN) blockers or catheter ablation of AVN
- Rhythm control: Prevent AF recurrence by using antiarrhythmic drugs or catheter ablation (pulmonary vein isolation)
- Stroke prophylaxis: Risk stratification and stroke prevention by oral anticoagulation or left atrial appendage closure
- Risk factor management or lifestyle modification: Prevent AF by weight management, intensive blood pressure lowering, and exercise training

Epidemiology

AF is the most common sustained arrhythmia in the adult general population. Globally, the estimated number of individuals with AF in 2010 was 33.5 million. Between 1990 and 2010, the global estimated age-adjusted prevalence rate of AF increased from 569.5 to 596.2 per 100,000 men and from 359.9 to 373.1 per 100,000 women. This increase in prevalence was accompanied by a substantial increase in health burden: disability-adjusted life-years increased by 18.8% in men and 18.9% in women from 1990 to 2010. Finally, the lifetime risk for development of AF in adults at age 40 is 1 in 4.

Risk Factors and Pathophysiology

Table 1 shows the known risk factors of AF; many of these are also risk factors for atherosclerotic disease. Traditional cardiovascular risk factors such as diabetes, hypertension, and obesity can lead to AF via the following pathway: Cardiovascular risk factors → left ventricular diastolic dysfunction → structural and functional alterations in the atria (enlargement, impaired function, fibrosis, etc.) → AF. The aforementioned pathway creates the substrate for AF; premature atrial contractions and supraventricular ectopic beats are the trigger for AF. Other pathophysiological pathways include inflammation and increased oxidative stress leading to electrical remodeling, and, consequently, AF.

Clinical Manifestations

Common symptoms of AF include palpitations, irregular heart beat sensation, lightheadedness, dyspnea, chest discomfort, and fatigue. Some patients may have no symptoms at rest but report poor stamina or easy fatigability with physical activity. Other patients, particularly in the elderly, may be asymptomatic.

Diagnosis

The absence of distinct P waves with irregularly irregular RR interval on the ECG are the sine qua non for diagnosing AF. Rhythm documentation can be obtained via the standard 12-lead ECG, Holter monitors that can record up to 48 hours, leadless patch monitors that can record up to 2 weeks, or implantable loop recorders. Newer wearable technologies that can diagnose AF include smart watches and smart phones with specialized apps.

Family history
Genetics (polygenic and monogenic inheritance)
Inflammation
Low serum magnesium
Heavy alcohol consumption
Poor cardiorespiratory fitness
Low physical activity
Premature atrial contractions or supraventricular ectopy

Paroxysmal AF is defined as AF that terminates spontaneously typically in <24 hours and in all cases <7 days. AF that continues for >7 days and requires cardioversion for conversion to sinus rhythm is termed *persistent AF*. Long-standing persistent AF refers to AF that has been continuous for longer than one year. Permanent AF refers to a clinical scenario when both patients and physician have decided not to pursue further attempts to maintain sinus rhythm.

Differential Diagnosis

These include other supraventricular arrhythmias such as atrial tachycardia, atrial flutter, long runs of premature atrial contractions, and multifocal atrial tachycardia.

Treatment

Rate Control

The goal of rate control is to prevent excessive ventricular rate response. This is a reasonable treatment strategy given data from randomized controlled trials, which did not show any difference in cardiovascular outcomes between rate versus rhythm control strategy.

The AFFIRM (Atrial Fibrillation Follow-up Investigation of Rhythm Management) trial found no difference in mortality or stroke rates between patients assigned to rhythm control or ventricular rate control strategies. Similarly, the RACE (Rate Control versus Electrical Cardioversion for Persistent Atrial Fibrillation) trial found that rate control was not inferior to rhythm control for prevention of death.

The RACE II study showed that lenient ventricular rate control targeting heart rate of lower than 110 beats/min was not inferior to stricter rate control of less than 80 beats/min. Lenient rate control is more convenient and requires fewer outpatient visits and fewer medications.

Other than pharmacologic agents (Table 2), catheter ablation of the AVN is effective in controlling ventricular rate in patients with AF. AVN ablation is indicated if patients fail to achieve adequate ventricular rate control despite maximum doses of AVN blockers.

Rhythm Control

Although AF is associated with an increased risk of stroke and mortality, current evidence indicates that there is no difference in the rates of these cardiovascular outcomes between rhythm and rate control strategy. However, in selected younger patients with

paroxysmal AF, rhythm control may be a better approach. Additionally, in patients who continue to have symptoms despite an adequately controlled ventricular rate, rhythm control is an appropriate next step.

Rhythm control can be achieved by the use of antiarrhythmic drugs (Table 3) or catheter ablation. In patients with paroxysmal and persistent AF who have failed at least 1 antiarrhythmic drug, catheter ablation by pulmonary vein isolation is indicated to maintain sinus rhythm. In persistent AF, STAR AF-II showed that performing additional linear ablation or ablation targeting complex fractionated electrograms does not improve rhythm control compared with pulmonary vein isolation alone. The optimal approach to ablate persistent AF remains to be defined.

Stroke Prophylaxis

Stroke prevention is a 2-staged process: determination of thromboembolic stroke risk and selection of prevention strategy. The most commonly used risk stratification scheme for stroke prevention is the CHA₂DS₂-VASC score (Table 4). Oral anticoagulation is recommended for CHA₂DS₂-VASC score ≥2 and no oral anticoagulation is recommended for CHA₂DS₂-VASC score of 0. For CHA₂DS₂-VASC score of 1, clinical judgment and shared decision making are needed. Aspirin¹ should not be used for stroke prevention in AF.

Oral Anticoagulants

These include vitamin K antagonists (warfarin [Coumadin]) and non-vitamin K oral anticoagulants or novel or direct oral anticoagulants (NOAC, DOAC) (Table 5). Compared with warfarin, NOACs are as effective in preventing thromboembolic stroke in AF. The risk of intracranial hemorrhage from the use of NOACs is 33% to 60% less than warfarin. Other advantages of NOACs over warfarin include fewer interactions with food and obviating the need for International Normalized Ratio monitoring. Warfarin is a better choice in those with kidney failure. NOACs should be avoided in those with a glomerular filtration of <30 mL/min.

Left Atrial Appendage Closure

The Watchman device is approved by the Food and Drug Administration (FDA) for stroke prevention in AF patients with a contraindication to long-term oral anticoagulation and who are at risk of

TABLE 2 Pharmacologic Agents for Rate Control

DRUG	INTRAVENOUS ADMINISTRATION	USUAL ORAL MAINTENANCE DOSE	MAJOR SIDE EFFECTS
β-Blockers			
Metoprolol (Lopressor) ¹	2.5–5 mg IV bolus; up to 3 doses	100–200 mg (long-acting) daily	Bradycardia, hypotension, heart block, asthma, heart failure
Atenolol (Tenormin) ¹	N/A	25–100 mg daily	
Esmolol (Brevibloc)	50–200 µg/kg/min IV	N/A	
Propranolol (Inderal)	1–3 mg IV	10–40 mg TID	
Carvedilol (Coreg) ¹	N/A	3.125–25 mg BID	
Non-Dihydropyridine Calcium Channel Antagonists			
Verapamil (Calan)	5–10 mg bolus	40 mg BID or up to 360 mg (long-acting) daily	Hypotension, heart block, heart failure
Diltiazem (Cardizem)	0.25–0.35 mg/kg	60 mg TID or up to 360 mg (long-acting) daily	
Digitalis Glycosides			
Digoxin (Lanoxin)	0.5–1 mg	0.125–0.5 mg daily	Digitalis toxicity, bradycardia, heart block

¹Not FDA approved for this indication.

TABLE 3 Pharmacologic Agents for Rhythm Control

DRUG	USUAL ORAL MAINTENANCE DOSE	MAJOR SIDE EFFECTS
Flecainide (Tambocor)	50–200 mg BID	Hypotension, atrial flutter with high ventricular rate
Propafenone (Rythmol)	150–300 mg TID	
Propafenone Extended Release (Rythmol SR)	225–425 mg BID	
Sotalolol (Betapace)	80–160 mg BID	Bradycardia, hypotension, QT prolongation, torsades de pointes
Dofetilide (Tikosyn)	125–500 µg BID	QT prolongation, torsades de pointes
Amiodarone (Pacerone)*	100–200 mg daily	Hypotension, bradycardia, QT prolongation
Dronedarone (Multaq)	400 mg BID	QT prolongation

*Not FDA-approved for AF.

TABLE 4 CHA₂DS₂-VASc Score

RISK FACTOR	SCORE
Congestive heart failure, LV dysfunction	1
Hypertension	1
Age ≥ 75 years	2
Diabetes mellitus	1
Stroke, TIA, or thromboembolism	2
Vascular disease (MI, PAD, complex aortic plaque)	1
Age 65–74 years	1
Sex category: Female	1

Abbreviations: LV = left ventricular; MI = myocardial infarction; PAD = peripheral arterial disease; TIA = transient ischemic attack.

TABLE 5 Non-Vitamin K Oral Anticoagulants

DIRECT THROMBIN INHIBITOR		
Drug	Usual dose	Comments
Dabigatran (Pradaxa)	150 mg BID	Reversal agent (Idarucizumab [Praxbind]) FDA-approved, interacts with P-glycoprotein inhibitors and inducers
Factor Xa Inhibitor		
Apixaban (Eliquis)	5 mg BID	Interacts with P-glycoprotein and CYP3A4 inhibitors and inducers
Edoxaban (Savaysa)	60 mg once daily	Avoid if CrCl >95 mL/min
Rivaroxaban (Xarelto)	20 mg once daily	Interacts with P-glycoprotein and CYP3A4 inhibitors and inducers, should be taken with evening meal

thromboembolic stroke. Patients, however, must be able to take OACs for at least 6 weeks after implantation of the device.

Risk Factor Management and Lifestyle Modification

Recent compelling evidence underscores the importance of a fourth pillar of AF management: Risk factor and lifestyle modifications.

Weight Loss

A randomized controlled trial (RCT) showed that weight reduction with intensive risk factor management resulted in a reduction of AF symptom burden and severity and reversal of cardiac remodeling.

Intensive Blood Pressure Lowering

Blood pressure lowering targeting a systolic blood pressure of 120 mm Hg is associated with lower incidence of AF compared with 140 mm Hg.

Exercise Training

A small RCT showed that, compared with nonexercise control patients, high-intensity interval training reduced AF burden and improved atrial contractile function. This time-efficient form of exercise can potentially overcome the lack of time problem—an oft-quoted reason for the poor compliance with regular aerobic exercise.

Complications

Other than thromboembolic stroke, heart failure, and death, AF is also associated with greater cognitive decline and risk of

dementia. More recently, AF has been reported to be associated with a higher risk of sudden cardiac death in the general population. Apart from stroke prevention and rate and rhythm control to prevent heart failure, we currently lack effective prevention strategies for dementia and sudden cardiac death.

Special Considerations

Subclinical AF

Subclinical AF is commonly detected from interrogation of cardiac implantable electronic devices. Whether subclinical AF poses the same health risks as clinical AF is the subject of much debate and active investigation.

AF Burden

A corollary to the problem of subclinical AF is that of AF burden—the amount of AF that a patient has. Studies based on cardiac implantable electronic devices suggest that higher AF burden is associated with higher risk of thromboembolic stroke, but it is unclear whether the risk increases continuously or whether a threshold exists.

CARDIAC ARREST: SUDDEN CARDIAC DEATH

Method of

Roy M. John, MD, PhD

Cardiac arrest, or sudden cardiac death, accounts for 60% of deaths from cardiac disease. It may be the initial manifestation or a complication of preexisting heart disease. Most cases are the result of potentially correctable arrhythmias, but the rate of successful resuscitation from an out-of-hospital cardiac arrest to neurologically intact survival remains dismally low. Recognition of patients who are at high risk for sudden cardiac arrhythmic death is critical for prevention. The ability to recognize those at risk for sudden death has increased appreciably, such that prophylactic measures can be implemented in a number of cardiac conditions to minimize risk.

Whereas specific antiarrhythmic drugs have proved disappointing in the prevention of sudden death, drugs that block the effects of β -adrenergic stimulation, angiotensin, and aldosterone have consistently led to reduced mortality among patients with cardiac disease and left ventricular (LV) dysfunction, partly through their salutary effects on sudden death. The implantable cardioverter-defibrillator (ICD) has emerged as a dominant therapeutic strategy based on clinical trials of its efficacy. This review addresses the clinical conditions associated with a high risk for sudden death and the current therapeutic options.

Definition and Causes

Sudden cardiac death is defined as abrupt, unexpected natural death occurring within a short time period (generally <1 hour) after onset of acute symptoms. Primary cardiac arrhythmia is responsible for most of the cases, but acute severe myocardial dysfunction, intracardiac obstruction, and acute aortic dissection are other important causes (Table 1). Structural abnormalities of the myocardium resulting from hypertrophy, scarring, and fibrosis serve as substrates for malignant arrhythmias. The majority of patients who die suddenly have atherosclerotic coronary artery disease (CAD). However, only about 20% of those who survive a cardiac arrest demonstrate evidence of an acute myocardial infarction. Instead, a large number have evidence of prior myocardial infarction and LV dysfunction. It is now recognized that chronic LV dysfunction is the most important predictor of sudden death in ischemic and nonischemic cardiomyopathy.

A significant number (10%) of sudden deaths occur in the absence of obvious structural heart disease. Young, active, and otherwise healthy individuals are often the victims. Inherited or spontaneous mutations in genes coding for ion channels are responsible

TABLE 1 Causes of Sudden Cardiac Death

Coronary artery disease
Atherosclerotic disease
Congenital anomalies
Spasm
Arteritis
Dissection
Embolism
Primary cardiomyopathies
Nonischemic dilated cardiomyopathy
Hypertrophic cardiomyopathy
Myocarditis
Valvular heart disease
Arrhythmogenic right ventricular dysplasia
Electrophysiologic abnormalities
Conduction system disease involving the His-Purkinje conduction system
Primary ventricular arrhythmia associated with the following cardiac conditions:
Abnormalities of the QT interval
Brugada syndrome
Wolff-Parkinson-White syndrome
Catecholaminergic ventricular tachycardia
Idiopathic ventricular fibrillation and early repolarization syndromes
Malignant ventricular arrhythmia resulting from metabolic abnormalities
Commotio cordis
Pulmonary hypertension
Hypertensive heart disease
Congenital heart disease
Noncompaction of the left ventricle
Inflammatory and infiltrative diseases of the myocardium
Sarcoidosis
Chagas' disease
Hemochromatosis
Amyloidosis
Hydatid cyst
Neuromuscular diseases
Muscular dystrophy
Myotonic dystrophy
Kearns-Sayre syndrome
Friedreich's ataxia
Intracardiac obstruction
Primary cardiac tumors (e.g., myxoma)
Intracardiac thrombus
Massive pulmonary embolism
Acute aortic dissection

for most of these cases. A number of specific syndromes have been recognized, allowing for screening of relatives.

Tests to Identify Risk for Sudden Death

Electrocardiography (ECG) and echocardiography can provide several clues. Assessment of ventricular function provides the most information in determining the risk for sudden death.

Several noninvasive tests, including detection of microvolt T-wave alternans, signal-averaged ECG, and heart rate variability, have been developed to predict the future risk of sudden death. These tests have poor generalized applicability because of their low positive predictive value. In addition, most have not been coupled with a therapeutic intervention to show that therapy based on them can reduce the risk of dying. Cardiac MRI showing evidence for myocardial scar is emerging as a useful tool for predicting risk.

Intracardiac electrophysiologic testing has retained some value, especially in patients with CAD. Inducibility of a sustained arrhythmia can be a marker for arrhythmic events, and therapy based on results of electrophysiologic testing has been shown to reduce mortality.

CARDIAC ARREST: SUDDEN CARDIAC DEATH

Method of

Roy M. John, MD, PhD

Cardiac arrest, or sudden cardiac death, accounts for 60% of deaths from cardiac disease. It may be the initial manifestation or a complication of preexisting heart disease. Most cases are the result of potentially correctable arrhythmias, but the rate of successful resuscitation from an out-of-hospital cardiac arrest to neurologically intact survival remains dismally low. Recognition of patients who are at high risk for sudden cardiac arrhythmic death is critical for prevention. The ability to recognize those at risk for sudden death has increased appreciably, such that prophylactic measures can be implemented in a number of cardiac conditions to minimize risk.

Whereas specific antiarrhythmic drugs have proved disappointing in the prevention of sudden death, drugs that block the effects of β -adrenergic stimulation, angiotensin, and aldosterone have consistently led to reduced mortality among patients with cardiac disease and left ventricular (LV) dysfunction, partly through their salutary effects on sudden death. The implantable cardioverter-defibrillator (ICD) has emerged as a dominant therapeutic strategy based on clinical trials of its efficacy. This review addresses the clinical conditions associated with a high risk for sudden death and the current therapeutic options.

Definition and Causes

Sudden cardiac death is defined as abrupt, unexpected natural death occurring within a short time period (generally <1 hour) after onset of acute symptoms. Primary cardiac arrhythmia is responsible for most of the cases, but acute severe myocardial dysfunction, intracardiac obstruction, and acute aortic dissection are other important causes (Table 1). Structural abnormalities of the myocardium resulting from hypertrophy, scarring, and fibrosis serve as substrates for malignant arrhythmias. The majority of patients who die suddenly have atherosclerotic coronary artery disease (CAD). However, only about 20% of those who survive a cardiac arrest demonstrate evidence of an acute myocardial infarction. Instead, a large number have evidence of prior myocardial infarction and LV dysfunction. It is now recognized that chronic LV dysfunction is the most important predictor of sudden death in ischemic and nonischemic cardiomyopathy.

A significant number (10%) of sudden deaths occur in the absence of obvious structural heart disease. Young, active, and otherwise healthy individuals are often the victims. Inherited or spontaneous mutations in genes coding for ion channels are responsible

TABLE 1 Causes of Sudden Cardiac Death

Coronary artery disease

Congenital anomalies
Spasm
Arteritis
Dissection
Embolism
Primary cardiomyopathies
Nonischemic dilated cardiomyopathy
Hypertrophic cardiomyopathy
Myocarditis
Valvular heart disease
Arrhythmogenic right ventricular dysplasia
Electrophysiologic abnormalities
Conduction system disease involving the His-Purkinje conduction system
Primary ventricular arrhythmia associated with the following cardiac conditions:
Abnormalities of the QT interval
Brugada syndrome
Wolff-Parkinson-White syndrome
Catecholaminergic ventricular tachycardia
Idiopathic ventricular fibrillation and early repolarization syndromes
Malignant ventricular arrhythmia resulting from metabolic abnormalities
Commotio cordis
Pulmonary hypertension
Hypertensive heart disease
Congenital heart disease
Noncompaction of the left ventricle
Inflammatory and infiltrative diseases of the myocardium
Sarcoidosis
Chagas' disease
Hemochromatosis
Amyloidosis
Hydatid cyst
Neuromuscular diseases
Muscular dystrophy
Myotonic dystrophy
Kearns-Sayre syndrome
Friedreich's ataxia
Intracardiac obstruction
Primary cardiac tumors (e.g., myxoma)
Intracardiac thrombus
Massive pulmonary embolism
Acute aortic dissection

for most of these cases. A number of specific syndromes have been recognized, allowing for screening of relatives.

Tests to Identify Risk for Sudden Death

Electrocardiography (ECG) and echocardiography can provide several clues. Assessment of ventricular function provides the most information in determining the risk for sudden death.

Several noninvasive tests, including detection of microvolt T-wave alternans, signal-averaged ECG, and heart rate variability, have been developed to predict the future risk of sudden death. These tests have poor generalized applicability because of their low positive predictive value. In addition, most have not been coupled with a therapeutic intervention to show that therapy based on them can reduce the risk of dying. Cardiac MRI showing evidence for myocardial scar is emerging as a useful tool for predicting risk.

Intracardiac electrophysiologic testing has retained some value, especially in patients with CAD. Inducibility of a sustained arrhythmia can be a marker for arrhythmic events, and therapy based on results of electrophysiologic testing has been shown to reduce mortality.

Treatment

This article summarizes the treatment modalities that have been shown to be effective in the various conditions leading to sudden cardiac death. Data based on randomized clinical trials are limited to common conditions such as CAD and the cardiomyopathies. The rarer diseases lack large clinical experience, and recommendations are based on the current consensus.

Acute Management of Survivors of Cardiac Arrest

Once stabilized with the use of standard advanced cardiac life support guidelines, patients should undergo cardiac evaluation by echocardiography and cardiac catheterization. Electrolyte abnormalities should be sought and corrected. Mild hypokalemia (3.0–3.5 mmol/L) is common after a cardiac arrest and resuscitation and is related to hypotension and transient acidosis. Hence, it is often the result and not the cause of the cardiac arrest. Similarly, in the acute phase after resuscitation, it is not uncommon to find global LV hypokinesis, but this should not be taken as a marker for preexisting heart disease. LV function tends to improve over the next 24 to 48 hours and should then be reassessed.

Ventricular fibrillation that occurs during the acute phase of a myocardial infarction (within the first 24–48 hours) is presumed to be secondary to electrical instability resulting from myocardial ischemia and reperfusion. If treated promptly by defibrillation, this arrhythmia has little prognostic value so long as overall myocardial function is preserved.

If acute ischemia or infarction is the documented cause of a cardiac arrest, revascularization by percutaneous angioplasty or coronary bypass surgery is the best treatment. The risk of recurrence is determined by the residual LV ejection fraction. In the Antiarrhythmic Versus Implantable Defibrillator (AVID) trial and Canadian trial of Implantable Defibrillators (CIDS), ICDs did not offer any survival benefit for patients with preserved LV function ($>35\%$). Therefore, postrevascularization electrophysiologic evaluation is recommended only for patients with impaired ejection fraction or significant LV scarring.

Survivors of a malignant arrhythmia other than that due to a reversible cause such as severe metabolic disturbance, toxic drug effect, or acute myocardial infarction are best treated with an ICD. In the largest prospective, randomized trial of drugs versus an ICD (the AVID trial), the ICD reduced mortality by 39% at 1 year and by 31% at 3 years, compared with amiodarone (Cordarone) or sotalol (Betapace). In the absence of specific contraindication, ICD therapy is currently the standard of care for secondary prevention of life-threatening ventricular arrhythmias. However, a permanent ICD is best reserved for patients who are expected to survive with a reasonable quality of life for a year or more. Temporary protection against ventricular arrhythmic death can be afforded by the use of a wearable defibrillator (LifeVest) when a permanent implant has to be delayed for reasons such as an ongoing infection or when awaiting recovery of cardiac function after an MI or revascularization procedure such as CABG or PTCL.

Primary Prevention of Ventricular Arrhythmias and Sudden Cardiac Death

Coronary Artery Disease

There are considerable data to guide efforts at primary prevention of sudden death in patients with CAD. β -Adrenergic blockers and angiotensin-converting enzyme inhibitors reduce mortality after myocardial infarction and should be routinely prescribed in the absence of major contraindications (Table 2). Part of the benefit on mortality offered by these drugs is achieved through reduction of the incidence of sudden death. There is no role for the use of antiarrhythmic drugs in primary prevention. Amiodarone, sotalol, and dofetilide (Tikosyn) have largely neutral effects, but class I antiarrhythmic drugs such as flecainide (Tambocor) and propafenone (Rythmol) are clearly harmful and increase mortality in patients with ventricular dysfunction.

Ventricular arrhythmias occurring late (>24 hours) after a myocardial infarction usually indicate a persisting propensity for recurrent arrhythmia and risk of death. Commonly, these patients have

TABLE 2 Drugs That Have Been Shown to Reduce Sudden Cardiac Death

impaired LV function and benefit from treatment with an ICD; an intracardiac electrophysiologic study is helpful in determining the risk of recurrence. Inducibility of ventricular tachycardia (VT) on electrophysiologic study is considered a predictor of sudden death, and treatment of such patients with an ICD lowers mortality.

For the stable patient with CAD, depressed ejection fraction and nonsustained VT are recognized risk factors for sudden death. If severe LV dysfunction is present (ejection fraction $<30\%$), implantation of an ICD will significantly reduce sudden death. In the presence of moderate LV dysfunction (ejection fraction $\leq 35\%$), a defibrillator is indicated if patients have New York Heart Association class II or III heart failure symptoms. Nonsustained VT occurring in the context of moderate LV dysfunction warrants an intracardiac electrophysiologic study (Table 3). In all cases ICD should be avoided in patients where meaningful survival is limited to less than a year from nonarrhythmic causes.

Idiopathic Dilated Cardiomyopathy

Unlike CAD, nonischemic dilated cardiomyopathy is more variable in its course. This is partly because the etiology is often unclear;

TABLE 3 Indication for ICD Therapy Based on the ACC/AHA 2008 Guidelines

Class I Indication*

1. Cardiac arrest due to VF or VT not due to a transient or reversible cause
2. Spontaneous sustained VT in association with heart disease
3. Recurrent syncope of undetermined origin in the presence of ventricular dysfunction and inducible ventricular arrhythmias on electrophysiologic study
4. NYHA class II or III heart failure and persistent systolic left ventricular dysfunction with LVEF $\leq 35\%$
5. Coronary artery disease and systolic left ventricular dysfunction (LVEF $\leq 30\%$) persisting >40 days after myocardial infarction or revascularization
6. Nonsustained VT with coronary disease, prior myocardial infarction, left ventricular dysfunction, and inducible VF or sustained VT on electrophysiologic study

Class II Indication†

1. Familial or inherited conditions with a high risk for life-threatening ventricular tachyarrhythmia
2. Unexplained syncope in the presence of left ventricular dysfunction and nonischemic cardiomyopathy
3. Patients with cardiac sarcoid, Chagas' disease, or giant cell myocarditis
4. Adult congenital heart disease with high risk for sudden cardiac death

Abbreviations: ACC/AHA = American College of Cardiology/American Heart Association Task Force; ICD = implantable cardioverter-defibrillator; LVEF = left ventricular ejection fraction; NYHA = New York Heart Association; VF = ventricular fibrillation; VT = ventricular tachycardia.

*There is good clinical evidence and general agreement that ICD is beneficial.

†There is inadequate data or some divergence of opinion regarding ICD benefit.

the disease process may be progressive in some and self-limited with spontaneous improvement in others. Consequently, benefit from ICD therapy is not as convincing as in patients with CAD. Nonsustained VT, syncope, and heart failure symptoms are predictors of high risk of sudden death in this population. In the Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation trial (DEFINITE), implantation of an ICD based on the presence of LV dysfunction, symptomatic heart failure, and nonsustained VT resulted in a reduction in arrhythmic mortality. The Sudden Death in Heart Failure trial (SCD Heft) showed that ICDs reduce mortality in the presence of heart failure symptoms and an LV ejection fraction of 35% or less.

Syncope in the presence of cardiomyopathy can be a harbinger of sudden death and merits the use of ICD therapy if another cause of syncope cannot be identified.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a genetically heterogeneous disease with an autosomal dominant mode of inheritance caused by mutations in genes coding for sarcomeric proteins. Unrecognized hypertrophic cardiomyopathy is a frequent cause of sudden death in young athletes.

Sudden death in hypertrophic cardiomyopathy is caused by ventricular arrhythmias and can be prevented by implantation of an ICD. A number of risk factors for sudden death have been identified in retrospective studies and are outlined in Table 4. The presence of any one of the major risk factors is an indication for ICD implantation. Electrophysiologic testing has no major value in risk stratification.

Genetic abnormalities do not always correlate with phenotypic expression of disease, and some abnormalities in the troponin gene may have minimal clinical features but high risk for arrhythmias. Genetic testing of the index case is useful in screening of family members.

Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic right ventricular dysplasia is characterized by progressive replacement of myocytes with fibrofatty tissue due to an inherited autosomal dominant abnormality in the genes coding for cell-to-cell junction proteins. Typically, the right ventricle is involved, but progressive involvement of the LV has been described. Right bundle branch blockade with late potentials (epsilon wave) and T-wave inversion in the precordial lead may be present on ECG. Ventricular arrhythmia and sudden death are common modes of presentation between the ages of 20 and 40 years, although occasionally heart failure is the presenting symptom.

TABLE 4 Clinical Risk Factors for Sudden Death in Hypertrophic Cardiomyopathy

Major Risk Factors

Cardiac arrest
Spontaneous sustained or nonsustained ventricular tachycardia
History of sudden cardiac death in first-degree relatives
Syncope
Left ventricular thickness ≥ 30 mm
Abnormal blood pressure response to exercise

Possible Risk Factors

Atrial fibrillation
Myocardial ischemia
Left ventricular outflow obstruction
High-risk mutations
Intense (competitive) physical exertion

Patients presenting with stable VT may respond to radio-frequency ablation and antiarrhythmic therapy, but the recurrence rates are high. Consequently, most patients will require ICD therapy. ICD is the first line of treatment for patients with prior cardiac arrest, inducible ventricular arrhythmias on electrophysiologic study, and unexplained syncope.

Sudden Death Associated with Abnormalities of the QT Interval

Congenital long QT (LQT) syndrome is commonly caused by inherited abnormalities of the potassium channel (e.g., LQT1 and LQT2) or of the sodium channel (e.g., LQT3) that result in abnormal cardiac repolarization. These patients carry a risk of developing torsades de pointes VT. Torsades de pointes can lead to syncope but is frequently self-limited. However, the arrhythmia can degenerate to ventricular fibrillation, and sudden death may be the initial manifestation.

The mortality rate is high in untreated patients (approximately 1% per year). Once syncopal episodes begin, the risk of death increases; in one study, 20% of patients had died within 1 year after a syncopal spell. However, ideal management of the congenital LQT syndrome remains controversial. β -Adrenergic blockers and left stellate ganglionectomy, at times in conjunction with cardiac pacing, have been shown to reduce symptoms and mortality. However, the response to beta blockers may vary based on the type of genetic mutations. Because most patients are children or teenagers at the time of diagnosis, there is concern about long-term therapy with implantable devices because of the need for generator changes, potential lead malfunction, and risk of infection. ICD therapy is currently reserved for high-risk patients identified by prior cardiac arrest, recurrent syncope, or VT while on β -blockers, QTc exceeding 500 msec, siblings with sudden death, and symptoms in the patient with LQT3 and possibly LQT2.

One of the major precipitants of torsades in the asymptomatic patient is iatrogenic effects. Numerous drugs have the potential to prolong the QT interval (Table 5). In addition, hypokalemia and hypomagnesemia can induce QT prolongation and torsades de pointes.

In patients without a recognized QT abnormality, drug-induced torsades is treated by discontinuation and avoidance of the offending drug. A number of risk factors have been recognized for drug-induced torsades. They include female gender, hypokalemia and hypomagnesemia, bradycardia, congestive heart failure, baseline QT prolongation, and high drug concentrations (with the exception of quinidine). Conversion of atrial fibrillation with rapid heart

TABLE 5 Drugs Known to Cause QT Prolongation and Torsades de Pointes

Common

Quinidine

Sotalol (Betapace)

Dofetilide (Tikosyn)

Ibutilide (Corvert)

rates to sinus rhythm in the presence of a QT-prolonging drug is a known risk for torsades because of the relative bradycardia interacting with QT prolongation. Administration of class III antiarrhythmic drugs such as sotalol, ibutilide (Corvert), and dofetilide used for conversion and prevention of atrial fibrillation should be commenced under telemetry monitoring. The potential for accumulation of antiarrhythmic drugs in the face of renal dysfunction (e.g., sotalol, dofetilide) should be recognized and dosing adjusted.

A familial form of the short QT syndrome associated with sudden death has been described. A family history of sudden death appears to confer a high risk of sudden arrhythmic death in these patients, warranting ICD therapy.

Brugada Syndrome

Brugada syndrome is characterized by ECG features of incomplete right bundle branch block, J-point elevation with ST-segment elevation in the right precordial leads, normal QT interval, and risk of ventricular fibrillation. The condition has been shown to be caused by an inherited abnormality of the sodium channel involving the same gene (*SCN5A*) that is responsible for LQT3. The clinical features share similarities with those of LQT3: relative inefficacy of β -blockade, high mortality in symptomatic patients, and sudden death occurring during rest or sleep. Diagnostic criteria are equivocal. ST-segment abnormalities may be transient and dynamic and tend to be augmented by administration of sodium channel blockers.

The general consensus is that symptomatic patients should be treated with an ICD. Asymptomatic patients with a malignant family history should also be considered for ICD therapy. As with the LQT syndromes, drugs have a potential for provoking arrhythmias; sodium channel blockers, including tricyclic antidepressants, have the potential for inducing ventricular arrhythmias and are best avoided in these patients.

Catecholaminergic Ventricular Tachycardia

Inherited defects in genes coding for handling of calcium by the sarcoplasmic reticulum result in ventricular arrhythmia triggered by exercise or emotional stress. The resting ECG is normal. Children are usually affected, but late onset of this condition has been recognized. An autosomal dominant form is caused by mutations in the gene coding for the cardiac ryanodine receptor. The autosomal recessive form is caused by mutation in the gene encoding for calsequestrin, a calcium-buffering protein in the sarcoplasmic reticulum. β -Blockers are the primary form of treatment. However, those patients who have had ventricular fibrillation or continue to have VT or syncope despite β -blocker therapy are considered to be at high risk and should receive ICD therapy.

Wolff-Parkinson-White Syndrome

In the Wolff-Parkinson-White (WPW) syndrome, atrial fibrillation can be conducted rapidly via an accessory pathway with a short refractory period, resulting in ventricular fibrillation and death. The risk of sudden death in patients with WPW syndrome is estimated to be less than 1 in every 1000 patient-years of follow-up. Although the risk is reportedly very low among asymptomatic patients, a potentially lethal arrhythmia can be the initial manifestation in a small number of patients (up to 10%).

The treatment of choice for WPW syndrome is catheter ablation of the accessory pathway; this is successful in 95% of patients. If ablation is ineffective or preferentially avoided because of a high risk of heart block, use of antiarrhythmic drugs such as flecainide or propafenone is an alternative. Rarely, amiodarone may be required to suppress arrhythmias including atrial fibrillation.

Management in the asymptomatic individual who exhibits the WPW pattern on ECG is controversial. Until recently, the consensus was that asymptomatic patients did not require invasive evaluation. Patients with intermittent ventricular preexcitation and those in whom the refractory period of the accessory pathway can be determined to be long are at low risk for sudden death. If a benign nature of the accessory pathway cannot be confirmed by noninvasive evaluation, intracardiac electrophysiologic testing

should be considered, with radiofrequency ablation if appropriate. A recent study showed that prophylactic ablation in asymptomatic patients younger than 35 years of age significantly reduced subsequent arrhythmias. Prophylactic ablation should also be considered for individuals in situations in which there is minimal tolerance of a potential for arrhythmias, such as in airline pilots.

Idiopathic Ventricular Fibrillation

A small number of patients who are resuscitated from sudden death episodes have no identifiable structural or electrical abnormalities. The term idiopathic ventricular fibrillation is applied to these patients. Clinically silent focal myocarditis, cardiomyopathy, or unrecognized ionic channel abnormalities may be responsible and may become apparent during subsequent follow-up. The current consensus is that drug therapy is ineffective, and ICD therapy is the safest and most effective secondary prevention strategy. An early repolarization pattern on ECG with >0.1 mV J-point elevation in the inferior and lateral leads has recently been associated with vulnerability to VF but the prognostic significance of this pattern in the general population is uncertain.

Adult Congenital Heart Disease

A number of congenital heart diseases can be corrected or palliated by surgery, and survival into adulthood is common. However, sudden arrhythmic cardiac death is a leading cause for late mortality. Unexplained syncope in such patients warrants evaluation by electrophysiologic testing. Intracardiac repair of tetralogy of Fallot has been accomplished since the mid-1950s, with favorable long-term outcome. Risk of late arrhythmic death increases with wide QRS duration, right ventricular dilatation from pulmonary regurgitation, and LV dysfunction. Ventricular arrhythmias or complete heart block may lead to sudden death. Syncope in such patients is an ominous symptom and should be investigated by electrophysiologic evaluation. Pulmonary valve replacement is known to reduce subsequent arrhythmia risk. Inducible VT and evidence for spontaneous ventricular arrhythmias should prompt the consideration of ICD therapy.

A rare condition called noncompaction, caused by an arrest in development of the LV, is known to be associated with sudden death. Prophylactic ICD implantation is recommended.

Neuromuscular Diseases

Some neuromuscular diseases are associated with conduction system disease and ventricular arrhythmias leading to sudden death. Myotonic dystrophy and Kearns-Sayre syndrome are situations in which prophylactic cardiac pacing at the first sign of conduction system disease can be lifesaving. If evidence of cardiac disease precedes the onset of respiratory muscle disease, the risk of cardiac arrhythmia is high, and ICD implantation is often necessary.

Bradyarrhythmia

Bradyarrhythmias resulting from atrioventricular blockade below the atrioventricular node is a cause for sudden death. Most cases of Mobitz type II block or complete heart block below the His bundle are caused by sclerodegenerative changes in the specialized conduction system. Occasionally, cardiac sarcoid or other infiltrative diseases may be responsible. Chagas' disease is a common cause in endemic areas in South America. A familial form of progressive heart block caused by a defect in the *SCN5A* gene has been identified in some families.

Symptomatic bradyarrhythmias and heart block due to disease in the His-Purkinje system are indications for permanent cardiac pacing. In the absence of the other structural heart disease, permanent cardiac pacing can restore longevity to match that of age-matched controls.

CONGENITAL HEART DISEASE

Method of

Richard A. Lange, MD; and Joaquin E. Cigarroa, MD

CURRENT DIAGNOSIS

- Examine blood pressures in arms and legs, pulse oximetry, mucous membranes and nail beds, respiratory rate, and peripheral pulses.
- In addition to listening over the precordium for heart sounds and murmurs, palpate for thrills and evidence of right or left chamber enlargement.
- Ancillary testing should include chest radiography, electrocardiography, and echocardiography.
- Consult a cardiologist if the physical examination or ancillary tests suggest congenital heart disease.

CURRENT THERAPY

- All congenital heart disease patients should have long-term follow-up for possible complications.
- Endocarditis prophylaxis is recommended for subjects with:
 - Unrepaired cyanotic congenital heart disease
 - Recently repaired congenital heart disease (<6 months after surgical or percutaneous repair)
 - Repaired congenital heart disease with residual defects
- Closure of defects with large left-to-right shunts (i.e., atrial septal defect, ventricular septal defect, atrioventricular canal, or patent ductus arteriosus) is recommended unless pulmonary vascular obstructive disease is far advanced.
- Patients with bicuspid aortic valves should be monitored for aortic root dilation.
- Pregnancy should be avoided in women with cyanotic congenital heart disease because of high maternal and fetal morbidity and mortality rates.

Congenital heart disease affects 0.4% to 0.9% of live births. Nowadays, most survive to adulthood because of improved diagnosis and treatment. Congenital cardiac defects can be categorized according to the presence or absence of cyanosis (due to right-to-left shunting) and the amount of pulmonary blood flow (Box 1).

Acyanotic Conditions

Atrial Septal Defect

Atrial septal defect (ASD) occurs in female patients two to three times as often as in male patients. Although most result from spontaneous genetic mutations, some are inherited.

The physiological consequences of ASD result from the shunting of blood from one atrium to the other; the direction and magnitude

BOX 1 Categorization of Congenital Heart Disease

Acyanotic Cardiac Defects

Increased pulmonary blood flow

- Atrial septal defect
- Ventricular septal defect
- Atrioventricular canal defect
- Patent ductus arteriosus

Normal pulmonary blood flow

- Aortic stenosis
- Pulmonic stenosis
- Aortic coarctation

Cyanotic Cardiac Defects

Normal pulmonary blood flow

- Ebstein's anomaly

Decreased pulmonary blood flow

- Tetralogy of Fallot
- Eisenmenger syndrome

of shunting are determined by the size of the defect and the relative compliances of the ventricles. A small defect (<0.5 cm in diameter) is associated with a small shunt and no hemodynamic sequelae, whereas a sizable defect (>2 cm in diameter) usually is associated with a large shunt and substantial hemodynamic consequences. In most patients with ASD, the right ventricle is more compliant than the left; as a result, left atrial blood is shunted to the right atrium, causing increased pulmonary blood flow and dilation of the atria, right ventricle, and pulmonary arteries (Figure 1). Eventually, if the right ventricle fails or its compliance declines, the magnitude of left-to-right shunting diminishes.

In a patient with a large ASD, a right ventricular or pulmonary arterial impulse may be palpable, and wide, fixed splitting of the second heart sound is present. A systolic ejection murmur, audible in the second left intercostal space, is caused by increased blood flow across the pulmonic valve; flow across the ASD itself does not produce a murmur.

Figure 1 Atrial septal defect. Blood from the pulmonary veins enters the left atrium, after which some of it crosses the atrial septal defect into the right atrium and ventricle (longer arrow). Thus left-to-right shunting occurs. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. First of two parts. *N Engl J Med* 2000;342:256–263.)

Because ASDs initially produce no symptoms or striking physical examination findings, they are often undetected for years. Small defects with minimal left-to-right shunting cause no symptoms or hemodynamic abnormalities, so they do not require closure. Even patients with moderate or large ASDs (characterized by a ratio of pulmonary to systemic blood flow of 1.5 or more) often have no symptoms until the third or fourth decade of life. Over the years, the increased blood volume flowing through the right heart chambers usually causes right ventricular dilation and failure. Obstructive pulmonary vascular disease (Eisenmenger syndrome) occurs uncommonly in adults with ASD.

The symptomatic patient with an ASD typically reports fatigue or dyspnea on exertion. Alternatively, the development of supra-ventricular tachyarrhythmias, right heart failure, paradoxical embolism, or recurrent pulmonary infections might prompt the patient to seek medical attention. Although an occasional patient with an unrepaired ASD survives to an advanced age, those with sizable shunts often die of right ventricular failure or arrhythmias in their 30s or 40s.

Echocardiography can reveal atrial and right ventricular dilation and identify the ASD's location. The sensitivity of echocardiography may be enhanced by injecting microbubbles in solution into a peripheral vein, after which the movement of some of them across the defect into the left atrium can be visualized.

An ASD with a pulmonary-to-systemic flow ratio of 1.5 or more should be closed (surgically or percutaneously) to prevent worsening right ventricular dysfunction. Prophylaxis against infective endocarditis is not recommended for patients with ASD (repaired or unrepaired) unless a concomitant valvular abnormality is present.

Ventricular Septal Defect

Ventricular septal defect (VSD) is the most common congenital cardiac abnormality, with similar incidence in boys and girls. Approximately 25% to 40% of them close spontaneously by 2 years of age.

The physiological consequences of a VSD are determined by the size of the defect and the relative resistances in the systemic and pulmonary vascular beds. A small defect causes little or no functional disturbance, because pulmonary blood flow is only minimally increased. In contrast, a large defect causes substantial left-to-right shunting, because systemic vascular resistance exceeds pulmonary vascular resistance (Figure 2). Over time, however, the pulmonary vascular resistance usually increases, and the magnitude of left-to-right shunting declines. Eventually, the pulmonary vascular resistance equals or exceeds the systemic resistance; the shunting of blood from left to right ceases; and right-to-left shunting begins (e.g., Eisenmenger physiology).

A small, muscular VSD can produce a high-frequency systolic ejection murmur that terminates before the end of systole (when the defect is occluded by contracting heart muscle). With a moderate or large VSD and substantial left-to-right shunting, a holosystolic murmur, loudest at the left sternal border, is audible and is usually accompanied by a palpable thrill. If pulmonary hypertension develops, the holosystolic murmur and thrill diminish in magnitude and eventually disappear as flow through the defect decreases.

Echocardiography is usually performed to confirm the presence and location of the VSD and to delineate the magnitude and direction of shunting. With catheterization, one can determine the magnitude of shunting and the pulmonary vascular resistance.

The natural history of VSD depends on the size of the defect and the pulmonary vascular resistance. Adults with small defects and normal pulmonary arterial pressure are generally asymptomatic, and pulmonary vascular disease is unlikely to develop. In contrast, patients with large defects who survive to adulthood usually have left ventricular failure or pulmonary hypertension (or both) with associated right ventricular failure.

Closure of VSDs (surgically or percutaneously) is recommended if the pulmonary vascular obstructive disease is not severe. Prophylaxis against infective endocarditis is recommended for patients with unrepaired VSD and those with a residual shunt despite surgical or percutaneous closure.

Figure 2 Ventricular septal defect. When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery (arrow), resulting in left-to-right shunting. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. First of two parts. *N Engl J Med* 2000;342:256–263.)

Atrioventricular Canal Defect

The endocardial cushions normally fuse to form the tricuspid and mitral valves, as well as the atrial and ventricular septa. Atrioventricular (AV) canal defects are caused by incomplete fusion of the endocardial cushions during embryonic development. They are the most common congenital cardiac abnormality in patients with Down syndrome. Such cushion defects include a spectrum of abnormalities, ranging from ASD with a cleft anterior mitral valve leaflet to a common AV canal defect in which a single AV valve in association with a large ASD and VSD is present.

A common AV canal defect permits substantial left-to-right shunting at both the atrial and ventricular levels, which leads to excessive pulmonary blood flow and resultant pulmonary congestion within months of birth. Eventually, the excessive pulmonary blood flow leads to irreversible pulmonary vascular obstruction (e.g., Eisenmenger physiology).

In the patient with an AV canal defect and left-to-right intracardiac shunting, the physical examination reveals a loud holosystolic murmur audible throughout the precordium. As pulmonary vascular resistance increases, the holosystolic murmur diminishes in intensity and duration, eventually disappearing as flow through the defect decreases.

AV canal defects require surgical repair if the magnitude of pulmonary vascular obstructive disease is not prohibitive. Although such patients might initially benefit from medical treatment with diuretics and afterload reduction, the onset of heart failure symptoms is generally the point at which surgery is considered. Prophylaxis against infective endocarditis is recommended for patients with repaired and unrepaired AV canal defects.

Patent Ductus Arteriosus

The ductus arteriosus connects the descending aorta (just distal to the left subclavian artery) and the left pulmonary artery. In the fetus, it permits pulmonary arterial blood to bypass the unexpanded lungs and to enter the descending aorta for oxygenation in the placenta. Although it normally closes spontaneously soon after birth, it fails to do so in some infants, so that continuous flow from the aorta to the pulmonary artery (i.e., left-to-right shunting) occurs (Figure 3). The incidence of patent ductus arteriosus (PDA) is increased in pregnancies complicated by persistent perinatal

Figure 3 Patent ductus arteriosus. Some of the blood from the aorta crosses the ductus arteriosus into the pulmonary artery (arrows), with resultant left-to-right shunting. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. First of two parts. *N Engl J Med* 2000;342:256–263.)

hypoxemia or maternal rubella infection as well as among infants born prematurely or at high altitude.

A patient with PDA and a moderate or large shunt has bounding peripheral arterial pulses and a widened pulse pressure. A continuous “machinery” murmur, audible in the second left intercostal space, begins shortly after the first heart sound, peaks in intensity at or immediately after the second heart sound (thereby obscuring it), and diminishes in intensity during diastole. If pulmonary vascular obstruction and hypertension develop, the murmur decreases in duration and intensity and eventually disappears.

With echocardiography, the PDA can usually be visualized, and Doppler studies demonstrate continuous flow in the pulmonary trunk. Catheterization and angiography allow one to quantify the magnitude of shunting and the pulmonary vascular resistance and to visualize the PDA.

The subject with a small PDA has no symptoms attributable to it and a normal life expectancy. However, it is associated with an elevated risk of infective endarteritis. A PDA of moderate size might cause no symptoms during infancy; during childhood or adulthood, fatigue, dyspnea, or palpitations can appear. Additionally, the PDA can become aneurysmal and calcified, with subsequent rupture. Larger shunts can precipitate left ventricular failure. Eventually, pulmonary vascular obstruction can develop; when the pulmonary vascular resistance equals or exceeds the systemic vascular resistance, the direction of shunting reverses.

One third of patients with an unrepaired moderate or large PDA die of heart failure, pulmonary hypertension, or endarteritis by 40 years of age, and two thirds die by 60 years of age. Because of the risk of endarteritis associated with unrepaired PDA (about 0.45% annually after the second decade of life) and the safety of surgical ligation (generally accomplished without cardiopulmonary bypass) or percutaneous closure, even a small PDA should be ligated surgically or occluded percutaneously. Once severe pulmonary vascular obstructive disease develops, ligation or closure is contraindicated.

Aortic Stenosis

A bicuspid aortic valve is found in 2% to 3% of the population and is four times more common in male than female patients. The bicuspid valve has a single fused commissure and an eccentrically oriented orifice. Although the deformed valve is not typically

stenotic at birth, it is subjected to abnormal hemodynamic stress, which can lead to leaflet thickening and calcification. In many patients, an abnormality of the ascending aortic media is present, predisposing the patient to aortic root dilation. Twenty percent of patients with a bicuspid aortic valve have an associated cardiovascular abnormality, such as PDA or aortic coarctation.

In patients with severe aortic stenosis (AS), the carotid upstroke is usually delayed and diminished. The aortic component of the second heart sound is diminished or absent. A systolic crescendo-decrescendo murmur is audible over the aortic area and often radiates to the neck. As the magnitude of AS worsens, the murmur peaks progressively later in systole.

In most patients, echocardiography with Doppler flow permits an assessment of the severity of AS and of left ventricular systolic function. Cardiac catheterization is performed to assess the severity of AS and to determine if concomitant coronary artery disease is present.

The symptoms of AS are angina pectoris, syncope or near syncope, and those of heart failure (dyspnea). Asymptomatic adults with AS have a normal life expectancy. Once symptoms appear, survival is limited. The median survival is 5 years once angina develops, 3 years once syncope occurs, and 2 years once symptoms of heart failure appear. Therefore patients with symptomatic AS should undergo valve replacement.

Pulmonic Stenosis

Pulmonic stenosis (PS) is the second most common congenital cardiac malformation (after VSD). Although typically an isolated abnormality, it can occur in association with VSD.

The patient with PS is usually asymptomatic, and the condition is identified by auscultation of a loud systolic murmur. When it is severe, dyspnea on exertion or fatigue can occur; less often, patients have retrosternal chest pain or syncope with exertion. Eventually, right ventricular failure can develop, with resultant peripheral edema and abdominal swelling.

In patients with moderate or severe PS, the second heart sound is widely split, with its pulmonic component soft and delayed. A crescendo-decrescendo systolic murmur that increases in intensity with inspiration is audible along the left sternal border. If the valve is pliable, an ejection click often precedes the murmur. On echocardiography, right ventricular hypertrophy is evident; the severity of PS can usually be assessed with measurement of Doppler flow.

Adults with mild PS are usually asymptomatic and do not require a corrective procedure. In contrast, patients with moderate or severe PS should undergo percutaneous balloon dilation.

Aortic Coarctation

Aortic coarctation typically consists of a diaphragm-like ridge extending into the aortic lumen just distal to the left subclavian artery (Figure 4), resulting in an elevated arterial pressure in both arms. Less commonly, the coarctation is located immediately proximal to the left subclavian artery, in which case a difference in arterial pressure is noted between the arms. Extensive collateral arterial circulation to the lower body through the internal thoracic, intercostal, subclavian, and scapular arteries often develops in patients with aortic coarctation. Aortic coarctation, which is two to five times as common in male as in female patients, can occur in conjunction with gonadal dysgenesis (e.g., Turner’s syndrome), bicuspid aortic valve, VSD, or PDA.

On physical examination, the arterial pressure is higher in the arms than in the legs, and the femoral arterial pulses are weak and delayed. A harsh systolic ejection murmur may be audible along the left sternal border and in the back, particularly over the coarctation. A systolic murmur, caused by flow through collateral vessels, may be heard in the back.

On chest radiography, increased collateral flow through the intercostal arteries causes notching of the posterior third through eighth ribs. The coarctation may be visible as an indentation of the aorta, and one may see prestenotic and poststenotic aortic dilation, producing the “reversed E” or “3” sign. Computed tomography, magnetic resonance imaging, and contrast aortography provide precise anatomic delineation of the coarctation’s location and length.

Figure 4 Coarctation of the aorta. Coarctation causes obstruction to blood flow in the descending thoracic aorta; the lower body is perfused by collateral vessels from the axillary and internal thoracic arteries through the intercostal arteries. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. First of two parts. *N Engl J Med* 2000;342:256–263.)

Most adults with aortic coarctation are asymptomatic. When symptoms are present, they are usually those of hypertension: headache, epistaxis, dizziness, and palpitations. Complications of aortic coarctation include hypertension, left ventricular failure, aortic dissection, premature coronary artery disease, infective endocarditis, and cerebrovascular accidents (due to rupture of an intracerebral aneurysm). Two thirds of patients older than 40 years who have uncorrected aortic coarctation have symptoms of heart failure. Three fourths die by the age of 50 years and 90% by the age of 60 years.

Surgical repair or intraluminal stenting should be considered for patients with a transcoarctation pressure gradient greater than 30 mm Hg, with the choice of procedure influenced by the age of the patient, anatomic considerations of the coarctation, and the presence of concomitant cardiac abnormalities. Persistent hypertension is common despite surgical or percutaneous intervention, and recurrent coarctation or aneurysm formation at the repair site may occur.

Cyanotic Conditions

Ebstein's Anomaly

With Ebstein's anomaly, the tricuspid valve's septal leaflet and often its posterior leaflet are displaced into the right ventricle, and the anterior leaflet is usually malformed and abnormally attached or adherent to the right ventricular free wall. As a result, a portion of the right ventricle is atrialized, in that it is located on the atrial side of the tricuspid valve, and the remaining functional right ventricle is small (Figure 5). The tricuspid valve is usually regurgitant, but it may be stenotic. Eighty percent of patients with Ebstein's anomaly have an interatrial communication (ASD or patent foramen ovale) through which right-to-left shunting of blood can occur.

The severity of the hemodynamic derangements in patients with Ebstein's anomaly depends on the magnitude of displacement and the functional status of the tricuspid valve leaflets. On the one extreme, patients with mild apical displacement of the tricuspid

Figure 5 Ebstein's anomaly. With Ebstein's anomaly, the tricuspid valve is displaced apically, a portion of the right ventricle is atrialized (i.e., located on the atrial side of the tricuspid valve), and the functional right ventricle is small. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. Second of two parts. *N Engl J Med* 2000;342:334–342.)

valve leaflets have normal valvular function; on the other extreme, those with severe leaflet displacement or abnormal anterior leaflet attachment, with resultant valvular dysfunction, have an elevated right atrial pressure and right-to-left shunting if an interatrial communication is present.

The clinical presentation of subjects with Ebstein's anomaly ranges from severe right heart failure in the neonate to the absence of symptoms in the adult in whom it is discovered incidentally. Older children with Ebstein's anomaly often come to medical attention because of an incidental murmur, whereas adolescents and adults may be identified because of a supraventricular arrhythmia.

On physical examination, the severity of cyanosis depends on the magnitude of right-to-left shunting. The first and second heart sounds are widely split, and a third or fourth heart sound is often present, resulting in triple or even quadruple heart sounds. A systolic murmur caused by tricuspid regurgitation is usually present at the left lower sternal border.

Echocardiography is used to assess the presence and magnitude of right atrial dilation, anatomic displacement and distortion of the tricuspid valve leaflets, and the severity of tricuspid regurgitation or stenosis.

Prophylaxis against infective endocarditis is recommended. Patients with symptomatic right heart failure should receive diuretics. Tricuspid valve repair or replacement in conjunction with closure of the interatrial communication is recommended for older patients with severe symptoms despite medical therapy and those with less severe symptoms who have cardiac enlargement.

Tetralogy of Fallot

Tetralogy of Fallot is characterized by a large VSD, an aorta that overrides both ventricles, obstruction to right ventricular outflow (subvalvular, valvular, supraventricular, or in the pulmonary arterial branches), and right ventricular hypertrophy (Figure 6).

Most patients with tetralogy of Fallot have substantial right-to-left shunting through the large VSD because of increased resistance to flow in the right ventricular outflow tract; the magnitude of right ventricular outflow tract obstruction determines the magnitude of

Figure 6 Tetralogy of Fallot. Tetralogy of Fallot is characterized by a large ventricular septal defect, obstruction of the right ventricular outflow tract, right ventricular hypertrophy, and an aorta that overrides the left and right ventricles. With right ventricular outflow tract obstruction, blood is shunted through the ventricular septal defect from right to left (arrow). (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. Second of two parts. N Engl J Med 2000;342:334–342.)

shunting. Because the resistance to flow across the right ventricular outflow tract is relatively fixed, changes in systemic vascular resistance affect the magnitude of right-to-left shunting: A decrease in systemic vascular resistance increases right-to-left shunting, whereas an increase in systemic resistance decreases it.

Patients with tetralogy of Fallot typically have cyanosis from birth or beginning in the first year of life. In childhood, they might have sudden hypoxic spells, characterized by tachypnea and hyperpnea, followed by worsening cyanosis and, in some cases, loss of consciousness, seizures, cerebrovascular accidents, and even death. Such spells do not occur in adolescents or adults. Without surgical intervention, most patients die in childhood.

On physical examination, patients with tetralogy of Fallot have cyanosis and digital clubbing. A right ventricular lift or tap is palpable. The second heart sound is single, because its pulmonic component is inaudible. A systolic ejection murmur, audible along the left sternal border, is caused by the obstruction to right ventricular outflow. The intensity and duration of the murmur are inversely related to the severity of right ventricular outflow obstruction; a soft, short murmur suggests that severe obstruction is present.

Laboratory examination reveals arterial oxygen desaturation and compensatory erythrocytosis. Echocardiography can be used to establish the diagnosis and to assess the location and severity of right ventricular outflow tract obstruction.

Complete surgical repair (closure of the VSD and relief of right ventricular outflow tract obstruction) is recommended to relieve symptoms and to improve survival; it should be performed when patients are very young. Those with tetralogy of Fallot (repaired or unrepaired) are at risk for endocarditis and therefore should receive antibiotic prophylaxis before dental or elective surgical procedures.

Patients with repaired tetralogy of Fallot require careful follow-up, because they can subsequently develop atrial or ventricular arrhythmias, pulmonic regurgitation, right ventricular dysfunction, or recurrent obstruction of the right ventricular outflow tract.

Figure 7 Eisenmenger syndrome. In response to substantial left-to-right shunting, morphologic alterations occur in the small pulmonary arteries and arterioles (inset), leading to pulmonary hypertension and the resultant reversal of the intracardiac shunt (arrow). In the small pulmonary arteries and arterioles, medial hypertrophy, intimal cellular proliferation, and fibrosis lead to narrowing or closure of the vessel lumina. With sustained pulmonary hypertension, extensive atherosclerosis and calcification often develop in the large pulmonary arteries. (Reprinted with permission from Brickner ME, Hillis LD, Lange RA: Congenital heart disease in adults. Second of two parts. N Engl J Med 2000;342:334–42.)

Eisenmenger Syndrome

With substantial left-to-right shunting, the pulmonary vasculature is exposed to increased blood flow under increased pressure, often resulting in pulmonary vascular obstructive disease. As the pulmonary vascular resistance approaches or exceeds systemic resistance, the shunt is reversed (right-to-left shunting develops), and cyanosis appears (Figure 7).

Most patients with Eisenmenger syndrome have impaired exercise tolerance and exertional dyspnea. Palpitations are common and most often result from atrial fibrillation or flutter. As erythrocytosis (due to arterial desaturation) develops, symptoms of hyperviscosity (visual disturbances, fatigue, headache, dizziness, and paresthesias) can appear. Patients with Eisenmenger syndrome can experience hemoptysis, bleeding complications, cerebrovascular accidents, brain abscess, syncope, and sudden death.

Eisenmenger syndrome patients typically have digital clubbing and cyanosis, a right parasternal heave (due to right ventricular hypertrophy), and a prominent pulmonic component of the second heart sound. The murmur caused by a VSD, PDA, or ASD disappears when Eisenmenger syndrome develops.

The chest x-ray reveals normal heart size, prominent central pulmonary arteries, and diminished vascular markings (pruning) of the peripheral vessels. On transthoracic echocardiography, evidence of right ventricular pressure overload and pulmonary hypertension is present. The underlying cardiac defect can usually be visualized, although shunting across the defect may be difficult to demonstrate by Doppler because of the low jet velocity.

Even though patients with Eisenmenger syndrome have severe pulmonary hypertension, they have a favorable long-term survival: 80% at 10 years after diagnosis, 77% at 15 years, and 42% at 25 years. Death is usually sudden, presumably caused by arrhythmias, but some patients die of heart failure, hemoptysis, brain abscess, or stroke.

Phlebotomy with isovolumic replacement should be performed in patients with moderate or severe symptoms of hyperviscosity; it should not be performed in asymptomatic or mildly symptomatic patients regardless of the hematocrit. Repeated phlebotomy can result in iron deficiency, which can worsen the symptoms of hyperviscosity, because iron-deficient erythrocytes are less deformable than iron-replete ones. Anticoagulants and antiplatelet agents should be avoided, because they exacerbate the hemorrhagic diathesis.

Patients with Eisenmenger syndrome should avoid intravascular volume depletion, high altitude, and the use of systemic vasodilators. Because of high maternal and fetal morbidity and mortality, pregnancy should be avoided. Patients with Eisenmenger syndrome who are undergoing noncardiac surgery require meticulous management of anesthesia, with attention to maintenance of systemic vascular resistance, minimization of blood loss and intravascular volume depletion, and prevention of iatrogenic paradoxical embolization. In preparation for noncardiac surgery, prophylactic phlebotomy (usually of 1 to 2 units of blood, with isovolumic replacement) is recommended for patients with a hematocrit greater than 65% to reduce the likelihood of perioperative hemorrhagic and thrombotic complications.

Lung transplantation with repair of the cardiac defect or combined heart–lung transplantation are options for patients with Eisenmenger syndrome who are deemed to have a poor prognosis (as reflected by the presence of syncope, refractory right heart failure, a high New York Heart Association [NYHA] functional class, or severe hypoxemia). Because of the somewhat limited success of transplantation and the reasonably good survival among patients treated medically, careful selection of patients for transplantation is imperative. Although pulmonary vasodilators improve exercise capacity, they have not been proved to improve survival.

CONGESTIVE HEART FAILURE

Method of

Bart L. Cox, MD; and Prasheda Bremjit, MD

CURRENT DIAGNOSIS

- Identify clinical symptoms and signs of heart failure.
- Determine left ventricular ejection fraction with echocardiography.
- Evaluate the potential causes of heart failure.

CURRENT THERAPY

- Beta blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blocking agents (ARB) and angiotensin

receptor-neprilysin inhibitors (ARNI) are vital to the management of patients with systolic heart failure.

- Diuretics should be used for the management of congestion and volume overload.
- Therapy for HFpEF (heart failure with preserved ejection fraction) entails management of volume overload with diuretics, treatment of atrial fibrillation, management of hypertension, and coronary revascularization if ischemia is believed to be contributing to symptoms.
- Referral for advanced therapies including left ventricular assist device and heart transplantation should be considered in those patients with refractory or stage D heart failure.

Heart Failure Definition

According to the 2013 heart failure guidelines, “heart failure is a clinical syndrome that occurs as a result of structural or functional impairment of either ventricular filling or ejection of blood.” It is a progressive condition that results from an index event that damages the heart muscle or impedes the myocardium from generating force. There are several compensatory mechanisms that are triggered after the decrease in pumping ability of the heart, including the adrenergic nervous system, renin angiotensin system, and the cytokine system. Although these systems may initially limit the damage that is already done, over the long term, activation of these systems leads to secondary end-stage organ damage and worse left ventricular (LV) remodeling. LV remodeling is the way in which the LV shape, size, and function change in response to various different mechanical and neurohormonal factors.

Epidemiology

Heart failure is reported to affect 2% to 3% of the US population. The lifetime risk for development of heart failure is 20% for Americans ≥ 40 years of age. The prevalence of heart failure increases with age. Patients with a primary diagnosis of heart failure make up >3 million physician visits per year, and the cost of heart failure is significant and was estimated to be \$39.2 billion in 2010. There are approximately 5.1 million patients with clinical heart failure in the United States, and the prevalence is increasing with time.

Heart Failure Classification Based on Left Ventricular Ejection Fraction (LVEF)

Heart failure with reduced ejection fraction (HFrEF): signs and symptoms of heart failure with LVEF $\leq 40\%$

Heart failure with preserved ejection fraction (HFpEF): signs and symptoms of heart failure with LVEF $\geq 50\%$

Heart failure with preserved ejection fraction, borderline (HFpEF, borderline): signs and symptoms of heart failure with LVEF 41% to 49%

Heart failure with preserved ejection fraction, improved (HFpEF, improved): signs and symptoms with current LVEF $\geq 40\%$ with a previous LVEF $<40\%$

Diagnosis

Three diagnostic schemes for diagnosing heart failure are the Framingham, Boston, and NHANES criteria. The Framingham criteria are one of the most widely used criteria for diagnosing heart failure. Table 1 lists the Framingham major and minor criteria for the diagnosis of heart failure, requiring either two major or one major and two minor criteria.

Functional Capacity

Exercise capacity can be subjectively assessed using the New York Heart Association (NYHA) functional classification and objectively by the 6-minute walk test or cardiopulmonary exercise testing (CPET). All three assessments have prognostic implications. Therapeutic decisions are dependent on NYHA classification. Advanced therapies, such as mechanical circulatory support and orthotopic

Phlebotomy with isovolumic replacement should be performed in patients with moderate or severe symptoms of hyperviscosity; it should not be performed in asymptomatic or mildly symptomatic patients regardless of the hematocrit. Repeated phlebotomy can result in iron deficiency, which can worsen the symptoms of hyperviscosity, because iron-deficient erythrocytes are less deformable than iron-replete ones. Anticoagulants and antiplatelet agents should be avoided, because they exacerbate the hemorrhagic diathesis.

Patients with Eisenmenger syndrome should avoid intravascular volume depletion, high altitude, and the use of systemic vasodilators. Because of high maternal and fetal morbidity and mortality, pregnancy should be avoided. Patients with Eisenmenger syndrome who are undergoing noncardiac surgery require meticulous management of anesthesia, with attention to maintenance of systemic vascular resistance, minimization of blood loss and intravascular volume depletion, and prevention of iatrogenic paradoxical embolization. In preparation for noncardiac surgery, prophylactic phlebotomy (usually of 1 to 2 units of blood, with isovolumic replacement) is recommended for patients with a hematocrit greater than 65% to reduce the likelihood of perioperative hemorrhagic and thrombotic complications.

Lung transplantation with repair of the cardiac defect or combined heart–lung transplantation are options for patients with Eisenmenger syndrome who are deemed to have a poor prognosis (as reflected by the presence of syncope, refractory right heart failure, a high New York Heart Association [NYHA] functional class, or severe hypoxemia). Because of the somewhat limited success of transplantation and the reasonably good survival among patients treated medically, careful selection of patients for transplantation is imperative. Although pulmonary vasodilators improve exercise capacity, they have not been proved to improve survival.

Heart failure with preserved ejection fraction, improved (HFpEF, improved): signs and symptoms with current LVEF $\geq 40\%$ with a previous LVEF $<40\%$

Diagnosis

Three diagnostic schemes for diagnosing heart failure are the Framingham, Boston, and NHANES criteria. The Framingham criteria are one of the most widely used criteria for diagnosing heart failure. Table 1 lists the Framingham major and minor criteria for the diagnosis of heart failure, requiring either two major or one major and two minor criteria.

Functional Capacity

Exercise capacity can be subjectively assessed using the New York Heart Association (NYHA) functional classification and objectively by the 6-minute walk test or cardiopulmonary exercise testing (CPET). All three assessments have prognostic implications. Therapeutic decisions are dependent on NYHA classification. Advanced therapies, such as mechanical circulatory support and orthotopic

TABLE 1 Criteria of CHF*

Major criteria

- Paroxysmal nocturnal dyspnea or orthopnea
- Neck-vein distention
- Rales
- Cardiomegaly
- Acute pulmonary edema
- S₃ gallop
- Increased venous pressure (≥ 16 cm of water)
- Circulation time ≥ 25 sec
- Hepatojugular reflux

Minor criteria

- Ankle edema
- Night cough
- Dyspnea on exertion
- Hepatomegaly
- Pleural effusion
- Vital capacity \downarrow 1/3 from maximum
- Tachycardia (rate of ≥ 120 /min)

Major or minor criterion

- Weight loss ≥ 4.5 kg in 5 days in response to treatment

*For establishing a definite diagnosis of congestive heart failure in this study, two major or one major and two minor criteria had to be present concurrently. From McKee PA, Castelli WP, McNamara PM, et al: The natural history of congestive heart failure: the Framingham Study. *N Engl J Med* 285:1441–1446, 1971.

heart transplantation, require both NYHA functional class and, if appropriate and possible, CPET.

Clinical Manifestations and Diagnosis

Heart failure is a clinical diagnosis. The clinical presentation of a heart failure patient is far more dependent on hemodynamics than on ventricular function. The cardinal symptoms are exercise intolerance due to dyspnea and fatigue and salt and water retention (congestion). Patients may be asymptomatic with severe LV dysfunction (e.g., LVEF 20%) or significantly symptomatic with preserved LVEF.

Elevated left-sided filling pressures give rise to pulmonary congestive symptoms (e.g., orthopnea, paroxysmal nocturnal dyspnea, dyspnea on exertion, nocturnal cough) and physical examination signs (e.g., left-sided S₃ gallop, mitral regurgitant murmur, loud P₂ in the presence of pulmonary hypertension, rales). Increased right-sided filling pressures are responsible for systemic congestive symptoms (e.g., anorexia, early satiety, constipation, right upper quadrant discomfort, weight gain, increased abdominal girth, shoes/jewelry/belt fitting tighter) and signs (e.g., jugular vein distention [JVD], abdominal jugular reflux, right-sided S₃, tricuspid regurgitant murmur, lower-extremity edema, anasarca, ascites, hepatomegaly). Evidence of reduced cardiac output includes a decreased arterial pulse pressure percentage ($<25\%$ – 30%), cold extremities, exercise intolerance, fatigue, hypotension in response to guideline-directed medical therapy (GDMT), cachexia, mental status changes, and inability to tolerate a regimen of GDMT that was once well tolerated. Decreased exercise capacity is multifactorial and includes deconditioning, pulmonary congestion, skeletal muscle abnormalities, reduced cardiac output, and arrhythmias.

Laboratory and Diagnostic Tests

As stated previously, heart failure is a clinical diagnosis and involves integrating clinical signs and symptoms, laboratory testing, as well as imaging to make the diagnosis. Useful laboratory tests include a complete blood count, urinalysis, complete metabolic count, fasting lipid profile, liver function tests, and thyroid-stimulating hormone. B-type natriuretic peptide (BNP) and N-terminal pro BNP (NT-proBNP) are heart failure-specific laboratory tests that can be very helpful in making the diagnosis of heart failure. BNP has 70% sensitivity and 99% specificity, whereas N-terminal proBNP has 99% sensitivity and 85% specificity. BNP is an activated form

of proBNP found in the both the atria and ventricles. In volume overload proBNP is released by the ventricles and breaks down into NT-proBNP and BNP. In addition to their utility in diagnosing heart failure, both NT-proBNP and BNP are helpful for prognosis of heart failure.

Twelve-lead electrocardiography (EKG) is an important test to perform in patients with suspected heart failure. Although it is usually abnormal in patients with heart failure, it can be normal in 10% of patients. Abnormalities that can be seen on EKG include ST- and T-wave changes, left ventricular hypertrophy, bundle branch block, and atrial fibrillation. The EKG can be a useful screening test, because a normal EKG is unlikely to be seen in patients with left-sided heart failure.

Echocardiography is vital in terms of noninvasive assessment of left ventricular function and should be performed in all patients with suspected heart failure. Patients who should undergo echocardiography include the following: patients with suspected heart failure, shortness of breath in the presence of a murmur, shortness of breath with atrial fibrillation, and patients at high risk of LV dysfunction.

Therapy

Diuretics

Diuretics are used for symptomatic improvement in patients with pulmonary and systemic congestion arising from elevated left- and right-sided filling pressures, respectively. In volume-overloaded patients, diuretics are used to optimize the filling pressures to eliminate all congestive signs and symptoms while avoiding signs and symptoms of hypovolemia. It is essential to evaluate for orthostatic hypotension in patients treated with diuretics. Additionally, close monitoring of electrolytes and renal function is indicated. Typically the loop diuretics furosemide (Lasix), bumetanide (Bumex), and torsemide (Demadex) are used. Rarely, thiazide and thiazide-like diuretics are effective at maintaining optimal filling pressures. Diuretic efficacy is evaluated by the physical examination demonstrating no edema, no JVD, no hepatomegaly, clear lungs, and absent symptoms of pulmonary congestion (orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, dyspnea on exertion) and systemic congestion (absence of anorexia, early satiety, abdominal discomfort due to hepatic and enteric congestion). A weight-based scale of diuretics, in which the daily diuretic dose is predicated on the morning weight, may be more effective than a fixed dose irrespective of weight change or increasing congestive signs and symptoms. Usually, a twice-daily regimen is effective for most patients, although a once-daily diuretic strategy can maintain optimal filling pressures in some patients. Adverse effects include hypokalemia, hypomagnesemia, orthostatic hypotension, renal insufficiency, electrolyte disturbance, ototoxicity, and gout.

Renin Angiotensin System Inhibitors

Angiotensin-Converting Enzyme Inhibitors (ACEI)

ACEI improve survival and decrease heart failure hospitalizations in HFrEF patients. The benefit appears to be generalized among all agents in this class. They are used in HFrEF irrespective of NYHA functional capacity. The initial doses are usually small and up-titrated every 2 weeks, with the goal of attaining those doses used in clinical trials demonstrating survival benefit and reducing HF hospitalization as recommended below. Approximately 20% of patients will have a nonproductive cough develop, because ACEI prevents the breakdown of bradykinin. When the cough is noted, it is imperative to distinguish the cough of pulmonary congestion (requiring diuretics) from the ACEI-induced cough (which may require the discontinuance of ACEI therapy). Additional adverse effects include hyperkalemia, renal insufficiency, hypotension, angioedema, rash, and dysgeusia. Starting doses of captopril (Capoten) are 6.25 mg 3 times daily (with a goal of 50 mg 3 times daily), enalapril (Vasotec) 2.5 mg twice daily (with a goal of 10 to 20 mg twice daily), and lisinopril (Prinivil) 2.5 to 5 mg once daily (with a goal of 20 to 40 mg daily). Other ACEI may be used for HFpEF as well. Once initiated, the renal function and potassium

should be evaluated 1 to 2 weeks later. Increasing the dose of ACEI has no significant effect on survival but clearly decreases hospitalizations.

Angiotensin Receptor Blockers (ARBs)

Notwithstanding the use of ACEI, angiotensin is synthesized via other pathways. The AT1 receptor is the site of the effects of angiotensin II, and thus antagonism of this receptor yields similar survival and hemodynamic benefits in HFrEF as ACEI. Three ARBs have been evaluated in HFrEF: losartan (Cozaar),¹ candesartan (Atacand), and valsartan (Diovan). Valsartan has also been evaluated in patients after myocardial infarction (MI) with LV dysfunction. One trial did not demonstrate superiority of losartan over captopril, and one trial demonstrated noninferiority to captopril. The combination of an ACEI and ARB may be useful in patients with a contraindication to mineralocorticoid receptor antagonists (MRA), and the simultaneous combination of the triad of ACEI, ARB, and MRA is contraindicated because of the risks of hyperkalemia. Use of an ARB is appropriate in those patients with an intolerable ACEI-induced cough. Although the incidence of angioedema is lower in ARBs than ACEI, crossover has been reported. ARBs and ACEI have similar physiological effects resulting in hypotension, renal insufficiency, and hyperkalemia. Like ACEI, the initiation of an ARB requires a follow-up evaluation of renal function and potassium 1 to 2 weeks afterward. The initial dose of losartan is 25 mg daily (with a goal of 150 g daily), valsartan is 40 to 80 mg twice daily (goal of 160 mg twice daily), and candesartan 4 to 8 mg daily (with a goal of 32 mg daily). Doses should be increased to those used in clinical trials demonstrating benefits unless contraindicated or not tolerated.

Angiotensin Receptor–Neprilysin Inhibitors (ARNI)

Neutral endopeptidases deactivate both vasoconstrictor and vasodilatory substances. Deactivation of angiotensin II is beneficial in HFrEF, but the same enzyme system also deactivates beneficial vasodilatory substances such as natriuretic peptides, substance P, and adrenomedullin. Sacubitril is such a neutral endopeptidase inhibitor. Combining sacubitril with an antagonist of the AT1 receptor (ARB) promotes the benefits of vasodilation by antagonizing the degradation of vasodilatory substances while inhibiting the effects of angiotensin II. The combination of valsartan–sacubitril (Entresto) has been evaluated for safety and efficacy and the sacubitril–valsartan combination is superior to ACEI in improving both cardiovascular (CV) and all-cause mortality while decreasing HF hospitalizations. Sacubitril, like ACEI, may precipitate angioedema, and thus the combination of an ACEI with sacubitril–valsartan is contraindicated; thus, the ACEI must be discontinued when an ARNI is initiated. At least 36 hours must elapse between the last dose of ACEI and the first dose of ARNI to avoid the increased risk of angioedema inherent to simultaneous ACEI and ARNI use. Because both sacubitril and valsartan have vasodilatory properties, the combination may precipitate hypotension. The diuretic dose may be decreased in response to hypotension. The initial dose of sacubitril–valsartan is 24/26 mg twice daily, and up-titration is recommended every 2 to 4 weeks to 49/51 mg twice daily, and finally to the maximum dose of 97/103 mg twice daily. Follow-up evaluation of renal function and potassium is appropriate 1 to 2 weeks after initiation and up-titration of the ARNI. Both cough and angioedema may be seen with ARNI use. Initiation is indicated in those patients who have been on a stable dose of ACEI or ARB for at least 4 weeks with an LVEF of $\leq 35\%$ to 40% and NYHA class II or III symptoms.

Beta Blockers

Three beta blockers that improve survival are carvedilol (Coreg), bisoprolol (Zebeta),¹ and metoprolol succinate (not metoprolol tartrate) (Loprol XL). They are to be initiated in euvoletic patients and are usually started simultaneously or shortly after initiation of

RAS antagonists. Up-titration may proceed by doubling the dose every 2 to 3 weeks once the current dose is well tolerated. The dose should be increased to attain those doses used in clinical trials demonstrated to prolong survival notwithstanding improvement in symptoms and functional class. The initial dose of carvedilol is 3.125 mg twice daily, 12.5 mg/d of metoprolol succinate, and 1.25 mg/d of bisoprolol. The goal dose of carvedilol is 25 mg twice daily (50 mg twice daily for patients weighing >85 kg), 200 mg once daily of metoprolol succinate, and 10 mg bisoprolol once daily. Evidence-based beta blockers are indicated in HFrEF patients irrespective of NYHA functional class.

Mineralocorticoid Receptor Antagonists (MRA)

Both spironolactone (Aldactone) and eplerenone (Inspra) improve survival and decrease HF hospitalizations in HFrEF patients with functional class NYHA 3–4 (spironolactone) and NYHA 2 (eplerenone) when added to a background of ACE and beta blockers. Contraindications include a serum creatinine >2.5 mg/dL in males, >2.0 mg/dL in females, potassium >5.0 , or eGFR <30 mL/min/1.73 m². The starting dose is spironolactone 12.5 to 25 mg/d and eplerenone 25 mg/d with up-titration to 25 to 50 mg/d of spironolactone and 50 mg/d of eplerenone if eGFR is ≥ 50 mL/min/1.73 m². Hyperkalemia is best avoided by monitoring potassium and renal function 3 and 7 days after initiation, then monthly $\times 3$, then every 3 months thereafter. A change in the dose of diuretic, ACEI, or ARB warrants repeating the monitoring cycle. Additionally, eplerenone improved survival in post-MI patients with LVEF $\leq 40\%$ with either heart failure at presentation or a history of diabetes mellitus (DM). For male patients, breast tenderness or gynecomastia with spironolactone conversion to eplerenone is appropriate. Use of MRA is appropriate in HFrEF patients with LVEF $\leq 35\%$ and NYHA functional class II to IV symptoms already treated with an RAS antagonist and beta blocker.

Hydralazine and Isosorbide Dinitrate Combination

Although not a substitute for GDMT RAS inhibitors, this combination demonstrated improved survival when compared with placebo and prazosin (Minipress)¹ and may be used in HFrEF patients in whom renal dysfunction, hypotension, or drug intolerance precludes the use of ACEI/ARB/ARNI. Additionally, this combination prolongs survival in self-described African American patients who remain with NYHA 3–4 symptoms despite the use of beta blockers, MRA, and RAS inhibitors. The starting dose of the combination (BiDil) is a single tablet of 37.5 mg hydralazine/20 mg isosorbide dinitrate 3 times daily and increased to 2 tablets 3 times daily.

Digoxin

Digoxin (Lanoxin) has been demonstrated to reduce heart failure hospitalizations in patients with HFrEF and NYHA 2 and 3 symptoms with no significant effect on mortality. It is indicated in HFrEF patients barring contraindications already treated with ACEI/ARB/ARNI, MRA, and beta blocker and who continue to have symptoms or in patients with severe symptoms while GDMT is being up-titrated. The plasma level should be kept between 0.5 to 0.9 ng/mL. There is no indication for a loading dose, and the usual dose is 0.125 mg daily.

Statins

Although statins have antiinflammatory effects and are indicated in primary and secondary prevention of coronary artery disease, there is no indication to use statins solely for heart failure in the absence of other established indications.

Omega-3 Polyunsaturated Fatty Acids (PUFA)

Omega-3 PUFA⁷ have salutary effects on inflammation and have been shown to reduce both all-cause mortality and all-cause

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

mortality and CV hospital admissions as per the GISSI-HF trial. Use of one gram daily of omega-3PUFA is reasonable in both HFrEF and HFpEF patients with NYHA class II-IV to reduce mortality and CV hospitalization.

Anticoagulation

Atrial fibrillation, whether paroxysmal, persistent, or permanent, in the presence of heart failure and one other risk factor for thromboembolism, warrants anticoagulation (INR 2-3 if warfarin is used). It is also reasonable to anticoagulate patients with atrial fibrillation and heart failure without other thromboembolic risks. Direct oral anticoagulants (apixaban [Eliquis], rivaroxaban [Xarelto], or dabigatran [Pradaxa]) may be used as a substitute for warfarin. Barring atrial fibrillation, a prior thromboembolic event, or a cardioembolic source, anticoagulation is not indicated in heart failure.

Devices

Implantable cardioverter-defibrillators (ICD) and cardiac resynchronization (also known as a biventricular pacemaker) therapy have both been demonstrated to improve survival in appropriate patients. In the setting of left bundle branch block, the right ventricle depolarizes first, precipitating desynchrony between septal activation and the left ventricular free wall. This desynchrony results in deterioration of both LV filling and contraction. Cardiac resynchronization therapy (CRT) involves implanting a pacemaker lead in the RV apex and a lead in the coronary sinus positioned near the base of the LV in the posterolateral branch of the coronary vein, allowing simultaneous activation of both ventricles. This pacemaker-induced synchronization may result in restoration of LV volumes, LVEF, and improved functional class and survival. The primary indication for CRT is a LVEF $\leq 35\%$, sinus rhythm with a LBBB (QRS width ≥ 150 msec), NYHA II-ambulatory IV symptoms despite optimized guideline directed therapy. ICD implantation is indicated for primary prevention in those patients with LVEF $< 35\%$, NYHA II and III symptoms despite optimized GDMT, at least 40 days after MI or 90 days after revascularization. In patients with a nonischemic cardiomyopathy, treatment with optimal doses of GDMT are required for 3 to 9 months with reassessment of LV function at that time, demonstrating LVEF $\leq 35\%$ with NYHA II-III symptoms.

Therapy for HFpEF

Neurohormonal antagonists that are effective in improving survival in patients with HFrEF have not been shown to confer the same benefit in HFpEF patients. The current paradigm of HFpEF is that it is the final common pathway of a systemic proinflammatory state associated with comorbidities leading to LV remodeling with resulting signs and symptoms. The clinical presentation of patients with HFpEF is remarkably similar to patients with HFrEF, and differentiation of HFpEF and HFrEF cannot be made by history and physical examination alone. There are currently no data supporting survival-prolonging agents in HFpEF. The treatment of HFpEF is thus aimed at symptomatic improvement by optimizing filling pressures while treating comorbidities. The recommended therapy for HFpEF is use of diuretics in the presence of congestion, control of hypertension per guidelines (e.g., reduce the SBP to < 130 mm Hg), treatment of atrial fibrillation in accordance with the latest guidelines, revascularization if ischemia is thought to be significantly contributing to heart failure symptoms, and the use of ACEI, ARB, or beta blockers as first-line therapy to control hypertension. Two agents that appear to decrease HF hospitalizations are candesartan (Atacand) and spironolactone (Aldactone).

Advanced Therapies

For patients with end-stage heart failure, two options exist. The first option is mechanical circulatory support such as a left ventricular assist device or orthotopic heart transplantation. Mechanical circulatory support may be used as a bridge to transplant (bridge to transplantation therapy) or to be used indefinitely in patients ineligible for transplantation (destination therapy). Mechanical

circulatory support may also serve as a temporary device in those patients with hemodynamic compromise due to a reversible cause while awaiting myocardial recovery. Transplantation is the final option for patients with end-stage heart failure who have failed to respond or deteriorated despite optimal GDMT, device/surgical/catheter-based therapies barring contraindications.

HEART BLOCK

Method of

Kelley P. Anderson, MD

CURRENT DIAGNOSIS

- Assess risk for heart block in the absence of symptoms or heart block on electrocardiogram (ECG).
- Review cardiac or systemic disorders associated with cardiac conduction disease (CCD), ECG pattern, family history, maternal antibodies, cardiac interventions, and surgery.
- Evaluate documented asystole or bradycardia due to heart block.
- Classify heart block: transient, recurrent, progressive, permanent.
- Grade signs and symptoms: none, mild, severe.
- Evaluate signs or symptoms of possible transient heart block with no documentation.
- Establish temporal pattern: recent versus remote onset, solitary versus recurrent, daily, weekly, monthly, yearly.
- Grade signs and symptoms: none, mild, severe.
- Document rhythm during symptoms: telemetry monitoring, Holter monitor, external loop recorder, implantable recorder.

CURRENT THERAPY

- Methods of heart rate support:
 - Immediate: intravenous catecholamines, atropine, or aminophylline¹; transcutaneous pacing
 - Short term: transvenous temporary pacing
 - Long term: permanent pacemakers
- Pacemaker configuration:
 - Number of leads: 1, 2, 3, 4
 - Lead locations: right atrial appendage, Bachman's bundle, right ventricular apex, outflow tract, left ventricle, coronary sinus
 - Programming to minimize ventricular pacing: manufacturer dependent

¹Not FDA approved for this indication.

mortality and CV hospital admissions as per the GISSI-HF trial. Use of one gram daily of omega-3PUFA is reasonable in both HFrEF and HFpEF patients with NYHA class II-IV to reduce mortality and CV hospitalization.

Anticoagulation

Atrial fibrillation, whether paroxysmal, persistent, or permanent, in the presence of heart failure and one other risk factor for thromboembolism, warrants anticoagulation (INR 2-3 if warfarin is used). ¹Not FDA approved for this indication.

Heart block refers to block or delay of electrical propagation between the atria and ventricles. It is a form of cardiac conduction disease (CCD), which applies more generally to disorders of electrical impulse formation or propagation anywhere along the cardiac conduction system from the sinus node to the ventricular myocardium. Heart block or CCD may present as a syndrome, as an electrocardiographic (ECG) pattern, or as a mechanism of serious signs and symptoms such as sudden death or syncope. Pacemaker therapy is an effective treatment, but it is associated with significant short- and long-term complications. This underscores the importance of recognizing preventable and reversible causes of heart block for accurate targeting of permanent pacing. Risk stratification of patients with heart block, assessment of the benefits and risks of the therapeutic options, and patient education and guidance are largely in the domain of heart rhythm specialists. However, heart block may be encountered unexpectedly in any patient during any clinical encounter. Furthermore, some patients may require evaluation in the absence of known cardiac disease because of increased risk of CCD, or increased risk of CCD in family members or future children. A basic understanding of heart block may be useful to initiate emergency treatment and to recognize patients who warrant further evaluation or specialist referral.

Epidemiology

The prevalence and incidence of heart block are difficult to establish because they are strongly dependent on the demographic and clinical characteristics of the population sample. The prevalence is higher among the elderly and those with cardiovascular disease. First-degree heart block, defined as prolongation of the PR interval >200 ms on ECG, occurs in the population setting with prevalence of 0.7% to 2% in the young and up to 14% in the elderly. Higher degrees of heart block can be expected to be less common but similarly associated with age and underlying cardiovascular disease. In a study of the Framingham population, the prevalence of first-degree heart block was 1.6% and was associated with an incidence of pacemaker implantation of 59 per 10,000 person-years in persons with a PR interval >200 ms compared to 6 per 10,000 person-years in persons with a PR interval <200 ms. Approximately 36% of the pacemakers were for high-grade atrioventricular (AV) block.

Risk Factors

Patients with genetic or acquired CCD and patients subject to trauma or surgical procedures that can damage the conduction system are at increased risk for developing symptomatic advanced heart block. In the Framingham population, subjects with first-degree AV block had an increased risk of mortality, atrial fibrillation, and pacemaker implantation. However, the vast majority with risk factors never develop symptomatic heart block and have not been shown to benefit from intense monitoring or prophylactic pacemaker placement. The few possible exceptions are discussed below.

Pathophysiology

The function of the cardiac conduction system is to initiate and coordinate cardiac contraction to circulate blood according to physiological needs. Electrical activation is initiated by pacemaker cells of the sinus node regulated by the autonomic nervous system. Unlike conduction in common electrical circuits in which electrons flow along a conductor according to the voltage gradient, electrical activity in cardiac cells propagates from segment to segment of the cell membrane in cardiac myocytes (myocardial cells) and in specialized cardiac conduction cells. Energy-requiring ion pumps maintain an electrochemical gradient across the insulating cell membrane. Electrical activity opens voltage-sensitive ion channels causing regenerative electrical activity as ions shift along their electrochemical gradient. Electrical activity in a single cell excites several adjacent cells via gap junctions. This cascade effect makes it possible for a single cell impulse to spread rapidly throughout the myocardium to enhance synchronous contraction. This also

provides a safety mechanism in that each myocardial cell can be activated by many electrical paths. In addition, specialized conduction cells exhibit automaticity (impulse formation). Although normally latent because normal activation inhibits spontaneous discharge, when the normal impulse is blocked, discharges from these subsidiary physiological pacemakers provide vital heart rate support.

Block of electrical activation can occur due to failure of any step in the process, for example, lack of metabolic energy, electrolyte imbalance, inflammatory disruption of the membrane, block of ion channels by drugs, or interference with gap junction function due to infiltration of fibrous tissue (Table 1). Because of the extensive redundancy and interconnectivity and because of the capacity to compensate for injury by electrical and anatomic remodeling, there may be extensive damage before signs or symptoms of heart block occur. Regions of the heart where there are fewer alternative paths for electrical activation, such as proximal portions of the His-Purkinje system where all conducting fibers are confined to a relatively small area, are more vulnerable to complete block. Subsidiary pacemakers sometimes fail to provide adequate rate support when heart block occurs because of preexisting injury. If the patient survives an episode of heart block, there is a possibility for recovery due to remodeling. However, remodeling can be maladaptive and result in an adverse long-term outcome by further conduction system damage, by left ventricular dysfunction, and by bradycardia-induced ventricular tachyarrhythmias (VTAs). The mechanisms of bradycardia-induced VTAs are not known, but bradyarrhythmias precipitate torsades de pointes, a specific form of VTA, in the presence of drugs that block potassium channels, electrolyte disturbances, certain genetic abnormalities of ion channel function, heart failure, and myocardial hypertrophy. A comprehensive list of drugs that may account for bradyarrhythmia-related ventricular arrhythmias is available at www.torsades.org.

Although there are many potential causes of heart block, the pathophysiology is not known for the vast majority of cases because there are no tests that allow detailed structural or functional examination in patients. By the time of death, morphologic examination may reveal only nonspecific changes such as fibrosis. Instead, most etiologies are inferred by history of recent or past exposures (e.g., trauma or radiation), concomitant disorders (e.g., muscular dystrophy, cardiac sarcoidosis), abnormal test results (e.g., Lyme disease) or family history (e.g., SCN5A sodium channel mutations) (Table 2). Because most etiologies cannot be verified, the clinician must remain open to alternative explanations and accept the likelihood of multiple contributors.

Some patients, usually young, otherwise healthy individuals, present with prolonged asystole due to heart block but have no other detectable abnormalities and have excellent outcomes in the absence of intervention beyond counseling. This suggests that autonomic influences alone can cause prolonged heart block and suppression of subsidiary pacemakers. It is not known whether

TABLE 1 Mechanisms of Conduction Disturbances (Examples)

- Prolonged refractory period (vagal activity, drugs, ischemia)
- Sarcolemmal ion gradient disturbances (hyperkalemia, hypokalemia)
- Sodium channel dysfunction (SCN5A mutations, sodium channel blocking drugs such as lidocaine, procainamide, flecainide [Tambacor], amiodarone [Cordarone], and imipramine [Tofranil])
- Calcium channel dysfunction (verapamil [Isoptin], diltiazem [Cardizem], mutations)
- Energy deprivation (ischemia, cyanide)
- Cell dysfunction (inflammation, barotrauma, thermal injury)
- Cell death (apoptosis, ischemic necrosis, inflammatory necrosis, surgical trauma, ablation)
- Congenital structural defects (endocardial cushion defects)
- Gap junction disturbances (fibrosis, edema, inflammation, genetic defects)
- Genetic defects (SCN5A and NKX2.5 mutations)

TABLE 2 Etiologies of Heart Block

- Frequently permanent or progressive (examples)
 - Alcohol septal ablation (acute, delayed)
 - Cardiomyopathies (hypertrophic, idiopathic, mitochondrial)
 - Catheter ablation (atrioventricular nodal reentry, accessory atrioventricular connections)
 - Congenital heart block (neonatal lupus)
 - Congenital heart disease (endocardial cushion defects)
 - Genetic disorders (SCN5A sodium channel mutations, gap junction gene mutations, fatty acid oxidation disorders, PRKAG2 mutations, LMNA gene mutations)
 - Hypertension
 - Idiopathic fibrosis and calcification (Lev's disease, Lenegre's disease)
 - Infectious disorders—destructive (endocarditis)
 - Infiltrative disorders (amyloidosis)
 - Myocardial infarction
 - Neuromyopathic disorders (myotonic dystrophy, Erb's dystrophy, peroneal muscular atrophy)
 - Noninfectious inflammatory disorders (HLA-B27-associated disorder, sarcoidosis)
 - Tumors (mesothelioma, metastatic cancer)
 - Valvular heart disease
- Frequently transient or reversible (examples)
 - Blunt trauma (baseball)
 - Cardiac surgery (valve replacement)
 - Cardiac transplant rejection
 - Central nervous system
 - Drugs (antiarrhythmics, digoxin [Lanoxin], edrophonium [Enlon])
 - Electrolyte disturbances (hyperkalemia)
 - Metabolic disturbances (hypothermia, hypothyroidism)
 - Increased vagal activity
 - Infectious disorders—nondestructive (Lyme disease)
 - Myocardial ischemia
 - Myocarditis (Chagas disease, giant cell myocarditis)
 - Rheumatic fever

such responses result from an abnormality or an exaggerated normal reflex. However, the identification of such patients is important because most can be managed without pacemakers.

Prevention

Prevention of heart block is a challenge for the future. Some instances can be prevented by treatment of inflammatory disorders that cause heart block, such as Lyme disease or cardiac sarcoid. Other individuals who should be identified are those with conditions that place them, their relatives, or their unborn children at risk for heart block. This includes patients and family members with genetic disorders associated with heart block. Genetic testing and counseling may be appropriate in some patients with a family history of CCD. Neonatal lupus syndrome is a rare disorder with a high mortality rate and risk of permanent complete heart block in survivors. This occurs in pregnant women with anti-Ro/SSA or anti-La/SSB antibodies. Some such women have autoimmune disorders such as systemic lupus erythematosus and Sjögren's syndrome, but many are symptom free. Members of this group may benefit from counseling and anticipatory evaluation and treatment of offspring. Although controversial, fetal monitoring of pregnant women with anti-Ro/SSA and/or anti-La/SSB antibodies and treatment of those with signs of fetal conduction system involvement have been recommended. It should be recognized that with current methods the vast majority of heart block events cannot be predicted or prevented, and the vast majority of persons with risk factors never develop symptomatic heart block.

Clinical Manifestations

Most of the symptoms experienced by patients with heart block are common and nonspecific, including syncope, lightheadedness, fatigue, and dyspnea. Asystole or profound bradycardia may cause syncope, death, or other manifestations of hypoperfusion. Rarely, first-degree AV block results in significant symptoms (e.g., fatigue,

palpitations, chest fullness), probably due to atrial contraction against a partially closed mitral valve.

Diagnosis

Because various arrhythmias and other cardiac and noncardiac disorders may be responsible for similar symptoms, it is important to identify the cause. An ECG recording of asystole or bradycardia due to heart block at the time of symptoms strongly suggests a causal relationship, but this is usually difficult to accomplish because the symptoms are often transient and infrequent. Absence of arrhythmias at the time of symptoms is also helpful in excluding heart block as the cause. Asymptomatic heart block is not infrequent. Cardiac conduction disturbances are classified by the pattern of ECG complexes. A normal 12-lead ECG lessens the probability of conduction disturbances due to structural changes but it does not eliminate the possibility of transient third-degree block due to reversible functional effects such as intense vagal activity or ischemia. Significant disease of the His bundle may be electrocardiographically silent, but more often concomitant distal disease is evident in the form of fascicular or bundle branch block or a nonspecific intraventricular conduction delay. In a patient with syncope, the presence of bifascicular block raises the possibility of transient third-degree block as the mechanism and of progression to permanent complete block. Most patients with conduction disorders are not symptomatic and do not progress to complete block. However, the combination of right bundle branch block (RBBB) and left posterior fascicle block has a greater tendency to progress to complete block than the more common RBBB and left anterior fascicle block. Nevertheless, conduction disturbances of the His-Purkinje system should not be assumed to be responsible for syncope or cardiac arrest because they are relatively common in patients with cardiovascular disorders that cause syncope or cardiac arrest due to other mechanisms. Conduction disturbances can cause dyssynchronous contraction and result in adverse remodeling. In addition, they can mask or mimic the ECG signs of myocardial infarction. Alternating bundle branch block refers to a changing ECG pattern in which both RBBB and left bundle branch block are observed or when the bifascicular block pattern switches between the anterior and posterior fascicle involvement. This pattern is considered a harbinger of complete block and warrants continuous monitoring and evaluation for permanent pacemaker implantation.

Differential Diagnosis

The challenge in second- and transient third-degree AV block is distinguishing between block in the AV node, which is often functional and reversible, and infranodal block, which often progresses to permanent complete heart block. ECG clues that block is in the AV node include normal QRS duration (<100 ms), type I (Wenckebach) pattern, PR prolongation before blocked impulses and PR shortening after pauses, occurrence during enhanced vagal activity (e.g., sleep), narrow QRS escape complexes, and no factors favoring infranodal block. ECG clues for infranodal block include prolonged QRS duration (≥ 120 ms), type II pattern, and escape QRS complexes broader than intrinsic complexes. Type II second degree AV block is almost always due to block in the His-Purkinje system. Other second-degree AV block ECG patterns have poor sensitivity and specificity for site of block.

Unsustained polymorphic ventricular tachycardia is an ominous sign in any context and may result from a variety of cardiac, metabolic, and autonomic abnormalities. However, in the presence of heart block it suggests that heart rate support may be necessary to prevent sustained VTA. QT prolongation and post-pause U-wave accentuation should be sought as other harbingers of bradycardia-related VTA.

The importance and value of ECG documentation of heart block cannot be overemphasized. ECGs are subject to artifact and may be misleading when standards for acquisition and analysis are not followed. Multiple tracings of suspicious events should be obtained in multiple leads when possible. A 12-lead simultaneous rhythm recording mode is available on most modern ECG machines

and should be used when continuous recordings are obtained to document arrhythmias.

Clinicians encounter heart block in three general contexts. For the patient with documented heart block, the clinician selects therapy based, in part, on whether the arrhythmia is permanent or likely to recur. There are currently no tests that provide direct information about the pathologic state of the AV conduction system. Instead, these outcomes must be inferred from functional assessment, that is, from the ECG or electrophysiological testing. Other indirect sources such as coronary angiography, magnetic resonance imaging, nuclear imaging, and myocardial biopsy, as well as a large number of specific laboratory tests, are often helpful for identifying disorders that may be causative or associated with heart block and that may affect the choice of treatment.

Another common context is the patient with symptoms for whom the objective is to verify or exclude heart block as the mechanism by correlating the cardiac rhythm with symptoms. Real-time monitoring (e.g., in-patient telemetry) is used for patients who might require immediate access to drugs or pacing devices to prevent or terminate asystole or bradycardia-dependent VTA. Holter monitoring is useful for patients who have very frequent events (at least 1 every 24 hours), and they are useful for capturing asymptomatic rhythm disturbances. External recorders are applied for a month or longer and are very helpful to associate rhythm abnormalities with symptoms and to rule out a rhythm disorder as the cause of symptoms in patients with at least one event per month. Patients with infrequent events may be candidates for implantable loop recorders, which monitor for greater than a year. Modern monitors will provide a permanent record of arrhythmias on activation by the patient or by a detection algorithm.

Electrophysiological studies allow precise measurements of AV node and His-Purkinje system function and can provide definitive information regarding the site of block if the conduction disturbance occurs during the study. Additional tests have been developed that “stress” the AV conduction system, including rapid atrial and ventricular pacing and administration of drugs such as procainamide and disopyramide (Norpace). The provocation of heart block is assumed to indicate a propensity for spontaneous AV block. Unfortunately, the sensitivity is low and a negative test does not imply a low risk of future episodes. Electrophysiological studies have the additional advantage of providing immediate test results, as well as providing the results of programmed stimulation for provocation of supraventricular and VTAs, which may be included in the differential diagnosis.

Therapy

The object of the evaluation and management for heart block is to prevent death and morbidity by (1) heart rate support in patients with poorly tolerated bradycardia; (2) monitoring and standby heart rate support in patients at high risk for asystole or severe bradycardia; (3) identifying and treating reversible causes of heart block; (4) identifying patients at high risk for sudden death, syncope, or recurrent symptoms; and (5) selecting and implanting the appropriate rate support system as soon as safety permits.

Advanced cardiac life-support guidelines apply to the patient who is unresponsive or severely compromised by heart block. However, heart block is rarely the primary problem. Therefore evaluation and treatment of other disorders should continue while efforts to obtain the appropriate heart rate are underway.

The initial evaluation should include a detailed history and physical examination and review of current and previous ECGs and rhythm strips to determine whether heart block is present or occurred in the past and whether there were symptoms or other evidence of hemodynamic compromise. Basic laboratory tests (electrolytes, metabolic panel, cardiac biomarkers, thyroid function, blood count, and coagulation studies) and basic imaging (chest x-ray and echocardiography) are usually appropriate. The patient should then be stratified for the appropriate level of care: (1) the unstable patient who requires ongoing evaluation and treatment in an intensive care setting, (2) the stable patient at high risk for asystole or complications who needs temporary transvenous pacing or other invasive

procedures, (3) the patient at moderate risk who requires continuous monitoring and standby noninvasive heart rate support measures, (4) the patient at low risk who requires rapid but not immediate access to heart rate support measures that hospital monitoring provides, and (5) the patient at low risk who can be evaluated and managed as an outpatient. Additional testing and procedures may be necessary to determine the etiology of heart block and to determine whether there is a significant risk of future adverse events.

Determination of the need for long-term heart rate support, as well as other issues that may affect implantable device selection (e.g., risk for VTAs), should be accomplished as soon as possible because the risk of complications and anxiety associated with temporary heart rate support measures increases over time. Major societies have developed guidelines for implantable rhythm management devices (<http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards.aspx>; <http://www.escardio.org/guidelines-surveys/esc-guidelines/Pages/GuidelinesList.aspx>). The reasons for the selected therapy, including the rationale for any deviation from established guidelines, should be documented and provided to the patient. This will reduce future confusion or misunderstanding about the original rationale for implantation that can affect management of patients with device complications, recalls (safety alerts), and those with a compelling need for device upgrade or explantation.

Patients with acute coronary syndromes require special consideration. The incidence of heart block in patients with myocardial infarction based on creatine phosphokinase as the marker of necrosis is approximately 10%. Although the incidence is probably lower using more sensitive markers such as troponin, heart block is still likely to be associated with increased in-hospital mortality due to larger infarct size. Tachycardia and high blood pressure increase myocardial oxygen consumption. Therefore overcorrection of heart rate and blood pressure should be avoided and ischemia should be relieved by reperfusion as soon as possible. Studies in the prethrombolytic era did not demonstrate a benefit in mortality with prophylactic temporary transvenous pacing, and complications were frequent. The risks of transvenous insertion may be higher in patients requiring administration of thrombolytics and other anticoagulants. Catheter-based revascularization methods should be given strong consideration because of established effectiveness, the possible avoidance of thrombolytic drugs, and because transvenous temporary pacing, if needed, is readily and safely accomplished during the procedure. Suggestions for standby temporary pacing (Table 3) should take into consideration the risks of transvenous pacing based on local circumstances (experience, fluoroscopic guidance, insertion site, use of anticoagulants, etc.). Most conduction disturbances associated with myocardial ischemia or infarction resolve quickly but can persist for days or weeks.

TABLE 3 Suggestions for Temporary Pacing in Acute Myocardial Infarction

- Transvenous pacing
 - Asystole or poorly tolerated bradycardia unresponsive to atropine or aminophylline
 - Persistent third-degree AV block
 - Alternating RBBB and LBBB, or RBBB and alternating LAFB and LPFB
 - Bifascicular block, new
 - Second-degree AV block (any type) and QRS >110 ms
 - Any indication listed below at time of cardiac catheterization if performed
- Standby transcutaneous pacing
 - Any indication listed above until transvenous pacing system inserted
 - Transient asystole or poorly tolerated bradycardia
 - Bifascicular block, uncertain time of onset, or old
 - Second-degree AV block (any type) and QRS <110 ms
 - New first-degree AV block

Abbreviations: AV = atrioventricular; LAFB, LPFB=left anterior, left posterior fascicle block; LBBB, RBBB=left, right bundle branch block.

The need for permanent pacemaker implantation as a consequence of myocardial infarction is rare, and prophylactic pacemaker implantation in high-risk subsets has not been shown to reduce mortality. Guidelines for temporary and permanent pacing in acute myocardial infarction have been published (<http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards.aspx>; <http://www.escardio.org/guidelines-surveys/esc-guidelines/Pages/GuidelinesList.aspx>).

Selection of the correct therapeutic approach balances the risks and benefits of therapy against the risks of heart block for both immediate and long-term management. Catecholamines (dobutamine, dopamine, epinephrine, isoproterenol [Isuprel]) are useful for emergency, temporary, and standby heart rate support. The standby mode is accomplished by a prepared infusion at the bedside. To avoid underdoses or overdoses at the time of sudden symptomatic heart block, the optimal dose can be established in advance by test doses starting at low infusion rates. Atropine (0.5 mg every 3–5 minutes, with a maximum dose of 0.04 mg/kg or total of 3 mg) may be useful for treatment or pretreatment of patients who develop heart block at the level of the AV node in the context of elevated vagal tone (e.g., in association with nausea or endotracheal tube suction). Atropine should be avoided in patients with infranodal AV block because prolonged asystole sometimes occurs due to more frequent His-Purkinje system depolarization from increased sinus rate. Vagal activity inhibits sympathetic activity; therefore, reduction of vagal tone by atropine disinhibits sympathetic activity and may account for the unpredictable effects of atropine on heart rate. Elevations in heart rate after atropine can persist for hours and cannot be readily reversed. Aminophylline¹ (2.5–6.3 mg/kg IV) is reported to reverse heart block resistant to atropine and epinephrine by antagonizing adenosine. Stimulation of β -adrenergic receptors increases sinus node and subsidiary pacemaker rates, AV node and His-Purkinje system conduction velocities, and myocardial contractility. The effective refractory period shortens in most tissue but this effect varies with dose and specific tissue type. Dobutamine¹ (2–40 μ g/kg/min) is a useful β -receptor agonist because it increases cardiac output and lowers filling pressures without excessive rise or fall of blood pressure. Dopamine¹ (2–20 μ g/kg/min IV) stimulates β_1 -adrenergic receptors and increases heart rate by enhancing impulse formation and conduction, as well as myocardial contractility. At higher doses (10–20 μ g/kg/min) dopamine causes vasoconstriction by α_1 -receptor stimulation. Isoproterenol (0.02–0.06 mg IV bolus, 0.5–10.0 μ g/min IV infusion) stimulates β_1 - and β_2 -adrenergic receptors and enhances vasodilation more than the other catecholamines. This can result in unwanted hypotension in some circumstances but it is also less likely to cause a reflex increase in vagal tone than drugs that cause vasoconstriction. Epinephrine (1 mg IV boluses for cardiac arrest, 0.2–1 mg subcutaneously, 0.5–10 μ g/min IV) stimulates both α - and β -adrenergic receptors. It is recommended for asystolic cardiac arrest in part because it increases myocardial and cerebral flow. However, the increase of systemic vascular resistance may be detrimental by augmenting metabolic acidosis and decreasing cardiac performance in patients with poor left ventricular function. The suggested dose ranges are broad because the response to β -adrenergic stimulants such as improved AV conduction varies widely and may be affected by β -adrenergic receptor down-regulation in patients with chronic elevations in sympathetic activity such as patients with long-standing heart failure.

Temporary pacing includes primarily transcutaneous and transvenous approaches. Transthoracic, transesophageal, and transgastric approaches are rarely used. Transcutaneous pacing provides noninvasive heart rate support, as well as immediate access to countershock, but it is often so painful that most patients require sedation. For these reasons its principal uses are for short-term pacing during cardiopulmonary resuscitation and standby pacing in patients at risk for bradyarrhythmias. Capture is not achieved in some patients. Therefore users should be ready to continue

mechanical cardiopulmonary support and seek alternative methods. If used in standby applications, ventricular capture should be verified in advance. Capture is often difficult to ascertain because transcutaneous stimuli cause large deflections on the ECG, and pectoral muscle stimulation can be confused with a pulse. Capture should be verified by careful ECG analysis at subthreshold and suprathreshold stimulus amplitudes and confirmed by appropriately timed femoral artery pulses, Korotkoff sounds, or arterial pressure waveforms.

Transvenous insertion of an electrode catheter is the method of choice for most patients who require temporary pacing. This approach is reliable and safe when performed by competent staff with strict aseptic technique, fluoroscopic guidance, and appropriate catheters. Small studies suggest that long-term (>5 days) temporary pacing can be accomplished with active-fixation permanent pacemaker leads attached to an external pulse generator (not approved by the US Food and Drug Administration [FDA]). Tunneling the lead may enhance stability and reduce the risk of infection.

Monitoring

Patients with high-grade or symptomatic heart block require close monitoring until the process is reversed by treatment or a pacemaker is implanted. All patients who receive pacemakers require lifelong follow-up by a trained team of physicians, nurses, and ancillary personnel using standard procedures guided by practice guidelines and manufacturer recommendations.

Complications

Catecholamines used to increase heart rate may precipitate tachyarrhythmias by electrophysiological effects mediated by adrenergic receptors or by myocardial ischemia, and they may worsen hemodynamic status. The adverse effects of catecholamines increase with duration of exposure. Ischemia and receptor-mediated electrophysiologic effects occur immediately after administration; changes in gene expression of ion channels begin as early as several hours; and long-term changes such as myocardial hypertrophy, apoptosis, and fibrosis occur within 24 hours and may progress over much longer periods. This suggests that the duration and dose of catecholamine infusions should be minimized. Complications of temporary transvenous pacing include inadequate pacing or sensing thresholds, vascular complications, pneumothorax, myocardial perforation, infection, and dislodgment. Permanent pacemakers are highly effective, safe, and cost-effective with few contraindications. Although the complications are rarely life threatening, they should be carefully considered and acknowledged. Septicemia or endocarditis has been reported in 0.5% of patients. In patients with pacemaker-related endocarditis, the in-hospital mortality rate is reported to be over 7% with a 20-month mortality rate over 25%. The rate of significant complications has been reported to be 3.5%. About 10% of pacemakers will become infected or develop some other type of failure that may require extraction. In a recent series the rate of major complications associated with extraction was 1.4%. There is a long-term continuous risk of infection, thrombosis, and erosion. In young persons there is a periodic need to replace generators and leads. Abandoned leads block venous access and extractions are associated with significant risks. Perhaps of greater consequence is the constant inconvenience of lifelong follow-up, electromagnetic interference, and false alarms from electronic surveillance devices, as well as exclusion from important procedures, such as magnetic resonance imaging of the thorax. Conventional pacing, that is, from the right ventricular apex, is now known to be detrimental and may cause adverse ventricular remodeling, atrial fibrillation, heart failure, and premature death. Although it has been shown that patients with reduced left ventricular function are at greater risk for adverse effects, it is not known how to identify other patients at risk. Strategies for reducing the adverse effects of conventional pacing are under study, and recommendations are evolving. Because the decision for pacemaker implantation includes selection of lead configuration, lead locations, and pacing mode, patient guidance and education are complex.

¹Not FDA approved for this indication.

Conclusions

Heart block remains a challenge because the cellular mechanisms responsible are poorly understood, prediction of symptomatic heart block (who and when) is unreliable, treatments that restore normal conduction do not exist for most conditions, and pacemaker therapy can have significant long-term adverse consequences. Fortunately, current devices and leads are much more reliable than in the past, and remote monitoring has enhanced early detection of problems and has substantially reduced the inconvenience of device monitoring. The newest generation of devices will allow many patients with pacemakers to safely undergo magnetic resonance imaging. Ongoing clinical trials will provide guidance in pacemaker configurations and programming that will minimize adverse effects. In the future, achievements in molecular biology will elucidate mechanisms and produce treatments that will replace artificial pacemakers to museum pieces.

HYPERTENSION

Method of

Timothy P. Graham, MD

CURRENT DIAGNOSIS

- Identification of individuals with hypertension is the first step.
- Screening should begin at 18 years of age for the general population.
- Adults with risk factors should be screened annually beginning at 40 years of age.
- Stage 1 hypertension is established at blood pressures of 140 mm Hg systolic and 90 mm Hg diastolic.
- Stage 2 hypertension is established at blood pressures of 160 mm Hg systolic and 100 mm Hg diastolic.
- Secondary causes of hypertension should be explored and identified to optimize treatment.

CURRENT THERAPY

- Initial interventions, regardless of stage, should include lifestyle modifications, including diet and exercise.
- Optimal pharmacologic therapy should be tailored to take into account age, race, and the presence or absence of chronic kidney disease.
- For individuals 60 years of age or older, consider initiation of pharmacotherapy when systolic blood pressure is 150 mm Hg and diastolic blood pressure is 90 mm Hg.
- For individuals younger than 60 years of age but at least 18 years of age, pharmacotherapy should be initiated when systolic blood pressure is 140 mm Hg and diastolic blood pressure is 90 mm Hg.

- First-line agents for nonblack individuals should include thiazide-type diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers.
- First-line agents for black individuals should include thiazide-type diuretics or calcium channel blockers.
- Individuals with chronic kidney disease should have therapy that includes angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.

Epidemiology

Hypertension is one of the most common conditions encountered in primary care offices. It affects 33% of individuals over the age of 20 in the United States, which translates to more than 78 million Americans. The most commonly affected individuals are black adults, making up 44% of the total.

In the pediatric population the prevalence of hypertension in the United States is between 1% and 5%, with obese children having the highest prevalence at 11%.

Risk Factors

Diet and Sodium Intake

Diet is a clear target for nonpharmacologic management of hypertension. Diets that are high in sodium and fat can put individuals at risk for suboptimal blood pressure control. Limiting sodium to less than 2400 mg per day confers some health benefit to individuals at risk for hypertension. Limiting even further to 1500 mg or less is more ideal and results in a significant improvement in both systolic and diastolic blood pressure typically. Additionally, putting limits on the consumption of sweets, red meat, and soda, as well as other sugar-sweetened beverages, can help weight reduction and overall health.

Sedentary Lifestyle and Obesity

Lack of physical activity is another important risk factor contributing to poor overall health and obesity. Current recommendations endorse engaging in at least 150 minutes of moderate-intensity activity per week. If patients are unable or unwilling to commit to that level of physical activity, then encouraging any physical activity is prudent, as it will convey at least some health benefit. Participation in physical activity results in absolute reduction in chronic comorbidities including hypertension, stroke, heart disease, diabetes, and metabolic syndrome. Resultant weight loss also results in significant improvement in blood pressure. It is noted that a weight loss of 22 pounds has the potential to reduce systolic blood pressure by 5 to 20 mm Hg.

For children and adolescents, elevated body mass index is the greatest risk factor for the development of hypertension.

Alcohol Intake

Although moderate alcohol intake is thought to actually reduce cardiovascular risk, heavier consumption is a risk factor for hypertension. Limiting alcohol intake to no more than two drinks per day (with "drink" defined as 12 oz. of beer, 5 oz. of wine, or 1 oz. of liquor) for men and no more than one drink per day for women (or lightweight men) is beneficial for overall health.

Smoking

Along with the myriad other reasons that smoking is not a good choice (cancer risk, chronic obstructive pulmonary disease, stroke, coronary artery disease, etc.), it is also a risk factor for hypertension. This is believed to be at least in part due to a resultant increase in sympathetic nervous system activity, which leads to an increase in myocardial oxygen demand. Additionally, smoking is the leading modifiable cause of death in the United States.

Sleep Apnea

Obstructive sleep apnea is a well-known secondary cause of and independent risk factor for hypertension. Statistically, at least half of individuals with sleep apnea also have hypertension.

Conclusions

Heart block remains a challenge because the cellular mechanisms responsible are poorly understood, prediction of symptomatic heart block (who and when) is unreliable, treatments that restore normal conduction do not exist for most conditions, and pacemaker therapy can have significant long-term adverse consequences. Fortunately, current devices and leads are much more reliable than in the past, and remote monitoring has enhanced early detection of problems and has substantially reduced the inconvenience of device monitoring. The newest generation of devices will allow many patients with pacemakers to safely undergo magnetic resonance imaging. Ongoing clinical trials will provide guidance in pacemaker configurations and programming that will minimize adverse effects. In the future, achievements in molecular biology will elucidate mechanisms and produce treatments that will replace artificial pacemakers to museum pieces.

- Optimal pharmacologic therapy should be tailored to take into account age, race, and the presence or absence of chronic kidney disease.
- For individuals 60 years of age or older, consider initiation of pharmacotherapy when systolic blood pressure is 150 mm Hg and diastolic blood pressure is 90 mm Hg.
- For individuals younger than 60 years of age but at least 18 years of age, pharmacotherapy should be initiated when systolic blood pressure is 140 mm Hg and diastolic blood pressure is 90 mm Hg.

- First-line agents for nonblack individuals should include thiazide-type diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers.
- First-line agents for black individuals should include thiazide-type diuretics or calcium channel blockers.
- Individuals with chronic kidney disease should have therapy that includes angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.

Epidemiology

Hypertension is one of the most common conditions encountered in primary care offices. It affects 33% of individuals over the age of 20 in the United States, which translates to more than 78 million Americans. The most commonly affected individuals are black adults, making up 44% of the total.

In the pediatric population the prevalence of hypertension in the United States is between 1% and 5%, with obese children having the highest prevalence at 11%.

Risk Factors

Diet and Sodium Intake

Diet is a clear target for nonpharmacologic management of hypertension. Diets that are high in sodium and fat can put individuals at risk for suboptimal blood pressure control. Limiting sodium to less than 2400 mg per day confers some health benefit to individuals at risk for hypertension. Limiting even further to 1500 mg or less is more ideal and results in a significant improvement in both systolic and diastolic blood pressure typically. Additionally, putting limits on the consumption of sweets, red meat, and soda, as well as other sugar-sweetened beverages, can help weight reduction and overall health.

Sedentary Lifestyle and Obesity

Lack of physical activity is another important risk factor contributing to poor overall health and obesity. Current recommendations endorse engaging in at least 150 minutes of moderate-intensity activity per week. If patients are unable or unwilling to commit to that level of physical activity, then encouraging any physical activity is prudent, as it will convey at least some health benefit. Participation in physical activity results in absolute reduction in chronic comorbidities including hypertension, stroke, heart disease, diabetes, and metabolic syndrome. Resultant weight loss also results in significant improvement in blood pressure. It is noted that a weight loss of 22 pounds has the potential to reduce systolic blood pressure by 5 to 20 mm Hg.

For children and adolescents, elevated body mass index is the greatest risk factor for the development of hypertension.

Alcohol Intake

Although moderate alcohol intake is thought to actually reduce cardiovascular risk, heavier consumption is a risk factor for hypertension. Limiting alcohol intake to no more than two drinks per day (with "drink" defined as 12 oz. of beer, 5 oz. of wine, or 1 oz. of liquor) for men and no more than one drink per day for women (or lightweight men) is beneficial for overall health.

Smoking

Along with the myriad other reasons that smoking is not a good choice (cancer risk, chronic obstructive pulmonary disease, stroke, coronary artery disease, etc.), it is also a risk factor for hypertension. This is believed to be at least in part due to a resultant increase in sympathetic nervous system activity, which leads to an increase in myocardial oxygen demand. Additionally, smoking is the leading modifiable cause of death in the United States.

Sleep Apnea

Obstructive sleep apnea is a well-known secondary cause of and independent risk factor for hypertension. Statistically, at least half of individuals with sleep apnea also have hypertension.

Age

Age is a nonmodifiable risk factor for cardiovascular disease. Risk is higher in men 55 years of age or older and women 65 years of age or older.

Gender

Gender is another nonmodifiable risk factor. Men are at greater risk for hypertension prior to age 45. After age 45 and until age 64, the risk for men and women is approximately equivalent. At 65 years of age or older, women have a higher hypertensive risk than men.

Race

Black individuals have a higher risk of hypertension than nonblack individuals. Statistics from 2015 demonstrated that in the general population aged 18 and older, approximately 34% of black individuals had hypertension, compared to approximately 24% of white individuals. Native Americans had a slightly higher risk than white individuals at 28%, and Asians had the lowest prevalence at approximately 20%. Hispanic/Latino individuals had a slightly lower prevalence than white individuals at 23%.

Family History

Family history is another nonmodifiable risk factor for cardiovascular disease. Individuals with family history of premature cardiovascular disease (men younger than 45 years of age and women younger than 55 years of age) are at increased risk themselves.

Pathophysiology

The pathophysiology of hypertension is a matter of debate. Essential hypertension, which is defined as hypertension without a clear secondary cause, makes up the majority of cases. Two primary mechanisms have been proposed for essential hypertension: neurogenic and renogenic (or nephrogenic). The neurogenic model suggests that hypertension is the result of a chronic increase in sympathetic nervous system activity. This is in contrast to the renogenic model, which attributes blood pressure increase to renal origins either through decreased renal blood flow or through renal parenchymal disease.

Prevention

Prevention of hypertension involves optimization of modifiable risk factors. Maintaining a healthy body weight, avoiding smoking, and moderating alcohol use are all key factors in minimizing risk. Additionally, engaging in regular, moderate-intensity cardiovascular exercise and eating a healthy diet without excessive sodium or fat can help significantly reduce cardiovascular risk and optimize health. These risk factors were discussed in detail in the preceding section.

Clinical Manifestations

Hypertension may have very few symptoms or none at all. If symptoms are present, they can include headaches, visual changes, dizziness, nausea, or chest pain. Oftentimes, however, there are no symptoms, and individuals can function for years without being diagnosed.

Dagnosis

Screening

As noted previously, hypertension is oftentimes an asymptomatic condition. As such, screening plays a critical role in early detection to minimize the end-organ damage that could result from untreated, long-standing hypertension. The U.S. Preventative Services Task Force (USPSTF) recommends screening for hypertension in adults who are 18 years or older (grade A recommendation). Adults 40 years and older and those with increased risk of hypertension should be screened annually. A review of the existing evidence demonstrated minimal harm in screening and a significant resultant benefit in the form of a reduction in cardiovascular events. Adults 18 to 39 years of age with no additional risk factors should be screened every 3 to 5 years. Recommended screening techniques include measurement of blood pressure in the office setting with either a manual or automatic cuff and ambulatory or

home blood pressure measurement. Office measurement should be done with the patient seated and after at least 5 minutes of the patient arriving in the room. Home measurement may be beneficial after the initial screening for confirmation purposes.

For children and adolescents, the USPSTF indicates that the current evidence is insufficient to assess the risk versus benefit of screening in asymptomatic individuals (grade I evidence). The predictive value of childhood hypertension for adult hypertension is modest, with a risk for false-positive readings.

Clinical Diagnosis

Hypertension is classified in two stages based on degree of elevation. In stage 1 hypertension, systolic blood pressure is greater than or equal to 140 mm Hg to 159 mm Hg and diastolic blood pressure is greater than or equal to 90 mm Hg to 99 mm Hg. Stage 2 hypertension is reached when systolic blood pressure is 160 mm Hg or greater and diastolic blood pressure is 100 mm Hg or greater. This classification is important as the approach to treatment differs for each category, as will be discussed later.

Primary (Essential) Hypertension

Primary hypertension encompasses persistent blood pressure elevation without a discernable cause (idiopathic or of unknown cause). The majority of cases of hypertension will have no discernable cause and fall into this category.

Secondary Hypertension

Secondary hypertension is persistent blood pressure elevation that is the result of some other underlying cause. About 10% of all cases of hypertension will fall into this category. If another cause can be identified, in many cases it may be correctable.

Looking for Secondary Causes

Identifying these underlying causes can be a challenge. Using a systematic method of investigating potential etiologies can simplify this process and improve the chances of identifying a source that with treatment can improve outcomes. One such approach is the *ABCDE* mnemonic. The A in this mnemonic stands for *accuracy* (making sure the reading is correct—such as checking the cuff for appropriate sizing and measurement technique—and repeating readings that are obtained on automatic cuffs manually), *apnea* (considering the presence of obstructive sleep apnea, which is a known contributor to difficult-to-control hypertension), and *aldosteronism* (investigating for the presence of primary hyperaldosteronism through urinary potassium excretion and an elevation in plasma aldosterone level to plasma renin activity). B stands for *bruits* (looking for renovascular sources of hypertension/renal artery stenosis, which would often present with renal bruits upon auscultation) and *bad kidneys* (hypertension resulting from renal parenchymal disease). C stands for *catecholamines* (elevation that can contribute to “white coat” hypertension, as well as overproduction with pheochromocytoma or associated with other conditions such as obstructive sleep apnea and acute stress reactions), *coarctation* (of the aorta), and *Cushing syndrome* (with mineralocorticoid effects of excess glucocorticoids in this setting). D represents both *drugs* (including nonsteroidal anti-inflammatory drugs, decongestants, estrogens, and immunosuppressive agents, as well as nicotine and alcohol) and *diet* (particularly excess sodium intake). The final letter in the mnemonic, E, stands for *erythropoietin* (high endogenous levels—such as in chronic obstructive pulmonary disease—or exogenous levels) and *endocrine disorders* (hypothyroidism or hyperparathyroidism). Utilizing a methodical and organized approach to considering potential causes of hypertension can assist with maximizing the chances of optimally controlling blood pressure.

Differential Diagnosis

The differential diagnosis for hypertension coincides with the array of potential secondary causes that were noted earlier (see Looking for Secondary Causes section). It is important to rule out potentially treatable secondary causes in the initial phases of hypertension management.

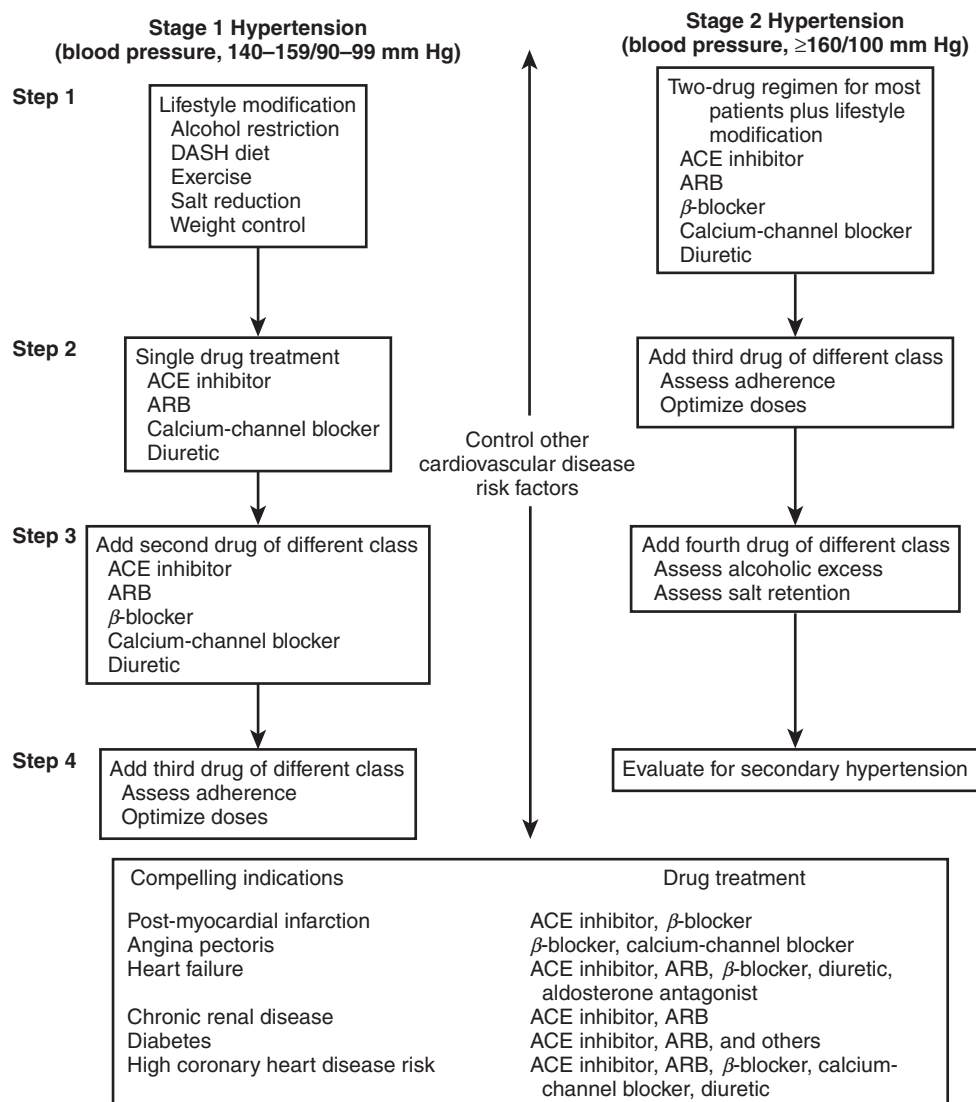

Figure 1 Algorithm for management of hypertension. *Abbreviations:* ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; DASH = dietary approaches to stop hypertension. Treatment Approaches

Approaching treatment of a patient with hypertension can be challenging. Many factors need to be considered when making these decisions, including reflection on patient age, race, gender, and comorbidities. Each of these factors can influence what the optimal treatment strategy might be. [Figure 1](#) provides a stepwise strategy to blood pressure management.

Initial treatment should always include lifestyle modification as discussed previously, and this modification needs to be continued throughout the remainder of any management strategies.

In 2014, the Eighth Joint National Committee (JNC 8) released new recommendations regarding the treatment of hypertension. These guidelines were a divergence from the prior JNC 7 recommendations, effectively loosening the goals and the levels at which treatment is initiated. The following is a summary of the eight treatment recommendations from JNC 8. (Please note that the strength of recommendation that is referenced corresponds to the following: grade A—strong recommendation based on evidence; grade B—moderate recommendation based on evidence; grade C—weak recommendation with moderate certainty of a small benefit; grade D—recommendation against; grade E—expert opinion with insufficient or conflicting evidence; grade N—no recommendation for or against).

Recommendation 1

Individuals aged 60 years or older in the general population should have pharmacologic treatment initiated at a systolic blood pressure level of 150 mm Hg or a diastolic blood pressure of 90 mm Hg with treatment goals of less than 150 mm Hg systolic and less than 90 mm Hg diastolic. (Strength of recommendation: grade A.)

An additional aspect of this recommendation is that if the pharmacologic treatment results in adequate blood pressure reduction and there is no adverse effect on quality of life or patient health, then the treatment can be continued without alteration. (Strength of recommendation: grade E.)

Recommendation 2

Individuals younger than 60 years in the general population should have pharmacologic treatment initiated at a diastolic blood pressure of 90 mm Hg with a treatment goal of less than 90 mm Hg. (Strength of recommendation: grade A for ages 30–59 years, grade E for ages 18–29 years.)

Recommendation 3

Individuals younger than 60 years in the general population should have pharmacologic treatment initiated at a systolic blood pressure of 140 mm Hg with a treatment goal of less than 140 mm Hg. (Strength of recommendation: grade E.)

Recommendation 4

Individuals aged 18 years or older with chronic kidney disease should have pharmacologic treatment initiated at a systolic blood pressure of 140 mm Hg or a diastolic blood pressure of 90 mm Hg with a treatment goal of less than 140 mm Hg systolic and less than 90 mm Hg diastolic. (Strength of recommendation: grade E.)

Recommendation 5

Individuals older than 18 years with diabetes should have pharmacologic treatment initiated at a systolic blood pressure of 140 mm Hg or a diastolic blood pressure of 90 mm Hg with a treatment goal of less than 140 mm Hg systolic and less than 90 mm Hg diastolic. (Strength of recommendation: grade E.)

Recommendation 6

The treatment of nonblack individuals in the general population (including those with diabetes) who require pharmacologic treatment should include thiazide-type diuretics, calcium channel blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers. (Strength of recommendation: grade B.)

Recommendation 7

The treatment of black individuals (including those with diabetes) should include thiazide-type diuretics or calcium channel blockers. (Strength of recommendation: grade B for general population, grade C for patients with diabetes.)

Recommendation 8

The treatment of individuals older than 18 years with chronic kidney disease should include, either as initial or add-on treatment, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers to improve renal outcomes. (Strength of recommendation: grade B.)

Recommendation 9

The goal of hypertension treatment is to reach and maintain blood pressure goals consistent with the previous recommendations. If goals are not reached within a month of starting pharmacologic treatment, the dose of the initial agent should be increased or a second agent from recommendation 6 should be added. Blood pressure should continue to be assessed until the goal blood pressure is achieved. If blood pressure goals are not achieved with two agents, a third agent should be added.

- Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) should not be used together.
- If necessary, other classes of agents can be used if more than three agents are required or if there are contraindications to the agents in recommendation 6.
- Referral to a hypertension specialist should be considered for patients whose blood pressure goals cannot be met with the previous strategies or who are more complicated. Strength of recommendation: grade E.

ACC/AHA 2017 Hypertension Guidelines

In late 2017, the American College of Cardiology and the American Heart Association released an updated Hypertension Guideline. This guideline provided a different approach to hypertension management, particularly around blood pressure goals. Hypertension stages have tighter cut points than under the JNC-8 Guidelines. Under the ACC/AHA Guidelines, normal blood pressure is defined as less than 120/80. Blood pressure is considered elevated when systolic blood pressure is in the 120–129 mm Hg range and when diastolic remains under 80 mm Hg. Stage 1 hypertension is defined as systolic blood pressure between 130 and 139 mm Hg and a diastolic blood pressure between 80 and 90 mm Hg. Stage 2 hypertension is defined as blood pressures that are greater than 140/90. This classification is a deviation from the set points within the JNC-8 recommendations.

Nonpharmacologic

For stage I hypertension (140–159/90–99 mm Hg), the first treatment step is to aggressively modify lifestyle. This includes targeting

TABLE 1 Effect of Lifestyle and Diet Modifications on Systolic Blood Pressure

MODIFICATION	AMOUNT	REDUCTION IN SBP (mm Hg)
Dietary sodium restriction	< 30–50 mmol/d	2–8
Moderation of daily alcohol intake	150–200 mL	2–4
Increased physical activity	30 min 3 × per wk	4–9
Reduction in body weight	10 kg or 22 lb	5–10
Adoption of DASH eating plan (high potassium)		8–14

Abbreviations: DASH = dietary approaches to stop hypertension; SBP = systolic blood pressure.

both diet and exercise. These nonpharmacologic strategies should continue even if pharmacologic treatment is found to be necessary. The relative effects of lifestyle modification on blood pressure reduction are noted in Table 1. ACC/AHA Guidelines also recommend lifestyle changes as initial intervention for individuals with stage 1 hypertension without other cardiovascular risk factors and with a ASCVD risk of less than 10%; however, as noted above, the definition of stage 1 hypertension is at a lower blood pressure level (130–139/80–90 mm Hg.)

Diet

Dietary modifications include salt restriction to a level of less than 2400 mg per day but ideally less than 1500 mg per day. Suggested dietary interventions also include the use of the DASH (dietary approaches to stop hypertension) framework. This nutritional framework includes recommendations such as increased consumption of fruits and vegetables, preferential use of complex carbohydrates, and consumption of low-fat dairy products. The DASH diet emphasizes the intake of whole grains, fish, poultry, legumes, nuts, and nontropical vegetable oils. This diet also endorses decreasing higher-fat foods.

Exercise

Current exercise recommendations suggest that engaging in a minimum of 150 minutes of moderate-intensity exercise on a weekly basis confers the greatest health benefits. Exercise at this level of intensity reduces the risk of multiple chronic conditions including cardiovascular disease and type 2 diabetes, as well as overall all-cause mortality.

Other Lifestyle Modifications

In addition to diet and exercise, other lifestyle interventions can optimize health. Smoking cessation is an important modifiable risk factor and is the single leading cause of preventable death in the United States. Smoking increases the risk of cardiovascular morbidity and mortality, including myocardial infarction.

Alcohol consumption is another important lifestyle modification that can have a significant impact on overall health. The effects of alcohol consumption, unlike smoking, depend on quantity. It has been shown that at moderate levels of consumption, alcohol can actually decrease blood pressure (defined as no more than two drinks per day for males and no more than one drink per day for females). However, when consumed in greater quantity, alcohol can increase blood pressure, contributing to hypertension. It is emphasized that alcohol consumption should not be promoted in nondrinkers simply for the purpose of decreasing blood pressure.

Stress reduction is another lifestyle change that can have effects on blood pressure control. The mechanism of this reduction is not clear, but it is hypothesized that it may be related to decreasing autonomic nervous system output. Studies suggest that activities such as transcendental meditation can lead to modest blood pressure reduction.

As such, inclusion of these activities in patient treatment plans may provide additional nonpharmacologic options.

Patients frequently ask about the utility of dietary supplements or other natural alternatives for blood pressure management. There is some evidence for select supplements in the management of hypertension, although such effects appear to be small. Examples of natural substances that may convey a small benefit include garlic and cocoa. Evidence is lacking for other agents including vitamin C, coenzyme Q10, omega-3 fatty acids, and magnesium.

Pharmacologic

In cases where hypertension is more significant or nonpharmacologic methods have failed to adequately reduce blood pressure, initiation of medications is indicated (Table 2). The selection of an agent or agents is based on a number of factors including race and comorbidities. As noted earlier, JNC 8 provides a stepwise, evidence-based approach to blood pressure management including recommended cut points where pharmacologic intervention is appropriate.

One of the points of emphasis of JNC 8 is that the point of intervention for individuals age 60 years or older is higher than those younger than that age. One should also balance the side effects or risks of medications with the benefits of intervention in this age group. The cut points for individuals with chronic kidney

disease and diabetes do not differ from the general population. The choice of agent according to JNC 8 does not differ based on the presence or absence of diabetes, but does differ based on race (see recommendations 6 and 7 earlier). Individuals with chronic kidney disease also should have an ACEI or an ARB included in their treatment regimen (either as a lone agent or an add-on). In practice, decisions will need to be tailored to individual patient needs and also should consider other factors including whether or not the patient is a reproductive-age female (as ACEIs and ARBs are contraindicated in pregnancy). This is where our role as family physicians becomes increasingly important—embracing our ability to look at the whole patient when making treatment decisions.

ACC/AHA recommends the initiation of pharmacologic therapy in adults with high cardiovascular risk or preexisting cardiovascular disease and stage 1 or greater hypertension. Patients with both diabetes and hypertension are also assumed to fall into the high-risk category. Again, the defined level of blood pressure classified as stage 1 hypertension under ACC/AHA (130–139/80–90 mmHg) is lower than the JNC8 criteria as noted above. ACC/AHA also emphasizes the need to balance comorbidities as well as preferences, life expectancy, and clinical judgment when making decisions regarding antihypertensive initiation and titration in older individuals (65 or older.)

TABLE 2 Antihypertensive Classes

Diuretics				
GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Chlorthalidone	Thalitone	Thiazide	Inhibits sodium and chloride reabsorption in distal tubules	25 mg by mouth once daily. May increase to maximum of 100 mg once daily.
Hydrochlorothiazide	Microzide	Thiazide	Inhibits sodium and chloride reabsorption in distal tubules	25 mg by mouth once daily to maximum of 50 mg in single or divided doses.
Metolazone	Zaroxolyn	Thiazide	Inhibits sodium and chloride reabsorption in distal tubules	5–20 mg by mouth once daily.
Triamterene/hydrochlorothiazide	Dyazide	Potassium-sparing/thiazide	Inhibits sodium reabsorption in the distal tubules	1–2 capsules by mouth once daily (37.5/25 mg capsules).
Furosemide	Lasix	Loop	Inhibits sodium and chloride reabsorption in the ascending loop of Henle	40 mg twice daily by mouth initially.
Torsemide	Demadex	Loop	Inhibits sodium and chloride reabsorption in the ascending loop of Henle	5 mg once daily by mouth initially. May increase to 10 mg once daily.

Angiotensin-Converting Enzyme (ACE) Inhibitors

Mechanism of action: Suppress the renin-angiotensin-aldosterone system

GENERIC	BRAND NAME	CLASSIFICATION	SPECIAL NOTE	DOSING
Fosinopril	Monopril	ACE inhibitor	Only ACE excreted by both renal and hepatic routes	5 mg by mouth daily initially. May be increased to 40 mg daily.
Captopril	Capoten	ACE inhibitor		Take 1 hour before meals. 25 mg two to three times daily by mouth. May increase to 50 mg two to three times daily by mouth. Maximum 450 mg per day.
Ramipril	Altace	ACE inhibitor		2.5 mg once daily by mouth. May increase to maximum of 20 mg once daily by mouth.
Enalapril	Vasotec	ACE inhibitor		5 mg daily by mouth initially. Typical dose range is 10–40 mg by mouth daily (may be divided doses).
Lisinopril	Prinivil, Zestril	ACE inhibitor		10 mg by mouth daily initial dose. Usual dose range 10–40 mg daily. Doses above 40 mg are not shown to have greater effect.
Quinapril	Accupril	ACE inhibitor		10–20 mg daily by mouth initial dose.

TABLE 2 Antihypertensive Classes—cont'd**Angiotensin II Receptor Blockers (ARBs)**

Mechanism of action: Block binding of angiotensin II to angiotensin I receptors with a resultant inhibition of angiotensin II–mediated vasoconstriction, sodium retention, and release of aldosterone

GENERIC	BRAND NAME	CLASSIFICATION	SPECIAL NOTE	DOSING
Losartan	Cozaar	ARB		50 mg daily by mouth initial dose (25 mg initial dose if also on diuretics). Titrate to a maximum of 100 mg daily.
Valsartan	Diovan	ARB	Adding a diuretic has greater effect than dose increases over 80 mg daily.	80–160 mg daily by mouth initial dose. May titrate to a maximum dose of 320 mg daily.
Olmesartan	Benicar	ARB		20 mg daily by mouth initial dose. May be titrated to 40 mg daily.
Eprosartan	Teveten	ARB		600 mg daily by mouth initial dose. May increase to 800 mg daily maximum dose. Usual range 400–800 mg daily.
Azilsartan	Edarbi	ARB		80 mg once daily by mouth. If on diuretics start at 40 mg once daily.

Beta-Blockers

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Atenolol	Tenormin	Beta-1 selective		50 mg once daily by mouth. May increase to maximum of 100 mg once daily
Metoprolol	Lopressor, Toprol XL	Beta-1 selective		Immediate-release formulations: 50–100 mg in single or divided doses. Maximum 450 mg per day. Extended-release formulations: 25–100 mg daily in a single dose. Maximum 400 mg per day.
Propranolol	Inderal LA, InnoPran XL	Beta-1 noncardioselective		Immediate-release formulations: 40 mg by mouth twice daily initial dose. Typical dosing 120–240 mg daily. Maximum 640 mg daily. Extended-release formulations: 80 mg once daily initial dose. Extended-release formulations: 80 mg once daily initial dose.
Bisoprolol	Zebeta	Beta-1 selective	More beta-1 specific than other beta-blockers	5 mg by mouth once daily initial dose (2.5 mg if patient has bronchospastic disease—i.e., asthma, chronic obstructive pulmonary disease). May titrate to a maximum of 20 mg per day.
Timolol		Beta-1 noncardioselective	CAUTION: Avoid abrupt discontinuation as may exacerbate ischemic heart disease.	10 mg twice daily by mouth initially. May titrate to a maximum of 60 mg per day in divided doses.
Labetalol	Trandate	Alpha and beta antagonist		100 mg twice daily by mouth (initial dose). May titrate in 2–3 days by 100 mg twice-daily increments. Maximum dose 2400 mg per day.

Calcium Channel Blockers

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Nifedipine, extended release	Adalat CC, Procardia XL	Dihydropyridine	Binds to L-type calcium channels in sinoatrial (SA) and atrioventricular (AV) node, as well as myocardium and vasculature	30–60 mg by mouth once daily. Maximum 120 mg daily.
Diltiazem, extended release	Cardizem CD, Cardizem LA, Cartia XT, Dilacor XR	Nondihydropyridine	Binds to L-type calcium channels in SA and AV node (primarily), as well as myocardium and vasculature	180–240 mg by mouth per day initially. May titrate after 14 days. Maintenance dosing typically 180–420 mg daily. Maximum dose 480 mg per day.
Verapamil	Calan, Calan SR	Nondihydropyridine	Binds to L-type calcium channels in SA and AV node, as well as myocardium and vasculature	80 mg by mouth every 8 hours initially. Usual dose range: 240–480 mg per day.
Amlodipine	Norvasc	Dihydropyridine	Binds to L-type calcium channels in smooth muscle (vasculature)	5 mg by mouth daily (initially). May increase by 2.5 mg every 1–2 weeks. Maximum 10 mg per day.

Continued

TABLE 2 Antihypertensive Classes—cont'd

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Felodipine	Plendil	Dihydropyridine	Binds to L-type calcium channels in smooth muscle (vasculature)	2.5–5 mg by mouth once daily initially. May increase to a maximum of 20 mg by mouth once daily.*

Aldosterone Antagonists

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Spironolactone	Aldactone	Selective aldosterone antagonist	Competes with aldosterone receptor sites. Reduces sodium reabsorption	25–100 mg by mouth once daily or divided twice daily (if being used for more than 2 weeks).
Eplerenone	Inspira	Selective aldosterone antagonist	Competes with aldosterone receptor sites. Reduces sodium reabsorption	50 mg by mouth once daily initially. May increase to twice daily if needed. (May cause hyperkalemia if doses exceed 100 mg per day.)

Alpha-2 Agonists

Mechanism of action: Stimulate presynaptic aldosterone receptors, decreasing sympathetic nervous activity

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Clonidine	Catapres, Catapres-TTS	Centrally acting alpha-2 agonist	Stimulation of alpha-2 adrenoreceptors, reducing sympathetic nervous system output	0.1 mg every 12 hours by mouth. Maximum 2.4 mg per 24 hours. (Usual dose range 0.1–0.2 mg every 12 hours.) If using transdermal formulation, 0.1 mg patch applied once every 7 days. May increase by 0.1 mg to maximum of 0.3 mg per week.
Methyldopa		Centrally acting alpha-2 agonist	Directly affects peripheral sympathetic nerves through stimulation of central alpha-adrenergic receptors	250 mg by mouth every 8–12 hours initially then can increase every 2 days. (Maximum 3 g per day.) Typical maintenance dose is 250–1000 mg by mouth divided every 6–12 hours.

Alpha Blockers

Mechanism of action: Selectively block postsynaptic alpha-1 adrenergic receptors

GENERIC	BRAND NAME	CLASSIFICATION	MECHANISM OF ACTION	DOSING
Prazosin	Minipress	Alpha-1 blocker	Competitive antagonist, reduces vascular resistance	1 mg by mouth every 8–12 hours (initial). Maintenance dose typically 6–15 mg divided every 6–8 hours. Typical maximum 20 mg per day in divided doses (although may increase to 40 mg per day in divided doses in some patients).
Terazosin	Hytrin		Selective competitive inhibitor, decreases vascular resistance	1 mg by mouth at bedtime (initial). Typical maintenance 1–5 mg daily or in divided dose every 12 hours. Maximum 20 mg per day.
Doxazosin	Cardura		Selective postsynaptic alpha-1 receptor inhibitor, vasodilation	1 mg once daily initially, titrate to maximum of 16 mg/day.

*Exceeds dosage recommended by the manufacturer.

Monitoring

Clinical practice guidelines vary in their recommendations regarding optimal monitoring. It is clear that monitoring in the early stage or during periods of treatment change should be more frequent than during times of stability, somewhere between monthly and every 6 weeks. Once the patient is stabilized, periodic monitoring can occur either every 3 to 6 months for everyone or in a more risk-stratified manner, with lower-risk patients being seen every 6 months and higher-risk patients every 3 months.

JNC 8 recommendations, as previously discussed, suggest that patients with hypertension be monitored on at least a monthly basis until goal blood pressure is achieved, with any necessary adjustments being made at these visits.

Complications

Hypertension is often referred to as “the silent killer.” This menacing name refers to the fact that this condition often presents without any discernable symptoms, which at times can make treatment

compliance challenging. One of the greatest concerns with uncontrolled hypertension is the risk of end-organ damage, which is far-reaching.

Uncontrolled hypertension can lead to serious complications including myocardial infarction, stroke, peripheral artery disease, retinopathy, and renal failure. Given that hypertension is at the same time the most common condition we treat as primary care physicians, the opportunities to circumvent these sources of morbidity and mortality present themselves on a daily basis.

HYPERTROPHIC CARDIOMYOPATHY

Method of

Sandeep Sangodkar, DO, MS

CURRENT DIAGNOSIS

- The cardiac outflow tract is obstructed.
- Left ventricular wall thickness is at least 15 mm.

CURRENT THERAPY

Asymptomatic Disease

- The patient should follow a strategy to modify risk factors for coronary artery disease.
- The patient should have periodic follow-up to assess symptoms and risk for sudden cardiac death.

Symptomatic Disease

- β -Blockade or calcium channel blockers are drugs of choice.
- Implantable defibrillator is indicated if the patient has risk factors for sudden cardiac death.
- Surgical myectomy may be undertaken in patients who do not respond to pharmacologic therapy.
- Alcohol ablation may be used in patients who are not candidates for surgery.

Definition

Many names, terms, and acronyms (more than 80) have been used to describe hypertrophic cardiomyopathy (HCM). Common names such as idiopathic hypertrophic subaortic stenosis and hypertrophic obstructive cardiomyopathy, popular in the literature in the 1960s and 1970s, imply that left ventricular outflow tract (LVOT) obstruction is a required component of the disease, whereas one third of patients have no obstruction at rest or exertion. The term *hypertrophic cardiomyopathy*, first used in 1979, encompasses both the obstructive and nonobstructive hemodynamic variants of this disease and is now considered the formal name.

Epidemiology

Although once thought of as a rare entity, HCM is now recognized as a common inherited cardiovascular disease. Epidemiologic studies from various parts of the world report a similar prevalence, thought of as 1 in 500 people, which occurs equally among sexes and ethnic groups. This may in fact be underreported because many people with HCM are not clinically diagnosed and achieve normal life expectancy without any HCM-related complications.

Risk Factors

HCM is caused by mutations in genes coding for thin and thick filament proteins of the sarcomere. These mutations are inherited in an autosomal dominant pattern with variable penetrance and expression. At least 11 genes have been identified as responsible for causing HCM, with 70% of successfully genotyped patients found to have mutations in the 2 most-common genes: beta-myosin heavy chain and myosin binding protein C. Over 1500 individual mutations have been identified, and this complicated genetic heterogeneity has limited the role of mutational analysis in predicting prognosis for individual patients.

Clinical Manifestations

Initial presentations of HCM are seen in every age range from pediatric to geriatric. On physical examination, the murmur of HCM classically is a systolic ejection murmur which increases in intensity with valsalva. Most patients with HCM have normal life expectancy without a need for major intervention. Clinically, most patients with HCM are asymptomatic or only mildly symptomatic, with the most common presenting complaints being dyspnea or chest pain. The most worrisome manifestation is sudden cardiac death due to ventricular tachyarrhythmia, seen more commonly in younger symptom-free patients. Heart failure is another manifestation of HCM with both preserved systolic function or with systolic dysfunction due to myocardial scarring. Heart failure in HCM rarely presents with symptoms of volume overload and more commonly symptoms of dyspnea and also chest pain thought secondary to microvascular ischemia. In addition, atrial fibrillation with an increased risk of thromboembolism is a concern for patients with HCM.

Pathogenesis

The pathophysiology of HCM stems from multiple abnormalities including LVOT obstruction, diastolic dysfunction, mitral regurgitation, cardiac ischemia, and arrhythmias. The peak instantaneous LV outflow gradient is important in determining treatment options. The obstruction was originally thought to be caused by a hypertrophied basal septum that caused ventricular outflow obstruction during systolic contraction. However, now evidence points toward mitral valve systolic anterior motion and mitral-septal contact (possibly as a result of hypertrophied or anomalous papillary muscles), resulting in drag force on the mitral leaflets, with displacement into the outflow tract. The increased LV systolic pressure in turn results in elevated diastolic pressures, prolonged diastole, mitral regurgitation, and, ultimately, decreased cardiac output.

Diagnosis

Clinically, HCM is defined as maximal LV wall thickness of at least 15 mm based on echocardiography. Patients with thickened LV wall and concurrent presence of HCM genetic substrates or family members with pathologic sarcomere mutations are considered to have genotype-positive–phenotype-negative HCM or subclinical HCM. A distinction between HCM and physiological LV hypertrophy from athletic conditioning must be recognized because the athletic hearts may demonstrate enlargement of the left ventricle, right ventricle, left atrium, and aorta and thickening of the septum. The likelihood of clinically significant HCM is determined by identification of sarcomere mutations, marked LV thickness (more than 25 mm), and LV outflow tract obstruction with systolic anterior motion and mitral-septal contact. Measurement of outflow gradients show a characteristic dynamic pattern that can be enhanced by loading conditions.

Over 1500 individual mutations have been identified, and this complicated genetic heterogeneity has limited the role of mutational analysis in predicting prognosis for individual patients.

Clinical Manifestations

Initial presentations of HCM are seen in every age range from pediatric to geriatric. On physical examination, the murmur of HCM classically is a systolic ejection murmur which increases in intensity with valsalva. Most patients with HCM have normal life expectancy without a need for major intervention. Clinically, most patients with HCM are asymptomatic or only mildly symptomatic, with the most common presenting complaints being dyspnea or chest pain. The most worrisome manifestation is sudden cardiac death due to ventricular tachyarrhythmia, seen more commonly in younger symptom-free patients. Heart failure is another manifestation of HCM with both preserved systolic function or with systolic dysfunction due to myocardial scarring. Heart failure in HCM rarely presents with symptoms of volume overload and more commonly symptoms of dyspnea and also chest pain thought secondary to microvascular ischemia. In addition, atrial fibrillation with an increased risk of thromboembolism is a concern for patients with HCM.

Pathogenesis

The pathophysiology of HCM stems from multiple abnormalities including LVOT obstruction, diastolic dysfunction, mitral regurgitation, cardiac ischemia, and arrhythmias. The peak instantaneous LV outflow gradient is important in determining treatment options. The obstruction was originally thought to be caused by a hypertrophied basal septum that caused ventricular outflow obstruction during systolic contraction. However, now evidence points toward mitral valve systolic anterior motion and mitral-septal contact (possibly as a result of hypertrophied or anomalous papillary muscles), resulting in drag force on the mitral leaflets, with displacement into the outflow tract. The increased LV systolic pressure in turn results in elevated diastolic pressures, prolonged diastole, mitral regurgitation, and, ultimately, decreased cardiac output.

Diagnosis

Clinically, HCM is defined as maximal LV wall thickness of at least 15 mm based on echocardiography. Patients with thickened LV wall and concurrent presence of HCM genetic substrates or family members with pathologic sarcomere mutations are considered to have genotype-positive–phenotype-negative HCM or subclinical HCM. A distinction between HCM and physiological LV hypertrophy from athletic conditioning must be recognized because the athletic hearts may demonstrate enlargement of the left ventricle, right ventricle, left atrium, and aorta and thickening of the septum. The likelihood of clinically significant HCM is determined by identification of sarcomere mutations, marked LV thickness (more than 25 mm), and LV outflow tract obstruction with systolic anterior motion and mitral-septal contact. Measurement of outflow gradients show a characteristic dynamic pattern that can be enhanced by loading conditions.

Imaging

The mainstay of imaging has been held by echocardiography. Transthoracic echocardiography is recommended in the initial evaluation of all patients with suspected HCM, as well as family members of those with diagnosed HCM. Transesophageal echocardiography is used for intraoperative guidance of surgical myectomy and intraprocedural guidance of alcohol septal ablation.

In recent years, Cardiac MRI has proven to be a useful modality in the diagnosis and treatment of HCM. Contrast enhanced CMR allows imaging of presumed myocardial fibrosis. Late gadolinium enhancement (LGE) is commonly seen in HCM and an amount >15% of left ventricular mass is associated with a higher risk of sudden cardiac death. An absence of LGE is associated with a lower risk of sudden cardiac death and can often provide reassurance.

Treatment

Asymptomatic Disease

Given that a large subset of HCM patients are symptom free and will achieve normal life expectancy, it is important to educate patients about the disease process, screening family members, and avoiding strenuous activity. Coronary artery disease has an impact on survival, and thus aggressive modification of risk factors contributing to atherosclerosis (diabetes, hyperlipidemia, obesity) are recommended. Low-intensity aerobic exercise is reasonable to allow the patient to maintain fitness. Adequate hydration and avoidance of situations leading to vasodilation are encouraged to minimize exacerbation of an existing LVOT obstruction.

Septal reduction therapy is not indicated in a symptom-free patient with any degree of obstruction.

Symptomatic Disease

Pharmacologic Management

β -Blockade is the mainstay of treatment due to negative inotropic effects, as well as antagonizing adrenergic tachycardia. β -Blocking agents are recommended for angina and dyspnea in adult patients with either obstructive or nonobstructive HCM. Disopyramide may be added to beta blockers for further symptom relief. Verapamil or diltiazem is recommended for those who do not respond or have contraindications to β -blockade. IV phenylephrine (Neo-Synephrine) is recommended for acute hypotension with obstructive HCM in those who do not respond to fluids.

Nifedipine (Procardia)¹ or other dihydropyridine calcium channel blocking agents are potentially harmful owing to their vasodilative effects, which can worsen LVOT obstruction. Digitalis is potentially harmful in patients without atrial fibrillation. Dopamine, dobutamine, norepinephrine (Levophed), and other positive inotropic agents may be harmful for the treatment of acute hypotension. Aldosterone inhibitors have not been shown to impede development or progression of myocardial fibrosis.

For the treatment of atrial fibrillation in HCM, it is recommended to keep a low threshold for initiating prophylactic anticoagulation due to the higher risk of thromboembolic stroke because the CHADS score is not validated in these patients.

Invasive Therapies

The major septal reduction therapies are surgical myectomy and alcohol ablation. Septal reduction therapy should not be performed in symptom-free adults.

Surgical septal myectomy is considered the most appropriate therapy for eligible patients unresponsive to optimal medical therapy. The most common procedure is a Morrow procedure in which a rectangular trough is created in the basal septum below the aortic valve which abolishes or reduces the LV outflow tract gradient. Eligible patients include those with severe dyspnea, chest pain, or exertional syncope that affect everyday activity despite with maximal medical therapy. Hemodynamic considerations that determine eligibility consist of an LVOT gradient of at least 50 mm Hg associated with septal hypertrophy and mitral valve

systolic anterior motion. Studies have shown that surgical myectomy reliably reverses heart failure symptoms as it permanently removes LV outflow tract obstruction and can reduce mitral regurgitation. In experienced centers, operative mortality is now less than 1%.

When surgery is contraindicated, alcohol septal ablation can benefit adult patients with HCM and LVOT obstruction. This percutaneous procedure involves injection of ethanol into a major septal perforator coronary artery, with the intent of inducing infarction of the basal septal wall near the anterior leaflet contact point. The effectiveness of alcohol septal ablation is not clear in patients with more than 30 mm of septal hypertrophy, and it should not be performed in patients with disease (coronary artery disease, mitral valve repair) that would need surgical correction regardless. Other downsides of septal ablation include an increased risk of complete heart block requiring pacemaker implantation and an undefined risk of arrhythmogenicity due to scar tissue.

Role of Implantable Devices

Determining which patients with HCM should receive an Implantable Cardiac Defibrillator is challenging given the unpredictability of the disease. ICDs are the only treatment that have proven to decrease mortality given their ability to reliably abort life-threatening arrhythmias. All patients with HCM need comprehensive sudden cardiac death risk stratification, with strong consideration of ICDs for primary prevention in those with personal history of ventricular fibrillation, sustained ventricular tachycardia, family history of sudden cardiac death, unexplained syncope, abnormal exercise blood pressure response, late gadolinium enhancement >15% of LV mass, massive LVH (>30 mm), or documented nonsustained ventricular tachycardia on Holter monitor. Implantable defibrillators are recommended for secondary prevention in patients with prior cardiac arrest, ventricular fibrillation, or hemodynamically significant VT. Device related complications and issues such as inappropriate shocks and multiple generator changes for those patients receiving a device at a young age must also be weighed when considering implantation of ICD. Subcutaneous defibrillators are still largely untested in the HCM population, and thus it is recommended to exercise caution when considering this modality.

Participation in Competitive Sports

HCM is a common cause of sudden death in young patients, including competitive athletes. It has been reported that 1/3 of deaths in US high school and college athletes are due to HCM, which occurs more often in males without previous suspicion of having HCM and African Americans. In the United States, there have been cardiovascular screening initiatives including history and physical in addition to 12 lead ECG with limited success. The American College of Cardiology and American Heart Association does not currently recommend a national mandatory cardiovascular screening program.

It is reasonable for HCM patients to engage in low-intensity competitive sports (golf, bowling) and recreational sporting activities. Participation in competitive sports is a modifiable risk factor, and it is recommended that HCM patients avoid participation in intense competitive sports regardless of age, sex, LVOT obstruction, prior septal reduction, or ICD.

Monitoring

The unpredictability of HCM disease makes regular surveillance a necessity. Patient age has been seen as a predictor of HCM-related events, with sudden death events more common in young patients. With a family history of sudden cardiac death, periodic screening by transthoracic echocardiography (every 12 to 18 months) is recommended in children by age 12 years (or younger if the child has signs of early puberty) or if there are plans for intense sports competition. Repeat transthoracic echocardiography is recommended for any change in clinical status or new cardiovascular event. As recognition of the genetic basis of this disease, genetic screening and counseling of all first-degree family members of patients with HCM is now recommended.

¹Not FDA approved for this indication.

Future Research

The perception of HCM has evolved from a rare and deadly condition to a more common and treatable disease. Effective use of ICDs for primary prevention and advances in surgical treatment of obstruction now allow most HCM patients to achieve normal life expectancy. Although significant progress has been made in elucidating the etiology and pathophysiology of HCM, there is much room for advancement. In addition, the relationship between genetics and environmental influences as well as the management of family members of genotype positive–phenotype negative patients is still unclear. Although rapid genetic testing to identify those at risk has become more widespread, further understanding of pathogenic mutations is needed. Furthermore, advancement in technology will hopefully lead to therapies that can specifically target these pathways.

INFECTIVE ENDOCARDITIS

Method of

Andrew Wang, MD

CURRENT DIAGNOSIS

- Infective endocarditis (IE) should be considered as a diagnosis in the setting of fever and heart murmur.
- Health care–associated interventions and resulting infections are an increasingly noted cause of IE, changing the epidemiology of this disease.
- Blood cultures show growth in approximately 90% of cases, and multiple sets should be obtained before initiating antibiotics to improve diagnostic yield.
- Echocardiography, particularly transesophageal echocardiography, improves diagnostic sensitivity for infective endocarditis as well as its complications (e.g., intracardiac abscess, fistula).
- The diagnosis of complications, including heart failure, embolic events, and abscess, requires close surveillance, particularly during the first week of therapy, and has adverse prognostic implications.

CURRENT THERAPY

- Because of changes in the epidemiology of infective endocarditis (IE), empiric antibiotic therapy for *Staphylococcus aureus* should be considered before results of blood cultures are available.
- Prompt initiation of antibiotic therapy is important, because the rate of complications such as embolization decreases rapidly within several days.
- Multidisciplinary care for the patient with IE should include evaluation by specialists in infectious diseases, cardiology, and cardiothoracic surgery, especially in cases of complicated IE.

- Surgery for IE has not been studied in randomized, controlled trials compared with medical therapy alone. Surgery should be considered for IE complicated by heart failure, embolism, intracardiac abscess, or persistent bacteremia.
- Although stroke due to embolism is not uncommon in IE, data do not suggest a benefit in delaying cardiac surgery after cerebral infarction if surgery is otherwise indicated.

Definition

Infective endocarditis (IE) is a microbial infection of the valves or endocardium of the heart.

Epidemiology and Risk Factors

The incidence of IE varies regionally from 2.6 per 100,000 population reported in France to 11.6 per 100,000 population in urban areas of the United States. This range of incidence has been attributed to differences in predisposing cardiac conditions or risk factors, such as use of injection drugs. The incidence of IE is also affected by age and sex. The incidence of native valve IE increases with age and exceeds 30 per 100,000 after 30 years of age. The average age of the patient with IE has increased over time, likely related to the decreased prevalence of rheumatic heart disease and increased prevalence of degenerative valvular disease in the aging population. IE is more commonly diagnosed in men, with studies showing male-to-female ratios as high as 9:1.

In earlier eras, streptococcal species were the predominant cause of native valve IE. However, changes in the delivery of health care, with increasing exposure to invasive procedures and devices, and the changing demographics of patients and their risk factors for IE have led to major changes in the microbiologic causes of endocarditis. There is an increasing incidence of health care–associated IE, including nosocomial infection and infection related to ambulatory care, which accounts for approximately 25% of IE cases. For example, in one large multinational study, the International Collaboration on Endocarditis (ICE) registry ($N = 2781$ patients with definite native or prosthetic endocarditis), 31% of cases were attributable to *Staphylococcus aureus*, 17% to viridans streptococci, 11% to enterococci, 10% to coagulase-negative staphylococci, 12% to other streptococcal species, 2% to the HACEK (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella* spp.) group, 2% to non-HACEK Gram-negative bacteria, and 2% to fungi. Among those with *S. aureus* endocarditis, health care–associated infection accounted for 39% of cases.

Predisposing cardiac conditions to the development of IE include degenerative valve disease (in approximately 40% of cases of mitral and 25% of aortic valve IE), presence of prosthetic valve, injection drug use, and rheumatic heart disease.

Pathophysiology

A preexisting valvular or endocardial condition, such as mitral valve prolapse with regurgitation, degenerative aortic valve disease (including bicuspid aortic valve), or congenital heart disease, is a major host factor related to development of IE. Endothelial damage and denudation of the endothelium exposes the underlying basement membrane and fosters platelet and fibrin deposition, a process that occurs spontaneously in persons with valvular heart disease. These deposits are called *nonbacterial thrombotic endocarditis* and form the nidus for vegetation to begin in the setting of bacteremia. The classic lesion of IE, the vegetation, is made up of fibrin, platelets, inflammatory cells, and microorganisms adherent to the endothelium of the heart.

The degree of mechanical stress exerted on the valve might contribute to endothelial denudation and the location of vegetation formation, with left-sided IE more common than right-sided IE. Endocarditis involving the nonvalvular endocardium of the heart similarly occurs at sites of endothelial damage due to mechanical stress, such as the left ventricular outflow tract in patients with hypertrophic obstructive cardiomyopathy and congenital heart defects (ventricular septal defects and patent ductus arteriosus).

Future Research

The perception of HCM has evolved from a rare and deadly condition to a more common and treatable disease. Effective use of ICDs for primary prevention and advances in surgical treatment of obstruction now allow most HCM patients to achieve normal life expectancy. Although significant progress has been made in elucidating the etiology and pathophysiology of HCM, there is much room for advancement. In addition, the relationship between genetics and environmental influences as well as the management of family members of genotype positive–phenotype negative patients is still unclear. Although rapid genetic testing to identify those at risk has become more widespread, further understanding of pathogenic mutations is needed. Furthermore, advancement in technology will hopefully lead to therapies that can specifically target these pathways.

IE is more commonly diagnosed in men, with studies showing male-to-female ratios as high as 9:1.

In earlier eras, streptococcal species were the predominant cause of native valve IE. However, changes in the delivery of health care, with increasing exposure to invasive procedures and devices, and the changing demographics of patients and their risk factors for IE have led to major changes in the microbiologic causes of endocarditis. There is an increasing incidence of health care–associated IE, including nosocomial infection and infection related to ambulatory care, which accounts for approximately 25% of IE cases. For example, in one large multinational study, the International Collaboration on Endocarditis (ICE) registry ($N = 2781$ patients with definite native or prosthetic endocarditis), 31% of cases were attributable to *Staphylococcus aureus*, 17% to viridans streptococci, 11% to enterococci, 10% to coagulase-negative staphylococci, 12% to other streptococcal species, 2% to the HACEK (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella* spp.) group, 2% to non-HACEK Gram-negative bacteria, and 2% to fungi. Among those with *S. aureus* endocarditis, health care–associated infection accounted for 39% of cases.

Predisposing cardiac conditions to the development of IE include degenerative valve disease (in approximately 40% of cases of mitral and 25% of aortic valve IE), presence of prosthetic valve, injection drug use, and rheumatic heart disease.

Pathophysiology

A preexisting valvular or endocardial condition, such as mitral valve prolapse with regurgitation, degenerative aortic valve disease (including bicuspid aortic valve), or congenital heart disease, is a major host factor related to development of IE. Endothelial damage and denudation of the endothelium exposes the underlying basement membrane and fosters platelet and fibrin deposition, a process that occurs spontaneously in persons with valvular heart disease. These deposits are called *nonbacterial thrombotic endocarditis* and form the nidus for vegetation to begin in the setting of bacteremia. The classic lesion of IE, the vegetation, is made up of fibrin, platelets, inflammatory cells, and microorganisms adherent to the endothelium of the heart.

The degree of mechanical stress exerted on the valve might contribute to endothelial denudation and the location of vegetation formation, with left-sided IE more common than right-sided IE. Endocarditis involving the nonvalvular endocardium of the heart similarly occurs at sites of endothelial damage due to mechanical stress, such as the left ventricular outflow tract in patients with hypertrophic obstructive cardiomyopathy and congenital heart defects (ventricular septal defects and patent ductus arteriosus).

The adhesion of bacteria to the denuded endothelium might depend on specific properties of the bacteria. Cell surface characteristics of the organism promote its adherence. For example, the adherence of *S. aureus* to a traumatized animal heart valve has been found to be reduced in the setting of impaired fibronectin binding. Similarly, the ability of bacteria to form biofilm may be associated with their ability to form localized clusters of infections that can make these clusters more resistant to killing by the host immune system and antimicrobial therapy.

With the progressive development of a vegetation, function of the specific heart valve is impaired. Regurgitation or insufficiency of the affected valve most commonly results, leading predominantly to volume overload of the ventricular chamber. In the setting of acute or rapid development of regurgitation, there may be no ventricular adaptation to this volume overload; as a result, acute, severe pulmonary edema and cardiogenic shock may quickly ensue. Less commonly, a large vegetation can result in stenosis of the valve orifice and pressure overload of the proximal or upstream cardiac chamber. As infection extends, destruction of other cardiac tissue, including myocardium and fibrous structures, can occur and result in intracardiac abscess or fistula formation between cardiac chambers.

Prevention

The efficacy of antimicrobial prophylaxis in preventing IE continues to be debated. Current recommendations are generally based on the likelihood of bacteremia occurring as a result of the procedure, the potential for adverse outcome as related to the predisposing cardiac condition and the level of evidence for antibiotic prophylaxis as effective for the prevention of IE. The American Heart Association has published updated guidelines for IE

prophylaxis with a continued trend toward fewer indications for prophylaxis.

Based on an extensive review of published literature and expert consensus, these guidelines have concluded that IE is more likely to result from bacteremia associated with daily activities than with a dental procedure. Antibiotic prophylaxis, even if 100% effective, is estimated to prevent only an extremely small number of cases of IE. These recommendations concluded that antibiotic prophylaxis should not be prescribed solely on the basis of an increased lifetime risk of IE but on the basis of cardiac conditions associated with highest risk of an adverse outcome from IE.

Conditions that warrant IE prophylaxis before dental procedures and procedures on respiratory tract, skin, and musculoskeletal structures are listed in [Box 1](#) and [Table 1](#). The American Heart Association no longer recommends prophylaxis before gastrointestinal or genitourinary procedures solely for the prevention of IE.

Clinical Manifestations and Diagnosis

The diagnosis of IE depends on findings of bacteremia with an organism associated with IE and evidence of endocardial involvement. Because these objective findings may not be sought unless the possibility of IE is considered, careful attention to the patient's history and physical examination is critical to the eventual diagnosis. The clinical presentation of IE is highly variable and can range from chronic fatigue with low-grade fever to acute heart failure due to new, severe valvular regurgitation. Although the virulence of the organism can influence acuity of presentation, the onset of infection is generally followed by the onset of symptoms of bacteremia within 2 weeks. Four processes contribute to the clinical presentation of IE: infection on the valve, including the local intracardiac complications; septic or aseptic embolization to distant organs; continuous bacteremia, often with metastatic foci of infection; and circulating immune complexes and other immunopathologic factors.

Approximately 85% of patients present with fever, although this finding might not be present in immunosuppressed states and in patients who have previously been on antibiotic therapy. Nonspecific signs and symptoms such as chills, sweats, anorexia, weight loss, malaise, dyspnea, and cough are common but generally occur in less than half of patients with IE. In addition, predisposing conditions or risk factors for the development of IE, including a history of structural heart disease, injection drug use, or recent invasive procedure, should be sought in the patient's history.

Evidence of a *new or changing* regurgitant murmur in the presence of fever of undetermined origin should prompt additional, timely evaluation for possible IE. Because of the lack of ventricular adaptation to acute volume overload and the resulting hemodynamic changes (tachycardia, hypotension), the murmur in acute aortic insufficiency may be poorly audible. Embolic phenomena, a common extracardiac complication of IE, can manifest with localizing symptoms such as focal neurologic deficit due to stroke

BOX 1 Prophylaxis Against Infective Endocarditis

Procedures Warranting Prophylaxis

Dental procedures that involve manipulating gingival tissue or the periapical region of teeth

Dental procedures that involve perforating the oral mucosa

Cardiac Conditions with High Risk of Adverse Outcome

Prosthetic heart valve or prosthetic material used for valve repair
Previous infective endocarditis

Congenital heart disease including unrepaired cyanotic lesions, palliative shunts or conduits, previous repair with residual defect at site of prosthetic patch or device, and recent repair (<6 months) involving prosthetic device or material

Cardiac transplant with valve regurgitation due to structurally abnormal valve

TABLE 1 Regimens for Dental Procedure

REGIMEN	ANTIBIOTIC AGENT	ADULT	CHILDREN
Oral	Amoxicillin	2 g	50 mg/kg
Penicillin allergy	Cephalexin	2 g	50 mg/kg
	or clindamycin	600 mg	20 mg/kg
	or azithromycin or clarithromycin	500 mg	15 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
Unable to take oral medication plus penicillin allergy	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
	or clindamycin	600 mg IM or IV	20 mg/kg IM or IV

Adapted from Bonow RO, Carabello BA, Kanu C, et al: ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to revise the 1998 Guidelines for the Management of Patients with Valvular Heart Disease): Developed in collaboration with the Society of Cardiovascular Anesthesiologists: Endorsed by the Society for Cardiovascular Angiography and Interventions and the Society of Thoracic Surgeons. *Circulation* 2006;114(5):e84–e231.

Note: The antibiotic agent is administered as single dose 30–60 minutes before the procedure.

or left upper abdominal pain due to splenic infarction. The patient should be carefully examined for any peripheral stigmata of IE such as petechiae, splinter hemorrhages, Janeway lesions, Osler nodes, and Roth spots. Many of these findings are immune-mediated yet infrequently present. Although Janeway lesions, Osler nodes, and Roth spots are more specific abnormalities for IE, they can occur in other conditions and their low incidence in cases of proven IE limits their diagnostic utility.

Blood Cultures

Blood cultures are the definitive microbiologic procedure for the diagnosis of IE. Continuous and low-grade bacteremia makes it unnecessary to await fever spikes or chills to obtain blood cultures, and the first two blood cultures yield an etiologic agent in 90% of cases. In patients who have not received antibiotics recently, it is recommended that at least three blood culture sets from separate venipunctures should be obtained over the first 24 hours, which will increase the yield to more than 95% in cases of untreated IE with continuous bacteremia. Each culture media bottle should be inoculated with at least 10 mL of blood to increase the number of colony-forming units per culture. The results of blood cultures should be interpreted based on the specific microorganisms identified as well as the recognized, constant nature of bacteremia in IE.

Other laboratory data may provide clues to the diagnosis yet lack specificity for IE. Hematologic parameters are often abnormal. A normocytic, normochromic anemia (70%–90%), thrombocytopenia (5%–15%), and leukocytosis (30%) are common findings. The erythrocyte sedimentation rate (ESR) and C-reactive protein concentrations are usually elevated. Similarly, the C-reactive protein concentration is also elevated in IE but is a non-specific finding. Rheumatoid factor assay is positive in up to half of the cases, especially if the illness is protracted. Urinalysis might demonstrate microscopic hematuria and mild proteinuria. Red

blood cell casts and heavy proteinuria can be seen in patients with immune complex glomerulonephritis.

Electrocardiography

Although the electrocardiogram (ECG) lacks sufficient sensitivity and specificity for the diagnosis of IE, ECG abnormalities commonly occur in patients with IE and are associated with invasive infection and increased in-hospital mortality. The presence of atrioventricular heart block in a patient with IE is diagnostic of the presence of a ring abscess, typically of the aortic valve, with invasion posteriorly toward the atrioventricular conduction system. One single-center study found that 53% of patients with invasive infection had ECG changes and about a third of the patients with ECG conduction abnormalities died during hospitalization among their cohort of 137 patients with definite IE.

Echocardiography and Diagnostic Criteria

The diagnosis of IE is based on clinical suspicion derived from signs and symptoms and, most importantly, the demonstration of associated bacteremia. Given the nonspecific nature of findings from history, physical examination, and even blood cultures, the inclusion of echocardiographic findings has improved the sensitivity of diagnostic criteria for this condition (see modified Duke criteria, Box 2).

ECG findings provide specific evidence of IE that include vegetations, evidence of periannular tissue destruction (abscess), aneurysm, fistula, leaflet perforation, and valvular dehiscence. Box 3 outlines specific definitions of these characteristic findings.

The diagnostic utility of transthoracic echocardiogram (TTE) for suspected IE is highest in patients with intermediate to high likelihood of this disease (e.g., a patient with a new or changed heart murmur and bacteremia). Hence, TTE should be performed in all patients with suspected IE. However, the diagnostic sensitivity

BOX 2 The Modified Duke Criteria and Case Definitions of Infective Endocarditis

Modified Duke Criteria

Major Criteria

Positive blood cultures

- Typical microbes consistent with IE from two separate blood cultures: viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; community-acquired enterococci in absence of another focus

or

- Microorganisms consistent with IE from persistently positive blood cultures defined as follows: at least 2 blood cultures drawn more than 12 hours apart or all of three or a majority of more than four separate blood cultures
- Single positive blood culture for *Coxiella burnetii* or antiphase IgG antibody titer >1:800

Evidence of endocardial involvement

Echo findings of IE, defined as:

- Oscillating intracardiac mass on valve or supporting structure
- Abscess
- New partial dehiscence of prosthetic valve
- New valvular regurgitation

Minor Criteria

Predisposition: predisposing heart condition or injection drug use
Fever, temperature >38°C

Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor

Microbiologic evidence: positive blood cultures but does not meet a major criterion as noted above, or serologic evidence of active infection with organism consistent with causing IE

Case Definitions

Definite Infective Endocarditis

Presence of any pathologic criteria:

- Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen

or

- Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

If there are no pathologic criteria, then clinical diagnosis of definite IE:

- Two major criteria
- One major and three minor criteria

or

- Five minor criteria

Possible Infective Endocarditis

One major criterion and one minor criterion

or

Three minor criteria

Rejected

Firm alternative diagnosis explaining evidence of IE

or

Resolution of IE syndrome with antibiotic therapy for ≤4 days

or

No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for <4 days

or

Does not meet criteria for possible IE, as above.

BOX 3

Echocardiographic Findings in Infective Endocarditis

Vegetation

Irregularly shaped, discrete echogenic mass

Adherent to but distinct from endocardial surface or intracardiac device

Oscillation of mass (supportive, not mandatory)

Abscess

Thickened area or mass within the myocardium or valve annulus

Evidence of flow into region (supportive, not mandatory)

Aneurysm

Echolucent space with thin surrounding tissue

Fistula

Blood flow between two distinct cardiac blood spaces or chambers through an abnormal path or channel

Leaflet perforation

Defect in body of valve leaflet with flow through defect

Valve dehiscence

Prosthetic valve with abnormal rocking motion/excursion >15 degrees in at least one direction

Adapted from Sachdev M, Peterson GE, Jollis JG: Imaging techniques for diagnosis of infective endocarditis. *Cardiol Clin* 2003;21:185–195.

of TTE for the visualization of an intracardiac vegetation or abscess is limited, ranging from 40% to 80%, and thus the diagnosis of IE cannot be ruled out on the basis of a negative study. The absence of five clinical criteria has been associated with zero probability of a TTE showing evidence of IE: positive blood cultures, presence of central venous access, recent history of injection drug use, presence of prosthetic valve, and vasculitic or embolic phenomena.

Transesophageal echocardiography (TEE) has greater spatial resolution compared with TTE and so is more sensitive than TTE for detecting intracardiac vegetations (sensitivity, 87%; specificity, 95%). As a result, TEE should be performed in patients with a high likelihood of IE and a negative TTE. Although TTE and TEE have been found to have concordant results in approximately half of patients with suspected IE, TEE provides additional diagnostic information in a high percentage of patients, particularly those

with prosthetic valves. Specific subsets of patients in whom TEE should be performed, even as the primary imaging modality (without TTE), include patients with prosthetic heart valves and suspected IE and patients with persistent staphylococcal bacteremia without known source or nosocomial infection. In addition, TEE should be performed in patients with IE when paravalvular abscess is suspected.

Other Cardiac Imaging Modalities

Cardiac magnetic resonance imaging with contrast appears promising for detecting paravalvular abscesses, thrombus associated with vegetations, valvular complications, and aortocameral fistulas, although temporal resolution might limit its use for detecting vegetation. Cardiac computed tomography has also been used to detect aortic root abscess. However, clinical experience with these techniques in IE patients is limited, and their sensitivities and specificities in comparison to echocardiography are not well defined. Positron emission tomography–computed tomography (PET-CT) scans have been used to evaluate prosthetic devices, including cardiac implanted electronic devices, for inflammation localized to these devices, and may help differentiate post-surgical changes from active infection.

Routine coronary angiography is recommended in patients older than 55 years and in those at high risk for coronary artery disease before surgery for IE.

Differential Diagnosis

Given the protean manifestations of IE, the differential diagnosis includes a number of systemic conditions: systemic lupus erythematosus, acute rheumatic fever, atrial myxoma, vasculitis, and renal cell carcinoma.

Treatment, Complications, and Outcome

Multidisciplinary care of the patient with IE, involving cardiologists, infectious disease specialists, and cardiac surgeons, improves the outcome of IE by optimizing appropriate antibiotic treatment and assessment for surgical indications and operative risk. Antibiotic therapy has improved survival in IE by 70% to 80% and has been shown to reduce the incidence of complications of IE. Detailed descriptions of antibiotic regimens for specific causative organisms are found in guidelines by the American Heart Association (updated in 2015) and the European Society of Cardiology (also updated in 2015). Recommended antimicrobial regimens against typical organisms causing IE are outlined in Table 2. Although the choice of antimicrobial therapy is mainly guided by the

TABLE 2 Antimicrobial Regimens against Typical Infective Endocarditis Organisms

ORGANISM	SUSCEPTIBILITY	REGIMEN	DOSAGE	DURATION (WK)
Native Valve				
<i>Streptococcus viridans</i> , <i>Streptococcus bovis</i>	Penicillin	Penicillin	12–18 MU IV per 24 h continuously or in 4–6 equally divided doses	4
		or Ceftriaxone	2 g IV or IM per 24 h	4
		or Vancomycin	30 mg/kg IV per 24 h in 2 divided doses Max: 2 g/24 h	4
	Penicillin-relative resistance	Penicillin	24 MU IV per 24 h continuously or in 4–6 equally divided doses	4
		or Ceftriaxone	2 g IV/IM per 24 h	4
		plus Gentamicin or Vancomycin	3 mg/kg IV/IM per 24 h in 1 dose 30 mg/kg IV per 24 h in 2 divided doses (limit 2 g/24 h)	2 4
<i>Enterococcus</i> spp.	Penicillin	Ampicillin	12 g IV per 24 h in 6 divided doses	4–6
		or Penicillin	18–30 MU IV per 24 h continuously or in 6 equally divided doses	4–6
		plus Gentamicin	3 mg/kg IV or IM per 24 h in 3 divided doses	2
		or Ampicillin	12 g IV per 24 h in 6 divided doses	6
	Penicillin-resistant	plus Ceftriaxone Vancomycin	2 g IV every 12 h 30 mg/kg IV per 24 h in 2 divided doses (limit 2 g/24 h)	6

infecting organism and its antibiotic susceptibilities, there are three basic principles of antibiotic treatment for the eradication of native valve infection.

First, a prolonged course of antibiotic treatment (4 to 6 weeks) is necessary to eradicate infection because bacterial concentration within vegetations is high and organisms deep within vegetations are inaccessible to phagocytic cells. Repeat sets of blood cultures after antibiotic initiation should be obtained every 24 to 48 hours until the resolution of bacteremia is confirmed. If surgery for IE is performed, completion of the 4- to 6-week course of antibiotic therapy is generally favored to reduce the risk of recurrent IE.

Second, parenteral administration of antibiotic therapy is necessary to achieve adequate drug levels required to eradicate infection. Parenteral therapy is typically initiated in the hospital setting, and the patient may receive outpatient parenteral treatment for the remaining duration after an initial period of observation to assess for clinical response to therapy (e.g., clearance of bacteremia and absence of complications).

Third, because of the need for prolonged therapy and rising antimicrobial resistance among organisms, combination therapy typically involving a β -lactam and aminoglycoside antibiotic is recommended. Combination therapy has been shown to reduce the duration of bacteremia in *S. aureus* endocarditis, although this more-rapid resolution of bacteremia was not associated with an improved clinical response or outcome. Both antibiotics should be given temporally close together so that maximum synergistic microbicidal effect is obtained. In addition, the dosage and kidney function should be monitored carefully, because combination therapy has been associated with a higher rate of kidney dysfunction.

IE can progress to the development of various intracardiac and extracardiac complications before or despite effective treatment. Heart failure or pulmonary edema is a common complication, occurring in about one third to one half of patients with IE, and it is the most common indication for urgent surgery. Valvular destruction and ensuing insufficiency can result in volume overload and heart failure; in rare cases of large vegetations, heart failure may be a result of valvular stenosis. Heart failure complicates aortic valve IE more often than mitral or tricuspid IE and can result in the setting of moderate, rather than severe, regurgitation, because the left ventricle is unable to compensate for the acute increase in preload and afterload in this condition.

Medical therapy alone is generally insufficient in managing IE complicated by heart failure, particularly in the setting of severe or progressive valvular regurgitation. Surgery should be prompt, and unnecessary delays should be avoided.

Para-valvular abscess complicates 30% to 40% cases of IE and is a result of invasive infection that spreads generally along contiguous tissue planes, particularly with aortic valve infection. In the International Collaboration on Endocarditis (ICE) cohort, 22% cases of definite aortic valve IE were complicated by a periannular abscess. These patients were more likely to have prosthetic valves and coagulase-negative staphylococcal infection. TEE is the diagnostic test of choice when an abscess is suspected clinically. An abscess is diagnosed by TEE as the visualization of a periannular area of thickening or mass with a heterogeneous echogenic or echolucent appearance. Rarely, antibiotic therapy alone may be used to treat an intracardiac abscess, although this treatment alone is generally reserved for patients who are poor surgical candidates. The vast majority of patients with an intracardiac abscess require cardiac surgery for débridement. In addition, surgery represents the gold standard for the diagnosis of abscess.

Embolic phenomena often complicate the clinical course in IE. Although clinical signs of embolization occur in approximately one third of patients with IE, at least another third of patients have silent embolism. In the majority of cases, embolic events occur before antibiotic therapy is initiated. The most frequent sites of embolic events were the central nervous system (approximately 40% of embolic events), lungs (approximately 20%), spleen (20%), peripheral artery (approximately 15%), and kidney (10%).

Factors including vegetation size, mobility, and location, as well as the causative organism have been associated with the likelihood of embolic event. Vegetations larger than 10 mm in greatest diameter are associated with an increased risk of embolization. Causative organisms such as *S. aureus* and *Streptococcus bovis* confer an independent risk of embolization. Embolism also occurs with greater frequency in IE caused by enterococci, fastidious gram-negative organisms (HACEK), and fungi as compared with streptococcal IE. In addition to causing infarction of distal vascular beds, embolic events can result in metastatic sites of infection.

Cerebral embolization occurs in 10% to 35% of cases and is at times complicated by meningitis, brain abscess, or intracerebral hemorrhage. The risk of stroke dramatically decreases with

initiation of antibiotic therapy. Findings from the ICE merged database suggested a 65% reduction in stroke incidence by week 2 of initiating antimicrobial therapy. Given the low incidence of embolic event after initiation of antibiotic therapy, routine screening for emboli in patients with IE is not recommended. However, patients with persistent fever or bacteremia or localizing symptoms of possible infarction should undergo computed tomographic imaging with radiographic contrast for the diagnosis of embolic complications.

Embolic events have been found to be an independent predictor of in-hospital death in IE. In patients who experience recurrent embolic events, particularly if they occur after initiation of antibiotic therapy, surgical treatment is indicated. For the prevention of embolic events, surgery may be considered for patients with IE who have residual large (>10 mm), mobile vegetations involving mitral or aortic valve. A recent, small, randomized trial of early surgery for native, left-sided IE has found significant reduction in embolic events in patients treated with earlier surgery.

Surgical intervention for IE may be performed in either the acute or active phase of infection or after the eradication of infection. The optimal timing of surgery in the setting of active IE has not been well evaluated. In patients with serious, life-threatening complications of IE, surgery should be performed emergently. A number of case series have shown that surgery in the active phase of IE can be performed with acceptable risk and without an obvious risk of infecting a prosthetic valve. Surgery during the active phase is generally considered for patients in whom the likelihood of cure of infection with antibiotic therapy alone is low or in whom severe complications have or will likely occur. In contemporary series, surgery is performed in 40% to 50% of patients with IE during the index hospitalization. Surgery after eradication of infection is predominantly performed for adverse hemodynamic effects of valvular regurgitation that results from valve damage.

Indications for surgery in IE are shown in Box 4. A majority of patients with left-sided IE will have an indication for surgery but may be poor candidates for surgery due to hemodynamic instability or other comorbid conditions. Heart failure is the most common indication for urgent surgical intervention, yet even without overt

heart failure symptoms, hemodynamic evidence of severe regurgitation (such as premature closure of the mitral valve in severe aortic regurgitation or pulmonary hypertension in severe mitral regurgitation) should also prompt surgical intervention because valvular regurgitation—or rarely, stenosis—is a mechanical complication of IE that will not improve with antimicrobial therapy alone. For mitral valve regurgitation, surgical repair of the native valve without replacing the valve with a prosthesis has been reported in a number of case series. However, the role of repair versus replacement has not been evaluated in controlled studies, and its feasibility will be limited by the extent of infection and valvular damage, as well as the experience of the surgeon. Surgery for IE may be performed with an acceptable operative mortality rate, although urgent or emergent surgery is associated with higher mortality.

Because embolic complications often involve the central nervous system and can worsen neurologic function after cardiopulmonary bypass, the timing of surgery after a cerebral embolic infarct is controversial. A high percentage of patients with left-sided IE may develop asymptomatic brain embolic events if MRI is performed. Studies found that neurologic deterioration did not occur among patients with IE who experienced transient ischemic attacks or asymptomatic emboli, even if surgery was performed acutely. However, patients with recent hemorrhagic strokes may be at risk for extension and deterioration after cardiac surgery. In patients with ischemic stroke with major neurologic deficit or intracranial hemorrhage, it is recommended to delay valve surgery for at least 4 weeks.

Regarding persistent bacteremia as an indication for surgery, it is important to recognize that certain microorganisms, particularly *S. aureus*, may be associated with prolonged bacteremia (up to 10 days) after initiation of antibiotic therapy. Because of possible difficulty in eradicating infection from prosthetic materials, all cases of prosthetic valve IE should receive surgical consultation. With valve conservation and improved surgical techniques, the surgical mortality rates have declined over time, with recent reported rates in the range of 7% to 14%. In comparison to therapy alone, surgery appears to confer a survival benefit for those patients with major complications of IE, such as heart failure or intracardiac abscess.

Despite the high rate of surgical intervention in IE, the in-hospital mortality rate for native valve IE in the contemporary era remains high at approximately 15% to 20%, and nearly 25% for prosthetic valve IE. Among host factors, older age, female sex, diabetes mellitus, acute physiology (APACHE II) score, elevated white blood cell count, serum creatinine level greater than 2 mg/dL, and lower serum albumin have been associated with worse outcome. Congestive heart failure, paravalvular complication (e.g., abscess formation), infection with virulent organisms (particularly *S. aureus*), prosthetic valve infection, and absence of surgical intervention are also factors related to higher mortality in IE.

BOX 4 Indications for Surgical Intervention in Infective Endocarditis

Class I Indications

- Valve dysfunction with heart failure symptoms
- Left sided IE due to *S. aureus*, fungal, or other highly resistant organism
- IE complicated by heart block, annular or aortic abscess, or destructive penetrating lesions
- Persistent bacteremia or fevers lasting longer than 5 to 7 days after onset of appropriate antimicrobial therapy
- Prosthetic valve endocarditis with relapsing infection
- Complete removal of pacemaker or defibrillator system when evidence of device infection

Class IIa Indications

- Recurrent embolic and persistent vegetation despite appropriate antibiotic therapy
- Complete removal of pacemaker or defibrillator system in patients with IE due to *S. aureus* or fungal organism, or when undergoing valvular surgery for valvular IE

Class IIb Indications

- Native IE with vegetation >10 mm in length, with or without emboli

MITRAL VALVE PROLAPSE

Method of

Kurt M. Jacobson, MD; Peter S. Rahko, MD; and Shenil Shah, MD

CURRENT DIAGNOSIS

- A midsystolic click with or without a middle- to late-peaking crescendo systolic murmur is the classic auscultatory finding of mitral valve prolapse (MVP).
- Key examination maneuvers can help differentiate MVP from other valvular heart diseases.
- Diagnostic echocardiographic findings of MVP are systolic billowing of the mitral valve leaflets 2 mm above the annulus into the left atrium.
- The presence of significant myxomatous thickening of the valve leaflets (>5 mm) is significant for prognosis.

CURRENT THERAPY

- Patients with physical findings of mitral valve prolapse (MVP) should have an echocardiogram to confirm the diagnosis, determine the severity of prolapse, determine the amount of myxomatous thickening, document the severity (if present) of mitral regurgitation, and determine left ventricular size and function.
- Uncomplicated MVP without significant mitral regurgitation can be evaluated clinically every 3 to 5 years.
- Complicated MVP (associated with significant mitral regurgitation, left ventricular structural changes, pulmonary hypertension, atrial fibrillation, or stroke) should be observed closely with serial clinical evaluation and echocardiography.
- Surgery may be required for complicated MVP associated with severe mitral regurgitation. Repair rather than replacement is the procedure of choice and should be performed at surgical centers experienced with mitral valve repair.
- Recommendations for surgery are the same for MVP as for other forms of chronic severe mitral regurgitation.
- Percutaneous intervention with the MitraClip (Abbott Vascular) is an option in symptomatic patients with moderate to severe or severe mitral regurgitation, prohibitive surgical risk, and acceptable anatomy.

murmur syndrome, myxomatous mitral valve disease, and billowing mitral cusp syndrome. MVP is a common cardiac valvular abnormality characterized by redundant, floppy mitral valve leaflets; it is often detected initially by characteristic nonejection clicks or a middle- to late-peaking crescendo systolic murmur on physical examination.

Prevalence

MVP is the most common congenital cause of mitral regurgitation (MR) in adults and the most common indication for mitral valve surgery in the United States today. Previously, it was one of the most overdiagnosed conditions within cardiology, with suggested prevalence rates ranging from 5% to 15%. With the use of current diagnostic standards, rates are much lower; the overestimation was a consequence of diverse and nonuniformly accepted two-dimensional echocardiographic diagnostic criteria. Freed and colleagues, using the Framingham study population and applying consistent and more stringent echocardiographic diagnostic criteria, demonstrated a much lower prevalence of MVP (approximately 2.4%). The incidence appeared to be similar among men and women. Gender differences do exist, however. Women tend to have a more benign course, whereas men tend to have more advanced myxomatous disease resulting in a greater chance of more severe MR.

Classification

Primary MVP is characterized by idiopathic myxomatous change of the mitral valve leaflets or the chordal structures or both. Secondary MVP is present when underlying conditions such as Marfan's syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, or other collagen vascular disorders are evident. Certain congenital cardiac abnormalities, including Ebstein anomaly, aortic coarctation, hypertrophic cardiomyopathy, and ostium secundum atrial septal defects, are also associated with MVP. Familial variants with an autosomal dominant pattern of inheritance have been identified, and work to identify the genes involved is under way. The reported prevalence of MVP in first-degree relatives is between 30% and 50%.

Pathology

Macroscopic and microscopic changes can involve both the anterior and posterior leaflets as well as the chordal structures of the leaflet apparatus. Macroscopically, the surface area of the leaflet is increased, providing the accentuated, billowing appearance of the valve leaflets. Additional notable changes are thickening of the individual leaflets, increased leaflet length, thinning and stretching of the chordae, and increased circumference of the mitral valve annulus. At the microscopic level (Figure 1), normal mitral valves have three well-defined layers, each containing cells and a characteristic composition and configuration of the extracellular matrix: the fibrosa, composed predominantly of collagen fibers densely packed and arranged parallel to the free edge of the leaflet; the centrally located spongiosa, composed of loosely arranged collagen and proteoglycans; and the atrialis, composed of elastic fibers. In myxomatous mitral valves, the spongiosa layer is expanded by loose, amorphous extracellular matrix that has more proteoglycans but less collagen and more fragmented elastic fibers. What collagen is present appears to be disorganized and fragmented, giving the appearance of a haphazard layering of the spongiosa. It is this thickening that produces the classic macroscopic appearance of the myxomatous valve on two-dimensional echocardiography.

Clinical Presentation

Most patients with MVP are asymptomatic and will remain so, testifying to the often benign nature of this disease. Previously, various nonspecific symptoms, including fatigue, dyspnea, palpitations, postural orthostasis, anxiety, and panic attacks, were described as an MVP syndrome when present in association with the characteristic nonejection systolic click or middle- to late-peaking crescendo systolic murmur. Other symptoms, including chest

Mitral valve prolapse (MVP) has been known by many names, including floppy valve syndrome, Barlow's syndrome, click/

- Recommendations for surgery are the same for MVP as for other forms of chronic severe mitral regurgitation.
- Percutaneous intervention with the MitraClip (Abbott Vascular) is an option in symptomatic patients with moderate to severe or severe mitral regurgitation, prohibitive surgical risk, and acceptable anatomy.

murmur syndrome, myxomatous mitral valve disease, and billowing mitral cusp syndrome. MVP is a common cardiac valvular abnormality characterized by redundant, floppy mitral valve leaflets; it is often detected initially by characteristic nonejection clicks or a middle- to late-peaking crescendo systolic murmur on physical examination.

Prevalence

MVP is the most common congenital cause of mitral regurgitation (MR) in adults and the most common indication for mitral valve surgery in the United States today. Previously, it was one of the most overdiagnosed conditions within cardiology, with suggested prevalence rates ranging from 5% to 15%. With the use of current diagnostic standards, rates are much lower; the overestimation was a consequence of diverse and nonuniformly accepted two-dimensional echocardiographic diagnostic criteria. Freed and colleagues, using the Framingham study population and applying consistent and more stringent echocardiographic diagnostic criteria, demonstrated a much lower prevalence of MVP (approximately 2.4%). The incidence appeared to be similar among men and women. Gender differences do exist, however. Women tend to have a more benign course, whereas men tend to have more advanced myxomatous disease resulting in a greater chance of more severe MR.

Classification

Primary MVP is characterized by idiopathic myxomatous change of the mitral valve leaflets or the chordal structures or both. Secondary MVP is present when underlying conditions such as Marfan's syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, or other collagen vascular disorders are evident. Certain congenital cardiac abnormalities, including Ebstein anomaly, aortic coarctation, hypertrophic cardiomyopathy, and ostium secundum atrial septal defects, are also associated with MVP. Familial variants with an autosomal dominant pattern of inheritance have been identified, and work to identify the genes involved is under way. The reported prevalence of MVP in first-degree relatives is between 30% and 50%.

Pathology

Macroscopic and microscopic changes can involve both the anterior and posterior leaflets as well as the chordal structures of the leaflet apparatus. Macroscopically, the surface area of the leaflet is increased, providing the accentuated, billowing appearance of the valve leaflets. Additional notable changes are thickening of the individual leaflets, increased leaflet length, thinning and stretching of the chordae, and increased circumference of the mitral valve annulus. At the microscopic level (Figure 1), normal mitral valves have three well-defined layers, each containing cells and a characteristic composition and configuration of the extracellular matrix: the fibrosa, composed predominantly of collagen fibers densely packed and arranged parallel to the free edge of the leaflet; the centrally located spongiosa, composed of loosely arranged collagen and proteoglycans; and the atrialis, composed of elastic fibers. In myxomatous mitral valves, the spongiosa layer is expanded by loose, amorphous extracellular matrix that has more proteoglycans but less collagen and more fragmented elastic fibers. What collagen is present appears to be disorganized and fragmented, giving the appearance of a haphazard layering of the spongiosa. It is this thickening that produces the classic macroscopic appearance of the myxomatous valve on two-dimensional echocardiography.

Clinical Presentation

Most patients with MVP are asymptomatic and will remain so, testifying to the often benign nature of this disease. Previously, various nonspecific symptoms, including fatigue, dyspnea, palpitations, postural orthostasis, anxiety, and panic attacks, were described as an MVP syndrome when present in association with the characteristic nonejection systolic click or middle- to late-peaking crescendo systolic murmur. Other symptoms, including chest

Mitral valve prolapse (MVP) has been known by many names, including floppy valve syndrome, Barlow's syndrome, click/

Figure 1 Morphologic features of normal mitral valves (*left*) and valves with myxomatous degeneration (*right*). Myxomatous valves have an abnormal layered architecture: loose collagen in fibrosa, expanded spongiosa strongly positive for proteoglycans, and disrupted elastin in atrialis (*top*). Movat pentachrome stain (collagen stains yellow, proteoglycans blue-green, and elastin black). (Modified from Rabkin E, Aikawa M, Stone JR, et al: Activated interstitial myofibroblasts express catabolic enzymes and mediate matrix remodeling in myxomatous heart valves. *Circulation* 2001;104:2525.)

discomfort, near-syncope, and syncope, have also been described by patients with MVP. However, in a community-based study, the prevalence of various clinical complaints including chest pain, dyspnea, and syncope was no higher in patients with MVP than in those without evidence of MVP, making such findings nonspecific. In a controlled study that compared symptomatic MVP patients with first-degree relatives with and without echocardiographic evidence of MVP, there also was no association of MVP with atypical chest pain, dyspnea, panic attacks, or anxiety. There was, however, a significant association of MVP with physical findings of systolic clicks, systolic murmurs, thoracic bony abnormalities, low body weight, and low blood pressure. Congestive heart failure, atrial fibrillation, stroke or transient ischemic attack, hypertension, diabetes, and hypercholesterolemia are no more likely in patients with MVP than in those without MVP. However, previous retrospective studies suggested a higher incidence of cerebral embolic events, infectious endocarditis, severe MR, and need for mitral valve replacement in patients with classic (complicated) versus nonclassic MVP. Symptoms of poor cardiac reserve, such as reduced exercise tolerance, dyspnea on exertion, and fatigue, may reflect the presence of significant MR and warrant clinical concern.

Diagnosis

Symptoms are not predictive of the presence or absence of MVP. Certain physical and auscultatory characteristics on examination do support the diagnosis of MVP. Patients with MVP more often have a lower body mass index, have a lower waist-to-hip ratio, and are taller. Findings of scoliosis, pectus excavatum, and hyperextensibility are also prevalent among patients with MVP. The classic auscultatory findings include a midsystolic click and a middle- to late-peaking crescendo systolic murmur heard best at the apex. The auscultatory findings are best elicited with the diaphragm of the stethoscope, and they change in relation to the first and second heart sounds (S_1 and S_2) in response to changes in left ventricular (LV) volume. Therefore the patient should be examined in several positions: supine (including lateral decubitus), sitting, standing, and, if possible, squatting. Changes in LV filling and volume affect the degree of prolapse.

The most important and most specific finding on auscultation is the presence of a nonejection midsystolic click or clicks caused by snapping of the valve apparatus as parts of the valve leaflets billow into the atrium during systole. Although these clicks can be heard over the entire precordium, they are best heard at the apex. The click can be misinterpreted as a split S_1 , a true S_1 with an S_4 , or a true S_1 with an early ejection click from a bicuspid valve. It can be differentiated from an ejection click heard in bicuspid aortic valves by its timing relative to the beginning of the carotid upstroke. Ejection clicks occur as the aortic valve opens and therefore precede the carotid upstroke, whereas the nonejection clicks of MVP occur afterward. Clicks from atrial septal aneurysms are

uncommon but can be difficult to distinguish from those of MVP. Ejection clicks and clicks from atrial septal aneurysms are not altered by changes in loading characteristics, allowing them to be differentiated from clicks of MVP. Often, but not always, a middle- to late-peaking crescendo systolic murmur can be appreciated by itself or after a click. The murmur terminates with closure of the aortic valve (A2). This represents MR, and, in general, the duration of the murmur correlates with the severity of the MR. The earlier in systole the murmur is detected, the more severe the MR. Eventually, with more severe MR, the murmur becomes holosystolic. MVP manifestations on examination vary, and they may not always be reproducible, even in the same patient.

Certain maneuvers can aid in more accurately diagnosing MVP on examination (Figure 2). MVP is very sensitive to LV filling, and subtle changes in auscultatory findings elicited by careful examination maneuvers can be instrumental in separating MVP from other valvular abnormalities. Generally, measures that decrease LV volume or increase contractility produce earlier and more prominent systolic prolapse of the mitral leaflets, causing the systolic click and murmur to move closer to S_1 . For example, in the transition from squatting to standing, LV volume is reduced, and the onset of the click and murmur is moved closer to S_1 . Conversely, anything that increases LV volume, such as leg-raising, squatting, or slowing the heart rate (increased diastolic filling), delays the onset of the click or murmur and usually diminishes its duration and intensity.

Use of Echocardiography

Two-dimensional echocardiography has proved to be the most accurate noninvasive tool for the diagnosis, assessment, and follow-up of clinically suspected MVP. In fact, physical signs of MVP in an asymptomatic patient are an American College of Cardiology/American Heart Association (ACC/AHA) class I indication for use of echocardiography to make the diagnosis of MVP and assess the severity of MR, leaflet morphology, and ventricular size and function. Once the diagnosis is made, follow-up is determined by the severity of MVP. Routine echocardiographic follow-up of asymptomatic patients with MVP is not recommended unless there are significant findings of MR or LV structural changes. Frequency of follow-up in patients with prolapse and MR is determined by the severity of MR and should be at least annual in patients with severe MR.

Diagnostic criteria for MVP on two-dimensional echocardiography are:

- Billowing of one or both mitral valve leaflets or their prolapse superiorly across the mitral annular plane in the parasternal long-axis view by greater than 2 mm during systole
- The degree of thickening of the leaflets
- Combined leaflet prolapse of greater than 2 mm and leaflet thickness greater than 5 mm are supportive of classic MVP,

Figure 2 Auscultative findings with changes in position in patients with mitral valve prolapse (MVP). Abbreviations: C = click of MVP; S₁, mitral valve closure; S₂, aortic valve closure. (Modified from Devereux RB, Perloff JK, Reichek N, et al: Mitral valve prolapse. *Circulation* 1976;54[1]:3–14.)

whereas prolapse in the absence of increased thickness is considered nonclassic MVP. In addition to more often being associated with the auscultative findings of the click and murmur, the classic form is more commonly associated with increased risk of endocarditis, stroke, progressive MR, and need for mitral valve repair or replacement.

Because the mitral apparatus is saddle-shaped, certain echocardiographic views are more specific than others for determining leaflet prolapse. Most practitioners agree that the parasternal long-axis and apical two-chamber or apical long-axis views are the most accurate for determining prolapse. A finding of prolapse as determined on other views, particularly the apical four-chamber view, is much less specific and frequently leads to a false-positive diagnosis.

Medical Management

Most patients with MVP remain asymptomatic and require no additional management aside from careful observation over time. It is appropriate to provide reassurance that uncomplicated (non-classic) MVP is a non-life-threatening condition and is unlikely to affect longevity. Periodic clinical evaluation every 3 to 5 years is reasonable. Patients who develop palpitations, lightheadedness, dizziness, or syncope should undergo Holter or event monitoring for detection of arrhythmias. Palpitations are frequently controlled with β -blockers or calcium channel blockers, although the presence of specific arrhythmias may mandate additional therapy. Endocarditis prophylaxis is no longer recommended for patients with MVP unless they have a history of endocarditis or valve replacement. Prophylaxis is recommended for patients who have undergone repair if prosthetic material was used (e.g., in ring repairs). Aspirin or warfarin (Coumadin) therapy may be recommended for certain symptomatic patients with neurologic events who have atrial fibrillation, significant MR, hypertension, or heart failure (Table 1).

Patients with classic (complicated) MVP deserve regular clinical follow-up, particularly if MR is present. These patients are more likely to develop moderate or severe MR over time. Patients with mild to moderate MR and normal LV function should be clinically evaluated at least annually and should undergo echocardiography every second or third year if stable. Patients with severe MR should have an annual echocardiogram and closer clinical follow-up. Those who have severe MR and develop symptoms or impaired LV systolic function require cardiac catheterization and evaluation for mitral valve surgery. Often the valve can be repaired rather than replaced, with a low operative mortality rate and excellent short- and long-term results when performed at experienced centers. Preservation of the native valve allows for lower risks of thrombosis and endocarditis than does prosthetic valve replacement.

Surgical Management

MVP is the most common cause of adult MR requiring mitral valve surgery. Symptoms of heart failure, severity of MR,

TABLE 1 ACC/AHA Recommendations for Oral Anticoagulation in Patients With Mitral Valve Prolapse

CLASS	RECOMMENDATION
I	ASA therapy (75–325 mg/d) for cerebral TIAs Warfarin (Coumadin) therapy for patients ≥ 65 years in atrial fibrillation with hypertension, MR, or history of congestive heart failure ASA therapy (75–325 mg/d) for patients < 65 years in atrial fibrillation with no history of MR, hypertension, or congestive heart failure Warfarin therapy after stroke for patients with MR, atrial fibrillation, or left atrial thrombus
Ia	ASA therapy is reasonable in patients after stroke who do not have MR, atrial fibrillation, left atrial thrombus, or echocardiographic evidence of thickening ≥ 5 mm or redundancy of leaflets Warfarin therapy is reasonable after stroke for patients without MR, atrial fibrillation, or left atrial thrombus who have echocardiographic evidence of thickening ≥ 5 mm or redundancy of leaflets
	Warfarin therapy is reasonable for TIAs that occur despite ASA therapy ASA therapy (75–325 mg/d) can be beneficial for patients with a history of stroke who have contraindications to anticoagulants
Iib	ASA therapy (75–325 mg/d) may be considered for patients in sinus rhythm with echocardiographic evidence of complicated MVP

Adapted from Bonow RO, Carabello BA, Chatterjee K, et al: 2008 Focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. *Circulation* 118(15):e23–661, 2008.

presence or absence of atrial fibrillation, LV systolic function, LV end-diastolic and end-systolic volumes, and pulmonary artery pressure (at rest and with exercise) influence the decision to recommend mitral valve surgery. Indications for surgery in patients with MVP and MR mirror those with other forms of nonischemic severe MR. Patient outcomes after mitral valve repair are typically very good, and the surgical risk is lower than for many other forms of cardiac surgery, including mitral valve replacement.

Based on a Cleveland Clinic review of 1072 patients who underwent primary isolated mitral valve repair for MR due to myxomatous disease, the in-hospital mortality rate was 0.3%.

TABLE 2 ACC/AHA Recommendations for Surgery in Patients With Chronic Primary Mitral Valve Regurgitation

CLASS	RECOMMENDATION
I	<p>Mitral valve (MV) surgery is recommended for symptomatic patients with chronic severe primary MR (stage D) and left ventricular ejection fraction (LVEF) >30%</p> <p>MV surgery is recommended for asymptomatic patients with chronic severe primary MR and left ventricular (LV) dysfunction (LVEF 30%-60% and/or left ventricular end-systolic dimension [LVESD] ≥40 mm, stage C2)</p> <p>MV repair is recommended in preference to mitral valve replacement (MVR) when surgical treatment is indicated for patients with chronic severe primary MR limited to the posterior leaflet</p> <p>MV repair is recommended in preference to MVR when surgical treatment is indicated for patients with chronic severe primary MR involving the anterior leaflet or both leaflets when a successful and durable repair can be accomplished</p> <p>Concomitant MV repair or replacement is indicated in patients with chronic severe primary MR undergoing cardiac surgery for other indications</p>
Ia	<p>MV repair is reasonable in asymptomatic patients with chronic severe primary MR (stage C1) with preserved LV function (LVEF >60% and LVESD <40 mm) in whom the likelihood of a successful and durable repair without residual MR is >95% with an expected mortality rate of <1% when performed at a Heart Valve Center of Excellence</p> <p>MV repair is reasonable for asymptomatic patients with chronic severe primary MR (stage C1) and preserved LV function (LVEF >60% and LVESD <40 mm) in whom there is a high likelihood of a successful and durable repair with 1) new onset of atrial fibrillation or 2) resting pulmonary hypertension (pulmonary artery systolic arterial pressure >50 mm Hg)</p> <p>MV repair is reasonable for asymptomatic patients with chronic severe primary MR (stage C1) and preserved LV function (LVEF >60% and LVESD <40 mm) with progressive increase in LV size or decrease in ejection fraction on serial imaging studies</p> <p>Concomitant MV repair is reasonable in patients with chronic moderate primary MR (stage B) undergoing cardiac surgery for other indications</p>
Iib	<p>MV surgery may be considered in symptomatic patients with chronic severe primary MR and LVEF less than or equal to 30% (stage D)</p> <p>MV repair may be considered in patients with rheumatic mitral valve disease when surgical treatment is indicated if a durable and successful repair is likely or if the reliability of long-term anticoagulation management is questionable</p> <p>Transcatheter MV repair may be considered for severely symptomatic patients (New York Heart Association class III/IV) with chronic severe primary MR (stage D) who have a reasonable life expectancy but a prohibitive surgical risk because of severe comorbidities and remain symptomatic despite optimal goal directed medical therapy for heart failure</p>
III Harm	<p>MVR should not be performed for treatment of isolated severe primary MR limited to less than one half of the posterior leaflet unless MV repair has been attempted and was unsuccessful</p>

Adapted from 2017 AHA/ACC focused update of the 2014 ACC/AHA guidelines for the management of patients with valvular heart disease. *Circulation* 135(25); e1159–e1195, 2017.

The Mayo Clinic reviewed 1173 patients who underwent mitral valve repair for MVP from 1980 to 1999, observing mortality rates of 0.7%, 11.3%, and 29.4% at 30 days, 5 years, and 10 years, respectively.

Because of the remarkably low mortality rates associated with MVP repair, some experts advocate earlier rather than later repair of MVP in asymptomatic patients with severe MR and no evidence of LV dysfunction, pulmonary hypertension, or atrial fibrillation. AHA/ACC recommendations for surgery in patients with chronic primary mitral valve regurgitation are shown in Table 2.

Percutaneous Management

In 2013 the FDA approved the MitraClip (Abbott Vascular) for patients with symptomatic degenerative MR who are deemed high risk for mitral valve surgery. The MitraClip technology is based on the Alfieri edge-to-edge repair in which the middle segments of the anterior and posterior leaflet are sutured together to create a double-orifice. It is approved for use in patients with New York Heart Association Class III or IV heart failure despite medical therapy, chronic moderate to severe or severe primary MR, favorable anatomy typically involving the middle segments of the anterior and posterior leaflets, reasonable life expectancy, and prohibitive surgical risk. This approval is based on the results of the Endovascular Valve Edge-to-Edge Repair Study (EVEREST II), which randomized 279 patients to either percutaneous repair or conventional surgery for repair or replacement of the mitral valve with a primary endpoint of freedom from death, from surgery for mitral valve dysfunction, and from grade 3+ or 4+ MR at 12 months. The rates of the combined primary endpoints were 55% in the percutaneous group and 73% in the surgery group ($p=0.007$). Rates of death (6% and 6%, respectively) and 3+ or 4+ MR (21% and 20%, respectively) were similar in each group. Major adverse events occurred in 15% of patients in the percutaneous repair group versus 48% in the surgery group at 30 days ($p<0.001$). Although the MitraClip was less effective at reducing MR, it was approved on the bases of its superior safety and similar clinical outcomes.

CURRENT DIAGNOSIS

- Acute pericarditis is an inflammatory syndrome thought to be caused by a viral infection in most cases. It is diagnosed when 2 of the following are present: (1) typical anterior pleuritic chest pain, (2) pericardial friction rub, (3) electrocardiography (ECG) changes (widespread ST segment elevation or PR depression, and (4) new or worsening pericardial effusion.
- Leukocytosis and an elevated high-sensitivity C-reactive protein or erythrocyte sedimentation rate (ESR) are present in most cases.
- Echocardiography is routinely used to detect pericardial effusion. Cardiac magnetic resonance imaging or computed tomography can be used to support the diagnosis.

CURRENT THERAPY

- Limitation of physical activity and high-dose aspirin¹ or other nonsteroidal antiinflammatory drugs such as ibuprofen (Advil)¹ plus colchicine¹ is the treatment of choice for idiopathic (presumed viral) pericarditis.
- Corticosteroids with gradual taper can be added for recurrences.
- Antiinflammatory drugs such as azathioprine (Imuran),¹ anakinra (Kineret),¹ and human intravenous immunoglobulin (Gammagard)¹ have been used in difficult cases of recurrent pericarditis.
- Pericardiectomy is reserved for refractory cases and constrictive pericarditis.

¹Not FDA approved for this indication.

Anatomy and Functions of the Pericardium

The pericardium consists of 2 layers. A visceral monolayer comprised of mesothelial cells is adherent to the epicardium and reflects over the origin of the great vessels, where it is continuous with the inner layer of the parietal pericardium. The latter is approximately 2 mm thick and comprised mainly of collagen and elastin. The pericardial sac is the space between visceral and parietal layers and normally contains up to 50 mL of serous fluid. The pericardium has several functions, including (1) acting as a barrier to infections, (2) providing a mechanism whereby hydrostatic pressure is exerted on the surface of the heart when gravitational or inertial forces are altered, (3) participating in neuro-humoral responses, and (4) limiting short-term distention and displacement of the heart, facilitating interactions between the cardiac chambers and modulating pressure-volume relationships and cardiac output.

Acute Pericarditis

The main inflammatory pericardial syndromes include acute and recurrent pericarditis and constrictive and effusive-constrictive pericarditis. These can be isolated to the pericardium or be a component of a systemic disease.

Acute pericarditis is the most common pericardial syndrome and is responsible for approximately 5% of emergency room visits for chest pain and 2% of patients presenting with ST elevations on ECG. An in-hospital mortality rate of approximately 1% has been reported. Acute pericarditis is more common in males. Recurrence occurs in

15% to 20% of patients within 18 months after a first episode. Acute pericarditis can also involve the myocardium and cause myopericarditis, with elevated cardiac injury biomarkers (e.g., troponin I).

Etiology

Almost any disease that affects the pericardium can cause acute pericarditis. Acute pericarditis can also cause pericardial effusion; the incidence is highly dependent on etiology. Infectious etiologies are considered to be responsible for the majority of cases. In developed countries 80% to 90% of cases are idiopathic, that is, no specific cause is detected on routine evaluation. These cases are assumed to be viral in etiology. Bacterial and rarely fungal infections account for a small percentage of cases in the developed world. However, *Mycobacterium tuberculosis* is the most common cause of pericarditis in developing countries. Very rarely, parasitic diseases such as echinococcus and toxoplasma species can cause acute pericarditis.

Autoimmune diseases are another common cause of acute pericarditis. These include systemic autoimmune diseases such as lupus erythematosus (SLE), rheumatoid arthritis, Sjögren syndrome, and scleroderma, as well as vasculitic diseases such as eosinophilic granulomatosis with polyangiitis or allergic granulomatosis (previously named *Churg-Strauss syndrome*), Takayasu disease, and Behçet syndrome. Other autoimmune disorders associated with acute pericarditis are sarcoidosis, familial Mediterranean fever, and inflammatory bowel disease.

Malignancies affecting the pericardium also cause acute pericarditis. Almost all neoplastic pericarditis is caused by secondary metastases from extracardiac tumors, especially lung and breast cancer.

Pericarditis can occur after myocardial infarction (MI), both early (i.e., 2 to 4 days after MI) and late (Dressler syndrome, ≈1 week to 2 months after MI), and after heart surgery. The incidence of post-MI pericarditis has markedly declined because of reperfusion therapy. Trauma such as penetrating and non-penetrating thoracic injury, esophageal perforation, and procedural complications of cardiac procedures (coronary stenting, pacemaker lead insertion, radiofrequency ablation) are all reported. Although these can cause acute cardiac tamponade, acute pericarditis occurs as a late complication within 1 to 2 weeks to as late as 3 months after the initial event. These causes are collectively termed *post-cardiac injury syndromes* and are believed to have an autoinflammatory basis. Acute pericarditis has also been reported as an immune-mediated response to various drugs.

Presentation

The diagnosis of acute pericarditis is made if two of the following are present: (1) typical anterior chest pain, (2) pericardial friction rub, (3) typical ECG changes (widespread ST segment elevation or PR depression, and (4) new or worsening pericardial effusion. In cases with typical chest pain but no other criteria, additional findings that can establish the diagnosis are elevated cardiac injury biomarkers and evidence of pericardial inflammation or thickening based on advanced imaging modalities (cardiac magnetic resonance imaging [cMRI], computed tomography [CT]). An elevation of either high-sensitivity C reactive protein (hsCRP) or the erythrocyte sedimentation (ESR) rate is supportive but not diagnostic.

Chest pain is the most common symptom of acute pericarditis, present in >90% of cases. The pain is typically sharp, located under the sternum or over the left anterior chest, and almost always pleuritic. The trapezius ridge is a classic radiation. The pain is worst supine and improved by sitting forward. Approximately one-third of patients have a pericardial friction rub (a scratchy or squeaking sound at the left sternal border) because of contact between the layers of the pericardium. The friction rub ordinarily has 3 components. Typical ECG changes include ST elevation in all leads except AVR and sometimes V1, as well as PR segment depression. Over time, these changes either simply disappear or go through a phase of ST segment normalization and T-wave inversion before disappearing. Both the friction rub and ECG changes are often evanescent. In cases where it is difficult to establish a diagnosis, repeated auscultation and ECGs can be rewarding. A pericardial effusion has been reported in as

many as two-thirds of patients with acute pericarditis. The great majority are small. Sinus tachycardia and low-grade fever are also common. If cardiac tamponade is present, elevated jugular venous pressure, muffled heart sounds, hypotension, and pulsus paradoxus are seen. Other diagnoses that can be confused with acute pericarditis include acute MI, pleuritis, pulmonary embolism, costochondritis, and herpes zoster before appearance of vesicles.

Features accompanying acute pericarditis that indicate an elevated risk (mainly for development of cardiac tamponade) include fever $>38.5^{\circ}\text{C}$, subacute onset of symptoms, moderate to large pericardial effusion, lack of response to aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), immunosuppression, white blood cell count $>13,000/\text{mm}^3$, anticoagulant therapy, and suspicion of a non-idopathic/viral cause such as cancer, SLE, or bacterial infection.

Diagnostic Evaluation

Routine evaluation is directed toward identifying patients with or at elevated risk for cardiac tamponade or patients with a non-idopathic/viral cause. In addition to a careful history, physical examination, and ECG, routine evaluation should include a chest radiograph, CBC, hs-CRP, routine blood chemistries, and an echocardiogram. Echocardiography should be performed in all patients to detect pericardial effusion, which can be hemodynamically significant despite a normal radiographic cardiac silhouette, and to assess cardiac function in cases with myopericarditis. In the vast majority of cases myopericarditis has no long-term prognostic significance.

Clinical Laboratory Data

Leukocytosis and elevated hs-CRP or ESR are present in most cases. The hs-CRP in particular is increased in about 75% of cases and usually normalizes within 1 to 2 weeks. Failure of normalization within this time frame is associated with higher rates of recurrence. In patients with concomitant myocarditis, markers of cardiac injury such as troponin-I are elevated.

ECG

As discussed earlier, typical ECG changes considered to be hallmarks of acute pericarditis include widespread ST segment elevations or PR segment depression (Figure 1). ECG changes are dynamic, and about 60% of patients have the following evolution over time: stage I (PR depression, ST segment elevation), stage II (ST normalization), stage III (T-wave inversion after ST segment normalization), and stage IV (ST-T normalization). These evolutionary changes have no known prognostic significance.

Imaging

The chest radiograph is normal in acute pericarditis unless a moderate- to large-size pericardial effusion or associated pulmonary pathology is present. The echocardiogram is usually normal except for the common presence of small pericardial effusions (Figure 2). In cases with associated myopericarditis, the left ventricular ejection fraction is almost always normal.

Cardiac MRI or CT typically shows pericardial thickening and enhanced gadolinium uptake (Figure 3). Advanced imaging

Figure 2 Parasternal long-axis view of a transthoracic echocardiogram performed in a patient with acute pericarditis showing small to moderate-sized pericardial effusion (asterisk). Also note a pacemaker lead in the right ventricle (arrow) and associated acoustic shadowing artifact.

modalities can be used to support the diagnosis of pericarditis in difficult cases.

Treatment

Treatment of common pericardial syndromes is summarized in Table 1. Reliable patients without high-risk features need not be hospitalized. For treatment of an initial episode of acute idiopathic pericarditis, avoidance of physical activity greater than walking at a normal pace is recommended until symptoms resolve and CRP has normalized. Athletes should refrain from competitive sports activities for at least 3 months. NSAIDs plus colchicine¹ is a first-line pharmacologic treatment. We recommend ibuprofen (Advil)¹ 600 to 800 mg by mouth 3 times daily or aspirin¹ 2 to 4 g by mouth daily in divided doses and colchicine¹ 0.6 mg twice daily (0.6 mg once daily for patients <70 kg) until symptoms resolve and CRP normalizes. The NSAID should then be tapered over 1 to 2 weeks and colchicine continued for 3 months from onset of symptoms. All patients should receive a proton pump inhibitor while receiving NSAIDs.

In pregnancy ibuprofen, aspirin >100 mg/day by mouth, and colchicine are contraindicated after 20 weeks' gestation. Corticosteroids are preferred in this circumstance. In addition, colchicine is contraindicated during lactation.

In patients in whom a specific cause for acute pericarditis other than idiopathic/viral has been identified, the treatment should be directed at that cause. Thus, in patients with autoimmune diseases, corticosteroids may be more appropriate as the initial treatment.

¹Not FDA approved for this indication.

Figure 1 Electrocardiogram demonstrating typical changes of acute pericarditis. Note the widespread ST segment elevations with concomitant PR segment depression.

Figure 3 Cardiac MRI image in a patient with acute pericarditis after intravenous gadolinium administration. Note late gadolinium enhancement of the pericardium along with pericardial thickening indicating inflammation (asterisk). Other findings are pericardial fat (arrowhead) and trivial pericardial effusion (arrow).

Recurrent Pericarditis

Recurrent pericarditis is the most common complication of acute pericarditis and is defined as a repeat episode after a symptom-free interval of at least 4 to 6 weeks. The recurrence rate after an initial episode of acute pericarditis is approximately 15% to 20% and may increase to as much as 50% after a first recurrent episode. Patients with recurrent pericarditis can be severely incapacitated. Certain rare conditions such as familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome, and other periodic fever syndromes are often characterized by bouts of recurrent pericarditis. Inadequate treatment of a first episode (e.g., inadequate drug doses, too short a treatment duration or too rapid discontinuation, or tapering of medications) can be responsible for recurrences.

Recurrent pericarditis after an initial bout of idiopathic/viral pericarditis is currently considered to be an autoinflammatory process (as opposed to an autoimmune disease such as SLE). It is hypothesized that, after an initial viral infection, immune system cross-reaction between viral particles and host tissue occurs. A similar mechanism is believed to be operative in the periodic fever syndromes. Of course, pericarditis due to other, specific causes can also recur.

The most feared complication of recurrent pericarditis is constrictive pericarditis. The incidence is high ($\leq 30\%$) in cases of bacterial pericarditis and low to moderate ($< 5\%$) in systemic inflammatory diseases and cancer. In patients with recurrences after an initial bout of viral/idiopathic pericarditis, symptoms almost always eventually resolve, and progression to constrictive pericarditis is very rare ($< 1\%$).

The diagnosis of a recurrence is based on the same criteria as for an initial episode (i.e., history, friction rub, ECG findings, and a new or worsening pericardial effusion). Elevated hs-CRP, ESR, and white blood cell count remain useful for monitoring disease activity and response to treatment. More advanced imaging modalities such as CT or cMRI are rarely required to diagnose a recurrence but are useful if there is a concern about development of constriction.

In general, for patients with a recurrence after an index episode of idiopathic/viral pericarditis we recommend that treatment be the same as for the initial episode (i.e., restriction of physical activity, NSAID, and colchicine¹) until complete resolution of symptoms

TABLE 1 Treatment Summary of Common Pericardial Syndromes

PERICARDIAL SYNDROME	TREATMENT OVERVIEW	SPECIFIC CONSIDERATIONS
Acute pericarditis	Physical activity restriction <i>and</i> NSAIDs <i>plus</i> Colchicine ¹	Restriction of physical activity until resolution of symptoms NSAIDs until symptoms resolve and CRP normalizes Colchicine for 2 to 3 months See text for pregnancy and lactation considerations
Recurrent pericarditis	Acute pericarditis treatment <i>plus</i> Corticosteroids (in refractory cases) <i>or</i> Immunosuppressive therapy (for multiple recurrences) <i>or</i> Pericardiectomy (last resort)	Restriction of physical activity until resolution of symptoms NSAIDs until symptoms resolve and CRP normalizes for 1 to 2 weeks with subsequent taper Colchicine ¹ for at least 6 months For multiple recurrences, low to moderate doses of corticosteroids until resolution of symptoms and normalization of CRP followed by slow taper Immunosuppressants (anakinra [Kineret], ¹ azathioprine [Imuran], ¹ intravenous immunoglobulin ¹) for multiple recurrences Pericardiectomy in refractory cases (last resort)
Constrictive pericarditis	Treatment of underlying condition (ie, tuberculosis, inflammation) <i>or</i> Pericardiectomy (if chronic and refractory)	In cases of pericardial inflammation, an empiric antiinflammatory regimen may reverse the disease process and obviate the need for pericardiectomy.

¹Not FDA approved for this indication.

and normalization of hs-CRP. Some patients are able to manage recurrences by initiating treatment at the very first sign of symptoms. If the response is prompt, the recurrence is converted to a minor illness.

Use of corticosteroids for treatment of recurrent pericarditis should be reserved for cases where the above-mentioned measures have failed, especially if recurrences are frequent and severe and do not respond well to NSAIDs. Unusual patients with an initial episode who do not respond to first-line therapy are also candidates. Corticosteroids usually provide rapid relief of symptoms, and almost all patients respond favorably initially. However, corticosteroids appear to increase the chance of further recurrences, especially when high initial doses are used with rapid tapering. High doses also have a much higher incidence of

¹Not FDA approved for this indication.

adverse effects. If a decision is made to use corticosteroids, we recommend low to moderate doses (e.g., prednisone¹ 0.25 to 0.5 mg/kg/day or equivalent) usually for about 4 to 8 weeks, followed by gradual tapering (assuming symptom resolution and normalization of hs-CRP) in conjunction with colchicine. NSAIDs may also be included or added later as corticosteroids are tapered. Colchicine should ordinarily be continued for 6 months. During tapering, recurrences typically occur with doses <10 to 15 mg/day dose of prednisone or equivalent. Patients symptom free at this threshold should be treated with smaller subsequent dose decrements at intervals of 2 to 6 weeks. If possible, recurrences occurring during tapering should be treated with NSAID optimization rather than increasing corticosteroids. To prevent side effects of long-term corticosteroid use, specifically bone loss, consideration should be given to supplementary calcium and vitamin D. Bisphosphonates are recommended in all men ≥ 50 years and postmenopausal women in whom long-term treatment with corticosteroids at a dose of 5.0 to 7.5 mg/day of prednisone or equivalent is required.

In patients with multiple recurrences (≥ 3 episodes) despite the aforementioned strategies, alternative drugs have been suggested based on case reports, case series, and small randomized trials. These include azathioprine (Imuran),¹ methotrexate (Trexall),¹ and intravenous human immunoglobulin.¹ Recently, the interleukin-1 antagonist anakinra (Kineret)¹ (1 to 2 mg/kg/day up to 100 mg subcutaneously for several months) has shown promise. Finally, as a last resort for refractory cases of recurrent pericarditis, pericardiectomy may be effective.

Constrictive Pericarditis

Etiology

Constrictive pericarditis is a consequence of chronic forms of pericarditis, especially bacterial (20% to 30%), immune-mediated, and neoplastic (2% to 5%) disease. Some cases are idiopathic. Other causes include cardiac injury syndromes, post-radiation, uremia, and sarcoidosis. Before the availability of effective antimicrobial therapy, tuberculous pericarditis was the most important cause, but this is now rare in the developed world. In the third world, tuberculosis remains an important cause of pericardial disease in general and constrictive pericarditis in particular, often in association with HIV/AIDs. It is very rare (<1%) for idiopathic/viral pericarditis to result in constrictive pericarditis.

When tuberculosis was the major cause of constrictive pericarditis, cases typically presented as a very chronic disease with the features described below. Heavy pericardial calcification was a classic feature. In contemporary practice, most cases of constrictive pericarditis occur in conjunction with the syndrome of effusive-constrictive pericarditis, where pericardial effusion and constriction coexist in varying combinations.

Presentation and Physical Findings

Patients with constrictive pericarditis present with signs and symptoms of right heart failure, with small cardiac volumes and preserved ejection fraction (EF). (In extreme cases EF may be reduced due to severely impaired filling.) Symptoms include fatigue, peripheral edema, dyspnea, hepatomegaly, pleural effusions, and ascites. On physical examination, the venous pressure is markedly elevated, with an M- or W-shaped waveform caused by rapid atrial pressure descents. There is a paradoxical rise in venous pressure with inspiration (Kussmaul's sign), consistent with impaired filling of the right ventricle. A paradoxical pulse is present in as many as one-third of patients. Auscultation may reveal a pericardial knock, an early diastolic, medium-frequency sound (occurring slightly earlier than a usual third heart sound) that reflects abrupt cessation of rapid filling of the ventricles caused by the constricting pericardium. Atrial fibrillation is very common.

By definition, patients with effusive-constrictive pericarditis have pericardial effusions of variable size, which often contain adhesions and fibrous strands and are sometimes large enough to cause cardiac tamponade. In these cases, the diagnosis of

constriction is often made after pericardiocentesis, when right heart filling pressures remain elevated and typical hemodynamic features become apparent.

Diagnostic Tests

The ECG often reveals nonspecific repolarization abnormalities, but there are no specific findings. In effusive-constrictive pericarditis, low-voltage and electrical alternans may be apparent if there is a large effusion. The chest X-ray film may reveal pericardial calcification, but its incidence is now low. Pleural effusions are common.

Major echocardiographic-Doppler findings include small cardiac chambers, a septal "bounce" because of exaggerated septal motion related to increased ventricular interdependence, increased mitral and tricuspid respiratory flow variation, and pericardial thickening and calcification. Interdependence is explained on the basis of a fixed intrapericardial volume, as a result of which when the volume of one ventricle changes (e.g., during respiration), the volume of the other must change reciprocally.

Cardiac catheterization reveals rapid atrial pressure descents, equalization of left- and right-sided filling pressures, increased respiratory variation in LV and RV systolic pressure (also due to ventricular interdependence) and a characteristic "dip and plateau" or "square root" sign evident in the ventricular diastolic pressure.

Cardiac CT and MRI are the best methods for imaging the pericardium. These demonstrate variable increases in pericardial thickness and calcification if present, although rare cases without increased thickness have been reported. Pericardial calcifications can be especially well visualized by cardiac CT and increased ventricular interdependence can be appreciated on real-time cine MR images. Modern cases of constrictive and effusive-constrictive pericarditis often have prominent pericardial inflammation, best imaged by gadolinium uptake during cMRI.

Treatment

Medical management of constrictive pericarditis is symptomatic and supportive, primarily consisting of diuretics to manage signs of right heart failure. It is important to avoid drugs that slow the heart rate, as these patients are critically dependent on heart rate to maintain cardiac output. Ultimately, these patients become refractory to diuretics.

Pericardiectomy has been considered the most definitive treatment for constrictive pericarditis. However, these are often difficult surgeries with high morbidity and mortality rates and delayed benefit. A number of patients are deemed too debilitated for surgery. Postradiation constriction has been considered a specific contraindication. Before pericardiectomy is undertaken, consideration should be given to a trial of an antiinflammatory regimen, especially in idiopathic cases, cases due to systemic inflammatory diseases, and cases due to post-cardiac injury syndromes. High-intensity gadolinium uptake on cardiac MRI in association with pericardial thickening is a signal that such a regimen may be successful, and apparent cures have been reported. Patients with evidence of intense inflammation often have a subacute course and belong in the subset with effusive-constrictive pericarditis. There have been no formal trials of specific antiinflammatory regimens. We favor a course of intermediate-dose prednisone¹ followed by a gradual taper similar to that recommended for recurrent pericarditis, along with colchicine¹ for at least 6 months. In cases of effusive-constrictive pericarditis presenting with cardiac tamponade, a few days of higher-dose prednisone initially may be reasonable. If an antiinflammatory regimen is to be attempted, we recommend committing to at least 2 to 3 months of prednisone treatment before tapering is begun. Reimaging the pericardium to ensure that inflammation has resolved before tapering is helpful.

PERIPHERAL ARTERY DISEASE

Method of

Iftikhar J. Kullo, MD

CURRENT DIAGNOSIS

- The diagnosis of peripheral artery disease (PAD) is based on clinical presentation and noninvasive testing that includes measurement of the ankle–brachial index.
- Conventional computed tomography or magnetic resonance angiography is useful in planning for revascularization.
- Ultrasound combined with Doppler (duplex scanning) is commonly used to assess stent or graft patency after revascularization.

CURRENT THERAPY

- The main goals in managing patients with PAD are to reduce risks of adverse cardiovascular outcomes by high-intensity statin and antiplatelet therapy, improve functional capacity by a supervised exercise program, and preserve limb viability.
- Cilostazol (Pletal) may be useful as an adjunct to increase walking distance, and revascularization is indicated if there is a suboptimal response.

Peripheral artery disease includes several disease entities that affect noncardiac, non-intracranial (peripheral) arteries. The most common cause of lower extremity PAD is atherosclerosis; less common etiologies include inflammatory disorders of the arterial wall (vasculitis) and “bland” arteriopathies such as fibromuscular dysplasia and arterial entrapment.

Epidemiology

The burden of symptomatic PAD in the community is unknown. Based on the prevalence of an abnormal ankle–brachial index (ABI)—the ratio of systolic blood pressure (BP) at the ankle to systolic BP in the arm—in population-based cohorts, it is estimated that at least 5 million people in the United States and more than 200 million people worldwide have PAD. The prevalence of PAD is similar in men and postmenopausal women, but men are more likely to have classical symptoms of claudication. PAD poses a significant health care burden, and total annual costs associated with hospitalization of patients with PAD in the United States are estimated to be in excess of \$21 billion, a number projected to rise as the population ages.

Risk Factors

Risk factors for PAD are similar to those for other atherosclerotic vascular diseases, with smoking and diabetes mellitus being the

strongest. Markers of inflammation and thrombosis, elevated lipoprotein(a) and homocysteine levels, and chronic kidney disease are also associated with PAD. African Americans have a lower ABI than whites, but this may be the result of physiologic factors rather than true differences in atherosclerotic burden. Women tend to have a lower ABI than men and this may partly result from lower height in women. Twin studies suggest a genetic predisposition to PAD, and in a case-control study, family history of PAD was associated with a doubling of the odds of having PAD.

Pathophysiology

Atherosclerotic plaque results in stenosis or occlusion of lower extremity arteries, leading to exertional leg symptoms. Additional factors that reduce functional capacity include endothelial dysfunction, abnormalities of the microvasculature, abnormal rheology, and poor oxygen extraction. There are two broad subtypes of atherosclerotic PAD affecting the lower extremities: proximal, involving the aortoiliac and femoropopliteal locations, and distal, involving the infrapopliteal location. Distal disease is often accompanied by medial arterial calcification that leads to poorly compressible (“stiff”) arteries and is associated with higher mortality than proximal disease.

Prevention

Preventive measures for PAD are similar to other forms of atherosclerotic vascular disease, with avoidance of smoking being the most important. Early detection of PAD may identify patients at increased risk of adverse cardiovascular events. The U.S. Preventive Services Task Force does not recommend routine screening with ABI because of lack of evidence that early detection results in more effective treatment of risk factors or better outcomes. Targeted screening of individuals who are at increased risk, such as those aged older than 65 years and those aged older than 50 years who are smokers or who have diabetes, is recommended by the American College of Cardiology/American Heart Association (ACC/AHA) guidelines.

Clinical Manifestations

The classical symptom of PAD is claudication—an aching, cramping, or tightness provoked by exercise, involving one leg or both legs, and occurring at a fairly constant walking distance. Relief is obtained by standing still. However, some patients with PAD may be asymptomatic or have leg discomfort atypical for claudication. A subset of patients may present with acute or chronic critical limb ischemia. Signs of PAD include diminished pulses, arterial bruits, decreased capillary refill, elevation pallor, dependent rubor, and trophic changes. Patients with critical limb ischemia often have pain at rest and ulceration or gangrene of the toes on examination.

Diagnosis of Peripheral Artery Disease

The diagnosis of PAD is based on clinical presentation and noninvasive testing in the lower extremities.

Noninvasive lower extremity arterial testing typically includes measurement of ABIs at rest, segmental BPs, and continuous wave Doppler (Figure 1, Table 1). To obtain segmental BPs, cuffs are placed at three to four sites in the lower extremities. Generally a drop in BP of more than 12 mm Hg between two locations indicates a hemodynamically significant stenosis between the cuffs. Continuous wave Doppler waveforms can be qualitatively analyzed to assess arterial blood flow. Normally a triphasic or biphasic response is present, whereas a reduced biphasic or monophasic signal indicates a hemodynamically significant stenosis. Additional testing may include treadmill exercise testing to detect mild disease and measure pain-free and maximum walking times, toe–brachial indices in patients with poorly compressible arteries, and transcutaneous oximetry to assess tissue oxygenation in the setting of severe PAD/critical limb ischemia (see Figure 1, Table 1). Ultrasound combined with Doppler (duplex scanning) is a relatively inexpensive, readily available modality for imaging atherosclerotic plaque in peripheral arteries and is commonly used to assess stent or graft patency after revascularization.

Preventive measures for PAD are similar to other forms of atherosclerotic vascular disease, with avoidance of smoking being the most important. Early detection of PAD may identify patients at increased risk of adverse cardiovascular events. The U.S. Preventive Services Task Force does not recommend routine screening with ABI because of lack of evidence that early detection results in more effective treatment of risk factors or better outcomes. Targeted screening of individuals who are at increased risk, such as those aged older than 65 years and those aged older than 50 years who are smokers or who have diabetes, is recommended by the American College of Cardiology/American Heart Association (ACC/AHA) guidelines.

Clinical Manifestations

The classical symptom of PAD is claudication—an aching, cramping, or tightness provoked by exercise, involving one leg or both legs, and occurring at a fairly constant walking distance. Relief is obtained by standing still. However, some patients with PAD may be asymptomatic or have leg discomfort atypical for claudication. A subset of patients may present with acute or chronic critical limb ischemia. Signs of PAD include diminished pulses, arterial bruits, decreased capillary refill, elevation pallor, dependent rubor, and trophic changes. Patients with critical limb ischemia often have pain at rest and ulceration or gangrene of the toes on examination.

Diagnosis of Peripheral Artery Disease

The diagnosis of PAD is based on clinical presentation and noninvasive testing in the lower extremities.

Noninvasive lower extremity arterial testing typically includes measurement of ABIs at rest, segmental BPs, and continuous wave Doppler (Figure 1, Table 1). To obtain segmental BPs, cuffs are placed at three to four sites in the lower extremities. Generally a drop in BP of more than 12 mm Hg between two locations indicates a hemodynamically significant stenosis between the cuffs. Continuous wave Doppler waveforms can be qualitatively analyzed to assess arterial blood flow. Normally a triphasic or biphasic response is present, whereas a reduced biphasic or monophasic signal indicates a hemodynamically significant stenosis. Additional testing may include treadmill exercise testing to detect mild disease and measure pain-free and maximum walking times, toe–brachial indices in patients with poorly compressible arteries, and transcutaneous oximetry to assess tissue oxygenation in the setting of severe PAD/critical limb ischemia (see Figure 1, Table 1). Ultrasound combined with Doppler (duplex scanning) is a relatively inexpensive, readily available modality for imaging atherosclerotic plaque in peripheral arteries and is commonly used to assess stent or graft patency after revascularization.

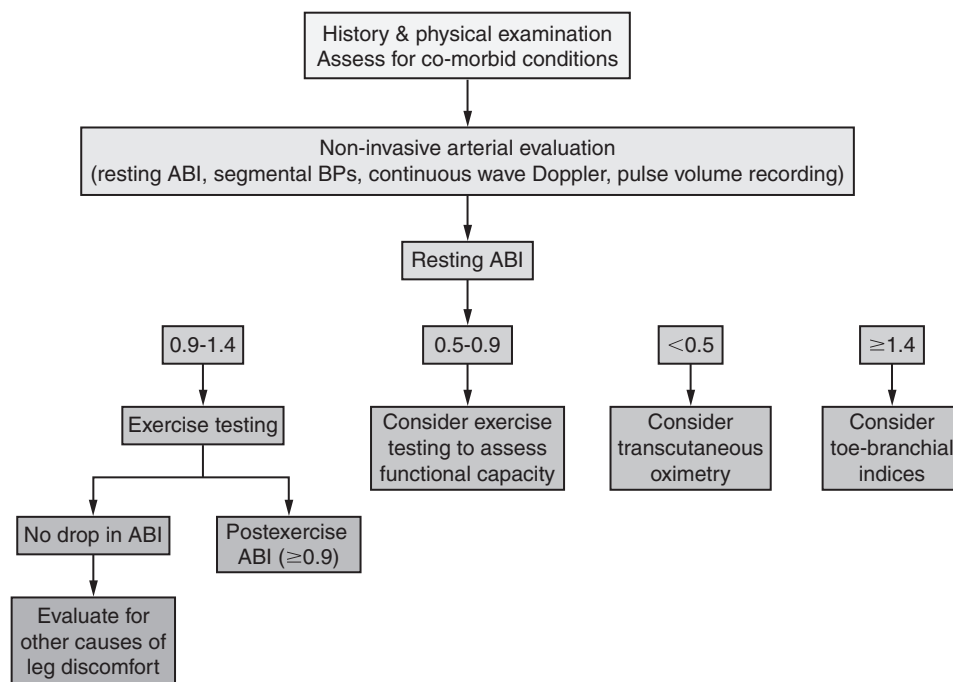

Figure 1 Noninvasive evaluation of patients suspected to have peripheral artery disease.

TABLE 1 Noninvasive Evaluation of Lower Extremity Arterial Disease

Diagnosis of PAD is made based on resting or postexercise ABIs

- PAD is considered present when (1) ABI is ≤ 0.90 (values of 0.91–0.99 are considered borderline low and 1.0–1.3 as normal) and (2) if the resting ABI is normal but postexercise ABI is ≤ 0.90 or there is a $\geq 20\%$ decrease in ABI.
- A high ABI (>1.4) is suggestive of poorly compressible arteries and an ABI of 1.3–1.4 is borderline high. Toe–brachial indices/toe pressures can be useful in such a setting.

Disease severity is quantified based on resting or postexercise ABIs

- Mild: resting ≤ 0.9 ; postexercise ≤ 0.9
- Moderate: resting ≤ 0.7 ; postexercise ≤ 0.5
- Severe: resting ≤ 0.5 ; postexercise ≤ 0.15

Disease location is inferred based on continuous wave Doppler and segmental BPs

- Proximal
- Distal
- Proximal and distal (multilevel)

Functional capacity is measured by distance walked during treadmill exercise

- Pain-free walking distance
- Maximal walking distance

Tissue oxygenation is assessed by using transcutaneous oximetry

- Useful in assessing the healing potential of ischemic wounds and possible amputation sites, as well as candidacy for hyperbaric oxygen or intermittent pneumatic compression therapy

Concomitant disease can also be identified

- Coronary heart disease: ECG positive for ischemia during exercise
- Subclavian artery disease: >12 mm Hg difference in arm BPs

Abbreviations: ABI = ankle–brachial index; BP = blood pressure; ECG = electrocardiogram; PAD = peripheral arterial disease.

Angiography is useful in planning for revascularization. Computed tomographic angiography is widely available, requires relatively short scanning time, has low operator dependency, and provides high-resolution images that can be processed for three-dimensional reconstruction. The drawbacks of computed tomography angiography are that it requires a contrast load and may provide suboptimal delineation of heavily calcified or small

distal vessels. Magnetic resonance angiography provides good spatial resolution and avoids radiation but is technically more challenging, cannot be used in patients with certain metallic or electronic implants, and carries a risk of nephrogenic systemic fibrosis when gadolinium contrast is administered to patients with chronic kidney disease. Conventional angiography is indicated in symptomatic patients for whom revascularization is being contemplated.

Differential Diagnosis

In older individuals, lumbar spinal stenosis and giant cell arteritis can mimic atherosclerotic PAD, whereas in younger individuals, thromboangiitis obliterans and arterial occlusive disease due to arterial entrapment can cause symptoms of claudication.

Spinal stenosis can lead to leg discomfort (pseudoclaudication) that may be confused with claudication. Pseudoclaudication is usually a paresthetic discomfort that occurs with standing and walking, usually bilateral and relieved by sitting or leaning forward. Often there is a history of chronic back pain or previous lumbosacral spinal surgery. The diagnosis of lumbar spinal stenosis can be confirmed from characteristic findings on computed tomography (CT) or magnetic resonance imaging of the lumbar spine, electromyography, and normal or minimally abnormal ABIs before and after exercise. Occasionally patients may have both claudication and pseudoclaudication.

Giant cell arteritis can involve peripheral arteries, and symptoms of peripheral artery involvement may dominate the clinical picture. Therapy is directed mainly at the underlying disease, and only after the inflammatory process is controlled should revascularization of chronically ischemic extremities be contemplated.

Thromboangiitis obliterans (Buerger disease) is a segmental inflammatory disease involving the small and medium vessels of the arms and legs. The Shionoya diagnostic criteria for thromboangiitis obliterans include history of smoking, onset before age 50, infrapopliteal arterial occlusive disease, upper extremity involvement or phlebitis migrans, and absence of atherosclerotic risk factors other than heavy smoking. Angiography usually shows multiple, bilateral focal segments of stenosis or occlusion with normal proximal vessels. Treatment includes avoidance of all forms of tobacco to reduce the risk of ulcer formation and amputation. Symptoms of claudication may improve with aspirin, clopidogrel (Plavix),¹ pentoxifylline (Trental),¹ and cilostazol (Pletal).¹ In

¹Not FDA approved for this indication.

severe digital ischemia with ulceration, sympathectomy may be useful to control pain and to improve cutaneous blood flow. Options for revascularization are generally limited.

Popliteal artery entrapment (PAE) can occur owing to compression from the medial head of the gastrocnemius muscle, the plantaris muscle, or the popliteal muscle. Repeated compression of the popliteal artery can lead to localized atherosclerosis, poststenotic dilatation, or thrombosis, resulting in ischemia in the distal leg or foot. The diagnosis should be considered in a young man with claudication in the arch of the foot or calf with reduced pedal pulses on sustained active plantar flexion and can be confirmed with duplex ultrasonography or CT/magnetic resonance angiography. If PAE has been diagnosed in one limb, the contralateral limb should be screened because bilateral disease occurs in more than 25% of patients. Although the natural history of PAE is not well defined, surgery is advocated to prevent progression of the disease from repetitive arterial trauma.

Treatment of Peripheral Artery Disease

The main goals in managing patients with PAD are to reduce risks of adverse cardiovascular outcomes, improve functional capacity, and preserve limb viability (Table 2). Multiple comorbidities are common in patients with PAD and present additional challenges in management.

Treatment of Cardiovascular Risk Factors

Hyperlipidemia. High-intensity statin therapy is indicated in patients with PAD to lower low-density lipoprotein cholesterol (LDL-C) by 50% or more. A specific target LDL-C level is not mandated by the AHA/ACC, although other expert bodies recommend a target of less than 70 mg/dL for patients with atherosclerotic cardiovascular disease (ASCVD). In the Heart Protection Study, the subgroup of patients with PAD assigned to simvastatin (Zocor) (vs. placebo) had a 25% relative risk reduction in cardiovascular events over 5 years of follow-up (a reduction similar to that in persons without PAD). In a large registry study, statin use was associated with an ~18% lower rate of adverse limb outcomes (including worsening of symptoms, peripheral revascularization, and amputation). Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors should be considered in patients with PAD who are intolerant of statins or do not achieve the target LDL-C level while on the maximal dose of a statin. In the FOURIER trial, patients with PAD derived as great a benefit, if not a greater benefit, than other subgroups, with PCSK9 inhibition.

Hypertension. There is controversy related to BP targets, with a recent trial suggesting a systolic BP goal of less than 120 mm Hg in those at higher cardiovascular risk. There are no comparative trials to support use of a particular class of antihypertensive agents over

another in patients with PAD. However, angiotensin-converting enzyme inhibitors may be the preferred antihypertensive agents to reduce the adverse cardiovascular events associated with PAD. In the Heart Outcomes Prevention Evaluation (HOPE) study of 9297 patients with diabetes or vascular disease (including 4051 with PAD), ramipril (Altace) reduced adverse cardiovascular outcomes compared to placebo over a 5-year follow-up. Beta-blockers are not contraindicated and can be safely used in patients with PAD when indicated.

Diabetes. Treatment of diabetes does not reduce cardiovascular events but may lower risks of microvascular disease and neuropathy. This is important in patients with PAD and diabetes in whom foot ulceration is a highly morbid adverse outcome. Since intensive blood glucose control may increase mortality in patients with established cardiovascular disease, a target A1C should be chosen based on age, duration of diabetes, and presence of comorbid conditions. In a recent study of patients with diabetes and ASCVD, empagliflozin (Jardiance), an oral hypoglycemic agent, reduced adverse cardiovascular events.

Smoking cessation. Persons with PAD who quit smoking have a lower risk of death, progression of disease, critical limb ischemia and amputation, myocardial infarction, stroke, and bypass graft failure than patients who continue to smoke. Referral for counseling and/or use of adjunctive pharmacotherapy (varenicline [Chantix], bupropion [Zyban], or nicotine replacement therapy) may increase abstinence rates.

Antiplatelet agents. Patients with symptomatic PAD should receive antiplatelet therapy in the form of aspirin (75–325 mg daily). A metaanalysis of randomized trials showed that aspirin use in patients with PAD led to a nonsignificant reduction in cardiovascular events and a significant reduction in nonfatal stroke. Aspirin did not improve outcomes among persons with an ABI less than or equal to 0.95 but without symptoms. In the Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) randomized trial of patients with symptomatic PAD or other manifestations of atherosclerotic disease, clopidogrel (Plavix) (75 mg daily) was slightly more effective than aspirin in reducing risk for a composite outcome of ischemic stroke, myocardial infarction, or vascular death. Dual antiplatelet therapy can be considered in patients with symptomatic PAD who are not at increased risk of bleeding. Vorapaxar (Zontivity), a new antiplatelet agent that blocks the thrombin protease-activated receptor-1, reduced the risk of cardiovascular death or ischemic events in patients with ASCVD but increased the risk of bleeding, including intracranial hemorrhage. In the subgroup with PAD, the drug reduced acute limb ischemia and peripheral revascularization events, leading to its approval for use in patients with PAD without a history of stroke. Warfarin (Coumadin)¹ is not recommended, as the combination of warfarin and aspirin did not result in greater reduction in cardiovascular events than aspirin alone and was associated with more bleeding. In the Examining Use of Ticagrelor in Peripheral Artery Disease (EUCLID) study, ticagrelor (Brilinta)¹ was not superior to clopidogrel in patients with symptomatic PAD. In the Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) study, low-dose rivaroxaban (Xarelto)¹ alone or in combination with aspirin was superior to aspirin alone in reducing adverse cardiovascular events.

Improving Functional Capacity

Poor functional capacity in patients with PAD is often multifactorial, including comorbidities such as coronary heart disease (CHD), pulmonary disease, and degenerative joint disease. The degree of functional limitation varies depending on the degree of arterial stenosis, collateral circulation, exercise capacity, and comorbid conditions. Several strategies may improve functional capacity in PAD.

Supervised exercise. A program that incorporates walking at least three times per week (30–60 minutes/session) for at least 12 weeks should be the first-line therapy for claudication. In the

TABLE 2 Management of Peripheral Artery Disease

1. Reduce cardiovascular risk
 - High-intensity statin
 - Treatment of hypertension, target BP <140/90 mm Hg
 - Treatment of diabetes, target A1C <7.0%
 - Smoking cessation
 - Antiplatelet aspirin (75–325 mg/day) or clopidogrel (Plavix) (75 mg daily); dual antiplatelet therapy can be considered in patients not at risk for bleeding
2. Improve functional capacity
 - Supervised exercise program
 - Cilostazol (Pletal) (100 mg PO bid)
 - Revascularization if no response to exercise and medication and lifestyle-limiting symptoms
3. Treat comorbid conditions
4. Follow up
 - Follow up annually to assess for compliance with lifestyle changes and drugs
 - Assess functional capacity, comorbid conditions
 - In patients who have undergone surgical bypass, surveillance of grafts

¹Not FDA approved for this indication.

Claudication: Exercise Versus Endoluminal Revascularization (CLEVER) trial comparing supervised exercise and stenting in patients with aortoiliac disease on optimal medical therapy, supervised exercise resulted in significantly greater improvements in mean peak walking time at 6 months (5.8 vs. 3.7 minutes); however, quality-of-life indicators were better in those randomized to stenting. Supervised exercise for PAD is not reimbursed by U.S. insurers. A home-based group-mediated cognitive-behavioral walking intervention that included goal setting, self-monitoring, managing pain during exercise, and walking at least 5 days per week improved 6-minute walking distance by 53 m compared to a control group that received health education alone. Exercise may be a useful adjunct to revascularization. In a trial of 212 patients with PAD and claudication, those randomized to endovascular revascularization and supervised exercise had a greater improvement in maximal walking distance at 12 months than those randomized to exercise alone (1237 vs. 955 m).

Medications. Pharmacotherapy is only modestly effective for improving symptoms of claudication. Cilostazol (Pletal), a phosphodiesterase inhibitor with antiplatelet and vasodilatory properties, improves maximal treadmill walking distance by ~25%. Side effects include tachycardia, diarrhea, and increased bleeding tendency. Because it increases intracellular cyclic adenosine monophosphate (cAMP), it is contraindicated in patients with heart failure or low ejection fraction. The dose is 100 mg orally daily (50 mg orally twice daily in patients taking diltiazem [Cardizem], ketoconazole [Nizoral], or other inhibitors of cytochrome P450 3A4). Naftidrofuryl, a 5 hydroxy-tryptamine receptor blocker² that inhibits platelet aggregation, may be more effective than cilostazol

and is approved in Europe for claudication. Atorvastatin (Lipitor)¹ (80 mg daily for 12 months) modestly improved pain-free walking time, but not maximal walking time, compared to placebo.

Revascularization (Figure 2). Revascularization is indicated when there are limiting symptoms in spite of an exercise program and medical therapy, and there is a reasonable likelihood of symptomatic improvement (including absence of other conditions that might limit functional capacity such as heart failure or lung disease), as well as limb salvage in the setting of critical limb ischemia. The revascularization strategy for each patient should be individualized based on patient preferences, anatomic factors, availability of optimal conduits, and operative risk.

Aortoiliac angioplasty and stenting have high procedural success rates (~96%) and a 3-year patency rate of ~82%. Stent placement is generally avoided in the common femoral artery owing to the risk of biomechanical stress-related stent fractures and the potential for interference with future arterial access. Endovascular intervention in the superficial femoral artery is associated with high rates of restenosis, and several technologies to limit restenosis including drug-eluting or covered stents, drug-coated balloons, and brachytherapy are being evaluated. Endovascular therapy of isolated infrapopliteal disease is not recommended for claudication. Patients should receive dual antiplatelet therapy for at least 30 days, and longer if a drug-eluting stent is placed.

Surgical bypass (see Figure 2) should be considered when an endovascular approach has failed or is not feasible from an anatomic standpoint. Aortofemoral bypass is a durable operation for aortoiliac disease, with patency rates up to 90% at 5 years. In patients who are poor surgical candidates, cross-clamping of

²Not available in the United States.

¹Not FDA approved for this indication.

Figure 2 Normal lower limb arterial anatomy and percutaneous and surgical revascularization for peripheral artery disease.

the aorta can be avoided by an axillary–femoral graft often combined with a femoral–femoral graft. Endarterectomy is the procedure of choice for common femoral artery lesions and is often combined with an endovascular approach. The saphenous vein is the preferred conduit for infrainguinal bypass, but a prosthetic conduit can be used for femoral–popliteal bypass if the above-knee popliteal artery is the target vessel and good runoff is present. Femoral–tibial bypass is an option in patients with critical limb ischemia and infrapopliteal disease. There is no clear guidance on antithrombotic therapy after surgical revascularization; however, in patients undergoing infrainguinal bypass surgery, venous grafts had better patency with warfarin¹ than aspirin therapy, whereas prosthetic grafts had better patency on aspirin. For below-knee prosthetic grafts, dual antiplatelet therapy is preferred. A cardiac stress imaging study may be indicated preoperatively to assess the presence and severity of CHD in patients with PAD with poor functional capacity. However, there is no benefit from “prophylactic” coronary revascularization in patients with PAD undergoing surgical revascularization.

Preserving limb viability. Weight reduction (if obese), avoidance of vasoconstrictor drugs, proper foot care, daily inspection of the feet, and prompt evaluation of any skin lesion/ulceration are of paramount importance in patients with diabetes and PAD. Patients with diabetes are at the highest risk of amputation. The combination of peripheral neuropathy, small-vessel disease, or PAD in patients with diabetes makes foot trauma more likely to be associated with a nonhealing wound or ulcer. The presence of critical limb ischemia significantly increases risk of amputation, and the amputation rate over 1 year is 25%.

Monitoring

In patients with claudication, symptoms remain stable in 70% to 80%, worsen in 10% to 20%, and progress to critical limb ischemia in 1% to 2% over 5 years. Independent predictors of a decline in the ABI include advanced age, current tobacco use, hypertension, diabetes mellitus, and increased level of LDL-C. Patients should be followed to assess compliance with lifestyle measures and drug therapy and to assess for changes in functional capacity. Patients who have undergone revascularization should be monitored for stent/graft patency. Postsurgical graft stenosis is treated with open or endovascular intervention to prevent graft occlusion.

Complications

Adverse cardiovascular events and death. PAD is associated with substantial morbidity; CHD and/or cerebrovascular disease are present in more than half of persons diagnosed with PAD. An ABI of less than or equal to 0.9 is associated with doubling of mortality compared to a normal ABI. In patients with critical limb ischemia (ischemic rest pain, ulceration, and gangrene), 1-year mortality is 25%. Based on registry data, the 1-year incidence of cardiovascular death, myocardial infarction, and ischemic stroke was higher in persons with PAD than in those with CHD (5.35% vs. 4.52%).

Adverse limb outcomes. The incidence of adverse limb outcomes including worsening of symptoms, peripheral revascularization, and amputation was 26% over 4 years, based on registry data. Smoking and diabetes are associated with high rates of adverse limb outcomes. Continued use of tobacco results in a 10-fold increase in the risk for major amputation and a more than 2-fold increase in mortality. Diabetes is a major risk factor for amputation in patients with symptomatic PAD (12-fold increased risk of below-knee amputation and a cumulative risk of major amputation exceeding 11% over 25 years).

PREMATURE BEATS

Method of

Randell Wexler, MD

CURRENT DIAGNOSIS

- The cause of a premature beat may be either atrial (premature atrial contractions or PAC) or ventricular (premature ventricular contractions or PVC) in origin.
- PACs are most often benign but are associated with increased risk of atrial fibrillation.
- PVCs may be benign, but underlying structural heart disease is not uncommon and must be ruled out with echocardiography.
- PACs and PVCs are most commonly diagnosed by EKG although Holter or event monitoring may be required.
- A heavier PVC burden is associated with increased development of cardiomyopathy and cardiovascular morbidity and mortality.

CURRENT THERAPY

- PACs are treated if their presence causes the patient symptoms and interferes with daily life.
- Beta blockers are most often used for the treatment of symptomatic PACs.
- In patients with underlying structural heart disease, the treatment of PVCs is directed at the underlying cardiac condition.
- Antiarrhythmics show no benefit in treatment of PVCs in patients with cardiomyopathy and should not be used to suppress their presence post myocardial infarction.
- Patients with a PVC burden of > 15% should see an EPS specialist for evaluation and treatment, as there is an increased risk of a significant cardiac arrhythmia.

It is not uncommon for a patient to present to a primary care physician with the complaint of their “heart pounding,” “skipping beats,” or having “palpitations.” Though often the only symptom, patients may also complain of concomitant dizziness,

the aorta can be avoided by an axillary–femoral graft often combined with a femoral–femoral graft. Endarterectomy is the procedure of choice for common femoral artery lesions and is often combined with an endovascular approach. PREMATURE BEATS

Method of

Randell Wexler, MD

CURRENT DIAGNOSIS

- The cause of a premature beat may be either atrial (premature atrial contractions or PAC) or ventricular (premature ventricular contractions or PVC) in origin.
- PACs are most often benign but are associated with increased risk of atrial fibrillation.
- PVCs may be benign, but underlying structural heart disease is not uncommon and must be ruled out with echocardiography.
- PACs and PVCs are most commonly diagnosed by EKG although Holter or event monitoring may be required.
- A heavier PVC burden is associated with increased development of cardiomyopathy and cardiovascular morbidity and mortality.

CURRENT THERAPY

- PACs are treated if their presence causes the patient symptoms and interferes with daily life.
- Beta blockers are most often used for the treatment of symptomatic PACs.
- In patients with underlying structural heart disease, the treatment of PVCs is directed at the underlying cardiac condition.
- Antiarrhythmics show no benefit in treatment of PVCs in patients with cardiomyopathy and should not be used to suppress their presence post myocardial infarction.
- Patients with a PVC burden of > 15% should see an EPS specialist for evaluation and treatment, as there is an increased risk of a significant cardiac arrhythmia.

It is not uncommon for a patient to present to a primary care physician with the complaint of their “heart pounding,” “skipping beats,” or having “palpitations.” Though often the only symptom, patients may also complain of concomitant dizziness,

lightheadedness, or frank syncope. The patient may be young or old, have underlying structural heart disease (or not), or risk factors for heart disease such as hypertension. A patient with such a history may be experiencing one of a number of cardiac arrhythmias, although it is not uncommon to find no underlying etiology at all.

Normal electrical propagation in the heart begins with the spontaneous electrical discharge at the sinoatrial node, which is then propagated along the right atrial wall to the atrioventricular node and from there to the ventricles via the His-Purkinje System. Disruption anywhere along this pathway may lead to an arrhythmia, which is defined as a rhythm that is not sinus and is accompanied by an abnormal electrical conduction.

If an arrhythmia is present, it is classified by its anatomic location of origin. Common atrial arrhythmias include atrial fibrillation/flutter, paroxysmal supraventricular tachycardia, and premature atrial contractions (PACs). Ventricular arrhythmias are often designated as premature ventricular contractions (PVCs), ventricular tachycardia, and ventricular fibrillation. Other arrhythmias that are often seen include bradycardia, tachycardia, and first-, second-, and third-degree heart block (complex morphology is normal). This chapter will review arrhythmias commonly referred to as premature beats: PACs, and PVCs.

Premature Atrial Contractions

Epidemiology and Risk Factors

PACs are common and are found in both the general population as well as in those with underlying cardiac disease. Research has established that PACs exist in up to 99% of those over the age of 50 with increasing frequency with each decade of life. It has long been believed that atrial ectopy, especially in a patient with no underlying heart disease, is benign and more of a nuisance than a risk. However, it is now understood that PACs do present an increased risk for atrial fibrillation or ischemic stroke, and although most often benign, are not entirely so.

Underlying structural heart disease (such as mitral valve disease or left ventricular dysfunction) is significantly correlated to the risk of developing PACs. Additional risk factors associated with PACs include: 1) height (potentially due to the relationship between body size and left atrial measurements); 2) those with higher levels of B natriuretic peptide (BNP); as well as 3) those with abnormalities of high-density lipoprotein (HDL) lipid metabolism in which a lower HDL is associated with increased risk of PACs. This inverse relationship has also been reported between PACs and physical activity. The difficulty in determining the clinical significance of PACs is owing to their frequent presence in the population at large.

Pathophysiology

The true etiology of PACs is not well researched and therefore not well understood. Investigation has suggested that normally functioning sino-atrial (SA) and atrio-ventricular (AV) nodes can be impacted by stimuli arising from outside of the atria. It has been proposed that this stimuli leads to reversible nodal remodeling. As a result it has been hypothesized that PACs may occur due to an adversely impacted SA or AV node subsequent to such remodeling. Others have postulated that mechanisms such as reentry and abnormal automaticity initiate PAC transmission but the actual cause is not known.

An electrocardiogram (EKG) provides an electrical account of heart function. Electrical impulses begin in the sinus node and then travel through Bachmann's bundle (the sole specialized atrial conduction system) subsequently diffusing over the atria. The P wave represents atrial electrical activity. A normal P wave as seen on the EKG is smooth and never peaked or sharp. The leads best used to review the P wave are leads II and V1.

A patient may have a left atrial abnormality (LAA), right atrial abnormality (RAA), or both. An LAA abnormality results in prolonged atrial activation times, because left atrial activation is later than right atrial activation. Such abnormalities may result in "notched" P waves because of the spatial separation of the left and right atrial peaks. When a patient has a RAA, the P wave tends

to have increased amplitude due to the summation of the two peaks. Whenever possible, P wave abnormalities should be labeled left or right in nature.

A PAC will typically be seen on EKG as an abnormal P wave followed by a normal QRS complex. Morphologically, the P wave will be different than a normal (sinus) P wave. If the site of the PAC origin is near the AV node, it will be inverted, whereas if it is more distal, it will be upright. Should the PAC reach the SA node, the resulting finding on the EKG will be a longer interval between sinus beats, but it is not compensatory in nature. PACs may occur singularly or at regular intervals (every other beat is termed bigeminy) or in a group (two sequential PACs are termed a couplet). In addition, a PAC may be blocked (buried in a T wave) or conducted aberrantly (an atypical electrical configuration).

Prevention and Clinical Manifestations

The majority of PACs are idiopathic unless there is underlying heart disease. Potential non-cardiac causes include tobacco use, alcohol consumption, substance abuse, and coffee. Reducing and/or eliminating these substances can be helpful in preventing symptoms. Additionally, certain medications, supplements, or substances of abuse may cause PACs, and therefore in any patient presenting with the complaint of extra beats, a thorough review of all medications, supplements, and illicit substance use should be undertaken.

Although the vast majority of patients who are found to have PACs incidentally will not experience symptoms, patients presenting with the complaint of PACs may state that they feel that their heart is racing, skipping beats, or fluttering, or that they are experiencing palpitations. Though not common, some patients may experience dizziness.

PACs are now known to be precursors to atrial fibrillation or ischemic stroke. Thus the previous belief that atrial ectopy is benign and more of a nuisance has been shown to be incorrect. In fact, some studies suggest that a single PAC on EKG not only predicts atrial fibrillation but may also be a predictor of fatal outcome.

Diagnosis and Differential Diagnosis

The diagnosis of PACs is often made on EKG, especially if the patient is symptomatic at the time of testing. If the EKG does not demonstrate an etiology, a 24-hour Holter monitor or 30-day event monitor may also be considered. The diagnoses of a PAC can be made if the P wave has a morphology that is different from and occurs earlier in the cardiac cycle than that of a sinus P wave. Many patients experience palpitations in which the EKG evaluation suggests no underlying etiology. Therefore, in addition to electrocardiography, patients with PACs should have baseline labs drawn to include a thyroid stimulating hormone, complete blood count, magnesium and phosphate, and electrolytes. If drug use is a possible etiology, a toxicology screen can be useful.

Differential diagnosis includes other cardiac arrhythmias such as PVCs, atrial fibrillation, atrial flutter, and paroxysmal supraventricular tachycardia. Underlying disorders that may be the cause include underlying anxiety or thyroid and other metabolic disorder, as well as substance abuse.

Treatment and Monitoring

Echocardiography is helpful in determining if the patient has underlying structural heart disease requiring further evaluation and intervention. If the patient has no underlying structural heart disease, then no treatment is necessary, especially if the individual is asymptomatic and the PACs are found incidentally. If the patient does have symptomatic PACs to a degree that they interfere with the patient's quality of life, interventions include the use of beta blockers, and if they fail, a trial type IA, type IC, or type III antiarrhythmic agents may be considered. If the problem is electrophysiological in nature, catheter ablation or pulmonary vein isolation may be helpful.

If the patient has underlying structural heart disease, then treatment is directed at the underlying disorder. Patients with PACs should be educated as to the association of atrial fibrillation or

stroke with instructions to notify their physician or seek attention immediately should symptoms occur.

Premature Ventricular Contractions

Epidemiology and Risk Factors

Premature ventricular contractions (PVCs) are a common cardiac finding, with upward of 40% to 75% of apparently healthy people being affected. As with PACs, they tend to increase with age. Underlying cardiovascular disease, especially ischemic heart disease increases one's risk for PVCs. As such, evaluation should be focused on excluding structural heart disease. It should be noted that PVCs are also common in those with inherited channelopathies, so a good family history is also important. PVCs are also common in well-conditioned athlete's due to autonomic tone. Although this may be a normal compensatory mechanism, structural heart disease still needs to be eliminated. PVCs associated with exercise portend increased cardiac mortality.

Pathophysiology

After propagation through the atria, the electrical impulse activates the AV node that serves as the sole pathway for electrical transmission between the atria and the ventricles. The terminal portion of the AV junction becomes the bundle of His that propagates the electrical impulse to the bundle branches, which further divide into smaller subdivisions eventually connecting to the Purkinje fibers. From the Purkinje fibers, the electrical impulse diffuses synchronously across the ventricles.

PVCs arise from ectopic foci in the ventricle and occur earlier in the cardiac cycle than expected for a sinus beat. They may be generated by increased automaticity, reentry, or triggered activity. Monomorphic PVCs suggest a triggering component whereas polymorphic PVCs tend to suggest an underlying cardiomyopathy. If the patient has no structural heart disease, the focus is likely to be the right ventricular outflow tract, whereas if the patient has structural heart disease, the left ventricle is most likely to be the site of origin.

PVCs are not preceded by a P wave and demonstrate a prolonged QRS (> 120 ms) with a compensatory pause (as opposed to a non-compensatory pause found with PACs). Conflicting ST and T wave changes are also often seen. ST depression and T-wave inversion tends to occur in R-wave dominant leads, whereas ST elevation and an upright T wave occur in S-wave dominated leads. PVCs may be unifocal or multifocal and their morphology may at times resemble right or left bundle branch blocks. If the PVC occurs with every other beat, it is termed bigeminy (or trigeminy if every third, etc.), or if the PVC is paired with another PVC, it is called a couplet. One may also see an R on T phenomenon whereby the PVC occurs at or near the T wave of the previous QRS complex resulting in the R wave of the PVC blending with the T wave of the preceding beat.

Patients with frequent PVCs will often develop subsequent cardiomyopathy, though the etiology is unknown. There is an increased risk in developing cardiomyopathy the longer one is exposed to PVCs. It is suspected this may be due to a less efficient heartbeat with suboptimal cardiac output similar to bradycardia. Risk factors for progression to cardiomyopathy have been inconsistently identified but likely include increasing age, high body mass index, and male gender.

Prevention and Clinical Manifestations

Patients with symptoms caused by PVCs often present with palpitations, dizziness, chest pain, syncope, dyspnea, orthopnea, decreased exercise tolerance, and fatigue. If a patient has a cough of unknown etiology, they should be evaluated for PVCs, as PVCs are noted to produce cough as the only symptom. PVCs have also been associated with dysphagia, especially when intermittent, as well as paroxysmal choking or vomiting. As such, PVCs should be considered if a gastroenterological evaluation is normal, or if symptoms persist despite treatment for an underlying gastrointestinal disorder.

PVCs are associated with a multitude of pathologic cardiac processes including heart failure, myocardial ischemia, left ventricular

hypertrophy, idiopathic ventricular tachycardia, and right ventricular dysplasia. On exam patients may present with an irregular pulse or canon A wave. PVCs may also be associated with pulmonary or thyroid disease, the consumption of alcohol, caffeine, and the use of beta agonists. Cocaine, amphetamines, or other illicit drugs may precipitate symptoms as well. Syncope is uncommon with PVCs but, if present, represents a red flag for the presence of malignant arrhythmias.

PVCs are found on 40% to 75% of holter monitor evaluations and 1% of EKGs. They are defined as frequent if they are seen on an EKG, or are present at a rate of more than 30 an hour on event monitoring. In this instance there is a significantly increased cardiovascular risk as well as mortality. In the athlete, sinus bradycardia is common due to enhanced conditioning. This results in a lengthening of the RR interval and is thought to promote the occurrence of PVCs in this population.

The most important prognostic indicator for PVCs is the presence or absence of structural heart disease. Multifocal PVCs are considered to be risk factors for adverse cardiovascular events.

Potential contributors that are amenable to treatment include electrolyte abnormalities, hypoxia, drugs (including prescription as well as illegal), increased adrenergic drive, or ischemia.

Diagnosis and Differential Diagnosis

A 12-lead EKG is the initial test of choice. Echocardiography is necessary in individuals in which structural heart disease is suspected, or if PVC frequency is high (one or more PVCs on EKG, or more than 30 an hour on event monitoring). This is based on the understanding that the likelihood of underlying structural heart disease increases with PVC burden. In addition, if ischemia is suspected or if PVCs are triggered/evident on exertion, cardiovascular exercise stress testing is recommended. Polymorphic PVCs are more commonly seen in those with underlying cardiomyopathy.

Differential diagnosis includes ventricular arrhythmias such as ventricular tachycardia and ventricular fibrillation. Cardiac conditions include left ventricular hypertrophy in the setting of hypertension, myocarditis, acute coronary syndrome, heart failure, congenital heart disease, and hypertrophic cardiomyopathy.

Treatment and Monitoring

PVCs have been demonstrated to be an independent risk factor for cardiovascular mortality in heart failure and are associated with ejection fraction and wall motion abnormalities as well. Patients with a family history of frequent PVCs should be evaluated for inherited channelopathies such as catecholamine urgent polymorphic ventricular tachycardia. In patients with PVCs but without underlying coronary artery disease or structural heart disease, the clinical course is generally benign. It should be recalled, however, that patients with a history of PVCs can develop coronary artery disease or underlying structural heart disease, so periodic reevaluation of cardiac status is warranted.

Treatment for those with symptomatic PVCs may include beta blockers or non-dihydropyridine calcium channel blockers, but treatment is not necessary in asymptomatic patients. Use of antiarrhythmic medication to treat PVCs has not been shown to benefit patients with cardiomyopathy. In addition, treatment is not indicated following myocardial infarction to suppress PVCs that may be present. If the patient has a large PVC burden, considered to be greater than 15%, referral to an EPS specialist for consultation and possible radiofrequency ablation should be considered.

Premature Junctional Contractions

PJCs are less common than either PACs or PVCs and are rarely seen in the setting of a normal heart. These beats arise from the atrioventricular junction. On EKG they are seen as an aberrant beat with underlying sinus rhythm. The P wave may be absent, inverted, or occur following the associated QRS complex that is morphologically normal. Causes include electrolyte and thyroid abnormalities, underlying lung or cardiac disease, or the use of excessive amounts of caffeine, nicotine, or alcohol. Medication toxicity may also be a cause, with digitalis toxicity being the classic

example. If patients are asymptomatic, no treatment is required, though structural heart disease needs to be ruled out. In addition, the patient should be observed over time, as PJC's may be a harbinger of progression to a more serious arrhythmia. In the symptomatic patient, treatment is directed at the underlying cause. Supplemental oxygen may be of benefit.

TACHYCARDIAS

Method of

Stephen Boateng, DO

CURRENT DIAGNOSIS

- A hemodynamic assessment and a 12-lead ECG should be obtained on every patient presenting with tachycardia.
- Tachycardia is defined as a cardiac rhythm greater than 100 beats/min.
- Tachycardias may be supraventricular or ventricular in origin.
- SVTs may be narrow complex (QRS duration less than 120 ms) or wide complex (QRS duration greater than 120 ms). VTs are always wide complex.
- History taking is useful in aiding in the diagnosis and definition of tachycardia.
- Patients with tachycardias might complain of palpitations, fatigue, lightheadedness, chest discomfort, dyspnea, presyncope, or syncope.
- A history of syncope is a red flag and should prompt immediate referral to an electrophysiologist.

CURRENT THERAPY

- All wide-complex tachycardias should be treated as ventricular in origin unless proved otherwise. The misdiagnosis of SVT when VT is present is associated with worse prognosis.
- Radiofrequency ablation is often successful in curing SVTs and some VTs.

- Wide-QRS complex tachycardias are commonly secondary to VT in the setting of structural heart disease, and effective therapy is accomplished with cardioverter-defibrillator implantation.

Tachycardia

Tachycardia is any cardiac rhythm with a rate greater than 100 beats/min. It may be supraventricular or ventricular in origin. Supraventricular tachycardias (SVTs) almost always manifest as narrow-complex (less than 120 msec) tachycardias on an electrocardiogram (ECG). However, wide-complex (greater than 120 msec) tachycardias occur if there is aberrant conduction or a bundle branch block. Ventricular tachycardias (VTs) occur when there are more than three consecutive ventricular beats at a rate greater than 100 beats per minute. VTs always manifest as wide-complex tachycardias.

Epidemiology

Supraventricular Tachycardias

Though rarely life threatening, SVTs are common, may be persistent, and often reoccur throughout one's lifetime. The etiology of SVTs varies with age, sex, and comorbid conditions. Paroxysmal SVTs (PSVTs) are estimated to have a prevalence of 2.25 per 1000 and an incidence of 35 per 100,000 person-years, according to the Marshfield Epidemiologic Study Area (MESA) conducted in Wisconsin. In this study, the mean age of onset of PSVT was 57 years, and age of onset ranged from infancy to more than 90 years. Female patients were shown to have a twofold risk compared with their male counterparts in the MESA study.

Ventricular Tachycardias

VTs have a prevalence of about 20 per 100,000 persons in the general population and occur more commonly in men. An appreciable percentage (3.5%) of VTs occur after myocardial infarction (MI), and the incidence of post-MI VT increases with age.

Pathophysiology

All tachycardias are produced by one or more mechanisms that include disorders of impulse initiation (automaticity) and abnormalities of impulse conduction (reentrance). Tissues exhibiting abnormal automaticity that underlie SVT can reside in the atria, the AV junction, or vessels that communicate directly with the atria, such as the vena cava or pulmonary veins. Normally, the sinus node contains the dominant pacemaking function and is made of cells with faster rates of phase 4 diastolic depolarization (Figure 1). Cells with abnormal automaticity (enhanced diastolic phase 4 depolarization) can arise in other locations (ectopic foci), and if their firing rate exceeds that of the sinus node, then the ectopic focus becomes the predominant pacemaker of the heart.

Reentry is the most common mechanism by which SVT occurs. It is also the mechanism for atrial flutter, atrioventricular (AV) node reentry tachycardia (AVNRT), some atrial tachycardias, AV reciprocating tachycardia (AVRT), some VTs, and ventricular fibrillation (VF). Initiation and maintenance of a reentrant tachycardia requires a unidirectional block in one limb of the circuit and slow conduction in the other. A unidirectional block can result from acceleration of the heart rate or from a premature impulse that is blocked during the refractory period of the pathway.

As shown in Figure 1A, a normal impulse arriving at Π is propagated down both a and b . Conduction through pathway a is initially faster and unimpeded, while conduction through b is slow. A normal sinus beat is produced. A second impulse attempts to go down a and b ; however, this time finds a refractory, and thus no conduction occurs (unidirectional block). Pathway b , which is slow conducting and has a shorter refractory period, conducts the impulse. This results in a premature supraventricular beat with a prolonged PR interval. The impulse through b may continue in a retrograde pathway (c) to a , and if a is past its refractory period a circuit is created through which the impulse can continue to circle, producing a persistent reentrant tachycardia.

example. If patients are asymptomatic, no treatment is required, though structural heart disease needs to be ruled out. In addition, the patient should be observed over time, as PJC's may be a harbinger of progression to a more serious arrhythmia. In the symptomatic patient, treatment is directed at the underlying cause. Supplemental oxygen may be of benefit.

Supraventricular tachycardias (SVTs) almost always manifest as narrow-complex (less than 120 msec) tachycardias on an electrocardiogram (ECG). However, wide-complex (greater than 120 msec) tachycardias occur if there is aberrant conduction or a bundle branch block. Ventricular tachycardias (VTs) occur when there are more than three consecutive ventricular beats at a rate greater than 100 beats per minute. VTs always manifest as wide-complex tachycardias.

Epidemiology

Supraventricular Tachycardias

Though rarely life threatening, SVTs are common, may be persistent, and often reoccur throughout one's lifetime. The etiology of SVTs varies with age, sex, and comorbid conditions. Paroxysmal SVTs (PSVTs) are estimated to have a prevalence of 2.25 per 1000 and an incidence of 35 per 100,000 person-years, according to the Marshfield Epidemiologic Study Area (MESA) conducted in Wisconsin. In this study, the mean age of onset of PSVT was 57 years, and age of onset ranged from infancy to more than 90 years. Female patients were shown to have a twofold risk compared with their male counterparts in the MESA study.

Ventricular Tachycardias

VTs have a prevalence of about 20 per 100,000 persons in the general population and occur more commonly in men. An appreciable percentage (3.5%) of VTs occur after myocardial infarction (MI), and the incidence of post-MI VT increases with age.

Pathophysiology

All tachycardias are produced by one or more mechanisms that include disorders of impulse initiation (automaticity) and abnormalities of impulse conduction (reentrance). Tissues exhibiting abnormal automaticity that underlie SVT can reside in the atria, the AV junction, or vessels that communicate directly with the atria, such as the vena cava or pulmonary veins. Normally, the sinus node contains the dominant pacemaking function and is made of cells with faster rates of phase 4 diastolic depolarization (Figure 1). Cells with abnormal automaticity (enhanced diastolic phase 4 depolarization) can arise in other locations (ectopic foci), and if their firing rate exceeds that of the sinus node, then the ectopic focus becomes the predominant pacemaker of the heart.

Reentry is the most common mechanism by which SVT occurs. It is also the mechanism for atrial flutter, atrioventricular (AV) node reentry tachycardia (AVNRT), some atrial tachycardias, AV reciprocating tachycardia (AVRT), some VTs, and ventricular fibrillation (VF). Initiation and maintenance of a reentrant tachycardia requires a unidirectional block in one limb of the circuit and slow conduction in the other. A unidirectional block can result from acceleration of the heart rate or from a premature impulse that is blocked during the refractory period of the pathway.

As shown in Figure 1A, a normal impulse arriving at Π is propagated down both a and b . Conduction through pathway a is initially faster and unimpeded, while conduction through b is slow. A normal sinus beat is produced. A second impulse attempts to go down a and b ; however, this time finds a refractory, and thus no conduction occurs (unidirectional block). Pathway b , which is slow conducting and has a shorter refractory period, conducts the impulse. This results in a premature supraventricular beat with a prolonged PR interval. The impulse through b may continue in a retrograde pathway (c) to a , and if a is past its refractory period a circuit is created through which the impulse can continue to circle, producing a persistent reentrant tachycardia.

Figure 1 A, Diagram of reentry. The impulse is initiated at II. I and II represent two distinct pathways. *a* represents unidirectional block, *b* represents slow conduction, and *c* shows the propagation of the wavefront reentering the circuit. B, A cardiac action potential. The different phases of the action potential are 0–4. Phase 4 demonstrates automaticity, which, when it reaches threshold, will initiate the next cardiac action potential. C, A cardiac action potential demonstrating early afterdepolarization (EAD) at the end of phase 2. D, A cardiac action potential demonstrating a delayed afterdepolarization (DAD) during phase 4.

Clinical Manifestations

Patients with paroxysmal arrhythmias are often asymptomatic on presentation. When symptoms are present, they can include palpitations, fatigue, lightheadedness, chest discomfort, dyspnea, presyncope, and syncope. Syncope is observed in about 15% of patients with SVT. Patients with ventricular arrhythmias more often present with presyncope, syncope, or even cardiac arrest. A history of syncope should warrant immediate referral to an electrophysiologist.

Diagnosis

History taking is useful in aiding in the diagnosis and definition of tachycardia. It is important for the clinician to assess whether or not the palpitations are regular or irregular, the number of episodes, possible triggers, and the nature of onset and termination (whether abrupt or gradual). Recurrent episodes with abrupt onset and termination are designated *paroxysmal*. Episodes with a gradual onset and termination are nonparoxysmal (e.g., sinus tachycardia). Irregular palpitations likely are due to premature depolarizations, suggesting atrial fibrillation or multifocal atrial tachycardia. Multifocal atrial tachycardia is often encountered in patients with pulmonary disease. Premature beats are often described by the patient as pauses followed by a sensation of a strong heartbeat or as irregularities in heart rhythm.

On physical examination, if irregular cannon A waves are observed in the jugular vein or variation in the intensity of the S1 heart sound is heard, then a ventricular origin is strongly suggested. Termination of the tachycardia with vagal maneuvers strongly suggests a reentrant tachycardia involving AV nodal tissue such as AVNRT or AVRT.

A resting echocardiogram should be recorded. In the absence of symptoms this may be of low diagnostic yield. However, the presence of preexcitation (Figure 2) on the ECG suggests AVRT and is

Figure 2 A 12-lead electrocardiogram depicting typical AV node reentry tachycardia. Note the absence of obvious atrial activity or P wave.

enough to make a presumptive diagnosis. Baseline ECG with pre-excitation in combination with a history consistent with paroxysmal palpitations strongly suggests episodic atrial fibrillation and is concerning. These patients are at risk for sudden cardiac death and require immediate electrophysiologic evaluation. Patients without concerning symptoms such as syncope or persistent regular tachycardia may be sent home with an event monitor, with follow-up at a later date. A 24-hour Holter monitor can be used in patients who report daily transient tachycardia. In patients with infrequent arrhythmias, a loop recorder is more useful. An implantable loop recorder may be used in patients who have rare episodes associated with hemodynamic instability.

Differential Diagnosis

Narrow QRS-Complex Tachycardia

Narrow QRS-complex (less than 120 msec) SVTs are differentiated according to their mechanism and include sinus tachyarrhythmias, AVNRT, focal and nonparoxysmal junctional tachycardias, AVRT, focal atrial tachycardias, and macro-reentrant atrial tachycardia.

Wide QRS-Complex Tachycardia

Wide QRS-complex tachycardias may be supraventricular or ventricular in origin. Examples of wide QRS-complex SVTs include SVT with AV conduction via an accessory pathway, such as in Wolff–Parkinson–White (WPW) syndrome, or any SVT with aberrant conduction or ventricular pacing.

Specific Tachycardias

Supraventricular Tachycardias

Sinus Tachyarrhythmias

Sinus tachycardia can result from physiologic stimulation of the sinus node or sinus node reentry (sinus node reentry tachycardia). The latter results in paroxysmal nonsustained episodes of tachycardia. Normally, sinus tachycardia occurs as an appropriate response to physiologic stimulus such as exercise. Pathologic causes that can induce sinus tachycardia include hyperthyroidism, pyrexia, hypovolemia, infections, or anemia. Drugs that can cause sinus tachycardia include atropine, aminophylline, catecholamines, and anticancer treatments (such as doxorubicin [Adriamycin]). Stimulants such as caffeine, alcohol, and nicotine and recreational drugs such as cocaine, amphetamines, and ecstasy can induce sinus tachycardia. It can also result from an excessive stimulus such as hyperthyroidism. On ECG, a normal axis with upright P waves in I, II, and aVF and a negative P wave in aVR are revealed.

In addition to eliminating the underlying offensive agent such as excessive caffeine use or hyperthyroidism, β -blockers are very effective for terminating and suppressing sinus tachycardia. Nondihydropyridine calcium-channel blockers such as diltiazem (Cardizem) or verapamil (Istopin) may also be used. Vagal maneuvers, adenosine (Adenocard), β -blockers, and nondihydropyridine calcium-channel blockers are effective in treating reentry sinus tachycardia. In rare cases where inappropriate sinus tachycardia is refractory, catheter ablation may be performed.

Atrioventricular Nodal Reciprocating Tachycardia

AVNRT is the most common form of PSVT, and it produces rates of tachycardia between 140 and 250 beats per minute. It is more prevalent in female patients. Patients typically report associated palpitations, dizziness, and neck pulsations.

The mechanism of AVNRT is a reentry circuit that is now known to involve perinodal atrial tissue as well, and it is not always confined to the compact AV node as previously believed. In AVNRT, reciprocation occurs between two distinct pathways: the first, fast pathway, is located near the apex of Koch's triangle; the second is a slow pathway that extends from the compact AV-node tissue and stretches along the septal margin of the tricuspid annulus at the level of, or slightly superior to, the coronary sinus. The fast pathway conducts rapidly with a slow recovery time and a longer

Figure 3 A, Normal conduction system. *Abbreviations:* AVN = atrioventricular node; LA = left atrium; LBB = left bundle branch; LV = left ventricle; RA = right atrium; RBB, right bundle branch; RV = right ventricle; SN, sinus node. B, Diagram of heart depicting typical atrioventricular node reentry tachycardia (AVNRT) with anterograde conduction via the slow AVN and retrograde conduction via the fast AVN. C, Diagram of the heart depicting orthodromic atrioventricular reciprocating tachycardia (o-AVRT), with anterograde conduction via the AVN and retrograde conduction via the accessory pathway (AP).

refractory period, and the second pathway conducts slowly with a short refractory period. AVNRT is initiated when a premature impulse finds the fast pathway refractory and is thus conducted anterogradely through the slow pathway. The impulse continues past the AV node, down the His–Purkinje system, activates the ventricles, and approaches the His bundle. Here, the impulse finds the fast pathway in recovery. The fast pathway then serves as a retrograde pathway for conduction back to the atria (Figure 3). This produces a P wave during or very close to the QRS complex, often with a pseudo-R' in V1.

Rarely, an atypical AVNRT occurs in which there is anterograde conduction through the fast pathway and retrograde conduction through the slow pathway, producing a long R–P tachycardia. The P wave, negative in III and aVF, is inscribed prior to the QRS. Sometimes, though infrequently, the circuit is composed of slowly conducting tissues in both limbs of the circuit, resulting in a P wave inscribed after the QRS (a retrograde P wave) (Figure 4).

Adenosine 6 mg IV push is administered to terminate the rhythm, and if the initial dose is unsuccessful, two more doses of 12 mg of adenosine may be administered. Adenosine has a half-life of only 9 seconds, and it terminates the circuit by causing transient block in AVN conduction. Long-term therapy with a β -blocker or calcium channel blocker can prevent recurrence. If AVN is recurrent, radiofrequency ablation is the treatment of choice and has a low risk of complication.

Atrioventricular Reciprocating Tachycardia (Extranodal Accessory Pathways)

An accessory pathway is a pathway outside the AV node that connects the myocardium of the atrium and the ventricle. Accessory pathways may be located across the mitral or tricuspid annulus and may be capable of anterograde or retrograde conduction, or both. Accessory pathways that conduct in a retrograde function are referred to as “concealed” because they do not reveal preexcitation on ECG. Those capable of anterograde conduction are referred to as “manifest.” WPW syndrome is diagnosed if the patient has both preexcitation on ECG and tachyarrhythmias (Figure 5). AVRT may be orthodromic or antidromic.

Figure 4 Electrocardiogram lead V1 recorded during administration of adenosine. Termination of atrioventricular node reentry tachycardia occurs in the anterograde slow pathway. The arrow points to retrograde atrial activity at the terminal portion of the QRS that is sometimes apparent during tachycardia.

Figure 5 Electrocardiogram lead III recording of a QRS demonstrating ventricular preexcitation (arrow), also called Wolff–Parkinson–White pattern.

Orthodromic AVRT occurs when there is anterograde conduction down the AV node and retrograde conduction up the accessory pathway (Figure 6). In antidromic AVRT the reverse occurs.

Atrial fibrillation is considered life-threatening in patients with WPW syndrome. This is because rapid repetitive conduction can occur via the accessory pathway (which has a short refractory period), resulting in a rapid ventricular rate that can degenerate into VF.

Administration of adenosine can precipitate atrial fibrillation in 10% to 15% of patients with an extranodal accessory pathway. Therefore if it is unknown whether or not the patient has an anterogradely conducting accessory pathway, it is good practice to have a defibrillator present at the bedside during administration of adenosine. For patients with known WPW syndrome (or delta wave on baseline ECG), procainamide (Pronestyl)¹ or ibutilide (Corvert), drugs that slow conduction over the accessory pathway, can be administered instead of adenosine.

Focal and Nonparoxysmal Junctional Tachycardia

Focal Junctional Tachycardia

Focal junctional tachycardia is a generally rare phenomenon that can occur by automaticity or reentry mechanisms. By definition, focal junctional tachycardia originates from the AV node or His

¹Not FDA approved for this indication.

Figure 6 A 12-lead electrocardiogram depicting orthodromic atrioventricular reciprocating tachycardia. The arrow highlights the atrial activity, which is occurring well after the QRS complex.

bundle. On ECG, focal junctional tachycardia may be varied in its features. It often has a rate of 110 to 250 beats/min, with narrow QRS complexes or a bundle branch block (BBB) conduction pattern. AV dissociation often occurs. However, one-to-one retrograde conduction can also occur. Focal junctional tachycardia often occurs in young adulthood and is precipitated by exercise or stress. Patients might respond to β -blockers or flecainide (Tambocor) (which may be administered IV initially to terminate the tachycardia, followed by an oral dose), but drug therapy is not always effective. Catheter ablation is most effective and can be curative, though there is a 5% to 10% risk of AV block.

Nonparoxysmal Junctional Tachycardia

Nonparoxysmal junctional tachycardia is a benign arrhythmia that is characterized by narrow QRS complexes at a rate of 70 to 120 beats/min. It occurs via automaticity and can indicate serious underlying pathology such as digitalis toxicity, hypokalemia, hypoxia, or myocardial ischemia. It is treated by correcting the underlying abnormality.

Focal Atrial Tachycardias

Focal atrial tachycardias are usually benign unless they are persistent, when they can cause tachycardia-induced cardiomyopathy. They usually manifest with rates between 100 and 250 beats/min, rarely getting up to 300 beats/min. The mechanism is thought to be via automaticity, and the majority originate along the crista terminalis from the SA node to the AV node. Recommended initial therapy is with calcium channel blockers or β -blockers. If these are unsuccessful, flecainide or propafenone (Rythmol) may be added. If the tachycardia is refractory to drug therapy, catheter ablation may be performed; it had a success rate of up to 86% in one study. Though inadvertent, AV node blockage is of concern.

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia is exemplified by ECG findings of an irregular tachycardia with three or more different P-wave morphologies at different rates. It is commonly associated with underlying pulmonary disease or electrolyte abnormalities. Calcium channel blockers are a highly successful form of treatment. There is no role for direct-current cardioversion, antiarrhythmic drugs, or ablation.

Macro-Reentrant Atrial Tachycardia (Atrial Flutter)

Atrial flutter, also known as macro-reentrant atrial tachycardia, is characterized by an organized atrial rhythm at a rate between 250 and 350 beats/min and occurs via a reentry mechanism. Typical atrial flutter is sometimes called isthmus-dependent flutter (Figure 7), so named because it involves the cavotricuspid isthmus. Patients typically present with a 2:1 AV conduction block producing a ventricular rate of about 150 beats/min. Patients can also present with a variable AV block producing an irregular rhythm.

Figure 7 Electrocardiogram of leads II and III depicting typical atrial flutter. Note the sawtooth atrial activity.

Acute management focuses on ventricular rate control using AVN blocking agents such as β -blockers or calcium channel blockers. Rapid atrial overdrive pacing can also terminate the arrhythmia. Direct current cardioversion is also a very effective mode of therapy for patients who present with hemodynamic collapse. An energy level of 50 J is typically effective. In patients with atrial flutter for more than 48 hours, anticoagulant therapy should be started and an echocardiogram should be obtained to rule out the presence of an intracardiac clot before cardioversion. Anticoagulation is usually achieved with warfarin (Coumadin), with an international normalized ratio (INR) goal of 2 to 3.

Cure of atrial flutter can be achieved with radiofrequency ablation in more than 98% of patients. The macroreentrant circuit in atrial flutter uses the atrial tissue between the tricuspid valve annulus and the inferior vena cava, and radiofrequency energy delivered across the cavotricuspid isthmus prevents atrial flutter from recurring. Radiofrequency ablation is the treatment of choice for patients with recurrent atrial flutter.

Ventricular Tachycardias

Three broad categories of pathologies contribute to the development of VT: structural heart disease, prolonged QT syndrome, and accelerated idioventricular rhythm.

Structural Heart Disease

VT in patients with structural heart disease is secondary to reentry and is a result of fibrotic tissue or infiltrative disease causing areas of slow conduction. Common causes of structural heart disease include ischemia, congestive heart failure, and infiltrative heart disease (e.g., sarcoidosis, amyloidosis, and Chagas' disease). The mainstay of treatment is implantation of an implantable cardioverter-defibrillator (ICD) to prevent sudden death from VT or VF. An ICD is indicated in congestive heart failure patients with an ejection fraction less than 35% that is refractory to medical treatment. The administration of a class III antiarrhythmic drug or β -blocker can also reduce episodes of VT.

Long-QT Syndrome

A long QT interval may be congenital or drug induced. Patients with a long QT interval are prone to a specific form of polymorphic VT called torsades de pointes. This is characterized by rapid, irregular QRS complexes, which follow a twisting pattern around the baseline of the ECG. Torsades de pointes can degenerate into VF, causing significant hemodynamic compromise and death.

Congenital long QT syndrome results from genetic defects in cardiac ion channels that enhance sodium or calcium inward currents or inhibit outward potassium currents during the plateau phase of

the action potential. This results in prolongation of the action potential and causes the observed long QT. A common scenario for long QT syndrome on board questions is a young patient in whom sudden cardiac death is precipitated by exercising, especially swimming. Common drugs that can cause a prolonged QT include class Ia, Ic, or III antiarrhythmic agents, tricyclic antidepressants, phenothiazines, and certain antivirals and antifungals. Torsades de pointes is usually treated with unsynchronized direct-current cardioversion and sometimes defibrillation.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm usually has a heart rate that ranges from 60 to 120 beats per minute. It is characterized by gradual onset and offset. It is typically self-limiting and brief in duration. It is often encountered in the setting of cocaine intoxication, acute myocarditis, and digoxin intoxication and following cardiac surgery.

VENOUS THROMBOSIS

Method of

Thomas W. Wakefield, MD; and Andrea T. Obi, MD

CURRENT DIAGNOSIS

- The diagnosis of deep venous thrombosis (DVT) is made with duplex ultrasound imaging and secondarily laboratory testing, because history and physical examination are inaccurate in up to half of cases.

- Although clinical assessment and D-dimer levels are useful to rule out thrombosis, there is no combination of clinical findings and biomarker testing at this time that can rule in the diagnosis.
- Duplex ultrasound imaging is the gold standard for the diagnosis of DVT.
- Spiral computed tomographic (CT) scanning, especially higher-resolution multidetector-row CT imaging, is preferred as the initial imaging test to establish the diagnosis of pulmonary embolism.

CURRENT THERAPY

- Initial therapy includes anticoagulation, compression garments, and ambulation.
- The new direct oral anticoagulants (DOACs) are favored over warfarin for acute VTE treatment and no cancer. Rivaroxaban (Xarelto) and apixaban (Eliquis) are administered as monotherapy whereas dabigatran (Pradaxa) and edoxaban (Savaysa) require a low-molecular-weight heparin (LMWH) bridge.
- LMWH should be administered for at least 5 days, during which time an oral anticoagulant (warfarin, dabigatran, or edoxaban) is begun. If warfarin is used, it should be therapeutic (international normalized ratio 2.0–3.0) for 2 consecutive days before stopping LMWH.
- The duration of anticoagulation depends on a number of factors, including the presence of risk factors for thrombosis, the type of thrombosis (idiopathic or provoked), the number of times thrombosis has occurred and risk factors for bleeding.
- Reduced dose DOACs lessen VTE recurrences more than placebo or aspirin for long-term treatment after VTE.
- Significant iliofemoral DVT may be treated with aggressive pharmacomechanical thrombolysis if a trial of anticoagulation fails to improve moderate to severe symptoms and the patient is ambulatory, has no contraindications to thrombolysis, and places a strong value on reducing the severity of post-thrombotic syndrome (PTS) while accepting the inherent bleeding risk. Pulmonary embolism causing hemodynamic deterioration or right heart strain should be treated with thrombolysis.

Epidemiology

Venous thromboembolism (VTE) includes deep venous thrombosis (DVT) and pulmonary embolism (PE). VTE affects up to 900,000 patients per year and results in 300,000 deaths per year. The incidence has remained constant and may be increasing since the 1980s and increases with age. The annual VTE rate among persons of European ancestry ranges from 104 to 183 per 100,000 person years. Overall VTE incidence may be higher in blacks and lower in Asians and Asian- and Native-Americans. The increasing prevalence of obesity, cancer, and surgery account in part for the persistent VTE incidence. Treatment of an acute VTE appears to be associated with incremental direct medical costs of \$12,000 to \$15,000 (2014 US dollars) with subsequent complications to increase cumulative costs up to \$18,000 to \$23,000 per incident case. Sequelae from VTE including recurrent VTE, post-thrombotic syndrome (PTS), ulcers, and varicosities increase the incident cost by an average of 75%. The annual incident cost to the US healthcare system is \$7 to \$10 billion dollars each year.

Risk Factors

Risk factors for VTE include acquired and genetic factors. Acquired factors include increasing age, malignancy, surgery, immobilization, trauma, oral contraceptives and hormone replacement therapy, pregnancy and the puerperium, neurologic disease, cardiac disease, obesity, sepsis, pneumonia, and inflammatory bowel disease. Genetic factors include antithrombin deficiency,

the action potential. This results in prolongation of the action potential and causes the observed long QT. Pulmonary embolism causing hemodynamic deterioration or right heart strain should be treated with thrombolysis.

Epidemiology

Venous thromboembolism (VTE) includes deep venous thrombosis (DVT) and pulmonary embolism (PE). VTE affects up to 900,000 patients per year and results in 300,000 deaths per year. The incidence has remained constant and may be increasing since the 1980s and increases with age. The annual VTE rate among persons of European ancestry ranges from 104 to 183 per 100,000 person years. Overall VTE incidence may be higher in blacks and lower in Asians and Asian- and Native-Americans. The increasing prevalence of obesity, cancer, and surgery account in part for the persistent VTE incidence. Treatment of an acute VTE appears to be associated with incremental direct medical costs of \$12,000 to \$15,000 (2014 US dollars) with subsequent complications to increase cumulative costs up to \$18,000 to \$23,000 per incident case. Sequelae from VTE including recurrent VTE, post-thrombotic syndrome (PTS), ulcers, and varicosities increase the incident cost by an average of 75%. The annual incident cost to the US healthcare system is \$7 to \$10 billion dollars each year.

Risk Factors

Risk factors for VTE include acquired and genetic factors. Acquired factors include increasing age, malignancy, surgery, immobilization, trauma, oral contraceptives and hormone replacement therapy, pregnancy and the puerperium, neurologic disease, cardiac disease, obesity, sepsis, pneumonia, and inflammatory bowel disease. Genetic factors include antithrombin deficiency,

protein C deficiency and protein S deficiency, factor V Leiden, prothrombin 20210A, blood group non-O, abnormalities in fibrinogen and plasminogen, elevated levels of clotting factors (e.g., factors XI, IX, VII, VIII, X, and II), and elevation in plasminogen activator inhibitor-1. When a patient presents with an idiopathic VTE, family history of thrombosis, recurrent thrombosis, or thrombosis in unusual locations, a work-up for hypercoagulability, including testing for the conditions noted in the previous sentence, may be indicated, although even in these situations, testing is controversial. Routine testing for hypercoagulable states in the setting of a provoked DVT is not indicated. Hematologic diseases associated with VTE include heparin-induced thrombocytopenia and thrombosis syndrome, disseminated intravascular coagulation, antiphospholipid antibody syndrome, myeloproliferative disorders, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome. There are a number of risk prediction scores that have been advanced, the most widely-used being the Caprini risk score.

Pathophysiology

Although Virchow's triad of stasis, vein injury, and hypercoagulability has defined the events that predispose to DVT formation since the mid-19th century, the understanding today of events that occur at the level of the vein wall and thrombus, including the inflammatory response on thrombogenesis, thrombus resolution and the subsequent changes to the vein wall and venous valves, is increasingly becoming apparent.

Diagnosis

Deep Venous Thrombosis

The diagnosis of DVT can be ruled out with a clinical scoring system known as the Wells score and a negative D dimer. Wells has classified patients into a scoring system that emphasizes physical presentation, and the most common physical finding is edema. Characteristics that score points in the Wells system include active cancer, paralysis or paresis, recent plaster/cast immobilization of the lower extremity, being recently bedridden for 3 days or more, localized tenderness along the distribution of the deep venous system, swelling of the entire leg, calf swelling that is at least 3 cm larger on the involved side than on the noninvolved side, pitting edema in the symptomatic leg, collateral superficial veins (nonvaricose), and a history of previous DVT. With extensive proximal iliofemoral DVT there may be significant swelling, cyanosis, and dilated superficial collateral veins. The negative predictive value of a low or intermediate risk patient as stratified by Well's score and a negative D dimer is near 100%. The incidence of DVT over the next 3 months in this patient cohort is 0.0% to 0.6%, suggesting that additional testing is unlikely to improve outcomes.

Duplex ultrasound imaging has become the gold standard for ruling in the diagnosis of DVT. Duplex imaging includes both a B-mode image and Doppler flow pattern. Duplex imaging demonstrates sensitivity and specificity rates greater than 95%. According to the grade criteria for the strength of medical evidence, duplex ultrasound is given a 1B level of evidence, depending on the pretest probability for DVT. Even at the level of the calf, duplex imaging is an acceptable technique in symptomatic patients. Duplex imaging is painless, requires no contrast, can be repeated, and is safe during pregnancy. Duplex imaging also identifies other causes of a patient's symptoms. Other tests available for making the diagnosis include magnetic resonance imaging (MRI) (especially good for assessing central pelvic vein and inferior vena cava [IVC] thrombosis) and spiral computed tomographic (CT) scanning (especially with chest imaging during examination for PE).

A single complete negative duplex scan is accurate enough to withhold anticoagulation with minimal long-term adverse thromboembolic complications. This requires that all venous segments of the leg have been imaged and evaluated. If the duplex scan is indeterminate owing to technical issues or to edema, treatment may be based on factors such as biomarkers, with the duplex repeated in 24 to 72 hours. Combining clinical characteristics with a high-sensitivity D-dimer assay can decrease the number of duplex scans

performed in the low risk patient. Although clinical characteristics and D-dimer levels are useful to rule out thrombosis, the converse is not true, and there is no combination of biomarkers and clinical presentation that can rule in the diagnosis. Work is ongoing to establish new biomarkers based on the inflammatory response to DVT. We have data suggesting that a combination of soluble P-selectin and the Wells score can rule in the diagnosis of DVT, whereas D-dimer plus Wells is still the best combination to rule out the diagnosis of DVT.

Conditions that may be confused with DVT include lymphedema, muscle strain, and muscle contusion and systemic problems such as cardiac, renal, or hepatic abnormalities. These systemic problems usually lead to bilateral edema.

Rarely, massive iliofemoral DVT can result in phlegmasia alba dolens (white swollen leg) or phlegmasia cerulea dolens (blue swollen leg). If phlegmasia is not aggressively treated, it can lead to venous gangrene when the arterial inflow becomes obstructed owing to venous hypertension. Alternatively, arterial emboli or spasm can occur and contribute to the pathophysiology. Venous gangrene is often associated with underlying malignancy and is always preceded by phlegmasia cerulea dolens. Venous gangrene is associated with significant rates of amputation and pulmonary embolism and with mortality.

Pulmonary Embolism

The diagnosis of PE historically has involved ventilation-perfusion scanning and pulmonary angiography. However, the most current techniques include spiral CT scanning and MRI, along with assessments of pretest probability and high sensitivity D-dimer measurements. Age-adjusted D-dimer measurements may increase the diagnostic usefulness of these measurements. CT scanning demonstrates excellent specificity and sensitivity. Emboli down to the subsegmental level can be identified. The sensitivity for isolated chest CT imaging is increased when clinical analysis is added and when adding lower extremity imaging to the chest scan, although with the introduction of higher resolution multidetector-row CT imaging, the need for lower extremity imaging combined with CT is being questioned. Useful alternate techniques when there are contraindications to CT imaging include MRI and ventilation-perfusion imaging.

In low-risk individuals, a score of 0 on the PE Rule-Out Criteria gives confidence that further testing (d-dimer and CT) is not necessary. The PE Rule-Out Criteria include (1) pulse oximetry of 94% or less, (2) heart rate of 100 beats/min or greater, (3) age of 50 years or older, (4) unilateral leg swelling, (5) hemoptysis, (6) recent trauma or surgery, (7) previous PE or DVT, (8) exogenous estrogen use.

Axillary and Subclavian Vein Thrombosis

Thrombosis of the axillary and subclavian veins accounts for less than 5% of all cases of DVT. However, it may be associated with PE in up to 10% to 15% of cases and can be the source of significant disability. Upper extremity DVT may be primary (approximately 20%), such as from thoracic outlet syndrome, effort thrombosis, or idiopathic; or secondary (approximately 80%), such as from catheter-related, cancer-associated, surgery-related, or mediastinal tumors. Primary axillary and subclavian vein thrombosis results from obstruction of the axillary vein in the thoracic outlet from compression by the subclavius muscle and the costoclavicular space, the Paget-Schrötter syndrome, noted especially in muscular athletes. Patients with axillary and subclavian vein thrombosis present with arm pain, edema, and cyanosis. Superficial venous distention may be apparent over the arm, forearm, shoulder, and anterior chest wall.

Upper extremity venous duplex ultrasound scanning is used to make the diagnosis of axillary and subclavian vein thrombosis. A secondary DVT (such as related to a central venous catheter or other risk factor) is treated with anticoagulation alone, with the same recommendation regarding anticoagulant type, dose, and duration. If Paget-Schrötter syndrome is suspected, thrombolysis and phlebography are considered as next interventions. If

phlebography is performed, it is important that the patient undergo positional phlebography with the arm abducted to 120 degrees to confirm extrinsic subclavian vein compression at the thoracic outlet once the vein has been cleared of thrombus. Because a cervical rib may be the cause of such obstruction, chest x-ray should be obtained to exclude its presence (although its incidence is quite low). Ultimately, decompression of the thoracic outlet with first rib resection (and cervical rib, if present), is necessary to prevent recurrent DVT.

Treatment

Standard Therapy for Venous Thromboembolism

The traditional treatment of VTE is systemic anticoagulation, which reduces the risk of PE, extension of thrombosis, and thrombus recurrence. Because the recurrence rate for VTE is higher if anticoagulation is not therapeutic in the first 24 hours, immediate anticoagulation should be undertaken. For PE, this usually means anticoagulation followed by testing. For DVT, because duplex imaging is rapidly obtained, usually testing precedes anticoagulation. Recurrent DVT can still occur in up to one third of patients over an 8-year period, even with appropriate anticoagulant therapy.

The first line of therapy in the modern-day treatment of VTE is DOACs. Currently 4 DOACs are FDA approved for the treatment of DVT. These include rivaroxaban (Xarelto) and apixaban (Eliquis) as oral monotherapy (both require a loading dose period, followed by a lower dose) and dabigatran (Pradaxa) and edoxaban (Savaysa), which require a LMWH bridge. Alternatively, LMWH or unfractionated heparin is given for 5 days, during which time oral anticoagulation with vitamin K antagonists (warfarin) is begun as soon as anticoagulation is therapeutic. With warfarin, it is recommended that the international normalized ratio be therapeutic for 2 consecutive days before stopping heparin or LMWH.

The new agents for venous thrombosis treatment include factor Xa inhibitors and direct thrombin inhibitors. The new oral anticoagulants are favored over warfarin (grade 2B) for acute VTE and no cancer. Dabigatran targets activated factor II (factor IIa), whereas rivaroxaban, apixaban, and edoxaban target activated factor X (factor Xa). Dabigatran etexilate (Pradaxa) is FDA approved for stroke and systemic embolization prevention in patients with non-valvular atrial fibrillation and for treatment and reduction of DVT and PE in patients who have been treated with a parenteral anticoagulant for 5–10 days.

Rivaroxaban (Xarelto) is FDA approved for VTE prophylaxis in patients undergoing hip or knee replacements, for stroke and systemic embolization prevention in patients with nonvalvular atrial fibrillation, and for VTE treatment. The Einstein trial evaluated rivaroxaban compared with standard anticoagulation in the treatment of acute DVT. As monotherapy, rivaroxaban was found statistically noninferior to standard therapy, without increased bleeding. A similar finding with PE has been noted. Apixaban (Eliquis) is currently FDA approved for the prevention of complications of nonvalvular atrial fibrillation, for prophylaxis of DVT after hip or knee replacement surgery, for the treatment of DVT/PE, and for the reduction in risk of recurrence of DVT/PE. Edoxaban (Savaysa) has been approved for prevention of stroke and non-central-nervous system (CNS) systemic embolism in patients with nonvalvular atrial fibrillation and for treating DVT and PE in patients who have been treated with a parenteral anticoagulant for 5 to 10 days.

When an anticoagulant bridge is required, LMWH is the standard for initial treatment. LMWH is preferred because it is administered subcutaneously, it requires no monitoring (except in certain circumstances such as renal insufficiency or morbid obesity), and it is associated with a lower bleeding potential. Additionally, LMWH demonstrates less direct thrombin inhibition and more factor Xa inhibition. Compared with standard unfractionated heparin, LMWH has significantly improved bioavailability, less endothelial cell binding and protein binding, and an improved pharmacokinetic profile. The half-life of LMWH is dose independent. LMWH is administered in a weight-based fashion.

Warfarin (Coumadin), when used, should be started after heparinization is therapeutic to prevent warfarin-induced skin necrosis. For standard unfractionated heparin, this requires a therapeutic activated partial thromboplastin time (aPTT); for LMWH, warfarin is administered after an appropriate weight-based dose of LMWH is administered and allowed to circulate. Warfarin causes inhibition of protein C and S before factors II, IX, and X, leading to paradoxical hypercoagulability at the initiation of therapy. The goal for warfarin dosing is an international normalized ratio between 2.0 and 3.0.

Fondaparinux (Arixtra) is the final agent that is approved for the treatment of VTE. It is a synthetic pentasaccharide that has an antithrombin sequence identical to heparin and targets factor Xa. Fondaparinux has been additionally approved for thrombosis prophylaxis in patients with total hip replacement, total knee replacement, and hip fracture; in extended prophylaxis in patients with hip fracture; and in patients undergoing abdominal surgery. It is administered subcutaneously and has a 17-hour half-life. Dosage is based on body weight. It exhibits no endothelial or protein binding and does not produce thrombocytopenia. However, no antidote is readily available. For the treatment of VTE, fondaparinux was found equal to LMWH for DVT, and for PE, it was found equal to standard heparin.

Duration of Treatment

The recommended duration of anticoagulation after a first episode of provoked VTE is 3 months for both proximal (grade 1B evidence) and distal thrombi (if symptomatic, grade 2C evidence). After a second episode of VTE, the usual recommendation is prolonged oral anticoagulation indefinitely (grade 1B), unless the patient is at high bleeding risk (2 or more risk factors, grade 2B) or the patient is very young at the time of presentation. VTE recurrence is increased with homozygous factor V Leiden and prothrombin 20210A mutation, protein C or protein S deficiency, antithrombin deficiency, antiphospholipid antibodies, and cancer until resolved. Long-term oral anticoagulation is usually recommended in these situations. However, heterozygous factor V Leiden and prothrombin 20210A do not carry the same risk as their homozygous counterparts, and the length of oral anticoagulation is shortened for these conditions.

Regarding idiopathic DVT, in those with a low bleeding risk, the recommended length of treatment is extended therapy for more than 3 months (grade 2B evidence), provided the patient is at low or moderate risk of bleeding. Patients at high risk of bleeding should be treated for 3 months (grade 1B) and reevaluated. Additional tools that can aid in the decision making to continue or discontinue anticoagulation include thrombosis risk factors, residual thrombus burden, and coagulation system activation. In addition, there is growing evidence that in certain circumstances, such as active cancer, the use of LMWH is superior to LMWH converted to warfarin for long-term treatment, for at least the first 3 to 6 months (grade 2C evidence).

Extended therapy is now recommended with low-dose DOACs when the risk-benefit relationship favors continued treatment. Extended rivaroxaban showed a significant decrease in recurrent VTE without a significant increase in major bleeding compared with aspirin for an additional 6 to 12 months of therapy after initial therapy in the Einstein Choice trial. Apixaban as extended treatment of VTE was also investigated. After initial treatment, an additional 12 months of apixaban therapy was compared with placebo. This study revealed a significant decrease in the rate of VTE without an increase in bleeding risk. In patients who cannot continue on DOACs after initial therapy for VTE and who do not have a contraindication, aspirin should be administered to prevent recurrent thrombosis.

Complications

Bleeding is the most common complication of anticoagulation. Risk factors for bleeding while on anticoagulation include age >65, previous bleeding, cancer, renal or liver failure, thrombocytopenia, previous stroke, diabetes, anemia, concurrent antiplatelet therapy, poor anticoagulant control, recent surgery, frequent falls,

alcohol abuse, and nonsteroidal antiinflammatory drug use. Presence of zero risk factors (low risk) confers an absolute risk of major bleeding of 0.8% per year. Patients with one risk factor have a risk of 1.6% per year, and those with two or more have a 6.5% risk or higher per year. With standard heparin, bleeding occurs over the first 5 days in approximately 10% of patients. Warfarin is associated with a major bleeding rate of 1% to 2% per year. Even with the new DOACS, bleeding (major plus minor) may occur in 5% to 10% of cases, although the risk of intracerebral bleeding appears to be less than with warfarin. Problems specific to the DOACs include the inability at the present time to reliably reverse their anticoagulant effects and the difficulty with laboratory monitoring. Recently, a monoclonal antibody was approved by the Food and Drug Administration (FDA) for the reversal of dabigatran, called idarucizumab (Praxbind), whereas agents are under development for factor Xa inhibitors (andexanet alfa [AndexXa]⁵ and aripazine⁵).

Heparin-induced thrombocytopenia (HIT) occurs in 0.6% to 30% of patients. Although historically morbidity and mortality rates have been high, it has been found that early diagnosis and appropriate treatment have decreased these rates. HIT usually begins 3 to 14 days after unfractionated heparin is begun, although it can occur earlier if the patient has been exposed to heparin in the past. A heparin-dependent antibody binds to platelets, activates them with the release of procoagulant microparticles leading to an increase in thrombocytopenia, and results in both arterial and venous thrombosis. Both bovine and porcine unfractionated heparin and LMWH have been associated with HIT, although the incidence and severity of the thrombosis is less with LMWH. Even small exposures to heparin, such as heparin coating on indwelling catheters, can cause the syndrome. The diagnosis should be suspected with a 50% or greater drop in platelet count, when the platelet count falls below 100,000/ μ L, or when thrombosis occurs during heparin or LMWH therapy. The enzyme-linked immunosorbent assay detects the antiheparin antibody in the plasma. This test is highly sensitive but poorly specific. The serotonin release assay is used as a confirmatory test, that is more specific but less sensitive than the enzyme-linked immunosorbent assay test.

When the diagnosis is made, heparin must be discontinued. Oral anticoagulation should not be given until an adequate alternative anticoagulant has been established and until the platelet count has normalized. Because LMWHs demonstrate high cross-reactivity with standard heparin antibodies, they cannot be substituted for standard heparin in patients with HIT. Agents that have been FDA approved as alternatives include the direct thrombin inhibitor argatroban. Fondaparinux (Arixtra)¹ has also been found effective for treatment of HIT in most cases, but it is not FDA approved for this indication.

Nonpharmacologic Treatments

The symptoms of swelling and leg fatigue can be controlled after DVT by the use of compression stockings. Additionally, walking with good compression does not increase the risk of PE, whereas it significantly decreases the incidence and severity of the PTS. A recent multicenter randomized trial has suggested that stockings do not prevent development of PTS after a first proximal DVT, and for that reason, the most recent ACCP guidelines suggest not using compression stockings to prevent PTS (grade 2B evidence). It must be remembered that the use of strong compression and early ambulation after DVT treatment can significantly reduce the symptoms of pain and swelling resulting from the DVT, even if the development of PTS is not prevented.

Aggressive Therapies for Venous Thromboembolism

The goals of DVT treatment are to prevent extension or recurrence of DVT, prevent pulmonary embolism, and minimize the late sequela of thrombosis, namely chronic venous insufficiency.

Standard anticoagulants accomplish the first two goals but not the third goal. The PTS (venous insufficiency related to venous thrombosis) occurs in up to 30% to 50% of patients after DVT and in an even higher percentage of patients with iliofemoral level DVT. It has been hypothesized that reopening the vein will alleviate venous hypertension or prevent PTS. This is known as the "open vein hypothesis." The following evidence suggests more aggressive therapies for extensive thrombosis are indicated: experimentally, prolonged contact of the thrombus with the vein wall increases damage. The thrombus initiates an inflammatory response in the vein wall that can lead to vein wall fibrosis and valvular dysfunction. The longer a thrombus is in contact with a vein valve, the more chance that valve will no longer function.

Venous thrombectomy has proved superior to anticoagulation over 6 months to 10 years as measured by venous patency and prevention of venous reflux. Catheter-directed thrombolysis has been used in many nonrandomized studies and, in small, randomized trials, was more effective than standard therapy. Quality of life was improved with thrombus removal, and results appear to be optimized further by combining catheter-directed thrombolysis with mechanical devices. These devices include but are not limited to the Angiojet rheolytic catheter, the EKOS ultrasound accelerated catheter, and new larger bore extraction devices (Penumbra and angiovac). With these devices, thrombolysis is hastened, the amount of thrombolytic agent is decreased, and bleeding is thus decreased. Additionally, the use of venous stents for iliac venous obstruction has been shown to decrease the incidence of PTS and chronic venous insufficiency.

To more fully elucidate the role of aggressive therapy in proximal iliofemoral venous thrombosis, the ATTRACT trial randomized 692 patients with acute proximal DVT to either anticoagulation alone or anticoagulation plus pharmacomechanical thrombolysis. This study found that more aggressive therapy did not decrease the incidence of PTS but did result in more major bleeding. The severity of the PTS was lessened by the pharmacomechanical thrombolysis, suggesting that more aggressive therapy should be offered to patients with significant iliofemoral venous thrombosis, who do not respond appropriately to a course of anticoagulation.

For PE, evidence exists that thrombolysis is indicated when there is hemodynamic compromise from the embolism. It is controversial whether thrombolysis should be used in situations in which there is no hemodynamic compromise, but there is evidence of right heart dysfunction or there are positive biomarkers.

Inferior Vena Cava Filters

Traditional indications for the use of IVC filters include failure of anticoagulation, a contraindication to anticoagulation, or a complication of anticoagulation. Protection from PE is greater than 95% using cone-shaped, wire-based permanent filters in the IVC. With the success of these filters, indications have expanded to the presence of free-floating thrombus tails, prophylactic use when the risk for anticoagulation is excessive, when the risk of PE is thought to be high, and to allow the use of perioperative epidural anesthesia. IVC filters are not recommended as first-line therapy in patients who are treated with anticoagulants.

IVC filters can be either permanent or retrievable. If a retrievable filter is left, then it becomes a permanent filter; the long-term fate of these filters has yet to be defined adequately in the literature. Thus great efforts should be made to remove retrievable IVC filters when the risk period is over. Most filters are placed in the infrarenal location in the IVC. However, they may be placed in the suprarenal position or in the superior vena cava.

Indications for suprarenal placement include high-lying thrombi, pregnancy or childbearing age, or previous device failure filled with thrombus. Although some have suggested that sepsis is a contraindication to the use of filters, sepsis has not been found to be a contraindication because the trapped material can be sterilized with intravenous antibiotics. Filters may be inserted under x-ray guidance or using ultrasound techniques, either external ultrasound or intravascular ultrasound.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

VALVULAR HEART DISEASE

Method of

Arash Arshi, MD; Carlos Sanchez, MD; and Steven Yakubov, MD

CURRENT DIAGNOSIS

- The diagnosis of severe aortic valve stenosis is based on an integration of clinical symptoms and hemodynamic echocardiographic criteria.

- Classic symptoms of severe aortic stenosis include fatigue, dyspnea on exertion, angina, near syncope or syncope, and congestive heart failure.
- Chronic mitral regurgitation tends to be a slowly progressive disease, and symptoms may not be apparent.
- Cardiac imaging, especially echocardiography, is crucial to the management of patients with valvular heart disease.
 - Diagnostic echocardiographic findings of severe aortic stenosis are peak aortic valve velocity of ≥ 4 m/sec, transaortic mean gradient of ≥ 40 mm Hg, and aortic valve area ≤ 1 cm² or aortic valve area index of ≤ 0.6 cm²/m².
- Echocardiography should be performed to determine the etiology of and characterize the severity of mitral regurgitation.
- Left ventricular size and function should be assessed in patients with mitral regurgitation.

CURRENT THERAPY

- Medical therapy has not been shown to change hemodynamic progression or clinical outcomes in patients with aortic stenosis.
- Reevaluation for early symptoms and transthoracic echocardiography should be performed every 6 to 12 months in asymptomatic patients with severe aortic stenosis and normal left ventricular systolic function.
- Transcatheter aortic valve replacement is currently approved in patients with severe symptomatic aortic stenosis with intermediate to high surgical risk and patients who have a prohibitive surgical risk. It is currently used in clinical trials in low-surgical-risk candidates.
- The etiology of mitral regurgitation dictates its treatment.
 - Degenerative (primary) mitral regurgitation typically requires surgical repair or replacement.
 - The management of functional (secondary) mitral regurgitation requires treatment of the underlying cardiomyopathy.
- The decision-making process in the management of patients with severe aortic stenosis or severe mitral regurgitation is best achieved by a heart valve team and should include a systematic risk assessment of the patient's comorbidities and estimation of the 30-day cardiac surgical mortality using the Society of Thoracic Surgeons' Predicted Risk of Mortality (STS-PROM) score.

Aortic Stenosis

Aortic stenosis (AS) is the most common form of adult valvular heart disease, becoming more prevalent in the aging population. It is estimated that more than 4% of the US population over age 75 have AS. Aortic valve stenosis is the most common cause of left ventricular outflow tract obstruction, while less common causes of obstruction may also occur above (supra-aortic) or below (sub-aortic) the level of the aortic valve and will not be discussed in this chapter.

Etiology

There are three main causes of valvular AS: congenital in origin (which is usually a bicuspid aortic valve), rheumatic valve disease, and degenerative calcification of a normal aortic valve. Congenitally affected aortic valves may be unicuspid or bicuspid and may become stenotic during childhood. In the majority of cases, a congenital bicuspid valve will develop significant calcific stenosis later in life, usually presenting after the fifth decade.

Rheumatic AS is an important cause of aortic valve disease worldwide; however, with the decline of rheumatic fever in developed countries, it is now a rare cause of AS in the United States. Rheumatic valve disease is characterized by commissural fusion, fibrosis, and calcification. Rheumatic AS is also commonly associated with rheumatic involvement of the mitral valve.

VALVULAR HEART DISEASE

Method of

Arash Arshi, MD; Carlos Sanchez, MD; and Steven Yakubov, MD

CURRENT DIAGNOSIS

- The diagnosis of severe aortic valve stenosis is based on an integration of clinical symptoms and hemodynamic echocardiographic criteria.

- Classic symptoms of severe aortic stenosis include fatigue, dyspnea on exertion, angina, near syncope or syncope, and congestive heart failure.
- Chronic mitral regurgitation tends to be a slowly progressive disease, and symptoms may not be apparent.
- Cardiac imaging, especially echocardiography, is crucial to the management of patients with valvular heart disease.
 - Diagnostic echocardiographic findings of severe aortic stenosis are peak aortic valve velocity of ≥ 4 m/sec, transaortic mean gradient of ≥ 40 mm Hg, and aortic valve area ≤ 1 cm² or aortic valve area index of ≤ 0.6 cm²/m².
- Echocardiography should be performed to determine the etiology of and characterize the severity of mitral regurgitation.
- Left ventricular size and function should be assessed in patients with mitral regurgitation.

CURRENT THERAPY

- Medical therapy has not been shown to change hemodynamic progression or clinical outcomes in patients with aortic stenosis.
- Reevaluation for early symptoms and transthoracic echocardiography should be performed every 6 to 12 months in asymptomatic patients with severe aortic stenosis and normal left ventricular systolic function.
- Transcatheter aortic valve replacement is currently approved in patients with severe symptomatic aortic stenosis with intermediate to high surgical risk and patients who have a prohibitive surgical risk. It is currently used in clinical trials in low-surgical-risk candidates.
- The etiology of mitral regurgitation dictates its treatment.
 - Degenerative (primary) mitral regurgitation typically requires surgical repair or replacement.
 - The management of functional (secondary) mitral regurgitation requires treatment of the underlying cardiomyopathy.
- The decision-making process in the management of patients with severe aortic stenosis or severe mitral regurgitation is best achieved by a heart valve team and should include a systematic risk assessment of the patient's comorbidities and estimation of the 30-day cardiac surgical mortality using the Society of Thoracic Surgeons' Predicted Risk of Mortality (STS-PROM) score.

Aortic Stenosis

Aortic stenosis (AS) is the most common form of adult valvular heart disease, becoming more prevalent in the aging population. It is estimated that more than 4% of the US population over age 75 have AS. Aortic valve stenosis is the most common cause of left ventricular outflow tract obstruction, while less common causes of obstruction may also occur above (supra-aortic) or below (sub-aortic) the level of the aortic valve and will not be discussed in this chapter.

Etiology

There are three main causes of valvular AS: congenital in origin (which is usually a bicuspid aortic valve), rheumatic valve disease, and degenerative calcification of a normal aortic valve. Congenitally affected aortic valves may be unicuspid or bicuspid and may become stenotic during childhood. In the majority of cases, a congenital bicuspid valve will develop significant calcific stenosis later in life, usually presenting after the fifth decade.

Rheumatic AS is an important cause of aortic valve disease worldwide; however, with the decline of rheumatic fever in developed countries, it is now a rare cause of AS in the United States. Rheumatic valve disease is characterized by commissural fusion, fibrosis, and calcification. Rheumatic AS is also commonly associated with rheumatic involvement of the mitral valve.

Degenerative or calcific AS is now the most common cause of AS in adults in North America. It has been associated with the same risk factors as vascular atherosclerosis including age, smoking, hypertension, diabetes, and hyperlipidemia. Histopathologic data suggest that calcific aortic valve disease is a chronic inflammatory process with lipid deposition and active leaflet calcification leading to restriction of the cusps.

Pathophysiology

In adults with AS, the gradual obstruction of the left ventricular (LV) outflow produces a systolic pressure gradient between the left ventricle and aorta. The average time interval of disease progression from nonobstructive valve thickening (aortic sclerosis) to severe AS is 8 years. However, only 16% of individuals with aortic sclerosis will develop any grade of valve obstruction. The average rate of hemodynamic progression once moderate AS is present is an increase in aortic jet velocity of 0.3 m/s per year and mean pressure gradient of 7 mm Hg per year with a decrease in aortic valve area of 0.1 cm²/year. Left ventricular response to chronic pressure overload ultimately leads to concentric wall hypertrophy. This compensatory mechanism helps maintain normal LV contractile function to counteract the gradual increase in afterload at the expense of decreased LV compliance and delayed relaxation resulting in diastolic dysfunction.

Clinical Presentation

The cardinal symptoms of severe AS are angina, syncope, and congestive heart failure. Because symptoms in severe AS may not occur until late in the disease process, usually in the sixth to ninth decades of life, clinicians should obtain a careful history of symptoms during the patient's initial assessment. Particular attention must be directed at early symptoms of fatigue or decreased exercise tolerance because elderly patients may minimize and attribute these symptoms to aging.

Dyspnea on exertion occurs once the pulmonary capillary pressure increases as a result of excessive elevation in LV end-diastolic pressure in a poorly compliant ventricle. Symptoms of angina pectoris in severe AS may occur in a similar manner as in coronary artery disease, with symptoms precipitated by exertion and relieved by rest even in the absence of obstructive epicardial coronary artery disease. Syncope may result from the inability of the heart to increase cardiac output from the stenotic valve in the setting of transient vasodilatation during physical activity, resulting in decreased cerebral perfusion. Other causes of syncope may also be attributable to arrhythmias, either advanced forms of atrioventricular blocks from calcification impinging on the conduction system or tachyarrhythmias causing a sudden decline in cardiac output such as in atrial fibrillation.

Diagnosis and Management

Diagnosis of AS is usually suspected after a systolic ejection murmur is heard during cardiac auscultation. The classic physical findings in patients with severe AS are a loud, late-peaking systolic murmur at the base of the heart radiating to the carotid arteries

with a delayed and diminished carotid upstroke (*pulsus parvus et tardus*). The latter physical finding may be masked in elderly patients with stiff, inelastic arterial walls. Distinctively, a normally split second heart sound is the only reliable physical finding to help exclude the diagnosis of severe AS.

A transthoracic echocardiogram (TTE) is recommended as the initial diagnostic test in the evaluation of patients with aortic valve stenosis to determine hemodynamic severity, left ventricular size and function, and prognosis and to evaluate timing of valve intervention. Echocardiographic valve hemodynamics define the severity of AS (Table 1). Severe AS is characterized by a peak aortic valve velocity of 4 m/s or higher, transaortic mean gradient of 40 mm Hg or higher, and aortic valve area of less than or equal to 1 cm² or aortic valve area index of less than or equal to 0.6 cm²/m². In severe symptomatic patients with low-flow, low-gradient severe AS and abnormal left ventricular function (<50%), a dobutamine stress echocardiogram is used to differentiate between true severe AS and pseudo-severe AS. Low-flow, low-gradient, true severe AS is characterized by a severely calcified valve with aortic valve area ≤ 1 cm² and peak aortic valve velocity less than 4 m/s that increases to 4 m/s or higher with low-dose dobutamine administration. Conversely, in pseudo-severe AS the aortic valve area increases to more than 1 cm² and flow normalizes during dobutamine stress echocardiogram.

Patients with asymptomatic AS require frequent monitoring owing to the progressive nature of the disease. The frequency of echocardiograms in asymptomatic patients with AS and normal left ventricular systolic function should be performed every 6 to 12 months for reevaluation in severe AS, every 1 to 2 years for moderate AS, and every 3 to 5 years for mild AS (see Table 1). In seemingly asymptomatic patients with severe AS, exercise testing is safe and helpful to expose symptoms, arrhythmias, or abnormal blood pressure response. Exercise testing should not be performed in symptomatic patients.

Treatment

Indication for intervention in patients with severe AS is dependent on the presence or absence of symptoms, the severity of AS, and left ventricular function. Routine aortic valve replacement in asymptomatic AS is currently not recommended. Importantly, event-free survival at 2 years in asymptomatic patients with severe AS (jet velocity ≥ 4.0 m/s) is 30% to 50%, and as low as 21% in those with very severe AS (jet velocity ≥ 5.0 m/s). Therefore close clinical follow-up to evaluate for early-onset AS symptoms and education regarding the disease course should be performed routinely.

Medical therapy has not been shown to change hemodynamic progression or clinical outcomes in patients with AS. Clinical data have failed to support the use of statins specifically for the prevention of progression of AS. However, all patients with concomitant coronary artery disease or hypercholesterolemia should be treated per established guidelines. Likewise, concurrent hypertension in patients with severe AS is common and should receive appropriate treatment per standard guidelines starting at a low dose and slowly titrating upward with frequent blood pressure monitoring. Although indicated in the treatment

TABLE 1 Echocardiographic Stages of Aortic Valve Stenosis and Frequency of Echocardiograms in Asymptomatic Patients with Aortic Stenosis and Normal LVEF

	MAXIMUM AORTIC VELOCITY	MEAN PRESSURE GRADIENT	AORTIC VALVE AREA	TTE FOLLOW-UP IN ASYMPTOMATIC PATIENTS
Mild aortic stenosis	2.0–2.9 m/s	< 20 mm Hg	> 1.5 cm ²	Every 3–5 years
Moderate aortic stenosis	3.0–3.9 m/s	20–30 mm Hg	1.0–1.5 cm ²	Every 1–2 years
Severe aortic stenosis	≥ 4.0 m/s	≥ 40 mm Hg	≤ 1.0 cm ²	Every 6–12 months
Very severe aortic stenosis	≥ 5 m/s	≥ 60 mm Hg	≤ 1.0 cm ²	

Abbreviations: LVEF = left ventricular ejection fraction; TTE = transthoracic echocardiogram.

of acute heart failure, diuretics should be used with caution to avoid volume depletion, which may result in marked reduction in cardiac output.

Surgical Treatment

Transcatheter aortic valve replacement (TAVR) has expanded rapidly as an alternative to surgical aortic valve replacement (SAVR) since its approval in 2011, with more than 135,000 patients treated in the United States alone. It is currently approved for use in patients with severe symptomatic AS with intermediate to high surgical risk and patients who have a prohibitive surgical risk. It is currently used in clinical trials in low-surgical-risk candidates and will likely be commercially available in the future for this indication.

Recommendations and timing of intervention for aortic valve stenosis by either SAVR or TAVR are summarized in Table 2. Once the patient with AS is considered to meet an indication for aortic valve replacement, an important component when choosing between SAVR and TAVR is the underlying risk assessment for SAVR. In the United States, the Society of Thoracic Surgeons' Predicted Risk of Mortality (STS-PROM) risk score calculator is the initial step in predicting 30-day mortality for SAVR, with three categories: low risk defined as <4%, intermediate risk defined as 4% to 8%, and high risk defined as >8% STS mortality risk. This risk calculator, however, does not include certain comorbid conditions that would also increase the surgical mortality risk such as frailty, porcelain aorta, liver cirrhosis, severe pulmonary hypertension, chest wall abnormalities, and hostile mediastinum. If 3 or more

major organ systems are compromised, severe frailty or the morbidity and mortality risk is greater than 50% the patient is considered prohibitive risk for SAVR. In Patients with severe AS and a life expectancy less than 1 year, TAVR or SAVR is considered futile despite successful procedure and it is appropriate to avoid any intervention for severe AS. Hence, the risk assessment is a combination of the STS-PROM score, frailty, disability, and major cardiovascular and noncardiovascular comorbidities.

The final treatment decision should be individualized with a risk-benefit assessment by a multidisciplinary heart valve team (including structural interventional cardiologists, imaging specialists, cardiovascular surgeons, and nursing professionals). The heart valve team assesses potential procedural outcomes based on the patient's individual procedural risk, comorbidities, goals, expectations, life expectancy, and potential quality-of-life improvement with SAVR or TAVR. The importance of a collaborative and multidisciplinary heart team approach to the evaluation and management of patients with complex AS has been endorsed by professional guidelines to maximize appropriate outcomes.

Once the patient is considered to be a suitable candidate for TAVR, the evaluation of all patients undergoing the procedure should include (1) right and left heart catheterization to assess hemodynamic pressures and presence of coronary disease and (2) computed tomography of the chest, abdomen, and pelvis to determine preferred vascular access or contraindications to it and aortic annulus dimension for prosthesis sizing (Figure 1).

The currently available TAVR valves approved by the United States Food and Drug Administration (FDA) include the balloon-expandable Edwards Sapien XT and Sapien 3 (Edwards Lifesciences) and self-expandable Medtronic Evolut R and Evolut PRO systems. The choice of valve mostly depends on anatomic reasons and operator preference and experience. In general, self-expanding prostheses are preferred over balloon-expandable in patients with a dense left ventricular outflow tract and annular calcifications owing to the risk of annular rupture. Conversely, a balloon-expandable valve is the only option available for the transapical approach, when vascular access is contraindicated owing to severe peripheral artery disease. Although there is no evidence comparing long-term clinical outcomes between balloon- and self-expandable valve technologies, both valves have shown similar mortality and stroke rates.

A series of major procedural cardiovascular complications have been described after TAVR, including paravalvular aortic regurgitation, ischemic strokes, conduction disturbances, cardiac perforation, coronary occlusion, and vascular access complications. With the advancement of valve technology and increase in operator experience, the frequency of procedural complications has reduced since the arrival of TAVR procedures. Preprocedure planning by an expert heart valve team is essential to recognizing and preventing expected complications during and after transcatheter valve implantation.

Currently the optimal antithrombotic regimen following TAVR is daily clopidogrel (Plavix)¹ 75 mg and aspirin¹ 75 to 100 mg for 3 to 6 months followed by daily aspirin alone for life. If there is an indication for chronic anticoagulation, it should follow current guidelines' recommendations for each individual condition (e.g., atrial fibrillation, deep venous thrombosis). The safety of antiplatelet therapy use in conjunction with oral anticoagulation should be individualized based on the patient's bleeding risk.

Mitral Regurgitation

Mitral regurgitation (MR) is a common valvular disease, and pathology in any of the structures of the mitral valve apparatus may lead to dysfunction of the valve. The base of the leaflets of the mitral valve are attached to the annulus, and the leaflets themselves are attached to the papillary muscles of the left ventricle by the chordae tendineae. The mitral valve is an integral part of both the left atrium and left ventricle, and disorders of these structures

TABLE 2 Summary of Recommendations for AS: Timing of Intervention

RECOMMENDATIONS	COR	LOE
AVR is recommended for symptomatic patients with severe high-gradient AS who have symptoms by history or on exercise testing (stage D1)	I	B
AVR is recommended for asymptomatic patients with severe AS (stage C2) and LVEF <50%	I	B
AVR is indicated for patients with severe AS (stage C or D) when undergoing other cardiac surgery	I	B
AVR is reasonable for asymptomatic patients with very severe AS (stage C1, aortic velocity ≥ 5.0 m/s) and low surgical risk	IIa	B
AVR is reasonable in asymptomatic patients (stage C1) with severe AS and decreased exercise tolerance or an exercise fall in BP	IIa	B
AVR is reasonable in symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF (stage D2) with a low-dose dobutamine stress study that shows an aortic velocity ≥ 4.0 m/s (or mean pressure gradient ≥ 40 mm Hg) with a valve area ≤ 1.0 cm ² at any dobutamine dose	IIa	B
AVR is reasonable in symptomatic patients who have low-flow/low-gradient severe AS (stage D3) who are normotensive and have an LVEF $\geq 50\%$ if clinical, hemodynamic, and anatomic data support valve obstruction as the most likely cause of symptoms	IIa	C
AVR is reasonable for patients with moderate AS (stage B) (aortic velocity 3.0–3.9 m/s) who are undergoing other cardiac surgery	IIa	C
AVR may be considered for asymptomatic patients with severe AS (stage C1) and rapid disease progression and low surgical risk	IIb	C

AS indicates aortic stenosis; AVR, aortic valve replacement by either surgical or transcatheter approach; BP, blood pressure; COR, Class of Recommendation; LOE, Level of Evidence; LVEF, left ventricular ejection fraction; and N/A, not applicable.

affect mitral valve function; likewise, disorders of the mitral valve lead to abnormalities of the left atrium and left ventricle.

Etiology

Mitral regurgitation can be divided into degenerative (primary) MR and functional (secondary) MR (Figure 2). Degenerative MR refers to pathology of the mitral valve leaflets and chordae tendineae that results in valve dysfunction. The most common etiology is mitral valve prolapse, where the underlying pathology is myxomatous mitral valve degeneration that results in redundant leaflets, causing prolapse of the leaflets. A myxomatous mitral valve is also prone to rupture of the chordae tendineae, leading to a flail leaflet or segment of a leaflet. Other common etiologies of MR include rheumatic heart disease and endocarditis. Mitral annular calcification may cause mild to moderate MR, but severe regurgitation is uncommon.

In contrast, in functional MR, the mitral valve itself has a relatively normal structure. Instead, the pathology is an abnormality of the left ventricle. This most commonly occurs after myocardial infarction, with focal wall motion abnormalities and displacement of the papillary muscle causing tethering of the chordae and leaflets, along with dilatation of the mitral valve annulus, resulting in incomplete coaptation of the mitral valve leaflets during systole. Functional MR may also occur in a dilated cardiomyopathy.

Clinical Manifestations

The clinical presentation of MR is extremely variable and depends largely on the severity of the regurgitation and its acuity. Mitral regurgitation tends to be asymptomatic when mild to moderate, but severe MR frequently results in symptoms. Acute MR occurring from papillary muscle rupture complicating an acute myocardial infarction leads to rapid hemodynamic collapse and carries a high risk of mortality. These patients experience pulmonary edema due to the acute volume overload of the left ventricle and left atrium. In contrast, chronic severe MR may have a relatively indolent course, with some patients reporting few symptoms. While chronic MR typically manifests as congestive heart failure, with exertional dyspnea, orthopnea, and lower extremity edema as the hallmark symptoms, owing to the insidious nature of the disease, patients may not always recognize their symptoms. A detailed history with a specific focus on symptoms of congestive heart

failure in addition to fatigue and effort intolerance must be elicited. Atrial fibrillation is a common complication of MR and is associated with worse outcomes.

Diagnosis

Physical examination classically may reveal a soft S1 and a holosystolic murmur at the apex that radiates to the left sternal border or to the axilla. However, the intensity of the murmur does not correlate to the severity of disease, nor does the absence of a murmur reliably rule out severe MR. Physical examination is important to assess the patient's volume status, with pulmonary rales and lower extremity edema suggesting congestive heart failure, and an irregularly irregular rhythm indicative of atrial fibrillation.

Cardiac imaging, in particular echocardiography, is crucial in the evaluation of suspected MR. Transthoracic echocardiography can reveal abnormalities of the mitral valve and provide important information on left ventricular size and function and estimation of pulmonary arterial pressure. Given the orientation of the mitral valve and the limits of transthoracic echocardiography, the severity of MR can be grossly underestimated, particularly if the regurgitant jet is eccentric. Transesophageal echocardiography, especially with the availability of three-dimensional imaging, provides higher-quality images of the mitral valve and allows more precise evaluation of the severity and etiology of MR, and has become the gold-standard test in the evaluation of patients with clinically significant MR. Echocardiography with color Doppler can be used to provide a visual estimate of the severity of regurgitation. The presence of reversal of flow into the pulmonary veins during systole suggests severe regurgitation. Quantitative analysis can also be performed to determine the volume of regurgitation and the orifice of the regurgitant jet. There is currently no single echocardiographic parameter to define severe MR, but integration of multiple qualitative and quantitative measurements is recommended. Accurate assessment of left ventricular dimensions and function is important in patients with chronic severe MR. Methods of determining the left ventricular ejection fraction include visual estimation and volumetric analysis. Owing to the volume of blood exiting the left ventricle through both the mitral and aortic valves during systole, the ejection fraction will be increased. In the presence of severe MR, a normal left ventricular ejection fraction approaches 70%, and left ventricular dysfunction is deemed anything less than 60%.

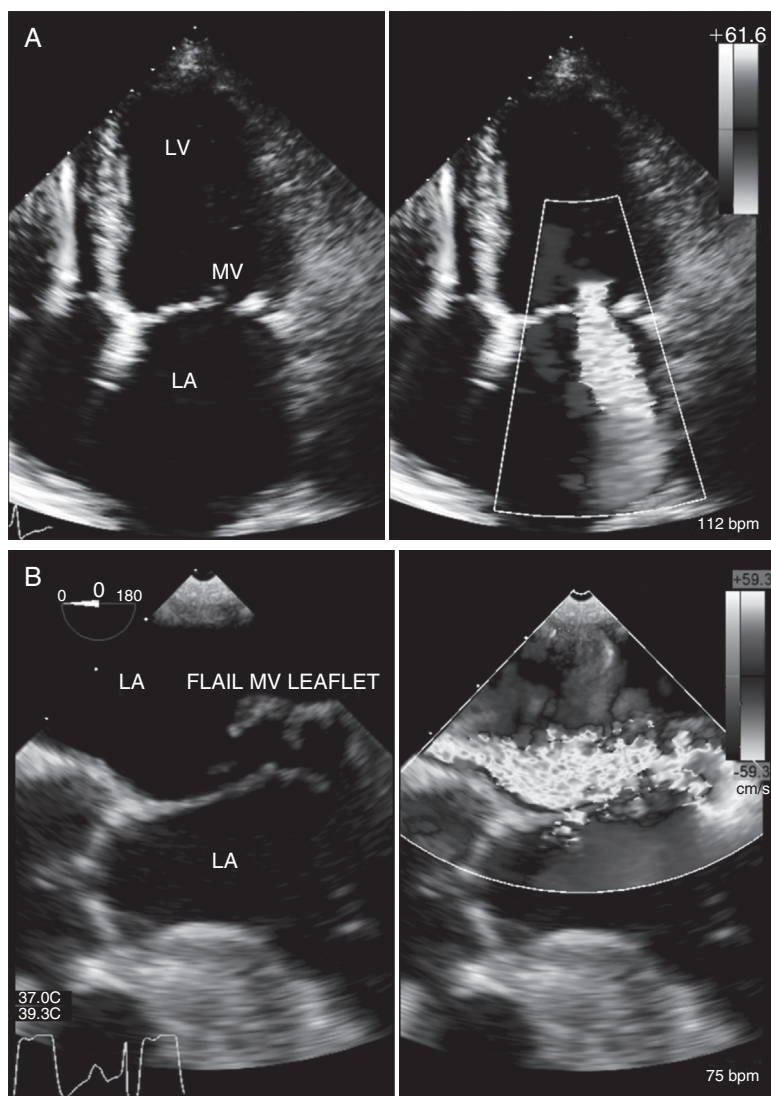

Figure 2 (A) Transthoracic echocardiogram of a patient with a dilated cardiomyopathy with annular dilation resulting in incomplete coaptation of the mitral valve leaflets and severe functional (secondary) mitral regurgitation. The regurgitant jet is central. (B) Transesophageal echocardiogram reveals a markedly myxomatous mitral valve with a large flail segment of the posterior leaflet resulting in severe degenerative (primary) mitral regurgitation. This jet is extremely eccentric. *Abbreviations:* LA = left atrium; LV = left ventricle; MV = mitral valve.

Even what would otherwise be considered a mildly reduced ejection fraction may indicate significant myocardial dysfunction in the presence of MR. Left atrial enlargement as a rule is found in chronic severe MR, and its absence should lead to reconsideration of the diagnosis. Exercise echocardiography can play an important role in patients with MR, especially in those with severe MR who report few symptoms, as it is an objective means to assess functional capacity and can also be used to assess changes in pulmonary pressures with exercise. In patients who have mild MR at rest but severe exertional symptoms, exercise echocardiography can identify ischemic MR with concomitant regional wall motion abnormalities.

Cardiac catheterization is performed in many patients with suspected severe MR. Right heart catheterization with measurement of right atrial, right ventricular, pulmonary arterial, and pulmonary capillary wedge pressures and cardiac outputs can help determine volume status and assess for pulmonary hypertension. Attention should be paid to the pulmonary capillary wedge waveform, with large “v” waves, corresponding to ventricular systole, suggestive of severe MR. Left heart catheterization with selective coronary angiography is recommended to identify concomitant obstructive coronary artery disease. Left ventriculography using contrast is commonly performed, and the presence of contrast in the left atrium suggests MR. However, the clinical utility of left ventriculography is limited with the ready availability of echocardiography. The visual estimation of MR by contrast ventriculography is subjective, and the etiology of valve pathology is unable to be

defined precisely. Furthermore, in a patient with congestive heart failure, the contrast load may result in acute decompensation.

Magnetic resonance imaging (MRI) is not currently a routinely used test in the evaluation of severe MR but may provide more reproducible quantification of the regurgitant volume and fraction and more accurate measurements of left ventricular size and function. Given the importance of defining the severity of the MR and abnormalities of left ventricular function in the management of MR, MRI may eventually have a central role in the evaluation of patients and is strongly recommended when echocardiographic data is not satisfactory.

Management and Treatment

The¹ etiology of MR dictates its treatment (Table 3). Degenerative (primary) MR is a mechanical problem of the valve or its apparatus and requires a mechanical solution such as a surgical or percutaneous repair or replacement. Functional (secondary) MR is a problem of the left ventricle and treatment of the underlying ventricular pathology is indicated, and the role of mitral valve intervention is less clear.

In patients with acute severe MR, the role of medical therapy is to stabilize the patient until surgery. Afterload reduction is the initial treatment strategy, which allows for greater flow through the aortic valve, thereby increasing cardiac output while diminishing

¹Not FDA approved for this indication.

TABLE 3 Paradigm for Management of Mitral Regurgitation Based on Etiology and Surgical Risk

	DEGENERATIVE (PRIMARY)	FUNCTIONAL (SECONDARY)
Low surgical risk	Surgical repair or replacement	CHF therapy Surgery in selected patients
High surgical risk	Percutaneous repair in selected patients	CHF therapy

Abbreviation: CHF = congestive heart failure.

the MR. Afterload reduction may be accomplished with intravenous vasodilators such as sodium nitroprusside (Nitropress)¹ or with an intraaortic balloon pump if the clinical situation requires. The role of medical therapy for chronic severe degenerative MR is less clear, especially in asymptomatic patients with normal left ventricular function. Symptomatic patients with a reduced ejection fraction (< 60%) may be treated with heart failure therapy such as angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), beta-adrenergic blockers, or aldosterone antagonists, in addition to loop diuretics for symptomatic relief while awaiting surgery. Ultimately most patients with severe degenerative MR will be referred to surgery (Table 4), and valve repair is preferable to replacement provided the anatomy is amenable to repair. If valve replacement is necessary, options include mechanical and bioprosthetic valves. Mechanical valves provide superior hemodynamic results and durability but are prone to thrombus formation and therefore require lifelong anticoagulation with warfarin (Coumadin). If after consultation with a cardiac surgeon the patient is deemed to be at prohibitive risk for surgery, percutaneous mitral valve repair with the MitraClip device (Abbott) is a reasonable alternative. This procedure is performed under general anesthesia with fluoroscopic and transesophageal echocardiographic guidance, and from the femoral vein via transseptal access, a clip is delivered to the regurgitant orifice of the mitral valve, grasping the anterior and posterior leaflets, thereby improving leaflet coaptation.

For patients with functional MR, the target for treatment is the left ventricle. Medical therapy for the underlying cardiomyopathy is recommended, with administration of ACE inhibitors or ARBs, aldosterone antagonists, and beta-blockers. If indicated, these patients may require cardiac resynchronization therapy. With medical and device therapy, left ventricular remodeling and function may improve, with reduction in the degree of MR. If severe MR persists despite maximally tolerated medical therapy, there may be a role for surgical valve repair or replacement. In patients with ischemic cardiomyopathy secondary to obstructive coronary artery disease with severe functional MR, surgical revascularization and

TABLE 4 Indications for Intervention in Severe Degenerative (Primary) Mitral Regurgitation

Symptomatic Recommended if LVEF > 30% May be considered if LVEF ≤ 30% TMVR may be considered if severely symptomatic with reasonable life expectancy but prohibitive surgical risk
Asymptomatic Recommended if LV dysfunction (LVEF 30%–60% or LVESD < 40 mm) Reasonable if preserved LV function (LVEF > 60% and LVESD > 40 mm) if > 95% chance of successful repair with < 1% mortality risk Reasonable if preserved LV function with new-onset atrial fibrillation or PASP > 50 mm Hg if high likelihood of successful repair

Abbreviations: LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension; PASP = pulmonary arterial systolic pressure; TMVR = transcatheter mitral valve repair.

concomitant mitral valve repair is frequently performed if the surgical risk is not prohibitive.

Mitral regurgitation can progress over time, as the volume overload can lead to left ventricular dilatation and worsening mitral leaflet coaptation. As the disease process may be slow and without sudden worsening of symptoms, patients will require close follow-up. Mild MR can be followed by serial transthoracic echocardiography every 3 to 5 years, and moderate MR every 1 to 2 years. In patients with asymptomatic severe MR who do not undergo surgery, transthoracic echocardiography should be performed at least annually, with special attention to left ventricular dimensions and function.

The Digestive System

ACUTE AND CHRONIC PANCREATITIS

Method of

George Van Buren, II, MD; and William E. Fisher, MD

CURRENT DIAGNOSIS

- Acute pancreatitis is usually caused by gallstones, and chronic pancreatitis is usually caused by alcohol abuse.
- Other less-common causes of acute and chronic pancreatitis are considered only when gallstones and alcohol are definitively ruled out.
- Pancreatic cancer and chronic pancreatitis can sometimes be difficult to distinguish.

CURRENT THERAPY

- There has been a recent trend toward conservative medical therapy for acute and chronic pancreatitis, reserving surgery as a last resort.
- In acute pancreatitis, try to avoid necrosectomy except in the setting of infected necrosis with organ failure.
- Asymptomatic pseudocysts can generally be observed.
- Persistent symptomatic pseudocysts can often be addressed endoscopically.
- Medical therapy for chronic pancreatitis includes pain management, nutrition, diabetes control, and cessation of drinking alcohol and smoking.
- Surgical treatment for chronic pancreatitis currently favors strict patient selection and parenchyma-preserving techniques.

Acute Pancreatitis

Acute pancreatitis is an inflammatory disease of the pancreas that is associated with little or no fibrosis of the gland. It can be initiated by several factors including gallstones, alcohol, trauma, and infections, and in some cases it is hereditary (Box 1). Very often, patients with acute pancreatitis develop additional complications such as sepsis, shock, and respiratory and renal failure, resulting in considerable morbidity and mortality.

Epidemiology

The annual incidence of acute pancreatitis is probably about 50 cases per 100,000 population in the United States. Roughly 3000 of these cases are severe enough to lead to death.

Risk Factors

Biliary tract stone disease accounts for 70% to 80% of the cases of acute pancreatitis. Alcoholism accounts for another 10%, and the remaining 10% to 20% is accounted for either by idiopathic disease or by a variety of iatrogenic and miscellaneous causes including trauma, endoscopy, surgery, drugs, heredity, infection, and toxins.

Pathophysiology

Pancreatitis begins with the activation of digestive zymogens inside acinar cells, which cause acinar cell injury. Digestive zymogens are colocalized with lysosomal hydrolase, and cathepsin-B catalyzed trypsinogen activation occurs, resulting in acinar cell injury and necrosis. This triggers acinar cell inflammatory events with the secretion of inflammatory mediators. Studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury. These include inflammatory cell recruitment and activation, as well as generation and release of cytokines, reactive oxygen species, and other chemical mediators of inflammation, ultimately leading to ischemia and necrosis. Early mortality in severe acute pancreatitis is caused by a systemic inflammatory response syndrome with multiorgan failure. If the patient survives this critical early period, a septic complication caused by translocated bacteria, mostly gram-negative microbes from the intestine, leads to infected pancreatic necrosis. Late deaths are caused by infected necrosis, leading to septic shock and multiorgan failure.

Prevention

Gallstones are present in about 15% to 20% of patients older than 60 years, but only a fraction become symptomatic. Although gallstone pancreatitis can rarely be the first symptom of gallstones, most patients have symptoms of cholecystitis before developing pancreatitis. Thus it is important to make early and prompt referral of patients with symptomatic cholelithiasis for laparoscopic cholecystectomy to prevent life-threatening complications such as acute pancreatitis.

Clinical Manifestations

All episodes of acute pancreatitis begin with severe pain, generally following a substantial meal. The pain is usually epigastric, but it can occur anywhere in the abdomen or lower chest. It has been described as penetrating through to the back, and it may be relieved by the patient's leaning forward. It precedes the onset of nausea and vomiting, with retching often continuing after the stomach has emptied. Vomiting does not relieve the pain, which is more intense in necrotizing than in edematous pancreatitis.

On examination the patient may show tachycardia, tachypnea, hypotension, and hyperthermia. The temperature is usually only mildly elevated in uncomplicated pancreatitis. Voluntary and involuntary guarding can be seen over the epigastric region. The bowel sounds are decreased or absent. There are usually no palpable masses. The abdomen may be distended with intraperitoneal fluid. There may be pleural effusion, particularly on the left side. With increasing severity of disease, the intravascular fluid loss may become life-threatening as a result of sequestration of edematous fluid in the retroperitoneum. Hemoconcentration then results in an elevated hematocrit. However, there also may be bleeding into the retroperitoneum or the peritoneal cavity. In some patients (about 1%), the blood from necrotizing pancreatitis can dissect through the soft tissues and manifest as a bluish discoloration around the umbilicus (Cullen's sign) or in the flanks (Grey Turner sign). The severe fluid loss can lead to prerenal azotemia, with elevated blood urea nitrogen and creatinine levels. There also may be

hyperglycemia, hypoalbuminemia, and hypocalcemia sufficient in some cases to produce tetany.

Diagnosis

Although serum amylase is often elevated in acute pancreatitis, there is no significant correlation between the magnitude of serum amylase elevation and severity of pancreatitis. Other pancreatic enzymes also have been evaluated to improve the diagnostic accuracy of serum measurements. Specificity of these markers ranges from 77% to 96%, the highest being for lipase. Measurements of many digestive enzymes have methodologic limitations and cannot be easily adapted for quantitation in emergency laboratory studies. Because serum levels of lipase remain elevated for a longer time than total or pancreatic amylase, it is the serum indicator of highest probability of the disease.

Abdominal ultrasound examination is the best way to confirm the presence of gallstones in suspected biliary pancreatitis. It also can detect extrapancreatic ductal dilations and reveal pancreatic edema, swelling, and peripancreatic fluid collections. However, in about 20% of patients, the ultrasound examination does not provide satisfactory results because of the presence of bowel gas, which can obscure sonographic imaging of the pancreas.

A computed tomographic (CT) scan of the pancreas is more commonly used to diagnose pancreatitis. CT scanning is used to distinguish milder (necrotic) forms of the disease from more severe necrotizing or infected pancreatitis, in patients whose clinical presentation raises the suspicion of advanced disease (Figures 1 and 2). Pancreatic protocol computed tomography (CT) scan of the abdomen and pelvis is recommended when not limited by renal

Figure 2 Computed tomographic scan confirming acute necrotizing, emphysematous pancreatitis.

insufficiency. A triphasic thin, multislice CT scan with an arterial, venous, and delayed phase in conjunction with sagittal and coronal views. No oral contrast, instead drink 1000 cc water to opacify the stomach. The scan assesses the degree of pancreatic necrosis, peripancreatic fluid collections, and the surrounding vascular structures.

Magnetic resonance cholangiopancreatography (MRCP) is also of value to assess the pancreatic duct and biliary tree. This can often reveal pancreatic ductal disruption.

Differential Diagnosis

The clinical diagnosis of pancreatitis is one of exclusion. Hyperamylasemia can also occur as a result of conditions not involving pancreatitis. The other upper abdominal conditions that can be confused with acute pancreatitis include perforated peptic ulcer and acute colecystitis, and occasionally a gangrenous small bowel obstruction. Because these conditions often have a fatal outcome without surgery, urgent intervention is indicated in the small number of cases in which doubt persists. A tumor should be considered in a nonalcoholic patient with acute pancreatitis who has no demonstrable biliary tract disease. Approximately 1% to 2% of patients with acute pancreatitis have pancreatic carcinoma, and an episode of acute pancreatitis can be the first clinical manifestation of a periampullary tumor.

Treatment

The severity of acute pancreatitis covers a broad spectrum of illness, ranging from the mild and self-limiting to the life-threatening necrotizing variety. Some cases are so mild they can be treated in an outpatient setting. However, most cases require hospitalization for observation and diagnostic study. A conservative approach has been advocated in the treatment of acute pancreatitis (Box 2). Severity is assessed with imaging results and clinical parameters and is quantitated with scores such as Ranson's criteria (Box 3), the Atlanta classification, and the APACHE II (Acute Physiology And Chronic Health Evaluation) score. Severe acute pancreatitis is defined by associated organ dysfunction. The Atlanta classification is based on an international consensus conference held in Atlanta in 1992 and has been updated. APACHE II was designed to measure the severity of disease for adult patients admitted to intensive care units. Though not specific to pancreatitis, APACHE II can be used in an effort to differentiate patients with mild and severe acute pancreatitis. APACHE II scores of 8 points or more correlate with a mortality rate of 11% to 18%.

On confirmation of the diagnosis, patients with severe disease should be transferred to the intensive care unit for observation and maximum support. Adequate fluid resuscitation optimizing

Figure 1 Computed tomographic scan confirming acute edematous pancreatitis.

BOX 2 Treatment of Acute Pancreatitis

- Assessment of severity
- Fluid resuscitation and oxygenation
- Early nasojejunal feeding
- Avoid prophylactic antibiotics (reserve antibiotic therapy for specific infections)
- Avoid or postpone necrosectomy if possible
- Options for necrosectomy
 - Open anterior approach with closed lavage
 - Open anterior approach with packing and reoperation
 - Open retroperitoneal approach
 - Laparoscopic anterior approach with closed lavage
 - Video-assisted retroperitoneal débridement (VARD)

BOX 3 Ranson's Criteria

There are 11 Ranson signs. Five of the signs are evaluated when the patient is admitted to the hospital, and the remaining six are evaluated 48 hours after admission. The signs are added to reach a score:

- If the score <3 , severe pancreatitis is unlikely.
- If the score ≥ 3 , severe pancreatitis likely.

or

- Score 0-2: 2% mortality
- Score 3-4: 15% mortality
- Score 5-6: 40% mortality
- Score 7-8: 100% mortality

At Admission

- Age in years >55 years
- White blood cell count $>16,000$ cells/mm³
- Blood glucose >11 mmol/L (>200 mg/dL)
- Serum AST >250 IU/L
- Serum LDH >350 IU/L

At 48 Hours

- Calcium (serum calcium) <2.0 mmol/L (<8.0 mg/dL)
- Hematocrit fall $>10\%$
- Oxygen (hypoxemia P_{O_2} <60 mm Hg)
- BUN increased by ≥ 1.8 mmol/L (≥ 5 mg/dL) after IV fluid hydration
- Base deficit (negative base excess) >4 mEq/L
- Sequestration of fluids >6 L

Abbreviations: AST = aspartate aminotransferase; BUN = blood urea nitrogen.

organ perfusion and oxygenation is essential. The use of prophylactic intravenous antibiotics in the initial stages of severe acute pancreatitis is not proved to be useful. Two randomized, controlled studies failed to show any benefit from antibiotics. Prophylactic antibiotics did not decrease the incidence of infected pancreatic necrosis or lower mortality. Data from these well-designed trials refutes prior data from less-rigorous studies suggesting that prophylactic antibiotics were useful. Additional studies are required, but there is increasing concern that the prolonged use of potent antibiotics might result in an increased prevalence of fungal infections and possibly increased mortality. Currently, antibiotic therapy should be reserved for treatment of specific infections such as positive blood, sputum, and urine cultures or percutaneous or operative cultures of necrotic tissue.

Randomized clinical trials have also shown a benefit from early nasojejunal feeding compared with total parenteral nutrition. Gastric decompression with a nasogastric tube is selectively used in patients with severe ileus and vomiting but is not necessary in a majority of cases.

In biliary pancreatitis, the gallbladder must eventually be removed, or recurrent acute pancreatitis will occur in 30% to

60% of cases. The timing of the cholecystectomy depends on the severity of the pancreatitis. Usually laparoscopic cholecystectomy is performed during the index admission as soon as the attack of acute pancreatitis has resolved. In more-severe cases, the cholecystectomy is delayed and often combined with interventions for late complications of acute pancreatitis. In cases with severe comorbidity, endoscopic sphincterotomy has been considered as an alternative to cholecystectomy. However, if the patient has a postinflammatory fluid collection, bacteria can be introduced during endoscopic retrograde cholangiopancreatography (ERCP), and sphincterotomy should be delayed.

Currently, there is no role for routine early laparotomy and necrosectomy or resection in the setting of acute necrotizing pancreatitis. If the necrotic pancreas becomes infected and the patient fails to respond to conservative treatment, then necrosectomy may be warranted. Patients with infected necrosis are rarely managed conservatively without eventual surgical intervention. However, even in the setting of infected necrosis, there has been consideration for antibiotic therapy until the acute inflammatory response has subsided, if possible, with the view that surgery that is deferred for several weeks is more easily accomplished with one intervention. Patients who suffer from infected necrosis without having clinical signs of sepsis or other systemic complications might not need immediate surgical necrosectomy.

A nonsurgical alternative for the treatment of infected necrosis is percutaneous catheter drainage. This is considered a temporary measure to allow stabilization of the patient so that a safer surgical necrosectomy can be done at a later time. Multiple large drains are required, and patients frequently undergo repeat CT and revision of the drains. Current recommendations are to postpone surgery for as long as possible, usually beyond the second or third week of the disease or later, when necrotic tissue can be easily distinguished from viable pancreas and débridement without major blood loss can be performed. When surgery is performed, tissue-preserving digital necrosectomy is the usual technique rather than a classic surgical resection of the pancreas (Figure 3).

Necrosectomy can be performed by an open anterior approach with closed lavage or with leaving the abdomen open and packing. The packing is replaced at intervals of 24 to 72 hours. Sometimes a left lateral retroperitoneal approach is helpful. Newer approaches are the video-assisted retroperitoneal débridement (VARD). This procedure is a combination of percutaneous drainage and the open lateral retroperitoneal approach. An anterior laparoscopic approach has also been described and mimics the open anterior approach using laparoscopic ports. Surgical necrosectomy is indicated in patients with sepsis caused by infected necrosis and in selected patients with extended sterile necrosis causing severe systemic organ dysfunction and sepsis without a septic focus.

Figure 3 Necrotic material débrided from the retroperitoneum in a case of acute necrotizing pancreatitis.

In some cases, the acute inflammatory process can lead to erosion into retroperitoneal vessels, and acute hemorrhage occurs. This acute emergent complication is best managed with immediate angiography to determine the exact site of bleeding and can often be treated with embolization rather than surgery (Figure 4).

Although previously frowned upon, there has been a move toward enteric drainage of all necrotic collections (even when infected) when technically feasible.

Monitoring

Despite a conservative operative approach, endocrine and exocrine insufficiency develop in as many as half of the patients and are determined by the extent of pancreatic necrosis. Therefore patients must be monitored with blood glucose measurements, stabilization of body weight, and proper nutrition.

Complications

The most common complication after successful management of acute pancreatitis is a pseudocyst. The term “pseudocyst” is currently used to broadly categorize most pancreatic and peripancreatic fluid collections (including walled-off pancreatic necrosis [WOPN] and acute peripancreatic fluid collection). The Acute Pancreatitis Classification Working Group recently proposed a revised Atlanta classification refers to collections within 4 weeks of symptom onset as either acute peripancreatic fluid collections (APFC) or postnecrotic pancreatic fluid collections (PNPFC) depending on the absence or presence of pancreatic/peripancreatic necrosis, respectively. After 4 weeks of the onset of symptoms, persistent collections with discrete walls are referred to as pseudocyst or WOPN, again depending on the absence or presence of necrosis, respectively. In addition, these collections are further classified as sterile or infected and the term “pancreatic abscess” has been abolished.

The management of pseudo-cysts has followed a minimally invasive trend. Most pseudo-cysts resolve spontaneously, even beyond 6 weeks, so asymptomatic pseudocysts are usually observed (70% of pseudocysts will resolve without intervention). Endoscopic cystogastrostomy is the approach of choice for symptomatic fluid-predominant pseudocysts when there is minimal necrosis. If there is significant necrotic debris or a solid-predominant pseudocyst, surgical drainage with laparoscopic cystogastrostomy is preferred (Figure 5). This can also be performed with the traditional open technique. Cystjejunostomy (laparoscopic or open) is used in cases in which the site of the pseudocyst precludes drainage into the posterior aspect of the stomach.

Chronic Pancreatitis

Chronic pancreatitis is a chronic inflammatory disease of the pancreas characterized by irreversible morphologic changes that typically are associated with pain, permanent loss of function, or both.

Epidemiology

Population studies suggest a prevalence of chronic pancreatitis that ranges from 5 to 27 persons per 100,000 population, with considerable geographic variation. Autopsy data are difficult to interpret because a number of changes associated with chronic pancreatitis, such as fibrosis, duct ectasia, and acinar atrophy, are also present in asymptomatic elderly patients. Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively since the 1960s. Chronic pancreatitis in the United States currently results in more than 120,000 outpatient visits and more than 50,000 hospitalizations per year.

Risk factors

Alcohol consumption and alcohol abuse are associated with chronic pancreatitis in up to 70% of cases. Other major causes include tropical (nutritional) and idiopathic disease, as well as

Figure 4 Acute necrotizing pancreatitis. A, Erosion into the splenic artery as seen on computed tomography. B, Erosion into the splenic artery as seen on angiogram. C, This complication of acute pancreatitis is best treated with angiographic embolization.

Figure 5 Computed tomographic scan showing fluid-predominant (A) and solid-predominant (B) pseudocysts. The former can be treated with endoscopic cystogastrostomy, and the latter is best treated with laparoscopic cystogastrostomy.

hereditary causes. There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis. The incidence is highest in heavy drinkers (15 drinks/day or 150 g/day). However, chronic pancreatitis can occur in patients who drink very little, and it occurs in less than 15% of documented alcoholics. The duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 and 40 years, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.

Pathophysiology

Multiple episodes (or a prolonged course) of pancreatic injury ultimately leading to chronic disease is widely accepted as the pathophysiology sequence. Most investigators believe that alcohol metabolites such as acetaldehyde, combined with oxidant injury, result in local parenchymal injury that is preferentially targeted to the pancreas in predisposed persons. Repeated or severe episodes of toxin-induced injury activate a cascade of cytokines, which in turn induces pancreatic stellate cells to produce collagen and cause fibrosis.

The pain caused by chronic pancreatitis is thought to be due to increased pressure in the pancreatic ducts and tissue. Neural and perineural inflammation is also thought to be important in pathogenesis of pain in chronic pancreatitis. Neuropeptides released from enteric and afferent neurons and their functional interactions with inflammatory cells might play a key role.

Prevention

Because alcohol is the cause of most cases of chronic pancreatitis, cessation of alcohol consumption is recommended to prevent progression to chronic pancreatitis. Unfortunately, the majority of patients are not able to recover from alcoholism, and relapse is common.

Clinical Manifestations

Symptoms of chronic pancreatitis may be identical to those of acute pancreatitis, typically midepigastric pain penetrating through to the back. Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting can accompany the pain, but anorexia is the most common associated symptom. Patients with continuous pain can have a complication of chronic pancreatitis, such as an inflammatory mass, a cyst, or even pancreatic cancer. Other patients have intermittent attacks of pain with symptoms similar to those of mild to moderate acute pancreatitis. The pain sometimes is severe and lasts for many hours or several days.

As chronic pancreatitis progresses, endocrine and exocrine insufficiency begin to appear. Patients describe a bulky, foul-smelling, loose (but not watery) stool that may be pale and float on the surface of toilet water. Patients often describe a greasy or oily appearance to the stool or describe an "oil slick" on the water's surface. In severe steatorrhea, an orange, oily stool is often reported. As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients might describe a good appetite despite weight loss, or they might have diminished food intake due to abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight. Usually islet cells are spared early in the disease process despite being surrounded by fibrosis, but eventually the insulin-secreting beta cells are also destroyed, gradually leading to diabetes.

Diagnosis

The diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies. Diagnosis is usually simple in the late stages of the disease because of the presence of structural and functional alterations of the pancreas. Early in the disease, the diagnosis is more difficult. Various classification systems have been developed. The Cambridge classification uses imaging tests such as ERCP, CT, and ultrasound to grade severity. The Mayo Clinic system is based on functional as well as imaging results. Tests of pancreatic function include the secretin-creatinine test, Lundh test, fecal excretion of pancreatic enzymes, and quantitation of fecal fat.

Chronic pancreatitis can be classified as calcifying (lithogenic), obstructive, inflammatory, autoimmune, tropical (nutritional), hereditary, or idiopathic. Autoimmune and hereditary pancreatitis have recently been better understood and diagnosed more than before. Autoimmune pancreatitis is associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies. It is usually associated with autoimmune diseases such as Sjögren's syndrome. Increased levels of serum β -globulin or immunoglobulin (Ig)G₄ are often present. This disease can be mistaken for chronic pancreatitis, with an inflammatory mass in the head of the pancreas suspicious for pancreatic cancer (Figure 6). Diagnosis is important because steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression.

Hereditary pancreatitis first occurs in adolescence with abdominal pain; patients develop progressive pancreatic dysfunction, and the risk of cancer is greatly increased. The disease follows an autosomal dominant pattern of inheritance with 80% penetrance and variable expression. Recent mutational analysis has revealed a

Figure 6 Computed tomographic scan of a patient with autoimmune pancreatitis and an inflammatory mass in the head of the pancreas. Preoperative diagnosis is not always possible, but surgery should be avoided because this disease often responds to steroid therapy.

missense mutation resulting in an Arg to His substitution at position 117 of the cationic trypsinogen gene, or *PRSS1*, one of the primary sites for proteolysis of trypsin. This mutation prevents trypsin from being inactivated by itself or other proteases, and it results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas. Similarly, *PSTI*, also known as *SPINK1*, has been found to have a role in hereditary pancreatitis and some cases of sporadic chronic pancreatitis. *SPINK1* specifically inhibits trypsin action by competitively blocking the active site of the enzyme.

It is likely that many of the “idiopathic” forms of chronic pancreatitis, as well as some patients with the more common forms of the disease, will be found to have a genetic linkage or predisposition.

Differential Diagnosis

There are several clinical conditions from which chronic pancreatitis needs to be distinguished. Other causes of upper abdominal pain, such as peptic ulcer disease, biliary tract disease, mesenteric vascular disease, or malignancy must be excluded. The major difficulty in the differential diagnosis of chronic pancreatitis is distinguishing it from pancreatic ductal adenocarcinoma. Chronic pancreatitis can closely mimic pancreatic cancer, both clinically and morphologically. In addition, chronic pancreatitis is a risk factor for the development of pancreatic cancer. Although in pancreatic resection specimens this problem may be finally resolved, distinguishing these two diseases preoperatively in small (needle) biopsy specimens is a formidable challenge for the pathologist. Therefore, especially in the setting of an inflammatory mass in the head of the pancreas, consideration of pancreatic cancer and surgical referral is important. Workup of these patients should include a pancreatic protocol CT scan, a MRCP, and an endoscopic ultrasound to evaluate the parenchyma and the ducts of the pancreas.

Treatment

Therapy for chronic pancreatitis is aimed at managing associated digestive dysfunction and relieving pain (Box 4). It is important to first address malabsorption, weight loss, and diabetes. When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop. Lipase deficiency tends to manifest itself before trypsin deficiency, so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency. As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients.

BOX 4 Treatment of Chronic Pancreatitis

- Pancreatic enzyme replacement
- Proper nutrition and vitamin supplementation
- Blood sugar control
- Long-acting narcotic analgesics at lowest effective doses
- Cessation of alcohol and tobacco
- Endotherapy (pancreatic duct stenting and removal of stones)
- Parenchymal preserving surgery (Frey, Beger) in carefully selected patients

The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and endoscopic stent therapy. Administration of pancreatic enzyme (e.g., Pancrease MT, Pancrelipase, Creon) serves to reverse the effects of pancreatic exocrine insufficiency and might also reduce or alleviate the pain¹ experienced by patients. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment. It has been taught that the pain of chronic pancreatitis decreases with increasing duration of the disease, the so called burn-out phase, where endocrine and exocrine insufficiency occurs and the pain decreases. However, recent studies have called this concept into question, demonstrating continued pain in patients with chronic pancreatitis despite longstanding disease and pancreatic insufficiency. Cessation of alcohol abuse, if possible, causes the pain to stop in about half of the patients.

Pain relief usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics. Celiac plexus neurolysis has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, its use in chronic pancreatitis has been disappointing, with about half of the patients deriving a benefit that lasts 6 months or less.

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct. Pancreatic duct stones can also be removed endoscopically. Stent therapy in chronic pancreatitis definitely plays a role and can help select patients for successful operative therapy. However, the duration of success with stent therapy for chronic pancreatitis is probably less than with surgical therapy.

Major pancreatic resections for chronic pancreatitis have a high complication rate, both early and late. Patients with large duct disease who can have nutrition restored, are working, are not drinking alcohol, and have a supportive family structure fare better. Failure to carefully select patients leads to disappointing results. The surgical management of pancreatic duct stones and stenoses has been shown to be superior to endoscopic treatment in randomized clinical trials. Beger introduced the duodenum-preserving pancreatic head resection (DPPHR) in the early 1980s. Later in the decade, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojejunostomy, which included excavation of the pancreatic head including the ductal structures in continuity with a long ductotomy of the dorsal duct. This operation is basically a hybrid of the Beger and Puestow (Partington-Rochelle modification) procedures and is more popular in the United States (Figures 7 and 8).

Recent randomized prospective studies have compared the Whipple, Beger, and Frey procedures for chronic pancreatitis. Patients who had a Beger procedure had a shorter hospital stay, greater weight gain, less postoperative diabetes, and less exocrine

¹Not FDA approved for this indication.

Figure 7 Computed tomographic scan of a patient with chronic calcific pancreatitis and a massively dilated pancreatic duct.

dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. In a study comparing the pylorus-preserving Whipple to the Frey procedure, there was a lower postoperative complication rate associated with the Frey procedure (19%) compared to the pylorus-preserving Whipple group (53%), and the global quality-of-life scores were better (71% vs 43%, respectively). Both operations were equally effective in controlling pain over a 2-year follow-up. Operation times, intraoperative blood loss, and transfusion requirements have been shown to be decreased with the Frey and Beger procedures compared with the Whipple procedure. In long-term (>8 years) follow-up, there was no difference between the Beger and Frey procedures in pain relief, pancreatic insufficiency, quality of life, and late mortality. Compared to the Whipple procedure, the Beger and Frey procedures seem to produce a lower incidence of immediate complications and diabetes but no significant differences in pain relief. Although these limited pancreatic procedures have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation.

Recent refinements in the methods of harvesting and preserving pancreatic islets, and standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, have improved the success and rekindled interest in islet autotransplantation for chronic pancreatitis. The ability to recover a sufficient quantity of islets from a sclerotic gland depends on the degree of disease present, so the selection of patients as candidates

Figure 8 A, The pancreatic duct is opened to reveal a preoperatively placed pancreatic duct stent. B, The residual stones removed from the pancreatic duct. C, In the Frey procedure, the head of the pancreas is cored out in addition to a longitudinal pancreatic ductotomy. The pancreas is drained with a Roux-en-Y limb of jejunum.

for autologous islet transplantation is important. As success with autotransplantation increases, patients with nonobstructive, sclerotic pancreatitis may be considered for resection and islet autotransplantation earlier in their course, because end-stage fibrosis bodes poorly for transplant success. As the necessary expertise with islet transplantation becomes more widespread, this therapy could become routine in the treatment of chronic pancreatitis.

Monitoring

Chronic pancreatitis is of course a chronic disease, so continued monitoring and maintenance therapy is essential after an acute exacerbation of chronic pancreatitis. Pain control, proper nutrition, and alcohol and smoking cessation must be maintained as an outpatient. The clinician must also be looking for the development of common complications.

Complications

Pseudocysts in the setting of chronic pancreatitis are less likely to resolve without intervention. Often, the pancreatic duct and bile

duct are compressed, and the compression might need to be addressed at the same time as the pseudocyst. A trend toward minimally invasive management remains appropriate, with endoscopic drainage preferred over laparoscopic cystogastrostomy unless additional procedures are required. Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct, or of the pseudocyst itself, should be considered when distal resection is being contemplated.

Pancreatic ascites results from a disrupted pancreatic duct with extravasation of pancreatic fluid that does not become sequestered as a pseudocyst but drains freely into the peritoneal cavity. Occasionally, the pancreatic fluid tracks superiorly into the thorax, causing a pancreatic pleural effusion. Both complications are seen more often in patients with chronic pancreatitis, rather than after acute pancreatitis. Paracentesis or thoracentesis reveals noninfected fluid with a protein level greater than 2.5 g/L and a markedly elevated amylase level. Paracentesis is critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP. Paracentesis and antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients. Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage can facilitate closure of the internal fistula. Surgical therapy is reserved for those who fail to respond to medical treatment.

ACUTE DIARRHEA

Method of

Tate de Leon, MD

CURRENT DIAGNOSIS

History

- Onset, duration, and frequency of diarrhea
- Related symptoms (fever, abdominal pain, nausea, emesis, bloody stool)
- Current medications, including recent antibiotic use
- Recent sick contacts or hospitalizations

- Recent foreign travel
- Exposure to contaminated water source or undercooked meats and seafood
- Immune status

Physical Examination

- Hydration status
- Abdominal examination

Laboratory Testing

- Acute secretory diarrhea: normally not necessary
- Acute bloody diarrhea: complete blood count, stool culture, consider ova and parasite testing and *Clostridium difficile* evaluation

CURRENT THERAPY

- Symptomatic therapy
- Rehydration: enteral versus parenteral
- Antibiotics (depending on duration, severity, and other risk factors)
 - Empiric therapy
 - Adults
 - Fluoroquinolones
 - Ciprofloxacin (Cipro) 500 mg PO twice daily for 3–7 days
 - Levofloxacin (Levaquin)¹ 500 mg PO four times daily for 3–5 days
 - Children
 - Azithromycin (Zithromax)¹ 5–12 mg/kg PO four times daily for 3–5 days
 - *C difficile*
 - Metronidazole (Flagyl)¹ 500 mg PO every 8 hours for 10–14 days
 - Vancomycin (Vancocin) 125 mg PO every 6 hours for 10 days
 - Antidiarrheal medications (if no contraindications such as fever or hematochezia)
 - Loperamide (Imodium) Initial 4 mg PO followed by 2 mg PO with each loose stool. Max 16 mg per day
 - Probiotics²

¹Not FDA approved for this indication.

²Not available in the United States.

Acute diarrhea in the United States is one of the most common diagnoses in general practice. Acute diarrhea can have a functional definition of a greater number of loose stools from normal lasting less than 14 days. If the episode lasts more than 14 days, it is called persistent diarrhea. If the episode lasts for more than 30 days, it is deemed chronic diarrhea. These episodes may be accompanied by nausea, vomiting, abdominal cramping, other systemic symptoms, and malnutrition. The majority of acute diarrhea cases are self-limited and do not need medical intervention. Most often, these cases are caused by infectious agents such as viruses, bacteria, or parasites. Infection is often spread through contaminated food or drinking water or from person-to-person. Pathogens that cause diarrhea are usually transmitted through a fecal–oral route. The main risk factor for this transmission is poor hand hygiene. Other risk factors include improper food preparation, inadequate food refrigeration, and exposure to contaminated water.

Thorough investigation of a patient with acute diarrhea should include a detailed history, physical examination, and laboratory testing when indicated (Boxes 1 and 2). Acute diarrhea can be classified into two subtypes: secretory diarrhea and inflammatory diarrhea. Determining the subtype of the diarrhea is useful for suggesting the etiology and therefore the management of the diarrhea.

duct are compressed, and the compression might need to be addressed at the same time as the pseudocyst. A trend toward minimally invasive management remains appropriate, with endoscopic drainage preferred over laparoscopic cystogastrostomy unless additional procedures are required. Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct, or of the pseudocyst itself, should be considered when distal resection is being contemplated.

Pancreatic ascites results from a disrupted pancreatic duct with extravasation of pancreatic fluid that does not become sequestered as a pseudocyst but drains freely into the peritoneal cavity. Occasionally, the pancreatic fluid tracks superiorly into the thorax, causing a pancreatic pleural effusion. Both complications are seen more often in patients with chronic pancreatitis, rather than after acute pancreatitis. Paracentesis or thoracentesis reveals noninfected fluid with a protein level greater than 25 g/L and a markedly elevated amylase level. Paracentesis is critical to differentiate pancreatic from hepatic ascites.

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP. Paracentesis and antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients. Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage can facilitate closure of the internal fistula. Surgical therapy is reserved for those who fail to respond to medical treatment.

ACUTE DIARRHEA

Method of

Tate de Leon, MD

CURRENT DIAGNOSIS

History

- Onset, duration, and frequency of diarrhea
- Related symptoms (fever, abdominal pain, nausea, emesis, bloody stool)
- Current medications, including recent antibiotic use
- Recent sick contacts or hospitalizations

- Recent foreign travel
- Exposure to contaminated water source or undercooked meats and seafood
- Immune status

Physical Examination

- Hydration status
- Abdominal examination

Laboratory Testing

- Acute secretory diarrhea: normally not necessary
- Acute bloody diarrhea: complete blood count, stool culture, consider ova and parasite testing and *Clostridium difficile* evaluation

CURRENT THERAPY

- Symptomatic therapy
- Rehydration: enteral versus parenteral
- Antibiotics (depending on duration, severity, and other risk factors)
 - Empiric therapy
 - Adults
 - Fluoroquinolones
 - Ciprofloxacin (Cipro) 500 mg PO twice daily for 3–7 days
 - Levofloxacin (Levaquin)¹ 500 mg PO four times daily for 3–5 days
 - Children
 - Azithromycin (Zithromax)¹ 5–12 mg/kg PO four times daily for 3–5 days
 - *C difficile*
 - Metronidazole (Flagyl)¹ 500 mg PO every 8 hours for 10–14 days
 - Vancomycin (Vancocin) 125 mg PO every 6 hours for 10 days
 - Antidiarrheal medications (if no contraindications such as fever or hematochezia)
 - Loperamide (Imodium) Initial 4 mg PO followed by 2 mg PO with each loose stool. Max 16 mg per day
 - Probiotics²

¹Not FDA approved for this indication.

²Not available in the United States.

Acute diarrhea in the United States is one of the most common diagnoses in general practice. Acute diarrhea can have a functional definition of a greater number of loose stools from normal lasting less than 14 days. If the episode lasts more than 14 days, it is called persistent diarrhea. If the episode lasts for more than 30 days, it is deemed chronic diarrhea. These episodes may be accompanied by nausea, vomiting, abdominal cramping, other systemic symptoms, and malnutrition. The majority of acute diarrhea cases are self-limited and do not need medical intervention. Most often, these cases are caused by infectious agents such as viruses, bacteria, or parasites. Infection is often spread through contaminated food or drinking water or from person-to-person. Pathogens that cause diarrhea are usually transmitted through a fecal–oral route. The main risk factor for this transmission is poor hand hygiene. Other risk factors include improper food preparation, inadequate food refrigeration, and exposure to contaminated water.

Thorough investigation of a patient with acute diarrhea should include a detailed history, physical examination, and laboratory testing when indicated (Boxes 1 and 2). Acute diarrhea can be classified into two subtypes: secretory diarrhea and inflammatory diarrhea. Determining the subtype of the diarrhea is useful for suggesting the etiology and therefore the management of the diarrhea.

BOX 1 Clinical History of Acute Infectious Diarrhea

- Description of diarrhea
 - Duration
 - Frequency
 - Presence of blood, pus, in stool
 - Symptoms of fever, tenesmus, dehydration
 - Weight loss
- Other gastrointestinal symptoms
 - Anorexia
 - Cramping
 - Emesis
 - Nausea
- Previous episodes with similar symptoms
- Recent antibiotic exposure
- Other medication exposure
 - Anticholinergics
 - Antimotility agents
 - Aspirin (ASA)
 - Proton pump inhibitors
- Recent dietary history
 - Shellfish
 - Undercooked meat (chicken)
 - Unsanitary water
 - Animal or reptile contacts
- Travel history
 - Travel to endemic or epidemic areas
- Sexual history
- Vaccination history
- Contact with institutions, e.g., hospitals, nursing homes, day care facilities
- Employment history
- Immune status
 - Presence of HIV
 - Presence of other congenital or acquired immunodeficiencies

BOX 2 Physical Examination for Acute Infectious Diarrhea

- Vital signs
- Blood pressure (look for postural changes)
- Heart rate (look for postural changes)
- Respiratory rate
- Temperature
- Weight changes (particularly useful to assess effects of rehydration)
- Cardiovascular examination
 - Volume status
- Respiratory examination
- Rule out hyperventilation (compensatory respiratory alkalosis for metabolic acidosis resulting from dehydration and loss of bicarbonate)
- Abdominal examination
- Focal tenderness
- Guarding
- Hepatosplenomegaly
- Consider rectal examination (look for bloody stool)
- Decreased skin turgor
- Lymphadenopathy
- Rashes

Secretory diarrhea is an electrolyte absorption impairment that leads to profuse, watery diarrhea that contains little or no blood or leukocytes. These episodes can last from a few hours to days. The main concern is dehydration and weight loss if oral intake is not continued. Clinical signs of severe dehydration include lethargy

or unconsciousness, dry or sunken eyes, dry mouth, decreased skin turgor, and a history of poor or absent fluid intake.

Inflammatory diarrhea is bloody, usually has leukocytes, and produces less volume. The most common causes are *Salmonella*, *Campylobacter*, *Shigella*, *Escherichia coli* O157:H7, and *Entamoeba histolytica*. The main concerns related to inflammatory diarrhea are intestinal damage, sepsis, and malnutrition. Stool cultures and evaluation for ova and parasites are recommended.

Preventive measures can help reduce the spread of infectious agents. Proper hand hygiene with soap and water, especially after exposure to feces or individuals with acute diarrhea, can help limit the spread of infection. Barrier precautions are an effective adjunct when dealing with the possibility of exposure to feces in a hospital setting. For children, vaccinations have been shown to be effective in reducing rotavirus infections. Furthermore, it is imperative to separate diaper-changing areas from food-preparation areas. Proper sanitization with a bleach-based cleaner is recommended. Proper food handling and storage, along with water purification, are important means to help prevent the spread of infectious agents. Probiotics² are finding a home in the prevention and treatment of diarrhea. Initial studies have suggested that probiotics are useful in reducing antibiotic-associated diarrhea. Currently, more studies are needed to confirm their usefulness. Prophylactic antibiotics are usually only reserved for possible exposure to traveler's diarrhea.

Epidemiology

Worldwide, acute diarrhea still accounts for significant morbidity and mortality. The very young, the very old, and the immunocompromised populations are the most adversely affected. Acute infectious diarrhea is more prevalent in developing countries and among travelers to developing countries. Diarrhea is the second leading cause of death worldwide in children under 5 years of age. The World Health Organization estimates that globally, there are over 1.7 billion cases of acute diarrhea each year and attributes 760,000 deaths to it annually. The majority of these deaths are in children who are younger than age 5 and live in developing countries. In the United States, foodborne infectious diarrhea accounts for approximately 325,000 hospitalizations and 5000 deaths each year.

Etiology and Treatment

The precise cause of acute diarrhea is usually not found. Causes can be both infectious and noninfectious. Noninfectious causes can include medications, food allergies, and other gastrointestinal diseases. In general, clinical investigation of acute infectious diarrhea is more useful in identifying consequences of diarrhea, such as dehydration, than it is in revealing the precise etiology. Most cases of diarrhea are likely viral, as indicated by negative stool culture results in most studies. Severe cases of diarrhea tend to be a result of bacterial infection. The most common pathogens for bacteria-induced diarrhea is discussed below. To date, the optimal strategy for obtaining stool cultures has not been ascertained. It is thus reasonable to treat the patient symptomatically for several days before obtaining a stool culture for mild to moderate cases because most cases of diarrhea are self-limited. The clinician should take into consideration individual comorbidities, immune status, the presence of severe or bloody diarrhea, underlying inflammatory bowel disease, and occupation (food handlers, day care employment, etc.) as possible indications for stool evaluation.

Bacteria

Campylobacter

Campylobacter is a common cause of diarrhea in the United States. The pathogen is often spread by consumption of undercooked meat and poultry. Symptoms may present 2 to 5 days after exposure and last up to 1 week. The patient presents with diarrhea (possibly bloody), abdominal pain, nausea, vomiting, and fever. Stool cultures are needed for a definitive diagnosis. Prevention includes thoroughly

²Not available in the United States.

cooking all meat products, good hand and utensil hygiene before preparing foods, and avoiding unpasteurized milk. The treatment for severe *Campylobacter* diarrhea includes azithromycin (Zithromax)¹ and ciprofloxacin (Cipro), although resistance to fluoroquinolones is growing. Antimicrobial susceptibility testing is required for specific resistance. Positive stool cultures should be reported to the local health department. *Campylobacter* infections have been linked to both rheumatoid arthritis and also Guillain-Barré syndrome.

Clostridium difficile

C difficile is the organism of antibiotic-associated colitis. Antibiotics disrupt the normal flora of the GI tract, which in turn provides a window of opportunity for *C difficile* to produce toxins and flourish. The most frequent antibiotics implicated are clindamycin (Cleocin), fluoroquinolones, and beta-lactam antibiotics. *C difficile* is treated with oral metronidazole¹ (Flagyl 500 mg PO every 8 hours for 10–14 days) and vancomycin (Vancocin 125 mg PO every 6 hours for 10 days). The diagnosis is confirmed with either polymerase chain reaction (PCR), enzyme immunoassay, or anaerobic culture. Endoscopy and biopsy can also be obtained if there is a high clinical suspicion for *C difficile* with negative laboratory results or if the patient did not respond to antibiotic treatment.

E coli

E coli are a large and versatile group of pathogens that can cause widespread disease and affect multiple organ systems. *E coli* is a part of the normal flora of both human and animal digestive tract. Certain *E coli* strains can cause acute diarrhea. Pathogenic strains include enterotoxigenic *E coli* (ETEC), enteropathogenic *E coli*, enteroaggregative *E coli*, enteroinvasive *E coli*, diffusely adherent *E coli*, and enterohemorrhagic *E coli* (EHEC may also be referred as Shiga toxin-producing *E coli* or verocytotoxin-producing *E coli*). The two most common and notorious strains are ETEC and EHEC. ETEC is a major cause of traveler's diarrhea and diarrhea in children of developing countries. EHEC has led to high-profile outbreaks of diarrhea as a result of contaminated meats.

ETEC is a type of *E coli* that produces toxins that stimulate the intestines to secrete excessive fluid, thus producing diarrhea. ETEC produces two different toxins: heat-stable toxin and heat-labile toxin. Both types of toxins produce similar illnesses. Contaminated food and water is the usual source of infection. Although stool culture is needed for definitive diagnosis, ETEC infections are usually diagnosed on history and clinical symptoms. Symptoms usually appear after 1 to 2 days after exposure and may last from 5 to 7 days. Most cases of ETEC diarrhea are treated symptomatically with adequate rehydration alone. Oral rehydration salts may be used and purchased over the counter to help address electrolyte losses. Both bismuth compounds (e.g., Pepto-Bismol) and antiperistalsis agents (e.g. loperamide [Imodium]) can help reduce severity of symptoms; they both may prolong the time the body takes to clear the toxin. Antibiotics are reserved for moderate to severe disease. The most common effective antibiotics include fluoroquinolones. Antibiotics can shorten the duration of symptoms but are usually not required.

EHEC is a strain of *E coli* that produces a Shiga toxin. The toxin acts on vascular endothelium of small vessels of multiple organ systems. The toxin causes the breakdown and hemorrhage of the endothelium. When the toxin affects the vascular endothelium of the digestive tract, it causes bloody diarrhea. The pathogen often invades the kidney and lungs. Sequelae of EHEC infection include hemorrhagic diarrhea, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura. *E coli* O157 is the most common strain of EHEC. The infection is spread via the oral–fecal route, which includes consumption of contaminated food, unpasteurized milk and cheeses, and unsanitary water. Good hand hygiene is imperative. Symptoms usually appear 3 to 4 days after exposure and may last as long as 10 days. Positive stool cultures should be

reported to the local health department. Supportive treatment, including rehydration, is the cornerstone of treatment. Antibiotics are contraindicated because of evidence of increased Shiga toxin release and thus increased risk of hemolytic uremic syndrome.

Salmonella

Salmonella is the most common foodborne cause of diarrhea in the United States. It is associated with ingestion of infected poultry, eggs, and milk products. *Salmonella* can also be transmitted from pets, especially reptiles. Stool cultures are required for definitive diagnosis. Fluoroquinolones remain the antibiotic of choice, although sensitivities will guide antibiotic usage.

Shigella

Shigella is the pathogen that causes dysentery and is a major cause of morbidity in developing countries. Dysentery usually presents as high fever, abdominal cramping, and bloody diarrhea. Positive stool cultures usually warrant treatment with fluoroquinolones.

Vibrio

Vibrio cholera is endemic to developing countries. Symptoms usually present 1 to 3 days after exposure. Symptoms usually include profuse watery diarrhea (rice-water stools), abdominal cramping, and vomiting. Fever is infrequent. Rehydration with appropriate electrolyte replacement is paramount. Antibiotics can be an adjunct to rehydration and include fluoroquinolones and tetracycline at 500 mg PO every 8 hours for 3 days.

Yersinia

Yersinia enterocolitica infections are less common. Symptoms include diarrhea, fever, abdominal pain, and vomiting. Stool cultures are needed to confirm the diagnosis.

Viruses

Viral pathogens are likely responsible for the majority of gastroenteritis in the United States. Given the transient nature and characteristic symptoms, the specificity of the exact virus is not usually obtained. The most common viral etiologies tend to be adenovirus, rotavirus, norovirus, and astrovirus. Rotavirus tends to affect infants and children from 3 to 36 months of age, resulting in a spectrum of disease from asymptomatic shedding to severe gastroenteritis. Vaccination has played an important role in decreasing the cases of rotavirus infections.

Norovirus (i.e., Norwalk virus) is responsible for many high-profile outbreaks in daycare centers, cruise ships, and hospitals. Norovirus can be easily transmitted from person to person, from contact of contaminated surfaces, or from exposure to contaminated food or water. Symptoms present 1 to 3 days after exposure. Symptoms include fever, explosive vomiting, and diarrhea. PCR testing can confirm the diagnosis but is not usually necessary unless there seems to be an outbreak.

Parasite

Entamoeba histolytica, *Cryptosporidium*, *Giardia*, and *Cyclospora* spp. are the most common parasitic or protozoal infections that cause diarrhea. Protozoa infections are even less common. It is usually not cost-effective to evaluate for ova and parasites unless there are specific indications, such as a history of immunocompromise, exposure to daycare centers, or history of exposure to contaminated water. Multiple stool samples are needed if there are concerns of parasite infection resulting from possible intermittent shedding. *E histolytica* can cause amoebic dysentery and lead to bloody diarrhea. Microscopy, antigen testing, and serology are all possible tests for diagnosis. Parasitic infections are usually treated with metronidazole (Flagyl), tinidazole (Tindamax 2 g PO four times daily for 1–3 days) or albendazole¹ (Albenza 400 mg PO four times daily for 5 days).

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Traveler's Diarrhea

Traveler's diarrhea is common to individuals from developed countries traveling to developing countries. Episodes can be caused by bacteria, viruses, and parasites. The most common pathogen is *E coli* (ETEC). Travelers should choose their food and water sources carefully. Water purification and avoiding foods prepared with contaminated water is useful. Prolonged or other symptoms such as fever or bloody stool should be further investigated.

Treatment

Fluid and electrolyte replacement are the most important therapies for acute diarrhea. The route of administration depends on the severity of the dehydration. For mild cases of diarrhea in a normally healthy individual, adequate oral intake of juices, soups, and electrolyte-infused water can be sufficient. For severe dehydration, IV fluids or oral rehydration therapy with isotonic electrolyte solutions may be needed. Oral hydration is preferred over IV fluids if possible. IV fluids are more expensive and less practical than oral rehydration. The World Health Organization has a lower-osmolarity oral rehydration solution (ORS), which is very effective in reducing stool volume and the need for switching to IV therapy in children. A number of effective ORSs are also available over the counter, including Pedialyte and Rehydralyte. IV fluids, including normal saline and lactated Ringers solution, are indicated in severe dehydration or in patients who cannot tolerate oral fluid intake.

Antimicrobial agents have a secondary role in treatment of acute diarrhea. Given the fact that most cases of diarrhea are mild, self-limited, and caused by nonbacterial pathogens, antibiotics should be used sparingly. Antibiotic treatment should be used in invasive bacterial infections, traveler's diarrhea, or in patients with immunosuppression. Empirical antibiotics can be appropriate as described above for *Campylobacter* or *C difficile* infections.

Antidiarrheal medications can be useful to help alleviate symptoms in patients with no other contraindications, such as fever or bloody diarrhea. Loperamide (Imodium initial 4 mg PO followed by 2 mg PO with each loose stool, maximum 16 mg per day) decreases intestinal peristalsis and facilitates intestinal absorption. Bismuth (Pepto-Bismol) is less effective. Bismuth produces both antisecretory and antimicrobial effects in the gastrointestinal tract.

BLEEDING ESOPHAGEAL VARICES

Method of

Cecilio M. Azar, MD; and Ala I. Sharara, MD

CURRENT DIAGNOSIS

- Endoscopic screening for esophageal varices is recommended in patients with liver cirrhosis.
- Noninvasive predictors of the presence of large varices, such as splenomegaly and thrombocytopenia, have limited accuracy.
- A combination of clinical and endoscopic findings including the Child-Pugh class, size of varices, and the presence of red wale

markings correlates with the risk of first bleeding in patients with cirrhosis.

- Measurement of hepatic venous pressure gradient may be the best indicator of risk and severity of bleeding in patients with varices. It is an invasive test and is not widely available or used routinely in practice.

CURRENT THERAPY

- Nonselective β -blockers and endoscopic band ligation are both effective first-line therapy in the primary prophylaxis of esophageal varices.
- The management of acute variceal hemorrhage consists of prompt resuscitation and correction of coagulation abnormalities, followed by endoscopic and pharmacologic therapy with vasoactive agents. Antibiotic prophylaxis is given to decrease the risk of infection and of rebleeding. Transjugular intrahepatic portosystemic shunt (TIPS) is reserved for refractory, uncontrolled, acute variceal bleeding.
- Strategies for secondary prophylaxis of variceal bleeding include endoscopic band ligation, pharmacologic therapy with nonselective β -blockers with or without nitrates, TIPS, and surgical shunts.
- Comparative cost-effectiveness of secondary prophylaxis strategies is unknown but should take into consideration the cost of failed therapy (e.g., rebleeding, shunt revision) and that of treatment related-complications (e.g., encephalopathy, esophageal stricture).

Epidemiology

Bleeding of esophageal varices is a major complication of portal hypertension, usually in the setting of liver cirrhosis, accounting for 10% to 30% of all cases of upper gastrointestinal hemorrhage. More than any other cause of gastrointestinal bleeding, this complication results in considerable morbidity and mortality, prolonged hospitalization, and increased affiliated costs. Variceal bleeding develops in 25% to 35% of patients with cirrhosis and accounts for up to 90% of upper gastrointestinal bleeding episodes in these patients. About 10% to 30% of these episodes are fatal, and as many as 70% of survivors rebleed following an index variceal hemorrhage. Following such events, the 1-year survival is 34% to 80%, being inversely related to the severity of the underlying liver disease.

Treatment of patients with esophageal varices includes preventing the initial bleeding episode (primary prophylaxis), controlling active variceal hemorrhage, and preventing recurrent bleeding after a first episode (secondary prophylaxis). Data on the optimal management of gastric varices are much more limited, and this topic is not covered in this article.

Pathophysiology

Chronic liver disease leading to cirrhosis is the most common cause of portal hypertension. The level of increased resistance to flow varies with the level of circulatory breach and can be divided into prehepatic, hepatic or sinusoidal, and posthepatic. In cirrhosis, several organ systems are involved in the pathophysiology of portal hypertension. At the splanchnic vascular bed level there is marked vasodilatation and increase in angiogenesis, leading to increase in portal blood flow and formation of collateral circulation, such as gastroesophageal varices, along with decrease in response to vasoconstrictors. At the systemic circulation level, there is an increase in cardiac output, decrease in vascular resistance, and hypervolemia. This hyperkinetic syndrome leads to an effective hypovolemia, with a resultant increase in vasoactive factors to maintain a normal arterial blood pressure.

Varices represent portosystemic collaterals derived from dilatation of preexisting embryonic vascular channels, such as those

Traveler's Diarrhea

Traveler's diarrhea is common to individuals from developed countries traveling to developing countries. Episodes can be caused by bacteria, viruses, and parasites. The most common pathogen is *E coli* (ETEC). Travelers should choose their food and water sources carefully. Water purification and avoiding foods prepared with contaminated water is useful. Prolonged or other symptoms such as fever or bloody stool should be further investigated.

Treatment

Fluid and electrolyte replacement are the most important therapies for acute diarrhea. The route of administration depends on the severity of the dehydration. For mild cases of diarrhea in a normally healthy individual, adequate oral intake of juices, soups, and electrolyte-infused water can be sufficient. For severe dehydration, IV fluids or oral rehydration therapy with isotonic electrolyte solutions may be needed. Oral hydration is preferred over IV fluids if possible. IV fluids are more expensive and less practical than oral rehydration. The World Health Organization has a lower-osmolarity oral rehydration solution (ORS), which is very effective in reducing stool volume and the need for switching to IV therapy in children. A number of effective ORSs are also available over the counter, including Pedialyte and Rehydralyte. IV fluids, including normal saline and lactated Ringers solution, are indicated in severe dehydration or in patients who cannot tolerate oral fluid intake.

Antimicrobial agents have a secondary role in treatment of acute diarrhea. Given the fact that most cases of diarrhea are mild, self-limited, and caused by nonbacterial pathogens, antibiotics should be used sparingly. Antibiotic treatment should be used in invasive bacterial infections, traveler's diarrhea, or in patients with immunosuppression. Empirical antibiotics can be appropriate as described above for *Campylobacter* or *C difficile* infections.

Antidiarrheal medications can be useful to help alleviate symptoms in patients with no other contraindications, such as fever or bloody diarrhea. Loperamide (Imodium initial 4 mg PO followed by 2 mg PO with each loose stool, maximum 16 mg per day) decreases intestinal peristalsis and facilitates intestinal absorption. Bismuth (Pepto-Bismol) is less effective. Bismuth produces both antisecretory and antimicrobial effects in the gastrointestinal tract.

BLEEDING ESOPHAGEAL VARICES

Method of

Cecilio M. Azar, MD; and Ala I. Sharara, MD

CURRENT DIAGNOSIS

- Endoscopic screening for esophageal varices is recommended in patients with liver cirrhosis.
- Noninvasive predictors of the presence of large varices, such as splenomegaly and thrombocytopenia, have limited accuracy.
- A combination of clinical and endoscopic findings including the Child-Pugh class, size of varices, and the presence of red wale

markings correlates with the risk of first bleeding in patients with cirrhosis.

- Measurement of hepatic venous pressure gradient may be the best indicator of risk and severity of bleeding in patients with varices. It is an invasive test and is not widely available or used routinely in practice.

CURRENT THERAPY

- Nonselective β -blockers and endoscopic band ligation are both effective first-line therapy in the primary prophylaxis of esophageal varices.
- The management of acute variceal hemorrhage consists of prompt resuscitation and correction of coagulation abnormalities, followed by endoscopic and pharmacologic therapy with vasoactive agents. Antibiotic prophylaxis is given to decrease the risk of infection and of rebleeding. Transjugular intrahepatic portosystemic shunt (TIPS) is reserved for refractory, uncontrolled, acute variceal bleeding.
- Strategies for secondary prophylaxis of variceal bleeding include endoscopic band ligation, pharmacologic therapy with nonselective β -blockers with or without nitrates, TIPS, and surgical shunts.
- Comparative cost-effectiveness of secondary prophylaxis strategies is unknown but should take into consideration the cost of failed therapy (e.g., rebleeding, shunt revision) and that of treatment related-complications (e.g., encephalopathy, esophageal stricture).

Epidemiology

Bleeding of esophageal varices is a major complication of portal hypertension, usually in the setting of liver cirrhosis, accounting for 10% to 30% of all cases of upper gastrointestinal hemorrhage. More than any other cause of gastrointestinal bleeding, this complication results in considerable morbidity and mortality, prolonged hospitalization, and increased affiliated costs. Variceal bleeding develops in 25% to 35% of patients with cirrhosis and accounts for up to 90% of upper gastrointestinal bleeding episodes in these patients. About 10% to 30% of these episodes are fatal, and as many as 70% of survivors rebleed following an index variceal hemorrhage. Following such events, the 1-year survival is 34% to 80%, being inversely related to the severity of the underlying liver disease.

Treatment of patients with esophageal varices includes preventing the initial bleeding episode (primary prophylaxis), controlling active variceal hemorrhage, and preventing recurrent bleeding after a first episode (secondary prophylaxis). Data on the optimal management of gastric varices are much more limited, and this topic is not covered in this article.

Pathophysiology

Chronic liver disease leading to cirrhosis is the most common cause of portal hypertension. The level of increased resistance to flow varies with the level of circulatory breach and can be divided into prehepatic, hepatic or sinusoidal, and posthepatic. In cirrhosis, several organ systems are involved in the pathophysiology of portal hypertension. At the splanchnic vascular bed level there is marked vasodilatation and increase in angiogenesis, leading to increase in portal blood flow and formation of collateral circulation, such as gastroesophageal varices, along with decrease in response to vasoconstrictors. At the systemic circulation level, there is an increase in cardiac output, decrease in vascular resistance, and hypervolemia. This hyperkinetic syndrome leads to an effective hypovolemia, with a resultant increase in vasoactive factors to maintain a normal arterial blood pressure.

Varices represent portosystemic collaterals derived from dilatation of preexisting embryonic vascular channels, such as those

between the coronary and short gastric veins and the intercostal, esophageal, and azygous veins. In the distal esophagus, over an area extending 2 to 5 cm from the gastroesophageal junction, veins are found more superficially in the lamina propria rather than the submucosa. This results in reduced support from surrounding tissues owing to the predominant intraluminal location of these varices and might explain the predilection for bleeding at this site. The opening and dilation of portosystemic collaterals appears to depend on a threshold portal pressure gradient (measured as hepatic venous pressure gradient [HVPG]) of 12 mm Hg, below which varices do not form. This pressure gradient is necessary but not sufficient for the development of gastroesophageal varices.

Diagnosis

The current consensus states that every patient with liver cirrhosis should undergo an upper endoscopy to detect gastroesophageal varices. The main aim behind screening for gastroesophageal varices is to identify patients requiring prophylactic treatment or further surveillance. Several invasive and noninvasive procedures help in detecting portal hypertension and can, with variable accuracy, predict the presence of gastroesophageal varices. Unfortunately, none are sensitive enough to replace endoscopy. A recent meta-analysis showed that transient elastography may be a useful screening tool for the detection of significant liver fibrosis and associated portal hypertension, but it is not useful at predicting the presence or size of esophageal varices. Smaller trials have evaluated the usefulness of spleen and liver MR elastography in assessing portal hypertension and varices, but this modality has not yet found its way into clinical practice. The combination of an elastography value below 20 kPa together and a platelet count above 150,000 nearly excludes the presence of esophageal varices requiring treatment. Endoscopic videocapsule is a new modality introduced for visualizing the esophagus; it allows correct identification of varices in 80% of cases but can have poor accuracy in identifying the presence of hypertensive gastropathy and gastric varices.

Not all esophageal varices bleed; hemorrhage occurs in only 30% to 35% of patients with cirrhosis. Variceal rupture is directly related to physical factors such as the radius, thickness, and elastic properties of the vessel in addition to intravariceal and intraluminal pressure and tension. Endoscopic findings that predict a higher risk of bleeding include larger size of varices and the presence of endoscopic red signs (described as red wale markings) on the variceal wall, indicating dilated intraepithelial and subepithelial superficial veins. A combination of clinical and endoscopic findings, including the Child-Pugh class, size of varices, and the presence or absence of red wale markings, was found to correlate highly with the risk of first bleeding in patients with cirrhosis. Hemodynamic parameters examined as predictors of bleeding include HVPG, azygous blood flow, and direct measurement of intravariceal pressure.

HVPG, calculated by the gradient of wedged and free hepatic vein pressure (normal value, 5 mm Hg), is used most often and provides reliable measurement of portal pressure in patients with cirrhosis. The extent of elevation of HVPG may be the best indicator of risk of bleeding, severity of bleeding, and survival. A rise in pressure in a patient with known varices increases the risk of bleeding, and the extent of portal pressure elevation has an inverse relationship to prognosis after hemorrhage has occurred. In general, however, a linear relationship between the degree of portal hypertension and the risk of variceal hemorrhage or formation of varices does not exist, so this technique cannot be used routinely to identify individual patients at high risk for bleeding.

Treatment

Primary Prophylaxis

The natural evolution of gastroesophageal varices without treatment is characterized by an increase in size from small to large varices, which eventually rupture and bleed. The progression rate ranges from 5% to 30% per year. The incidence of bleeding from small esophageal varices is estimated to be 4% per year, and it is as high as 15% per year for medium to large varices. In a randomized,

controlled trial, the nonselective β -blocker timolol (Blocadren)¹ failed to reduce the development of varices or variceal bleeding in patients without varices. Adverse events were more common in the timolol group. Therefore, it is not recommended to start β -blockers in patients who do not yet have esophageal varices.

Based on prospective studies of cirrhotic patients with varices identified at endoscopy and of untreated groups in randomized controlled trials, the risk of bleeding from esophageal varices has been estimated at 25% to 35% at 1 year. Therapy for primary prophylaxis against variceal bleeding (prevention of a first variceal bleeding) is summarized in Table 1.

Pharmacologic Therapy

The general objective of pharmacologic therapy for variceal bleeding is to reduce portal pressure and consequently intravariceal pressure. Drugs that reduce portocollateral venous flow (vasoconstrictors) or intrahepatic vascular resistance (vasodilators) have been used and include β -blockers, nitrates, β_2 -adrenergic blockers, spironolactone (Aldactone),¹ pentoxifylline (Trental),¹ molsidomine (Corvaton),² and simvastatin (Zocor).¹ Because varices do not bleed at an HVPG less than 12 mm Hg, reduction to this level is ideal, but substantial reductions in HVPG (i.e., by >20%) are also clinically meaningful.

β -Blockers exert their beneficial effect on portal venous pressure by diminishing splanchnic blood flow and consequently gastroesophageal collateral and azygous blood flow. The effectiveness of β -blockers for primary prophylaxis against variceal bleeding has been demonstrated in several controlled trials. Meta-analyses have revealed a 40% to 50% reduction in bleeding and a trend toward improved survival. The estimated overall response rate is 49%, with bleeding rates of 6% in responders and 32% in nonresponders, with a number needed to treat (NNT) of 10.

The nonselective β -blockers, such as propranolol (Inderal)¹ and nadolol (Corgard),¹ are preferred because of the dual benefit of β_1 - and β_2 -receptor blockade. In the absence of HVPG determination, β -blockers are titrated to achieve a reduction in resting heart rate to 55 beats/min or 25% of baseline. Propranolol is generally given as a long-acting preparation and titrated to a maximum dose of 320 mg/day. Nadolol is initiated at 80 mg daily up to a maximum daily dose of 240 mg. Carvedilol (Coreg)¹ is initiated at 6.25 mg daily and increased if tolerated to 12.5 mg/day. Carvedilol is superior to propranolol at reducing portal hypertension although available data do not allow a satisfactory comparison of adverse events. The portal pressure-reducing effects of β -blockers are not predictable; the resultant reduction in heart rate or the measurement of drug blood levels are not good indicators of response to therapy. For example, portal venous pressure is reduced in about 60% to 70% of patients who receive propranolol therapy, but only 10% to 30% of these patients show a substantial response (i.e., >20% reduction). Additionally, approximately 20% to 25% of patients have no measurable decline in portal pressure despite increasing dosage of propranolol. Of note, there is increasing evidence that the use of beta-blockers can be deleterious in patients with decompensated liver cirrhosis and refractory ascites (Sersté) or in patients with spontaneous bacterial peritonitis (Mandorfer).

In addition to β -blockers, a number of vasodilators have been investigated in patients with portal hypertension and in animal models of portal hypertension, most notably isosorbide mononitrate (Imdur).¹ Of note, there is increasing evidence that the use of β -blockers can be deleterious in patients with decompensated liver cirrhosis and refractory ascites or in patients with spontaneous bacterial peritonitis. The exact mechanism of action of nitrates is unclear but is thought to be mediated primarily by reducing intrahepatic resistance and possibly by splanchnic arterial vasoconstriction induced in response to venous pooling and vasodilation in other regional vascular beds. Monotherapy with nitrates is ineffective in primary prophylaxis and can have detrimental effects,

*Upon documentation of varices, variceal hemorrhage occurs in 25%–30% of patients by 2 years. β -Blockers reduce the risk to 15%–18%, and combination β -blockers plus nitrates reduce the risk to 7.5%–10%.

particularly in cirrhotic patients with ascites, and should not be used.

The addition of isosorbide mononitrate to β -blockers, however, has been shown to result in an enhanced reduction in portal pressure in humans. In a randomized, controlled trial involving 42 patients with cirrhosis and esophageal varices, a reduction of greater than 20% in HVPG was documented in only 10% in the propranolol group compared to 50% in the combination therapy group. In patients with Child-Pugh class A and B cirrhosis, the addition of isosorbide mononitrate to nadolol has been shown, in a randomized trial, to result in a greater than 50% additional reduction in variceal bleeding rate when compared with nadolol monotherapy (12% versus 29%). However, a large subsequent double-blind, placebo-controlled study failed to confirm these results. Based on the existing evidence, the combination of β -blockers and isosorbide is not recommended in primary prophylaxis.

Endoscopic Therapy

Endoscopic therapies play a prominent role in treatment of esophageal varices. Endoscopic band ligation (EBL) is the endoscopic procedure of choice in the management of esophageal varices. As of 2010, 16 randomized, controlled trials have compared EBL to β -blockers in the primary prevention of variceal bleeding. These studies suffered from significant heterogeneity, and a large number were published in abstract form. Two meta-analyses of these trials showed a slight advantage of EBL over β -blockers in terms of primary prevention of variceal bleeding, but there were no differences in mortality. A recent Cochrane database systematic review found a beneficial effect of band ligation compared to β -blockers in primary prevention of upper gastrointestinal bleeding in adult patients with esophageal varices. Again, there was no difference in mortality.

β -Blockers are cheaper and much easier to administer but are associated with issues of noncompliance and a higher incidence

of adverse events (e.g., hypotension, impotence, insomnia) than EBL. However, most of these side effects are easy to manage and none require hospitalization or result in direct mortality. On the other hand, adverse events related to EBL, such as bleeding from band-related ulcers, albeit infrequent, are more significant, often requiring hospitalization and blood transfusion, and may rarely be associated with death.

According to the Baveno consensus conference, nonselective β -blockers should be considered as a first choice for preventing first variceal bleeding in high-risk patients who have not bled, and EBL should be provided for patients with contraindications or intolerance to β -blockers. The recent guidelines by the American College of Gastroenterology (ACG) and American Association for the Study of Liver Diseases (AASLD) recommend using β -blockers in low-risk patients who have medium to large varices but suggest both EBL and β -blockers for high-risk patients as first-line therapy. The optimal primary prophylaxis in patients with decompensated cirrhosis remains unclear and is arguably expedited liver transplantation. The combination of pharmacologic plus endoscopic therapy has been investigated in such patients with conflicting results. In one study, EBL plus β -blockers offered no benefit in terms of prevention of first bleeding when compared to EBL alone. In a more recent study, combination therapy significantly reduced the occurrence of the first episode of variceal bleeding and improved bleeding-related survival in a group of cirrhotic patients with high-risk esophageal varices awaiting liver transplantation.

Management of Acute Variceal Hemorrhage

Variceal hemorrhage is usually an acute clinical event characterized by rapid gastrointestinal blood loss manifesting as hematemesis (which can be massive), with or without melena or hematochezia. Hemodynamic instability (tachycardia, hypotension) is common. Although variceal bleeding is common in patients with cirrhosis presenting with acute upper gastrointestinal hemorrhage, other causes of bleeding, such as ulcer disease, must be considered.

Urgent initiation of empiric pharmacologic therapy with vasoactive agents is indicated in situations where variceal hemorrhage is likely. Subsequently, direct endoscopic examination is critical to establish an accurate diagnosis and to provide the rationale for immediate and subsequent therapies. The immediate steps in the management of acute variceal bleeding include: volume resuscitation, prevention of complications, ensuring hemostasis, and initiating measures to prevent early and delayed rebleeding.

Patients with variceal hemorrhage and ascites are at increased risk for bacterial infections, particularly spontaneous bacterial peritonitis. This risk appears to be increased in the setting of uncontrolled hemorrhage or as a result of transient bacteremia following endoscopic sclerotherapy or variceal ligation. Short-term systemic antibiotics (e.g., third-generation cephalosporins or fluoroquinolones for 4–10 days) have been shown to decrease the risk of bacterial infections and to reduce rebleeding as well as mortality in cirrhotic patients with gastrointestinal bleeding.

The role of platelet transfusion or fresh frozen plasma administration has not been assessed appropriately. The use of recombinant activated coagulation factor VII (rFVIIa [Novoseven]),¹ which corrects prothrombin time in cirrhotic patients, has been assessed in two randomized, controlled trials. The first trial showed, in a post hoc analysis, that rFVIIa administration might significantly improve the results of conventional therapy in patients with moderate and advanced liver failure (Child-Pugh B and C) without increasing the incidence of adverse events. A more recent trial tested rFVIIa in patients with active bleeding at endoscopy and with a Child-Pugh score 8 points or higher. This trial failed to show a benefit of rFVIIa in terms of decreasing the risk of 5-day failure, but it did show improved 6-week mortality. In a small prospective study involving cirrhotic patients with acute variceal bleeding and new portal vein thrombosis identified by positive intra-thrombus enhancement on contrast ultrasonography, the use of low molecular weight heparin after hemostasis is achieved by band ligation was shown to be safe, well tolerated, and effective, with complete recanalization of the portal vein within 2 to 11 days and no recurrence of bleeding.

Pharmacologic Therapy

Pharmacologic therapy can be administered early, requires no special technical expertise, and is thus a desirable first-line option for managing acute variceal hemorrhage. Drugs that reduce portocolateral venous flow (vasoconstrictors) or intrahepatic vascular resistance (vasodilators) or both have been used to achieve this effect. Vasoconstrictors work by decreasing splanchnic arterial flow, and vasodilators are used in combination with vasoconstrictors to reduce their systemic side effects, but they can also exert an added beneficial effect on intrahepatic resistance (see Table 1).

Vasopressin and Terlipressin. Vasopressin (Pitressin)¹ is a nonselective vasoconstricting agent that causes a reduction of splanchnic blood flow and thereby a reduced portal pressure. Vasopressin, which is associated with severe vascular complications, has been largely replaced by other vasoconstrictors such as its synthetic analogue, triglycyl-lysine vasopressin (terlipressin [Glypressin]).² Terlipressin has fewer side effects and a longer biological half-life, allowing its use as a bolus intravenous injection (2 mg every 4 hours for the initial 24 hours, then 1 mg every 4 hours for the next 24–48 hours). Terlipressin has been shown in numerous placebo-controlled trials to control bleeding in about 80% of cases and is the only pharmacologic therapy proven, as of 2010, to reduce mortality from acute variceal hemorrhage. In patients with esophageal variceal bleeding, a 24-hour course of terlipressin was shown to be as effective as a 72-hour course when used as adjunct therapy to successful variceal band ligation. Terlipressin is not currently available in the United States.

Somatostatin, Octreotide, and Vapreotide. Somatostatin,² a naturally occurring peptide, and its analogues, octreotide

(Sandostatin)¹ and vapreotide (Sanvar),⁵ stop variceal hemorrhage in up to 80% of patients and are generally considered equivalent to vasopressin (Pitressin), terlipressin² (Glypressin), and endoscopic therapy for the control of acute variceal bleeding. Their precise mechanism of action is unclear but might result from an effect on the release of vasoactive peptides or from reduction of postprandial hyperemia. Somatostatin is used as a continuous intravenous infusion of 250 µg/hour following a 250-µg bolus injection. Octreotide is used as a continuous infusion of 50 µg/hour and does not require a bolus injection. Side effects are minor, including hyperglycemia and mild abdominal cramps. The addition of octreotide or vapreotide to endoscopic sclerotherapy or banding improves control of bleeding and reduces transfusion requirements, with no change in overall mortality. A continuous infusion of octreotide or vapreotide is therefore recommended for 2 to 5 days following emergency endoscopic therapy.

Endoscopy

Endoscopic sclerotherapy stops variceal hemorrhage in 80% to 90% of cases. Its drawbacks include a significant risk of local complications including ulceration, bleeding, stricture, and perforation. Rare systemic complications have been reported including bacteremia with endocarditis, formation of splenic or brain abscesses, and portal vein thrombosis. Randomized trials in patients with acute variceal bleeding have shown that EBL is essentially equivalent to endoscopic sclerotherapy in achieving initial hemostasis with lesser complications. These include superficial ulcerations, transient chest discomfort, and, rarely, stricture formation. Erythromycin infusion before endoscopy¹ in patients with acute variceal bleeding has been shown to significantly improve endoscopic visibility and to shorten the duration of the procedure.

Balloon Tamponade/SEMS

The use of the Sengstaken-Blakemore or Minnesota tube for hemostasis of variceal bleeding is based on the principle of the application of direct pressure on the bleeding varix by an inflatable—esophageal or gastric—balloon fitted on a rubber nasogastric tube. When properly applied, balloon tamponade is successful in achieving immediate hemostasis in almost all cases. However, early rebleeding following balloon decompression is high. Complications of balloon tamponade include esophageal perforation or rupture, aspiration, and asphyxiation from upper airway obstruction. Balloon tamponade or use of SEMS is generally not recommended and should largely be reserved for rescue of cases of hemorrhage uncontrolled by pharmacologic and endoscopic methods and as a temporary bridge to more definitive therapy. Self-expandable metal stents (SEMS) have recently been shown to be effective in controlling severe bleeding.

Transjugular Intrahepatic Portosystemic Shunt

Treatment with a transjugular intrahepatic portosystemic shunt (TIPS) consists of the vascular placement of an expandable metal stent across a tract created between a hepatic vein and a major intrahepatic branch of the portal system. TIPS can be successfully performed in 90% to 100% of patients, resulting in hemodynamic changes similar to a partially decompressive side-to-side portocaval shunt while avoiding the morbidity and mortality associated with a major surgical procedure. TIPS has been shown to be effective in treating refractory, uncontrolled, acute variceal bleeding. Patients with advanced liver disease and multiorgan failure at the time of TIPS have a 30-day mortality that approaches 100%.

Surgery

Surgery is generally considered in the setting of continued hemorrhage or recurrent early rebleeding—uncontrolled by repeated endoscopic or continued pharmacologic therapy—and when TIPS

¹Not FDA approved for this indication.

²Not available in the United States.

¹Not FDA approved for this indication.

²Not available in the United States.

⁵Investigational drug in the United States.

is not available or is not technically feasible. Surgical options include portosystemic shunting or esophageal staple transection alone or with esophagogastric devascularization and splenectomy (Sugiura procedure). Devascularization procedures may be useful in patients who cannot receive a shunt because of splanchnic venous thrombosis. Regardless of the choice of surgical technique, morbidity is high and the 30-day mortality for emergency surgery approaches 80% in some series. Understandably, rescue liver transplantation is not a practical option in patients with uncontrolled variceal hemorrhage.

Secondary Prophylaxis

Variceal hemorrhage recurs in approximately two thirds of patients, most commonly within the first 6 weeks after the initial episode. Patients with advanced liver disease (MELD [model for end-stage liver disease] score ≥ 18) have an increased risk of early rebleeding and death. Early rebleeding (within the first 5 days) is reduced by the adjuvant use of octreotide¹ or vaptotide⁵—and possibly terlipressin² and somatostatin²—after initial endoscopic or pharmacologic control of hemorrhage.

The severity of portal hypertension correlates closely with the severity and risk of rebleeding as well as actuarial probability of survival following an index episode. In a cohort of patients presenting with variceal hemorrhage, those with an initial HVPG greater than 20 mm Hg had a 1-year mortality of 64% compared to 20% for patients with lesser elevations in portal pressure. Given the high risk of recurrent hemorrhage and its associated morbidity and mortality, strategies aimed at prevention should be rapidly instituted following the index episode. The choice of preventive therapy should, therefore, take into consideration the efficacy of therapy, the side effects of the selected treatment, the patient's expected survival, and overall cost. Preventive strategies include pharmacologic, endoscopic, and surgical methods and are listed in Table 1. Relative effectiveness of these strategies is shown in Figure 1.

Figure 1 Relative effectiveness of available therapies for preventing recurrent variceal bleeding. The estimates shown are based on the cumulative data available in the literature for recurrent bleeding at 1 year. Abbreviations: EBL = endoscopic band ligation; ES = endoscopic sclerotherapy; TIPS = transjugular intrahepatic portosystemic shunt.

⁵Investigational drug in the United States.

Pharmacologic Therapy

Reducing the portal pressure by more than 20% from the baseline value pharmacologically results in a reduction in the cumulative probability of recurrent bleeding from 28% at 1 year, 39% at 2 years, and 66% at 3 years to 4%, 9%, and 9%, respectively. Although adjustment of medical therapy based on portal pressure measurement would be ideal, HVPG determination might not be readily available, and treatment must be adjusted using empiric clinical parameters. Several randomized, controlled trials, including a meta-analysis, have demonstrated that β -blockers prevent rebleeding and prolong survival. The addition of isosorbide mononitrate¹ to β -blockers appears to enhance the protective effect of β -blockers alone for preventing recurrent variceal bleeding but offers no survival advantage and reduces the tolerability of therapy. A recent randomized controlled trial showed that carvedilol¹ is as effective as the combination of nadolol plus isosorbide-5 mononitrate in the prevention of gastroesophageal variceal rebleeding, with fewer severe adverse events and similar survival. Compared with either sclerotherapy or endoscopic band ligation, combination medical therapy is superior in reducing the risk of recurrent bleeding in patients with esophageal variceal hemorrhage, primarily in patients with Child-Pugh class A and B cirrhosis. Notably, in patients who show a significant hemodynamic response to therapy (defined as a reduction in the hepatic venous pressure gradient to <12 mm Hg or $>20\%$ of the baseline value), the risk of recurrent bleeding and of death is significantly reduced.

Endoscopy

Endoscopic therapy has been established over the past decade as a therapeutic cornerstone for preventing esophageal variceal rebleeding. Gastric varices, however, are not effectively treated by sclerotherapy or ligation. Patients with recurrent gastric variceal hemorrhage are best treated by N-butyl-2-cyanoacrylate injection¹ or by nonendoscopic means such as TIPS. On the other hand, EBL is highly effective at obliterating esophageal varices and is considered the endoscopic therapy of choice for secondary prophylaxis.

Combination modality approaches, usually including an endoscopic and pharmacologic treatment, are pathophysiologically attractive and may be more effective than single therapy. Two randomized, controlled trials have shown that adding β -blockers to EBL reduces the risk of rebleeding and variceal recurrence, suggesting that if EBL is used, it should be used in association with β -blockers. One randomized, controlled trial has evaluated whether EBL could improve the efficacy of the combined administration of nadolol¹ plus isosorbide.¹ In this study, adding band ligation to nadolol plus isosorbide was shown to be superior to nadolol plus isosorbide alone in preventing variceal rebleeding, but there were no significant differences in mortality. The combination of the best endoscopic treatment (EBL) and the best pharmacologic treatment (β -blockers plus isosorbide) may be the best choice in preventing rebleeding but needs further studies for confirmation. Statins improve liver generation of NO and hepatic endothelial dysfunction in experimental models of cirrhosis and may also reduce liver fibrosis. Randomized placebo-controlled trials found that simvastatin¹ decreased HVPG and improved liver perfusion and had an additive effect in patients treated with NSBB, and showed survival benefit in patients with early stages of cirrhosis and variceal bleeding.

Transjugular Intrahepatic Portosystemic Shunt

Transjugular shunting is more effective than endoscopic therapy for preventing variceal rebleeding but offers no survival benefit. The cumulative risk of rebleeding following TIPS placement is 8% to 18% at 1 year. The trade-off, however, is that TIPS is associated with a higher incidence of clinically significant hepatic encephalopathy (new or worsened portosystemic encephalopathy was noted in about 25% of patients after TIPS). Advanced liver disease is the main determinant of poor outcome following TIPS.

¹Not FDA approved for this indication.

Consequently, in patients with advanced liver disease, TIPS is best used as a bridge to liver transplantation.

TIPS, using bare stents, has been compared with surgical shunts in two studies (8 mm portocaval H-graft shunt in one and distal splenorenal shunt in the second). Although the first study showed a significantly lower rebleeding rate in the surgical group, the second and larger trial did not find any differences in rebleeding rates, hepatic encephalopathy, or mortality, but it found a significantly higher reintervention rate in the TIPS group. However, the obstruction and reintervention rates are markedly decreased with the recent use of polytetrafluoroethylene (PTFE)-covered stents. According to these data, TIPS using PTFE-covered stents represents the best rescue therapy for failures of medical and endoscopic treatment.

Surgery

Portosystemic shunt surgery is the most effective means by which to reduce portal pressure. Although effective at eradicating varices and preventing rebleeding, nonselective portocaval shunts are associated with a significant incidence of hepatic encephalopathy, portal vein thrombosis, and occasionally liver failure. Commonly used shunts include the distal splenorenal shunt and the low-diameter (mesocaval or portocaval) interposition shunt. Rates of recurrent bleeding are on the order of 10%, with the highest risk of bleeding occurring in the first month after surgery. Devascularization procedures (i.e., esophageal transection and gastroesophageal devascularization) are usually considered in patients who cannot receive shunts because of splanchnic venous thrombosis and should be performed only by experienced surgeons. Surgical therapy has been largely supplanted by TIPS.

Cost-Effectiveness of Available Therapies

Data examining the cost of variceal bleeding and the cost-effectiveness of commonly used therapies are limited. The treatment cost of an episode of variceal bleeding has been estimated at \$15,000 to \$40,000. The cost-effectiveness of diagnostic methods used to guide therapy is unclear. For example, HVPG determination, which can accurately predict pharmacologic response to therapy, is an attractive, although invasive, adjunct in the management of patients with variceal bleeding, but its cost-effectiveness remains in question. Further, screening endoscopy for detecting large varices, while recommended, has not been demonstrated to be cost-effective.

There are areas in which management is controversial and not standardized. For example, given the right expertise, secondary prophylaxis with surgical shunts or TIPS may be more effective than medical or endoscopic therapy in Child-Pugh class A patients. On the other hand, patients with advanced cirrhosis are often intolerant of β -blockers—let alone in combination with nitrates—and therefore the use of combination therapy remains controversial in such patients. Arguably, the preferred treatment for such patients is TIPS as a bridge to early liver transplantation.

Therefore, when choosing a specific treatment plan, the clinician must take into consideration the direct costs of health care utilization, as well as the efficacy and morbidity of therapy. The treatment chosen should be tailored to fit the patient's clinical condition while also taking into account the possibility that the patient's liver disease can progress and thus necessitate transplantation. The cost-effectiveness of various treatment modalities should factor in the cost of failed therapy (e.g., rebleeding, shunt revision) and that of treatment-related complications (e.g., encephalopathy, esophageal stricture).

Summary

Esophageal variceal hemorrhage is a common and devastating complication of portal hypertension and is a leading cause of morbidity and mortality in patients with cirrhosis. Because the clinical outcomes are poor once variceal bleeding has occurred, primary prophylaxis with β -blockers or EBL should be considered in

high-risk patients. The treatment of acute variceal hemorrhage is aimed at volume resuscitation and ensuring hemostasis with pharmacologic agents and endoscopic techniques as well as prevention of complications, such as infections by the use of prophylactic antibiotics.

A high risk of rebleeding after an index episode mandates the institution of preventive strategies. Wedge pressure-guided medical therapy may be the preferred mode of secondary prophylaxis in patients with Child Pugh class A or B cirrhosis, but is invasive and not widely available. Patients at high risk for rebleeding, including those with decompensated or advanced liver disease, should be considered for TIPS followed by liver transplantation when applicable. Treatment with a combination of methods is pathophysiologically attractive, but the choice of therapy should ultimately be tailored to fit the patient's clinical condition, risk factors, and prognosis, taking into account issues of risk-to-benefit ratio, compliance, and cost.

CURRENT DIAGNOSIS

- True biliary colic is characterized by the abrupt onset and cessation of severe mid-epigastric or, less commonly, right upper quadrant pain.
- Pain commonly starts 1 to 2 hours after eating and can be localized or radiate to the back, right shoulder, or chest.
- The onset of biliary colic commonly occurs during sleep.
- Nausea and vomiting commonly follow the onset of pain.
- Elevations of total and conjugated bilirubin, ALP, and GGT with modest elevations in AST and ALT support a suspected diagnosis of choledocholithiasis.
- A normal serum biochemistry profile has a negative predictive value of 97% for ruling out choledocholithiasis.
- Transabdominal ultrasonography is a useful and cost-effective test for diagnosing cholelithiasis; however, it has significantly lower utility for choledocholithiasis.
- For intermediate-risk patients with suspected choledocholithiasis, examination of the common bile duct with magnetic resonance cholangiopancreatography (MRCP) or endoscopic ultrasonography (EUS) is warranted.

CURRENT THERAPY

- The treatment of choice for symptomatic cholelithiasis is laparoscopic cholecystectomy. Elective laparoscopic cholecystectomy should only be performed for true biliary colic. Vague symptoms such as bloating, dyspepsia, and atypical abdominal pain are not commonly related to gallstone disease and thus are not an indication for gallbladder removal.
- Laparoscopic cholecystectomy should generally take place within 72 hours of presentation for acute cholecystitis in appropriate surgical candidates.
- Laparoscopic cholecystectomy is recommended in pregnant patients with symptomatic cholelithiasis and acute cholecystitis. This is best done by experienced surgeons in the second or early third trimesters.
- Patients who should undergo preoperative ERCP for choledocholithiasis include those with high risk stratification and those deemed intermediate risk in whom a common bile duct stone is identified on MRCP or endoscopic ultrasonography.

Cholelithiasis

Epidemiology

Gallstone disease is common in Western populations, affecting 10% to 15% of adults. It is estimated that 6.3 million men and 14.2 million women in the United States have gallstones. Although the vast majority of patients remain asymptomatic throughout their lifetime, roughly one third develop symptoms or complications.

Pathophysiology

Gallstones can be categorized based on their composition. Of patients with gallstone disease in the Western world, 80% to 90% have cholesterol stones or cholesterol-predominant stones (mixed stones). Pigment gallstones account for the remaining 5% to 10%. Patients with hemolytic disorders are prone to pigment stone formation, and therefore the correspondence with disorders such as sickle cell anemia, hereditary spherocytosis, and Gilbert's syndrome is high.

Risk Factors

Risk factors for gallstone disease include female sex, age greater than 40 years, white, Latin American, and Native American descent, family history, obesity, rapid weight loss, starvation, total parenteral nutrition, bariatric surgery, diabetes mellitus, and hypertriglyceridemia.

Clinical Manifestations

The typical symptomatic presentation of gallstone disease is biliary colic. This is described as severe pain located in the mid-epigastrium or, less commonly, the right upper quadrant, that begins and ceases abruptly. The pain is typically constant, occurring 1 to 2 hours after a meal, and can either be localized or radiate to the back or right shoulder. Often the onset of pain occurs during sleep. Nausea and vomiting commonly accompany biliary pain, and, as with most surgical entities, pain typically precedes the onset of these symptoms. Biliary colic can also manifest as chest pain and is occasionally mistaken for cardiac angina. Prolonged episodes of pain localized to the right upper quadrant often herald cholecystitis rather than biliary colic. A clinical history containing the cardinal features of biliary colic carries a high diagnostic accuracy.

Diagnosis

Transabdominal ultrasonography is the preferred initial imaging test for cholelithiasis. The sensitivity for detecting the presence of gallstones within the gallbladder lumen on ultrasonography is 97%.

Biliary Sludge

Biliary sludge is often diagnosed on transabdominal ultrasonography. It appears as low-amplitude nonshadowing echoes that layer in dependent portions of the gallbladder. The clinical course of biliary sludge varies from patient to patient. Some patients remain symptom free, and others develop overt biliary colic. A fraction of patients demonstrate resolution of biliary sludge on repeat imaging. Symptomatic biliary sludge should be treated the same as cholelithiasis. Similarly, patients with asymptomatic biliary sludge should be managed expectantly.

Treatment

In patients with symptomatic cholelithiasis, treatment should be aimed at acute pain control and prevention of recurrent episodes. In patients without contraindications, cholecystectomy is the preferred choice for treatment of symptomatic uncomplicated cholelithiasis. This is preferably done via laparoscopy, which offers lower rates of complications and postoperative pain along with better cosmetic results when compared with open cholecystectomy.

Because of the high incidence of cholelithiasis, true biliary colic should be identified before a decision is made to proceed with laparoscopic cholecystectomy. Vague symptoms such as bloating or atypical abdominal pain are not typical of gallstone disease and thus often persist after surgery. In cases of asymptomatic uncomplicated cholelithiasis, elective cholecystectomy is not recommended unless the patient is diabetic or is undergoing an operation such as gastric bypass surgery, after which there is an increased risk of gallstone formation.

There is a very limited role for medical management of gallstone disease. Nonoperative management of symptomatic cholelithiasis involves bile dissolution with ursodeoxycholic acid (Actigall). The use of medical therapy is limited based on poor efficacy and high rates of recurrence and thus should be reserved only rarely for nonsurgical candidates.

Analgesia is an important adjunct in the treatment of symptomatic cholelithiasis. In patients with severe symptoms requiring narcotic pain medication, meperidine (Demerol) is preferred over morphine because it has less effect on the sphincter of Oddi. Nonsteroidal antiinflammatory drugs (NSAIDs) are another mainstay of therapy. Parenterally administered ketorolac (Toradol) is perhaps the most commonly used agent for biliary colic in the acute care setting. Studies have shown that NSAIDs are beneficial in the management of pain due to gallstones, and at least one study

has suggested that early administration of NSAIDs might decrease the progression to acute cholecystitis.

Complications

Complications that can potentially arise from cholelithiasis include acute cholecystitis, cholangitis, pancreatitis, obstructive jaundice, and, rarely, gallstone ileus.

Choledocholithiasis

Choledocholithiasis often manifests concomitantly with symptomatic gallstone disease and is a finding in 5% to 10% of patients undergoing laparoscopic cholecystectomy for symptomatic cholelithiasis. The workup for suspected choledocholithiasis combines history, physical examination, laboratory data, and various imaging modalities. If the clinical history and physical examination are suggestive, the clinician should obtain serum liver biochemistry tests including alanine aminotransferase (ALT), aspartate aminotransferase (AST), total and fractionated bilirubin, alkaline phosphatase (ALP), and γ -glutamyl transpeptidase (GGT).

The typical pattern of serum biochemistry is one of cholestasis. A conjugated hyperbilirubinemia along with high levels of GGT and ALP are seen often in the setting of modest elevation of the transaminases. ALP is usually elevated out of proportion to the transaminases; however, extreme levels of AST and ALT have been described. Transaminase levels greater than 1000 U/L, although rare in gallstone disease, should not dissuade the clinician from a diagnosis of choledocholithiasis. Serum biochemistries provide the most utility in ruling out common bile duct stones. A normal biochemical profile has a negative predictive value of 97%. Clinical predictors for assessing the likelihood of choledocholithiasis in patients with symptomatic cholelithiasis are listed in [Box 1](#).

Diagnosis

A variety of modalities are available for diagnosing choledocholithiasis. Perhaps the least expensive and most widely available test is transabdominal ultrasound. Although the sensitivity for cholelithiasis is quite high with transabdominal ultrasound, identifying stones in the common bile duct ([Figure 1](#)) is more difficult. Prospective studies have reported sensitivities ranging from 22% to 55% for detecting common bile duct stones; however, in our clinical

Figure 1 A large gallstone in the common bile duct (CBD) with dilatation of the CBD proximally. The endoscopic ultrasound probe is visualized in the top of the image, and a large cone-shaped shadow is cast distal to the gallstone.

experience the sensitivity is much lower. Other indirect indicators of choledocholithiasis such as common bile duct dilation (77%–88% sensitivity) can provide additional diagnostic clues. Based on the high false-negative rates for common bile duct stones and dilation, a negative transabdominal ultrasound scan cannot rule out choledocholithiasis. CT scanning has a higher sensitivity for choledocholithiasis than transabdominal ultrasound. Levels of radiation and cost have limited its use as a first-line diagnostic tool.

Three nonsurgical modalities offer true visualization of the common bile duct with comparable sensitivities: Magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasonography (EUS). MRCP has a diagnostic sensitivity of 85% to 92% for detecting choledocholithiasis, and, although it is useful for helping determine which intermediate-risk patients would benefit from preoperative ERCP, small and distal common bile duct stones are often missed.

EUS and ERCP are both minimally invasive techniques useful in the diagnosis and management of choledocholithiasis. Owing to the proximity of the extrahepatic bile duct to the proximal duodenum, EUS provides high sensitivity (89%–94%) for detecting common bile duct stones and is especially useful for detecting stones less than 5 mm in diameter. ERCP provides similar diagnostic sensitivity; however, ERCP offers therapeutic capability. Because of the reasonably high risk of complications including pancreatitis (1.3%–15.1%), infection (0.6%–5.0%), gastrointestinal hemorrhage (0.3%–2.0%), and perforation (0.1%–1.1%), ERCP as an initial modality should be reserved for patients who have a high pretest probability for choledocholithiasis and particularly for those with complications such as acute cholangitis or severe pancreatitis.

Research has evaluated the use of ultrasound-guided ERCP with the goal of avoiding unnecessary bile duct cannulation, and reserving its use for therapeutic purposes only. A systematic review from 2009 showed that compared with ERCP alone, the use of EUS avoided unnecessary ERCP in 67.1% of patients in whom no common bile duct stone was identified. As more gastroenterologists become trained in this modality, EUS-guided ERCP might prove to be the preferred diagnostic modality in intermediate-risk patients for the diagnosis and initial therapy of choledocholithiasis.

Treatment

Patients with choledocholithiasis should be treated to avoid recurrent symptoms and development of complications. Stones can be extracted from the common bile duct via ERCP or laparoscopic cholecystectomy with bile duct exploration. Studies have shown

BOX 1

Proposed Strategy to Assign Risk of Choledocholithiasis in Patients with Symptomatic Cholelithiasis, Based on Clinical Predictors

Predictors of Choledocholithiasis

Very Strong

Common bile duct stone on transabdominal ultrasound
Clinical ascending cholangitis
Total bilirubin > 4 mg/dL

Strong

Dilated common bile duct on transabdominal ultrasound (>6 mm with gallbladder in situ)
Total bilirubin 1.8–4 mg/dL

Moderate

Abnormal liver biochemistry test other than bilirubin
Age older than 55 years
Clinical gallstone pancreatitis

Likelihood of Choledocholithiasis Based on Clinical Predictors

Presence of any very strong predictor: High
Presence of both strong predictors: High
No predictors present: Low
All other patients: Intermediate

From ASGE Standards of Practice Committee, Maple JT, Ben-Menachem T, Anderson MA, et al: The role of endoscopy in the evaluation of suspected choledocholithiasis. *Gastrointest Endosc* 2010;71:1–9, with permission.

similar efficacies without significant differences in morbidity or mortality; however, clinical expertise varies widely with the laparoscopic approach. Ultimately, cholecystectomy should be performed to prevent recurrence in surgical candidates. In patients undergoing laparoscopic cholecystectomy for suspected choledocholithiasis, perioperative management differs based on the risk stratification of the patient (see [Box 1](#)). High-risk patients should proceed directly to ERCP before surgery for attempted stone extraction. In intermediate-risk patients, a preoperative MRCP or EUS should be performed, and, if the results are positive, the patient should undergo ERCP as a prelude to surgery. For suspected choledocholithiasis in low-risk patients, surgery should be performed without further imaging of the common bile duct.

Complications

The two most common adverse complications of choledocholithiasis are gallstone pancreatitis and acute cholangitis. Gallstone pancreatitis develops in 3% to 7% of patients with gallstones and is the most common cause of acute pancreatitis in the United States. The diagnosis and management of acute pancreatitis is discussed in a separate chapter.

Acute cholangitis is caused by obstruction and stasis of the biliary tract with complicating bacterial infection. The syndrome is characterized by fever, jaundice, and abdominal pain, also known as Charcot's triad. Patients who develop hypotension and changes in mental status (Reynold's pentad) have a poorer prognosis. Elderly patients often do not demonstrate the classic signs of acute cholangitis, but they can develop a delayed-sepsis-like syndrome, of which hypotension is the most pronounced feature. High biliary pressures promote the translocation of bacteria from the portal circulation into the biliary tree. The most common bacterial organism seen in acute cholangitis is *Escherichia coli* (25%–50%), followed by *Klebsiella*, *Enterobacter*, and *Enterococcus* species.

Treatment for acute cholangitis should focus on antimicrobial therapy and biliary drainage. Empiric antibiotic regimens should provide adequate activity against gram-negative and anaerobic organisms. Common regimens include monotherapy with ampicillin and sulbactam (Unasyn) or piperacillin and tazobactam (Zosyn) or combination therapy with a fluoroquinolone plus metronidazole (Flagyl).

Patients without hypotension or mental status changes commonly show initial improvement after empiric antibiotics are administered, and thus biliary drainage can be done nonurgently. In patients demonstrating signs of sepsis or severe infection, emergency biliary drainage via ERCP is warranted. Patients who are not candidates for ERCP may undergo percutaneous transhepatic biliary drainage as an alternative.

Acute Cholecystitis

Acute cholecystitis is a syndrome defined by right upper quadrant pain, fever, and leukocytosis in the setting of gallbladder inflammation. Nausea and vomiting often occur as concurrent symptoms. Patients commonly have a positive Murphy's sign on physical examination, which is defined as abrupt cessation of inspiration on deep palpation of the gallbladder fossa, just beneath the liver edge. Approximately 95% of patients with acute cholecystitis have gallstones. In these instances, cholecystitis is thought to be precipitated by obstruction of the cystic duct and by local irritation of the gallbladder wall. Local inflammation is followed by release of pro-inflammatory prostaglandins. Superimposed bacterial infection might or might not complicate acute cholecystitis. As with cholangitis, the main bacteria responsible for infections during acute cholecystitis are *E. coli* and *Klebsiella*, *Enterobacter*, and *Enterococcus* species.

Diagnosis

The diagnosis of acute cholecystitis can often be made on physical examination alone. The most common laboratory finding in acute cholecystitis is leukocytosis. Mild elevations in AST and ALT can also be seen. Elevations of bilirubin and ALP are typical of biliary obstruction and are not commonly seen in acute cholecystitis.

These abnormalities, if present, should raise suspicion for other conditions such as choledocholithiasis, cholangitis, or Mirizzi's syndrome. Mirizzi's syndrome is a rare cause of obstructive jaundice characterized by an impacted cystic duct stone that causes mass effect and compression of the common bile duct or common hepatic duct.

The initial imaging study of choice for acute cholecystitis is trans-abdominal ultrasound. Findings suggestive of cholecystitis include cholelithiasis, pericholecystic fluid ([Figure 2](#)), and a sonographic Murphy's sign ([Figure 3](#)). Thickening of the gallbladder wall supports a diagnosis of acute cholecystitis, but it is a nonspecific

Figure 2 Computed tomography (CT) scan demonstrating acute cholecystitis. The outline arrow indicates gallstones within the gallbladder lumen. The two solid arrows highlight mural thickening of the gallbladder wall and small amounts of pericholecystic fluid. (Image courtesy of Richard M. Gore, MD, Department of Radiology, NorthShore University Health System, Evanston, IL.)

Figure 3 Acute cholecystitis: ultrasound. Gallbladder (g) is distended, with mural thickening (arrowhead) and a stone in the gallbladder neck (arrow). Positive sonographic Murphy sign was present.

Figure 4 Hepatobiliary iminodiacetic acid (HIDA) scan demonstrating acute cholecystitis. There is nonfilling of the gallbladder (outline arrow), with isotope noted in the stomach and duodenum (solid arrows). (Image courtesy of Richard M. Gore, MD, Department of Radiology, NorthShore University Health System, Evanston, IL.)

finding. Transabdominal ultrasound has a sensitivity of 88% for diagnosing acute cholecystitis. Hepatobiliary cholescintigraphy (HIDA scan) (Figure 4) is recommended if the suspicion of cholecystitis remains after a negative transabdominal ultrasound. MRCP and CT scan are typically not necessary for the diagnosis, although CT scan can be useful if complications from cholecystitis such as perforation are suspected.

Treatment

The treatment for acute cholecystitis involves supportive care, analgesia, antibiotics, and either surgery or percutaneous gallbladder drainage. If treatment is delayed or inadequate, numerous potential complications can result. These include emphysematous or gangrenous cholecystitis and gallbladder perforation. All patients with acute cholecystitis should be admitted to the hospital and given supportive care including intravenous fluids. NSAIDs and opioid analgesics are typically used for pain control.

Although bacterial etiologies complicate less than half of all episodes, empiric antibiotics are commonly administered to patients with acute cholecystitis. Appropriate antibiotic regimens are the same as those used in the setting of acute cholangitis (see the discussion of complications of choledocholithiasis).

In patients who are adequate surgical candidates, cholecystectomy should be performed within 72 hours of initial presentation. Numerous prospective trials and a Cochrane Database review have evaluated early versus delayed (6–12 weeks) cholecystectomy. There is overwhelming consensus that early surgery carries no increase in complications or perioperative morbidity and is associated with shorter hospital stays. Furthermore, early laparoscopic cholecystectomy eliminates the risk of recurrent episodes of acute cholecystitis.

Acute Acalculous Cholecystitis

An estimated 5% to 10% of cases of acute cholecystitis develop without the presence of gallstones. Acute acalculous cholecystitis is often seen in the setting of serious medical illness, complicated surgery, severe blunt trauma, and burn injuries. Other conditions such as diabetes mellitus, vasculitis, AIDS, and congestive heart failure have also been implicated as risk factors. Acute acalculous

cholecystitis carries major risks of gangrene (50%) and perforation (10%), and mortality ranges from 30% to 50%. Numerous organisms have been associated with acute acalculous cholecystitis, including bacterial, viral, fungal, and parasitic infections.

The diagnosis is difficult. Patients are often critically ill and unable to elicit their symptoms. Transabdominal ultrasound is the best modality to evaluate acute acalculous cholecystitis in the critically ill patient owing to its availability, cost, and ease of performance. Hepatobiliary iminodiacetic acid (HIDA) and computed tomography (CT) scanning can have a role in difficult-to-diagnose acute acalculous cholecystitis and should be considered if ultrasound is nondiagnostic. Whereas false-positive test results can occur, a normal HIDA scan has a high negative predictive value in evaluating acute acalculous cholecystitis.

Because of the high rate of gangrene and perforation, early cholecystectomy should be performed in patients who are surgical candidates. In patients too ill to undergo surgery, biliary drainage with percutaneous cholecystostomy should be considered.

Gangrenous Cholecystitis, Emphysematous Cholecystitis, and Gallbladder Perforation

Gangrenous cholecystitis is most often seen in elderly patients and diabetics along with patients who delay seeking medical treatment for their symptoms. It is the most common complication of acute cholecystitis and carries a high mortality. Emphysematous cholecystitis is caused by gas-forming bacteria that infect the gallbladder. *E. coli* and *Clostridium* species are most commonly implicated. Gas in the gallbladder may be seen on imaging, particularly CT or magnetic resonance imaging (MRI). Patients with gangrenous or emphysematous cholecystitis are at an elevated risk for gallbladder perforation. Early empiric antibiotics and cholecystectomy are crucial in the management of these complications to minimize mortality and prevent perforation of the gallbladder, a condition that carries a mortality rate of 42% to 60%.

Gallbladder Disease in Pregnancy

Pregnancy is a major risk factor for cholesterol gallstone formation. Because of anatomic changes secondary to the gravid uterus, biliary colic can be difficult to delineate from other causes of abdominal pain. Pregnant patients often have gallstones on transabdominal ultrasound, and thus a detailed history and physical examination are needed to diagnose a patient's abdominal pain as biliary. Patients with other symptoms including bloating or dyspepsia should be evaluated for other etiologies.

In pregnant patients with recurrent symptomatic cholelithiasis, laparoscopic cholecystectomy remains the treatment of choice. The second and early third trimesters are the best times to perform cholecystectomy owing to ease and lower rates of complications. Nonsurgical management of gallstones is limited in pregnancy. NSAIDs are generally avoided late in pregnancy owing to the risk of premature closure of the ductus arteriosus, especially after 30 to 32 weeks of gestation.

After appendicitis, acute cholecystitis is the second most common nonobstetric surgical emergency during pregnancy. As with nonpregnant patients, pregnant women with acute cholecystitis should be treated with cholecystectomy in addition to medical management. Early surgery for pregnant patients with acute cholecystitis has been found to decrease relapse rates and hospital readmissions. No differences in maternal or fetal morbidity and mortality have been found in patients treated conservatively versus surgically for acute cholecystitis during pregnancy.

CHRONIC DIARRHEA

Method of

André de Leon, MD

CURRENT DIAGNOSIS

History

- Duration and frequency
- Presence of fever/blood
- Food/medication intake
- Travel history

Physical Examination

- Gastrointestinal examination
- Hydration status
- Digital rectal examination
- Other systems: endocrine, ophthalmologic, skin

Testing

- Fecal occult blood testing
- Stool for ova/parasites, *Clostridium difficile* and other bacteria
- Stool antigen for cryptosporidium, giardia
- Fecal electrolytes (Na, K, Osm)
- Fecal leukocytes
- Erythrocyte sedimentation rate (ESR)
- Complete blood count (CBC)
- Other: iron panel (celiac sprue), TSH (hyperthyroidism), liver function tests (LFTs)
- Colonoscopy with biopsy

CURRENT THERAPY

- Supportive care and rehydration, if necessary
- Trial of discontinuation of possible offending medication/food (lactose, gluten, sorbitol)
- Dietary modification with increased fiber intake (dietary or supplementation)
- Specific therapy as directed by culture and susceptibilities or biopsy
- Empiric therapy trial with antibiotics
- Empiric trial of probiotics¹ (limited evidence of efficacy in healthy adults with chronic diarrhea)

¹Not FDA approved for this indication.

Chronic diarrhea has traditionally been defined based on consistency, volume, and frequency of stools. However, recent studies have found that there is considerable variability in definition when

using these markers. Therefore the American Gastroenterological Association has released a consensus statement suggesting that chronic diarrhea should be defined as a decrease in fecal consistency lasting for 4 or more weeks.

Epidemiology

Chronic diarrhea is a common cause of death in developing countries, as well as the second leading cause of overall mortality in children 1 to 59 months old. The prevalence in the general population in developed nations and economic impact of chronic diarrhea has not been well established. This could be related to the variable nature of the studies that have been performed with regard to definition, population characteristics, and overall study design. Rough estimates based on this limited information suggest that chronic diarrhea can affect up to 5% of the population and can cost up to \$350,000,000 annually from work loss alone.

Classification Based on Pathophysiology

Elucidating the exact cause of chronic diarrhea can be very challenging, because there are several hundred conditions that can be related. It is often separated into three basic categories, including watery, fatty (malabsorption), and inflammatory (with blood and pus); however, these should not be strictly adhered to because there is often considerable overlap between the categories. Watery diarrhea can be further subdivided into osmotic, secretory, drug-induced, and functional types. Osmotic diarrhea is related to water retention; secretory diarrhea is due to reduced absorption of water; drug-induced is as stated in its name; and functional diarrhea is due to hypermotility of the gut.

Watery Diarrhea

Watery diarrhea can be subdivided into four categories, including osmotic, secretory, drug-induced, and functional types. Fecal osmotic gap can be calculated, which will help guide further workup and diagnosis. An elevated osmotic gap (>125 mOsm/kg) is suggestive of possible osmotic causes, such as lactose intolerance. A normal osmotic gap can be associated with irritable bowel syndrome or may be indicative of a further workup for possible celiac disease. A decreased osmotic gap (<50 mOsm/kg) points toward secretory causes, including infectious (ova, parasite, bacteria, giardia), endocrine (hyperthyroidism), autoimmune (Addison's), neoplastic (pheochromocytoma), and anatomic defect.

Fatty/Malabsorptive Diarrhea

Malabsorptive diarrhea is, as the name implies, secondary to impaired absorption along the gut. This can be due to structural abnormalities (gastric bypass, short bowel syndrome, celiac sprue, pancreatic insufficiency) or structural abnormalities related to vascular compromise (mesenteric ischemia). Impaired absorption can also occur secondary to infections such as *Tropheryma whipplei* (Whipple's disease), *Giardia*, small bowel bacterial overgrowth, and tropical sprue. Medications such as aminoglycoside antibiotics, orlistat (Alli, Xenical), thyroid supplementation, acarbose (Precose), and ticlopidine (Ticlid) can also cause malabsorptive diarrhea.

Inflammatory Diarrhea

Inflammation leading to diarrhea is often due to autoimmune, infectious, or neoplastic processes or radiation exposure. Autoimmune processes are felt to play a large role in inflammatory bowel disease (IBD), which often manifests as Crohn's disease or ulcerative colitis. Infections such as *Clostridium difficile*, *Mycobacterium tuberculosis*, *Yersinia*, cytomegalovirus, herpes simplex virus, amebiasis, and *Strongyloides* can lead to a diarrhea with associated inflammation of the bowel. Colon cancer (villous adenocarcinoma) and lymphoma can also cause inflammatory diarrhea.

Clinical Manifestations

History. Thorough investigation of a patient complaining of ongoing diarrhea-like features should always include a detailed medical history. A clear understanding of the patient's symptoms

- Food/medication intake
- Travel history

Physical Examination

- Gastrointestinal examination
- Hydration status
- Digital rectal examination
- Other systems: endocrine, ophthalmologic, skin

Testing

- Fecal occult blood testing
- Stool for ova/parasites, *Clostridium difficile* and other bacteria
- Stool antigen for cryptosporidium, giardia
- Fecal electrolytes (Na, K, Osm)
- Fecal leukocytes
- Erythrocyte sedimentation rate (ESR)
- Complete blood count (CBC)
- Other: iron panel (celiac sprue), TSH (hyperthyroidism), liver function tests (LFTs)
- Colonoscopy with biopsy

CURRENT THERAPY

- Supportive care and rehydration, if necessary
- Trial of discontinuation of possible offending medication/food (lactose, gluten, sorbitol)
- Dietary modification with increased fiber intake (dietary or supplementation)
- Specific therapy as directed by culture and susceptibilities or biopsy
- Empiric therapy trial with antibiotics
- Empiric trial of probiotics¹ (limited evidence of efficacy in healthy adults with chronic diarrhea)

¹Not FDA approved for this indication.

Chronic diarrhea has traditionally been defined based on consistency, volume, and frequency of stools. However, recent studies have found that there is considerable variability in definition when

using these markers. Therefore the American Gastroenterological Association has released a consensus statement suggesting that chronic diarrhea should be defined as a decrease in fecal consistency lasting for 4 or more weeks.

Epidemiology

Chronic diarrhea is a common cause of death in developing countries, as well as the second leading cause of overall mortality in children 1 to 59 months old. The prevalence in the general population in developed nations and economic impact of chronic diarrhea has not been well established. This could be related to the variable nature of the studies that have been performed with regard to definition, population characteristics, and overall study design. Rough estimates based on this limited information suggest that chronic diarrhea can affect up to 5% of the population and can cost up to \$350,000,000 annually from work loss alone.

Classification Based on Pathophysiology

Elucidating the exact cause of chronic diarrhea can be very challenging, because there are several hundred conditions that can be related. It is often separated into three basic categories, including watery, fatty (malabsorption), and inflammatory (with blood and pus); however, these should not be strictly adhered to because there is often considerable overlap between the categories. Watery diarrhea can be further subdivided into osmotic, secretory, drug-induced, and functional types. Osmotic diarrhea is related to water retention; secretory diarrhea is due to reduced absorption of water; drug-induced is as stated in its name; and functional diarrhea is due to hypermotility of the gut.

Watery Diarrhea

Watery diarrhea can be subdivided into four categories, including osmotic, secretory, drug-induced, and functional types. Fecal osmotic gap can be calculated, which will help guide further workup and diagnosis. An elevated osmotic gap (>125 mOsm/kg) is suggestive of possible osmotic causes, such as lactose intolerance. A normal osmotic gap can be associated with irritable bowel syndrome or may be indicative of a further workup for possible celiac disease. A decreased osmotic gap (<50 mOsm/kg) points toward secretory causes, including infectious (ova, parasite, bacteria, giardia), endocrine (hyperthyroidism), autoimmune (Addison's), neoplastic (pheochromocytoma), and anatomic defect.

Fatty/Malabsorptive Diarrhea

Malabsorptive diarrhea is, as the name implies, secondary to impaired absorption along the gut. This can be due to structural abnormalities (gastric bypass, short bowel syndrome, celiac sprue, pancreatic insufficiency) or structural abnormalities related to vascular compromise (mesenteric ischemia). Impaired absorption can also occur secondary to infections such as *Tropheryma whipplei* (Whipple's disease), *Giardia*, small bowel bacterial overgrowth, and tropical sprue. Medications such as aminoglycoside antibiotics, orlistat (Alli, Xenical), thyroid supplementation, acarbose (Precose), and ticlopidine (Ticlid) can also cause malabsorptive diarrhea.

Inflammatory Diarrhea

Inflammation leading to diarrhea is often due to autoimmune, infectious, or neoplastic processes or radiation exposure. Autoimmune processes are felt to play a large role in inflammatory bowel disease (IBD), which often manifests as Crohn's disease or ulcerative colitis. Infections such as *Clostridium difficile*, *Mycobacterium tuberculosis*, *Yersinia*, cytomegalovirus, herpes simplex virus, amebiasis, and *Strongyloides* can lead to a diarrhea with associated inflammation of the bowel. Colon cancer (villous adenocarcinoma) and lymphoma can also cause inflammatory diarrhea.

Clinical Manifestations

History. Thorough investigation of a patient complaining of ongoing diarrhea-like features should always include a detailed medical history. A clear understanding of the patient's symptoms

TABLE 1 Medications Commonly Associated with Diarrhea*Antiarrhythmic medications*

- Digoxin
- Quinidine

Antibiotic medications

- Aminoglycosides
- Macrolides

Antihypertensive medications

- ACE inhibitors
- Beta blockers

Antiinflammatory medications

- 5-aminosalicylates
- Nonsteroidal antiinflammatory drugs (NSAIDs)

Antiretroviral medications (many)*Chemotherapeutic medications* (many)*Dermatologic medications*

- Isotretinoin (occasionally causes diarrhea)

Endocrine medications

- Alpha-glucosidase inhibitors (cause diarrhea in $\geq 20\%$ of patients)
- Biguanides (cause diarrhea in $\geq 20\%$ of patients)
- Thyroid hormones

Gastrointestinal medications

- Acid-reducing medications
 - H_2 -receptor blocker
 - Proton pump inhibitors
- Antacid medications (magnesium containing)

Parasympathetic nervous system medication

- Cholinergic agonists

Psychiatric medications

- Selective serotonin reuptake inhibitors

Respiratory medications

- Xanthine derivative (Theophylline)

Data from Schiller LR, Sellin JH. Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management. 9th Edition, Philadelphia, 2010, Elsevier; and Soriano M, Vaziri H. Clinical Gastroenterology, Diarrhea: Diagnostic and Therapeutic Advances, New York, 2010, Humana Press, Springer.

is vital: not all complaints may truly be defined as diarrhea but may rather be symptoms related to an interplay between fecal incontinence and stool impaction. A detailed history of travel, food intake, and medication use is essential. This can help direct the early workup and diagnostic testing. Stool frequency, volume, and consistency can aid in categorization; however, they are no longer what define the condition, as noted above.

Physical Examination. The physical examination is very important to the workup and diagnosis of chronic diarrhea. Ophthalmologic findings such as episcleritis or exophthalmia can be related to IBD; skin findings such as dermatitis herpetiformis can be related to celiac sprue (seen in 15%–25% of patients with celiac disease). Prominent lymphadenopathy and weight loss can be suggestive of possible infection or malignancy. A thorough abdominal examination should include the evaluation of bowel sounds (hypermotility), skin for scars (surgical cause of diarrhea), tenderness (infection/inflammation), and masses (neoplasia) and should be followed by a digital rectal examination with fecal occult blood testing. Anoscopy can also be used to detect for ulcerations or fecal impaction, given that seepage around impacted stools can create a picture similar to diarrhea.

Testing for Diagnosis

Serum testing for chronic diarrhea should include a complete blood count (CBC), serum electrolytes, liver function tests, serum albumin, thyroid-stimulating hormone, and erythrocyte sedimentation

rate. An iron panel should be performed if indicated based on the results of the CBC. Serum anti-tissue transglutaminase antibody testing may be helpful if symptoms are suggestive of celiac sprue. Stool evaluation may include fecal occult blood testing, fecal leukocytes, stool ova and parasites, stool culture (including *Salmonella*, *Shigella*, and *Campylobacter*), and stool antigen for *Giardia*. Stool testing for *Cryptosporidium* should be considered, especially in the immunocompromised. Stool pH and electrolytes may be helpful, especially when the patient is lactose intolerant. Stool testing for *C. difficile* should be performed if the patient has recently used antibiotics or been hospitalized. If medication abuse is suspected as a possible cause, a stool laxative screen (i.e., stool phenolphthalein test) may be warranted. Diagnostic testing may include a colonoscopy with biopsy.

Treatment

The exact cause of chronic diarrhea can prove elusive, and treatment trials may be warranted. Specific treatment depends on the specific diagnosis. If there is concern about possible bacterial or protozoa infection, an empiric trial of vancomycin (Vancocin), ciprofloxacin (Cipro), or metronidazole (Flagyl) may be warranted. If there is concern for possible medication (Table 1) or food relation to diarrhea, a trial of discontinuation of offending substance/food may be reasonable. The effectiveness of probiotics¹ looks favorable; however, large intervention studies and epidemiologic investigations of long-term probiotic effects on healthy adults are largely missing. At this time, probiotics have been found efficacious in treatment of acute diarrhea, prevention of antibiotic-associated diarrhea, and prevention of traveler's diarrhea. Dietary modification continues to be an important starting point for treatment, with increased intake in bulk-forming agents such as fiber. Treatment of specific disorders such as Crohn's disease and ulcerative colitis are discussed in other chapters.

CIRRHOSIS

Method of

Andres F. Carrion, MD; and Paul Martin, MD

The term *cirrhosis* is a neologism derived from the Greek *kirrḥós*, which describes the yellowish discoloration of the liver during advanced stages of chronic liver disease, and the suffix *-osis*, which denotes a specific condition in medical terminology. Morphologically, cirrhosis reflects the consequences of chronic hepatic necroinflammatory activity with an incomplete and disorganized repair process that results in regenerative nodules and extensive fibrosis replacing normal hepatic parenchyma with disturbance of normal hepatic physiology. Cirrhosis can result from any etiology of chronic liver disease (Table 1). Activation of hepatic stellate cells

CIRRHOSIS

Method of

Andres F. Carrion, MD; and Paul Martin, MD

The term *cirrhosis* is a neologism derived from the Greek *kirrōs*, which describes the yellowish discoloration of the liver during advanced stages of chronic liver disease, and the suffix *-osis*, which denotes a specific condition in medical terminology. Morphologically, cirrhosis reflects the consequences of chronic hepatic necroinflammatory activity with an incomplete and disorganized repair process that results in regenerative nodules and extensive fibrosis replacing normal hepatic parenchyma with disturbance of normal hepatic physiology. Cirrhosis can result from any etiology of chronic liver disease (Table 1). Activation of hepatic stellate cells

TABLE 1 Etiologies of Cirrhosis

ETIOLOGY	EXAMPLES
Infectious	Hepatitis B Hepatitis C Hepatitis D
Autoimmune and cholestasis	Autoimmune hepatitis Biliary atresia Primary biliary cholangitis Primary sclerosing cholangitis Secondary biliary cirrhosis Secondary sclerosing cholangitis
Toxins	Alcohol Arsenic Drugs
Metabolic	Nonalcoholic steatohepatitis Alpha-1 antitrypsin deficiency Hemochromatosis Wilson disease Glycogen storage diseases Lysosomal storage diseases Galactosemia
Vascular	Cardiac cirrhosis Budd-Chiari syndrome Sinusoidal obstruction syndrome
Granulomatous	Sarcoidosis Tuberculosis Syphilis
Cryptogenic	Unrecognized nonalcoholic fatty liver disease, infections, or drugs

into myofibroblasts and matrix deposition are key steps in the pathogenesis of cirrhosis.

Epidemiology

The prevalence of cirrhosis varies significantly in different regions of the world and is directly influenced by the epidemiology of individual chronic liver diseases that lead to progressive hepatic fibrosis. The estimated global prevalence of cirrhosis is 4.5% to 9.5%; however, this estimate likely underestimates the real magnitude of disease burden, as a sizeable proportion of asymptomatic individuals remain undiagnosed. Similarly, it is difficult to obtain accurate estimates of mortality related to cirrhosis, but countries in Central and South America and Southern Europe exhibit the highest mortality rates, particularly in males. Epidemiologic trends of cirrhosis have changed considerably over time in many countries, underscoring variations in the incidence and prevalence of specific etiologies of chronic liver disease. For instance, widespread immunization against hepatitis B virus (HBV) has markedly reduced its incidence, prevalence, and associated liver disease including cirrhosis. Alcohol consumption has varied strikingly across different regions of the globe over the past several decades. A steady decline in mortality due to cirrhosis has occurred in some European countries (mainly Mediterranean) as alcohol use has diminished. A similar trend has also been noted in North America; however, hospitalizations for alcoholic hepatitis have increased over the recent past in the United States. In contrast, a significant increase in mortality related to cirrhosis has been noted in some Eastern European countries with increased alcohol consumption. In addition, eradication of hepatitis C virus (HCV) is associated with a reduction in hepatic dysfunction, liver-related and all-cause mortality, complications of cirrhosis such as hepatocellular carcinoma (HCC), and portal hypertension. The impact of highly effective direct-acting antiviral agents against HCV on the epidemiology of cirrhosis and its complications has just started to become evident, as these regimens have only been widely used in clinical practice for the past few years, although a decline in liver transplant

listings for HCV has already been reported. In contrast, the growing prevalence of nonalcoholic fatty liver disease (NAFLD) is reflected in its current prominence as a cause of cirrhosis. NAFLD is anticipated to become the single most frequent cause of chronic liver disease and cirrhosis in the mid- to second half of this century.

Clinical findings

In the absence of hepatic decompensation, the overwhelming majority of individuals with cirrhosis are asymptomatic and may only exhibit subtle clinical findings. Clues to the presence of cirrhosis can include elevated serum aminotransferases and/or bilirubin, decreased albumin, and prolongation of the prothrombin time. Approximately 10% to 17% of individuals with unexplained elevation of aminotransferases have unrecognized cirrhosis. Thrombocytopenia in the absence of a primary hematologic explanation is another clue to the presence of cirrhosis and primarily reflects hypersplenism due to portal hypertension but also diminished production of thrombopoietin, a platelet growth and development factor synthesized by the liver. A platelet count below $160 \times 10^9/\mu\text{L}$ provides the highest diagnostic accuracy for cirrhosis among routine blood tests (sensitivity 74%, specificity 88%, positive likelihood ratio 6.3, negative likelihood ratio 0.29). Thrombocytopenia is also a component of noninvasive scoring systems that predict fibrosis, such as the AST (aspartate aminotransferase) to Platelet Ratio Index (APRI) and Fibrosis-4 (FIB-4).

Physical examination may reveal somewhat diminished liver span by percussion and a firm liver edge on palpation. Splenomegaly is suggested by dullness to percussion in the left upper abdominal quadrant or a palpable spleen tip. Cutaneous signs of cirrhosis include palmar erythema, spider nevi, facial telangiectasia, decreased chest and/or axillary hair, inversion of the normal male pubic hair pattern, Terry nails ("ground glass" appearance of nails with absent lunula), and Muehrcke nails (paired, white, transverse bands separated by normal color). Nail clubbing may also be present in individuals with cirrhosis, particularly in those with hepatopulmonary syndrome. Dupuytren contracture is relatively common in alcoholic cirrhosis but its pathogenesis is not well understood. Palmar erythema due to altered sex hormone metabolism is more evident on the thenar and hypothenar eminences and typically spares the central portion of the palm. Hypogonadism in both sexes and gynecomastia and testicular atrophy in males can be detected, reflecting altered sex hormone metabolism (increased production of androstenedione, enhanced aromatization to estrone, and increased conversion to estradiol). The catabolic effects of advanced cirrhosis often result in marked sarcopenia, which adversely affects quality of life and survival and is also associated with poorer outcomes after liver transplantation.

Natural history of cirrhosis and prognostic models

Cirrhosis may be broadly categorized into two distinct clinical phases, regardless of the etiology: compensated and decompensated. Compensated cirrhosis implies the absence of index complications such as jaundice, ascites, hepatic encephalopathy, or gastroesophageal variceal hemorrhage. In contrast, hepatic decompensation indicates an advanced phase of the disease, which is rapidly progressive and characterized by development of one or more complications and diminished hepatocellular function with prolongation of the prothrombin time and hypoalbuminemia. Characterizing cirrhosis as compensated or decompensated is simple and reproducible, and offers useful prognostic information for clinical practice (Table 2).

More precise prognostic models such as the Child Turcotte Pugh (Table 3) and the Model for End-Stage Liver Disease (MELD) are also widely used, the latter being considered the most accurate predictor of short-term mortality for individuals with cirrhosis and serving as the basis for the current organ allocation system in liver transplantation in the United States and elsewhere (calculator available at www.optn.transplant.hrsa.gov).

The specific etiology of cirrhosis may help determine its prognosis. For instance, persistent viremia in individuals with chronic HBV or HCV infection is implicated in the development of

TABLE 2 Stages of Cirrhosis Based on Clinical Complications and 1-Year Outcome Probabilities

CIRRHOSIS	D'AMICO STAGE	COMPLICATIONS	PROBABILITY OF ADVANCING TO NEXT STAGE	1-YEAR MORTALITY
Compensated	Stage 1	(-) varices (-) ascites	7%	1%
	Stage 2	(+) varices (-) ascites	6.6%	3.4%
Decompensated	Stage 3	(+) ascites (+) varices	7.6%	20%
	Stage 4	(+) variceal hemorrhage (+) ascites	—	57%

From D'Amico G, Garcia-Tsao G, Pagliaro L. Natural history and prognostic indicators of survival in cirrhosis: A systematic review of 118 studies. *J Hepatol* 2006;44:217–31.

TABLE 3 Child-Turcotte-Pugh Classification

CLINICAL AND LABORATORY CRITERIA	POINTS		
	1	2	3
Albumin (g/dL)	> 3.5	2.8–3.5	< 2.8
Ascites	None	Mild to moderate (diuretic responsive)	Severe (diuretic refractory)
Bilirubin (mg/dL)	< 2	2–3	> 3
Encephalopathy	None	Mild to moderate (grade 1 or 2)	Severe (grade 3 or 4)
Prothrombin time	< 4	4–6	> 6
Prolongation in seconds International normalized ratio	< 1.7	1.7–2.3	> 2.3

decompensated cirrhosis. Effective antiviral therapy can abort progression of chronic viral hepatitis to cirrhosis and decompensation.

Although cirrhosis per se is not an indication for liver transplantation, it is important to identify individuals with cirrhosis who should be considered for liver transplantation. Development of an index complication of cirrhosis such as gastroesophageal variceal hemorrhage, ascites, or hepatic encephalopathy is an indication to refer a patient for liver transplantation and initiate pretransplant evaluation. The MELD score provides objective and reproducible prognostication of short-term survival without liver transplantation (Figure 1), and data from a seminal study

Figure 1 Relationship between Model for End-Stage Liver Disease (MELD) score and survival at 3 months. (From *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*, 10th ed., Chapter 97, page 1634. Elsevier; 2016.)

showed that liver transplantation is associated with improved survival in individuals with MELD scores greater than 17.

Major complications of cirrhosis

Portal Hypertension

Although portal hypertension can be inferred by clues such as splenomegaly with thrombocytopenia in a patient with cirrhosis, it is defined by a hepatic venous pressure gradient (HVPG) greater than 5 mm Hg. This gradient is calculated by subtracting the measured free hepatic vein pressure from the wedged hepatic venous pressure (a measurement that reflects portal venous pressure by using the same hemodynamic principle as the wedged pulmonary capillary pressure to assess left atrial pressure). Clinically significant portal hypertension typically occurs when the HVPG is 10 mm Hg or greater, at which threshold gastroesophageal varices and ascites occur. Unfortunately, accurate noninvasive measurement of portal pressure is not available, limiting its use in routine clinical practice as it requires passage of a transjugular catheter.

Increased intrahepatic resistance to portal venous flow aggravated by increased splanchnic blood flow in cirrhosis leads to portal hypertension. In addition to cirrhosis, which is the most common cause of portal hypertension in Western countries (hepatic schistosomiasis is the leading cause in areas where this infection is common), other disorders may result in pre- or posthepatic portal hypertension. Portal vein thrombosis is a common cause of prehepatic portal hypertension. Cardiomyopathy, constrictive pericarditis, Budd-Chiari syndrome, and inferior vena cava webs may result in posthepatic portal hypertension. Ascites and gastroesophageal variceal hemorrhage are the two most common complications of portal hypertension in cirrhosis. Less common but clinically significant complications include portal hypertensive gastropathy, hepatic hydrothorax, hepatopulmonary syndrome, portopulmonary hypertension, and hepatorenal syndrome.

Gastroesophageal Variceal Hemorrhage

Portal hypertension leads to formation of multiple portosystemic collaterals, including gastroesophageal varices. Formation of gastroesophageal varices typically occurs when the HVPG is 10 mm Hg or greater, with the risk for variceal hemorrhage increasing once HVPG is greater than 12 mm Hg. Gastroesophageal varices are present in approximately 50% of patients with cirrhosis and are more common in patients with hepatic decompensation (Child-Turcotte-Pugh class C). Variceal hemorrhage is the most dramatic complication of cirrhosis and occurs at a rate of 5% to 15% per year. Risk factors for variceal hemorrhage include larger variceal size, more advanced hepatic decompensation, and presence of vascular “red wale” signs during endoscopic evaluation. Esophageal varices are classified according to their size as small (≤ 5 mm) or large (> 5 mm).

Screening for gastroesophageal varices with esophagogastroduodenoscopy (EGD) is recommended when cirrhosis is suspected. Management strategies for patients with esophageal varices that have not previously bled (primary prophylaxis) are summarized in Table 4.

TABLE 4 Recommendations for Primary Prophylaxis Against Esophageal Variceal Hemorrhage

SIZE OF VARICES	RISK OF HEMORRHAGE	SURVEILLANCE INTERVAL	PRIMARY PROPHYLAXIS
No varices	CTP class A	EGD every 2 years if ongoing liver injury (i.e., obesity or alcohol abuse), or every 3 years if liver injury is quiescent (i.e., viral eradication or alcohol abstinence)	None
	CTP class B/C	EGD yearly	None
Small esophageal varices	CTP class A	EGD yearly if ongoing liver injury (i.e., obesity or alcohol abuse), or every 2 years if liver injury is quiescent (i.e., viral eradication or alcohol abstinence)	BB may be used
	CTP class B/C	EGD yearly; if BB are used, repeat EGD unnecessary	BB recommended
Large esophageal varices	CTP class A/B/C	If BB are used, repeat EGD unnecessary; if no BB, repeat EGD for EVL every 2-8 weeks until variceal eradication, then once in 3-6 months, and regularly every 6-12 months	Either BB or EVL recommended

Abbreviations: BB = beta-blocker; CTP = Child-Turcotte-Pugh; EGD = esophagogastroduodenoscopy; EVL = endoscopic variceal ligation. Child-Turcotte-Pugh class obtained by adding points for each variable

Class A: 5-6 points (compensated cirrhosis)

Class B: 7-9 points (decompensated cirrhosis)

Class C: 10-15 points (decompensated cirrhosis)

Management of esophageal varices that have previously bled (secondary prophylaxis) includes a combination of a nonselective beta-blocker with endoscopic variceal ligation (EVL). The dose of the nonselective beta-blocker should be titrated to the maximal tolerated dose (resting heart rate of 55 to 60 beats/minute or 25% decrease from baseline) and EVL should be repeated frequently (every 2 weeks or so) until complete variceal obliteration. Recurrence of esophageal varices may occur following EVL; thus, surveillance EGD is recommended: first EGD performed 3 to 6 months after variceal obliteration and then at 6- to 12-month intervals.

Gastric varices are classified according to relationship with esophageal varices and location (Table 5).

Acute variceal hemorrhage occurs at a yearly rate of 5% to 15% and is associated with high mortality (at least 20% at 6 weeks). Adequate resuscitation is crucial in acute variceal hemorrhage with some additional precautions. Patients with variceal hemorrhage are at high risk for aspiration, and endotracheal intubation for airway protection should be performed prior to endoscopy. Overly aggressive expansion of blood volume should be avoided as it may result in increased portal venous pressure. A target hemoglobin level of between 7 and 9 g/dL is appropriate. Current guidelines recommend against correcting the international normalized ratio

(INR) by use of fresh frozen plasma or recombinant factor VIIa, as this has not shown a clear benefit in individuals with acute variceal hemorrhage. There are no data to support or recommend against transfusion of platelets in this clinical scenario. Prophylactic broad-spectrum antibiotics (i.e., intravenous ceftriaxone [Rocephin]¹) reduce bacterial infections, risk of rebleeding, and mortality. Administration of vasoactive drugs such as octreotide (Sandostatin)¹ or terlipressin (Lucassin)⁵ result in increased rates of initial endoscopic control of bleeding, reduced 7-day mortality, and lower transfusion requirements. EGD is recommended within 12 hours and EVL is the endoscopic treatment of choice. Balloon tamponade (i.e., Sengstaken Blakemore, Minnesota, or Linton-Nachlas tubes) or esophageal stenting are effective rescue therapies when variceal hemorrhage cannot be controlled with standard endoscopic therapy. The role of transjugular intrahepatic portosystemic shunt (TIPS) has expanded from a salvage intervention for individuals with recurrent variceal hemorrhage following EVL to an early “preemptive” intervention in carefully selected individuals at high-risk for treatment failure (Child-Turcotte-Pugh class B or C but with MELD scores ≤ 13) following EVL, in which case it appears to be superior to beta-blocker plus EVL.¹⁴ Patients who survive an episode of variceal hemorrhage should receive secondary prophylaxis with a combination of a nonselective beta-blocker and repeated EVL until complete obliteration of the varices is achieved. Cyanoacrylate injection, TIPS, or balloon occluded transvenous obliteration (BOTO) are the treatments of choice for management of gastric variceal hemorrhage.

Ascites

Ascites denotes pathologic accumulation of fluid in the peritoneal cavity (> 25 mL) and is the most common complication of cirrhosis. Portal hypertension is required for development of cirrhotic ascites, as individuals with HVPg less than 12 mm Hg do not develop this complication.¹⁶ Importantly, sinusoidal hypertension appears to be a requirement for development of ascites, as prehepatic portal hypertension does not invariably result in development of this complication. Other relevant mechanisms include splanchnic vasodilatation and its consequences such as humorally mediated sodium retention and diminished free-water excretion by the kidneys, hypoproteinemia and reduced oncotic pressure, and disruption of normal lymphatic drainage in the liver due to extensive fibrosis.

Ascites can be demonstrated by physical examination when its volume is greater than 1500 mL, although ultrasonography can detect as little as 100 mL. Clinical signs include flank dullness on

TABLE 5 Classification of Gastroesophageal and Gastric Varices and Recommendations for Primary Prophylaxis

TYPE OF VARICES	CHARACTERISTICS	PRIMARY PROPHYLAXIS
Gastroesophageal varices type 1 (GOV1)	Extension of esophageal varices along the lesser curvature into the gastric cardia	Similar to esophageal varices
Gastroesophageal varices type 2 (GOV2)	Extension of the esophageal varices along the greater curvature into the gastric fundus	BB can be used, although data not as strong as for esophageal varices
Isolated gastric varices type 1 (IGV1)	Gastric varices localized in the fundus	If high risk, consider BB or cyanoacrylate injection
Isolated gastric varices type 2 (IGV2)	Gastric varices localized in the antrum	No data, consider BB if high risk

Abbreviations: BB = beta-blocker.

⁵Investigational drug in the United States.

TABLE 6 Characteristics of Ascitic Fluid and Differential Diagnosis

FLUID APPEARANCE	DIFFERENTIAL DIAGNOSIS	BIOCHEMICAL HINTS ON FLUID ANALYSIS
Clear	Uncomplicated transudative ascites due to cirrhosis	WBC < 500 cells/ μ L, PMN < 250 cells/ μ L, SAAG \geq 1.1
Turbid/cloudy	Infection	PMN \geq 250 cells/ μ L
Bloody	Traumatic paracentesis, hemoperitoneum	RBC > 10,000 cells/ μ L
Milky	Chylous ascites due to obstruction or trauma of lymphatic vessels or thoracic duct	Triglycerides > 200 md/dL

Abbreviations: PMN = polymorphonuclear cells; SAAG = serum-to-ascites albumin gradient; WBC = white blood cell.

percussion, shifting dullness, and, if the amount of ascites present is large, demonstration of a fluid wave. A diagnostic paracentesis is mandatory in the following settings: new-onset ascites, change in clinical status including hospitalization of a patient with previously diagnosed ascites, and suggestion of spontaneous bacterial peritonitis (SBP). The following tests on the fluid are indicated: leukocyte count with differential (purple or lavender top tube with ethylenediaminetetraacetic acid [EDTA]), culture (on two blood culture bottles inoculated at the bedside), total protein, and albumin (red top tube). The appearance of the ascitic fluid may yield important clinical clues (Table 6). The serum-to-ascites albumin gradient (SAAG), obtained by subtracting the ascitic fluid albumin value from the serum albumin value, helps make a distinction between transudative and exudative ascites. A gradient of 1.1 g/dL or greater confirms portal hypertension as the etiology of ascites, whereas a value less than 1.1 g/dL suggests etiologies other than portal hypertension. The absolute number of polymorphonuclear (PMN) cells in the ascitic fluid is an important clue to SBP.

Cirrhotic ascites is unlikely to resolve without specific therapeutic intervention. Management of ascites is centered on sodium restriction rather than free-water restriction; total dietary intake of sodium should be less than 2000 mg (88 mmol) per day and compliance with this intervention can be documented by monitoring urinary sodium concentrations. A sodium-to-potassium concentration ratio of greater than 1 on a random urine sample correlates well with a 24-hour sodium excretion greater than 78 mmol/day and implies compliance with sodium restriction. Nevertheless, dietary restriction of sodium is efficacious in only 10% of patients, and enhanced natriuresis is typically needed to provide adequate control of ascites. Combining diuretics that work at different sites of the nephron is more effective than using a single agent. Aldosterone is upregulated in cirrhosis owing to diminished effective arterial blood volume and consequential increased renin and angiotensin activity, resulting in enhanced renal sodium and free water retention. Spironolactone (Aldactone) competitively inhibits aldosterone-dependent sodium-potassium exchange in the distal convoluted renal tubule and the collecting ducts. The recommended initial dose of spironolactone for patients with ascites due to portal hypertension is 100 mg orally daily. Administration of a loop-acting diuretic such as furosemide (Lasix)¹ is recommended in addition to spironolactone, as it potentiates natriuresis. The recommended initial dose for furosemide is 40 mg orally daily. Further increases in doses of diuretics should be made maintaining this 100/40 ratio to a maximum dose of 400 mg orally daily of spironolactone and 160 mg orally daily of furosemide, as it prevents hypo- or hyperkalemia. Renal function and electrolytes must be monitored regularly, particularly after dose modifications. Tender gynecomastia is an unpleasant side effect of spironolactone,

and some patients may need to discontinue it, in which case amiloride (Midamor)¹ (10–40 mg orally daily) can be used. Two outcomes may occur in patients with ascites that is not adequately controlled with diuretics: (1) refractory ascites to maximum diuretic doses and sodium restriction, which typically recurs rapidly following large-volume paracenteses (LVP); and (2) inability to increase diuretic doses owing to symptomatic hypotension or deterioration in renal function as evidenced by increasing serum creatinine levels.

Repeated LVP with removal of more than 5 liters of ascitic fluid per session is a safe and effective intervention to treat refractory ascites; however, mortality within 6 months is 20% once this develops, reflecting the severity of the underlying liver disease, and thus patients should be referred for evaluation for liver transplantation. Continued dietary restriction of sodium is necessary to avoid overly frequent LVP, and continuation of diuretics should be assessed on a case-by-case basis taking into consideration potential benefits and adverse reactions. Expansion of plasma volume for patients undergoing LVP is endorsed by current guidelines and supported by data demonstrating reduced postparacentesis circulatory dysfunction and improved survival. Plasma volume should be expanded with albumin at a dose of 6 to 8 g/liter of ascitic fluid removed during or immediately after LVP.

Insertion of TIPS corrects portal hypertension and offers an attractive alternative for amelioration of refractory ascites in selected patients. TIPS is a minimally invasive technique in which an endovascular stent is used to create an intrahepatic portocaval shunt and has replaced surgical shunts. Transplant-free survival is superior with TIPS compared with repeated LVP. Assessment of systolic and diastolic heart functions is recommended prior to TIPS as significant hemodynamic changes occur following the creation of the portosystemic shunt that can result in post-TIPS heart failure in individuals with underlying systolic or diastolic dysfunction.

The MELD score is a prognostic model that was initially developed to assess risk of death following TIPS placement, and data demonstrate that patients with a MELD score greater than 18 are at high risk of death; thus TIPS should be avoided in this population. TIPS results in hepatic encephalopathy in a high proportion of patients, but pharmacologic therapy typically provides adequate treatment for this complication.

Spontaneous Bacterial Peritonitis

Cirrhosis and portal hypertension are associated with abnormal intestinal permeability leading to bacterial translocation resulting in SBP. The most commonly isolated microorganisms responsible for SBP are *Escherichia coli* (43%), *Klebsiella pneumoniae* (11%), *Streptococcus pneumoniae* (9%), other streptococcal species (19%), *Enterobacteriaceae* (4%), *Staphylococcus* (3%), and miscellaneous organisms depending on the region of the world (10%). A small-volume diagnostic paracentesis (30–60 mL) rather than LVP (which can increase the risk of hepatorenal syndrome in the setting of SBP) is mandatory for diagnosis of SBP and should be performed prior to administration of antibiotic therapy. Aerobic and anaerobic blood culture bottles should be inoculated at the bedside to avoid contamination and to increase diagnostic yield. Diagnosis of SBP is supported by the presence of 250 PMN/ μ L or more in the ascitic fluid without an obvious source of infection. Based on the PMN count and the microbiologic analysis of the ascitic fluid, four clinical scenarios summarized in Table 7 may be encountered.

Treatment of SBP is centered on administration of broad-spectrum empiric antibiotics with bactericidal activity against the likely infecting bacteria. Third-generation cephalosporins such as cefotaxime (Claforan) 2 g intravenously every 8 hours or ceftriaxone (Rocephin) 2 g intravenously daily offer appropriate antimicrobial coverage and are initial agents of choice for treatment of SBP. For patients allergic to beta-lactams, alternatives include fluoroquinolones such as levofloxacin (Levaquin),¹ although this

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

TABLE 7 Spontaneous Bacterial Peritonitis and Associated Conditions Based on Characteristics of the Ascitic Fluid

CLINICAL ENTITY	POLYMORPHONUCLEAR CELL COUNT	CULTURE RESULTS	ANTIBIOTICS RECOMMENDED
Spontaneous bacterial peritonitis	≥ 250 cells/μL	Positive, single organism	Yes
Culture-negative neutrocytic ascites	≥ 250 cells/μL	Negative	Yes
Monomicrobial nonneutrocytic bacterascites	< 250 cells/μL	Positive, single organism	Yes
Polymicrobial bacterascites	< 250 cells/μL	Positive, multiple organisms	Yes

agent exhibits less penetration into the ascitic fluid compared with a third-generation cephalosporin.

Current guidelines do not recommend routinely performing a follow-up paracentesis in patients with a typical initial presentation of SBP and when antibiotic therapy results in rapid clinical improvement. Repeat paracentesis, however, may be indicated to document sterility of ascitic fluid and reduction in the PMN count in patients with a slow or absent response to antibiotic therapy or in those with atypical microorganisms on initial culture results.

Plasma volume expansion with albumin is an important adjunct to antibiotic therapy in patients with SBP, as it decreases the incidence of acute kidney injury and reduces mortality. The physiologic effects of intravenous infusion of albumin include increased oncotic pressure with consequential expansion of the effective arterial blood volume, as well as its ability to bind a wide range of endogenous and exogenous ligands including bacterial lipopolysaccharides, reactive oxygen species, nitric oxide and other nitrogen reactive species, and prostaglandins, thus modulating the inflammatory response. Current guidelines recommend a selective approach for administration of intravenous albumin to patients with SBP. Specifically, this therapy should be reserved for high-risk individuals such as those with serum creatinine greater than 1 mg/dL, blood urea nitrogen greater than 30 mL/dL, or total serum bilirubin greater than 4 mg/dL. The recommended dosage of albumin is 1.5 g/kg of body weight within 6 hours of establishing the diagnosis of SBP and a second dose of 1 g/kg on day 3.

Following an episode of SBP, recurrence occurs in 69% of individuals within 1 year; thus secondary prophylaxis is indicated, and current guidelines recommend long-term use of norfloxacin (Noroxin)¹ 400 mg orally twice daily or trimethoprim/sulfamethoxazole (Bactrim DS)¹ one double-strength tablet orally daily. Risk factors for recurrent SBP include ascitic fluid total protein concentration less than 1 g/dL and gastroesophageal variceal hemorrhage. Recommended antibiotic prophylaxis for patients hospitalized with gastroesophageal variceal hemorrhage include ceftriaxone¹ 1 g intravenously daily; once the patient is able to tolerate oral antibiotics, this may be changed to trimethoprim/sulfamethoxazole¹ one double-strength tablet orally daily, ciprofloxacin (Cipro)¹ 500 mg orally daily, or norfloxacin¹ 400 mg orally twice daily for a total of 7 days of antibiotic therapy. Importantly, some data suggest an increased risk for SBP in patients with cirrhosis and ascites taking proton pump inhibitors; thus unnecessary use of these agents should be avoided. The exact mechanism by which acid suppression increases the risk of SBP in cirrhosis is unclear, but intestinal bacterial overgrowth, increased intestinal permeability, and altered intestinal immune response may play important roles.

Hepatorenal Syndrome

The ominous significance of impaired renal function as a predictor of mortality in patients with cirrhosis is reflected by inclusion of the serum creatinine level in the MELD score. Renal dysfunction is commonly encountered in patients with cirrhosis, particularly in those with hepatic decompensation. Some studies reported acute kidney injury (AKI) in approximately 20% of hospitalized patients with cirrhosis. The differential diagnosis of AKI in patients with cirrhosis is broad and includes common etiologies such as acute

tubular necrosis and nephrotoxicity, but specific glomerulopathies associated with HBV and HCV must be considered (i.e., membranous and membranoproliferative glomerulonephritides). In addition, nonalcoholic steatohepatitis is characterized by a high prevalence of type 2 diabetes mellitus and systemic hypertension; thus patients are at increased risk for diabetic and hypertensive nephropathies. Hepatorenal syndrome (HRS) is one of several potential causes of AKI that occurs in patients with cirrhosis and portal hypertension but has also been recognized in patients with acute liver failure. Importantly, HRS is a diagnosis of exclusion, and other etiologies of AKI should be considered. The pathophysiology of HRS includes splanchnic vasodilatation causing a decline in renal perfusion with consequent reductions in the glomerular filtration rate and renal excretion of sodium (typically < 10 mEq/L).

There are two distinct types of HRS depending on the acuity and severity of renal dysfunction. Type I HRS is characterized by rapid deterioration of renal function with at least a twofold increase in serum creatinine to a level greater than 2.5 mg/dL in less than 2 weeks and is often precipitated by SBP, acute alcoholic hepatitis, or gastrointestinal hemorrhage. Type II HRS is more indolent and is associated with less severe renal impairment, typically resulting in ascites resistant to diuretics. Prognosis also differs significantly for both types of HRS, with the median survival in the absence of liver transplantation being 2 weeks for HRS type I and 6 months for HRS type II.

Discontinuation of all diuretics and nephrotoxic agents is critical in patients with HRS. Plasma volume expansion with administration of intravenous albumin¹ at a dose of 1 g/kg of body weight (up to a maximum of 100 g/day) to increase renal perfusion is recommended. HRS is characterized by absent or minimal proteinuria (< 500 mg/day) and normal urine sediment reflecting the lack of intrinsic renal disease. Renal ultrasonography is also recommended as it provides good assessment for chronic parenchymal changes that may suggest the presence of a chronic underlying renal disease and accurately rules out obstructive nephropathy.

Patients with HRS require either improvement in hepatic function or liver transplantation for renal function to recover. Pharmacotherapy can be used as a bridge to liver transplantation. Based on the pathophysiology of HRS, vasoconstriction with alpha-adrenergic agonists (i.e., midodrine [ProAmatine]¹ or norepinephrine [Levophed]¹) or vasopressin analogs (i.e., terlipressin [Lucassin]³) is the therapy of choice along with plasma volume expansion achieved with intravenous albumin infusion. The use of norepinephrine is reserved for critically ill patients with HRS. Terlipressin is not licensed for use in the United States. The combination of the somatostatin analog octreotide¹ along with oral midodrine and intravenous albumin infusion appears to have beneficial effects based on results from small clinical trials and is currently recommended in the United States for noncritically ill patients with type I HRS. Data from a meta-analysis support the efficacy of vasoconstrictor therapy (terlipressin, octreotide + midodrine, or norepinephrine) in combination with intravenous albumin in reducing short-term mortality in patients with type I HRS. The largest randomized clinical trial to date evaluating terlipressin in combination with albumin versus placebo plus albumin showed no difference in

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

³Investigational drug in the United States.

reversal of type I HRS, but the terlipressin group had greater improvement in renal function. Renal replacement therapy may be needed for patients with HRS not responding to pharmacologic therapy awaiting liver transplantation; however, mortality is exceedingly high and hypotensive episodes commonly occur during hemodialysis. Following liver transplantation, renal function improves in approximately 60% of patients with HRS.

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a clinical syndrome of reversible neuropsychiatric impairment of varying severity. There is continuing controversy about its exact pathogenesis, but gut-derived toxins, including ammonia, are clearly implicated. Features of HE may be subclinical (covert) or clinically evident (overt) and include a wide range of neuropsychiatric signs and symptoms. The prevalence of HE varies depending on the clinical subtype and the severity of liver disease, with cumulative prevalence rates of up to 80% for covert HE and 30% to 40% for overt HE in patients with cirrhosis. Although the West Haven criteria are widely used for grading the severity of HE (Table 8), current guidelines recommend using three additional axes to classify HE based on the etiology, time course, and presence or absence of a precipitating factor (Table 9).

Covert HE is considered preclinical and encompasses minimal HE (features of HE that are only diagnosed by specialized neuropsychiatric testing) and grade 1 HE as per West Haven criteria. In contrast, overt HE is characterized by clinical findings of HE ranging from subtle changes in orientation and presence of asterixis to hepatic coma (grades 2 to 4 per West Haven criteria).

Specialized testing is necessary to establish a diagnosis of covert HE. The psychometric hepatic encephalopathy score is regarded as the gold standard, but additional assessments include the number connection test, computerized tests such as the inhibitory control test, the cognitive drug research battery, and electroencephalogram. These tests, however, are not applicable in routine clinical practice and usually require consultation with a specialist. A smartphone application that evaluates psychomotor speed and cognitive alertness has been developed and validated as a point-of-care screening tool for covert HE: EncephalApp Stroop.

The diagnosis of overt HE is clinical and supported by the presence of a wide spectrum of global neurologic deficits. Severe HE,

grades 3 and 4 West Haven criteria, should prompt attention to airway protection, and endotracheal intubation ought to be considered.

There are no laboratory markers that can be accurately used to diagnose overt HE. Blood ammonia levels lack sensitivity and specificity and correlate poorly with the severity of encephalopathy. Furthermore, a normal ammonia level does not preclude the presence of HE, and venous ammonia levels are influenced by several other factors including phlebotomy technique and handling of the blood specimen. Efforts must be directed at identifying potential precipitating factors for HE, such as compliance with treatment of HE, new medications, gastrointestinal bleeding, AKI, electrolyte imbalances, and infections.

Management of covert and overt HE is centered on the use of nonabsorbable disaccharides and antibiotics. Lactulose (Enulose) is the most widely used nonabsorbable disaccharide. Although the exact mechanism responsible for its therapeutic efficacy is still unclear, this agent is degraded by colonic microbiota to short-chain organic acids, resulting in acidification of the intestinal lumen and increased conversion of absorbable ammonia to nonabsorbable ammonium. The starting dosage for lactulose depends on the acuity and severity of HE but must be titrated to achieve two to four soft bowel movements per day. For patients who cannot tolerate oral administration (i.e., high risk for aspiration or coma), lactulose can be administered as an enema (300 mL of lactulose solution 10 g/15 mL in 700 mL of saline or water). The cathartic effects of nonabsorbable disaccharides may result in profuse diarrhea, dehydration, and hypernatremia. Rifaximin (Xifaxan) is a broad-spectrum antibiotic with activity against gram-positive, gram-negative, and anaerobic enteric bacteria that can be used in addition to lactulose for prevention of recurrent episodes of HE. Data from clinical trials show marked reductions in HE-related hospitalization and significant improvements in health-related quality of life in patients treated with a combination of lactulose and rifaximin without an increased rate of adverse events.

The efficacy and safety of other pharmacologic therapies such as probiotics⁷, branched-chain amino acids⁷, L-ornithine L-aspartate (LOLA)⁷, ammonia scavengers, and other laxatives

⁷Available as a dietary supplement.

TABLE 8 West Haven Criteria for Grading Hepatic Encephalopathy

GRADE	LEVEL OF CONSCIOUSNESS	INTELLECT AND BEHAVIOR	NEUROLOGIC FINDINGS
0	Normal	Normal	Normal examination, abnormal neuropsychiatric testing
1	Mild lack of awareness	Shortened attention span	Impaired addition or subtraction, mild asterixis
2	Lethargy	Mild–moderate disorientation, inappropriate behavior	Severe asterixis, slurred speech
3	Somnolence but arousable	Severe disorientation, inexplicable behavior	Clonus, hyperreflexia, muscular rigidity
4	Coma	Coma	Decerebrate posture

TABLE 9 Classification of Hepatic Encephalopathy Based on Four Different Axes

TYPE OF HEPATIC ENCEPHALOPATHY	GRADE		TIME COURSE	SPONTANEOUS/PRECIPITATED
A (acute liver failure)	MHE	Covert	Episodic (one episode in 6 months)	Spontaneous: no precipitating factor discovered
B (portosystemic bypass)	1	Covert	Recurrent (more than one episode in 6 months)	Precipitated by one or more specific factors
	2	Overt	Persistent (no return to normal baseline)	
C (cirrhosis)	3	Overt		
	4	Overt		

From Patidar KR, Bajaj JS. Covert and overt hepatic encephalopathy: Diagnosis and management. Clin Gastroenterol Hepatol 2015;13:2048–2061.

(i.e., polyethylene glycol [MiraLax]¹) need to be further confirmed by clinical trials. Because of concerns about oto- and nephrotoxicity, neomycin is no longer used.

Creation of a portosystemic shunt (now usually with TIPS) for management of complications of portal hypertension is associated with a 13% to 36% incidence of overt HE. Careful patient selection prior to insertion of TIPS and medical therapy with non-absorbable disaccharides with or without additional rifaximin remain standard therapy; however, despite compliance, approximately 3% to 7% of patients have recurrent or persistent overt HE post-TIPS. For these patients, endovascular techniques aimed at decreasing the size of the shunt should be considered.

Liver transplantation offers definitive therapy for patients with end-stage liver disease, resulting in restoration of hepatic synthetic function and resolution of complications associated with portal hypertension. However, residual cognitive impairments may persist following liver transplantation, adversely impacting health-related quality of life.

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is the most common primary hepatic malignancy in adults, currently representing the fifth most common cancer and the second leading cause of cancer-related death worldwide. The epidemiology of HCC varies significantly by region and ethnicity. The majority of patients with HCC in Western populations (95%) have underlying cirrhosis (predominantly due to chronic HCV infection, alcoholic liver disease, and nonalcoholic steatohepatitis), thus limiting applicability of surgical resection (see later) as curative therapy. In contrast, only 60% of patients with HCC in Eastern populations have cirrhosis, largely reflecting the high prevalence of chronic HBV infection and its oncogenic potential. Regions of the world with intermediate to high incidence of this malignancy (more than 3 cases per 100,000 persons per year) include Asia, sub-Saharan Africa, and Western Europe. North and South America have been typically considered low-incidence regions; however, over the past two decades there has been a steady increase in the incidence of HCC, particularly in the United States.

Current guidelines endorse implementation of surveillance strategies for early diagnosis of HCC in individuals at risk for this malignancy and recommend the use of ultrasonography every 6 months as the primary surveillance modality. Populations at risk for HCC that benefit from surveillance include individuals with cirrhosis of any etiology, Asian males with chronic HBV over age 40, Asian females with chronic HBV over age 50, patients with chronic HBV and family history of HCC, African/North American blacks with chronic HBV, and individuals with stage 4 primary biliary cholangitis.

HCC can be accurately diagnosed without the need for liver biopsy by contrast-enhanced multiphase cross-sectional imaging modalities such as computed tomography (CT) or magnetic resonance imaging (MRI) based on specific patterns of contrast enhancement of the tumor in relation to the hepatic parenchyma. Key diagnostic characteristics for HCC on CT or MRI are contrast enhancement of the tumor during the early arterial phase and “washout” of contrast from the tumor during the portal venous and delayed phases. Additional features include presence of a capsule and interval growth of the lesion when previous imaging studies are used for comparison. Biopsy of the tumor carries a small risk for tumor seeding in the biopsy-needle tract (approximately 3%) and is rarely required to diagnose HCC owing to high accuracy of CT and MRI. The use of serum alpha-fetoprotein (AFP) has been controversial for routine surveillance owing to its low sensitivity and poor specificity; however, data from a recent meta-analysis suggest that addition of AFP to ultrasound increases the sensitivity of HCC detection. If not previously available, once a focal liver lesion is identified on imaging studies, AFP should be obtained as an additional diagnostic tool. AFP levels greater than 200 ng/mL

are highly specific for HCC, and longitudinal follow-up of serum levels permits evaluation of response to therapeutic interventions. Additional serologic markers for HCC under investigation include the L3 isoform of AFP (AFP-L3) and des-gamma carboxy prothrombin (DCP); however, further validation of these tests for surveillance of individuals at risk for HCC is still required.

The Barcelona Clinic Liver Cancer (BCLC) staging system can be used to categorize patients with HCC and to assist with therapeutic decisions (Figure 2). Surgical resection of HCC is reserved for patients with a single lesion and no evidence of cirrhosis or portal hypertension. Locoregional therapies include radiofrequency ablation, percutaneous ethanol injection, transarterial chemoembolization, radioembolization, and microwave ablation. These modalities are typically used for patients with early and intermediate stages (BCLC stages A and B, respectively). Liver transplantation is an effective treatment for patients with cirrhosis and HCC within the so-called Milan criteria: a single lesion up to 5 cm or no more than three lesions with the largest one being less than 3 cm, and in the absence of portal venous invasion or metastatic disease. Liver transplantation for HCC within these limits results in long-term survival equivalent to that seen in patients with cirrhosis but no HCC. Under the current organ allocation policy in the United States, patients with HCC within Milan criteria are listed for liver transplantation with their biological MELD score (calculated by the MELD formula and without exception points) for 6 months, after which time they automatically accrue MELD exception points and the score increases to 28, with 10% increments thereafter every 3 months until the maximum score of 34 is reached. MELD exception points are granted to patients with HCC 2 cm or greater in an effort to balance risk of death that is not adequately represented by the degree of hepatic dysfunction. For patients with HCC listed for liver transplantation, the use of locoregional therapies is recommended to prevent tumor progression that may result in dropout from the waiting list. Furthermore, active surveillance is recommended to evaluate for tumor recurrence or progression, development of new lesions, and metastatic disease while awaiting liver transplantation.

Systemic chemotherapeutic agents licensed for use in patients with HCC include sorafenib (Nexavar), regorafenib (Stivarga), and nivolumab (Opdivo). Sorafenib is currently recommended for patients with BCLC stage C, and regorafenib and nivolumab are licensed to treat patients with HCC who have been previously treated with sorafenib. Adverse reactions, tolerability, and potential benefits must be carefully weighed and individualized according to overall health and performance status, as well as severity of hepatic dysfunction. The survival benefit of these agents is modest.

Portopulmonary Hypertension

Pulmonary artery hypertension in a patient with established portal hypertension is indicative of portopulmonary hypertension (PPHTN), but other etiologies of pulmonary hypertension must be excluded prior to establishing this diagnosis. The prevalence of PPHTN varies depending on the severity of liver disease and has been reported in 0.7% of patients with cirrhosis but can be as high as 12.5% in patients undergoing evaluation for liver transplantation.

The exact pathophysiology of PPHTN remains enigmatic, but increased exposure to humoral vasoconstrictors in the pulmonary vasculature due to portosystemic shunting and hyperdynamic circulation is among the most widely accepted hypotheses. Histologic findings in the pulmonary vasculature of patients with PPHTN are indistinguishable from those found in idiopathic pulmonary arterial hypertension and include medial hypertrophy with remodeling of the pulmonary artery walls and occasional *in situ* microthrombosis.

The majority of patients with PPHTN remain largely asymptomatic for extended periods of time. Symptoms associated with PPHTN are similar to those of other types of pulmonary arterial hypertension and include dyspnea on exertion, syncope, chest pain, fatigue, hemoptysis, and orthopnea. Physical examination may demonstrate jugular venous distention and lower extremity edema, the latter typically being out of proportion to the severity of ascites.

¹Not FDA approved for this indication.

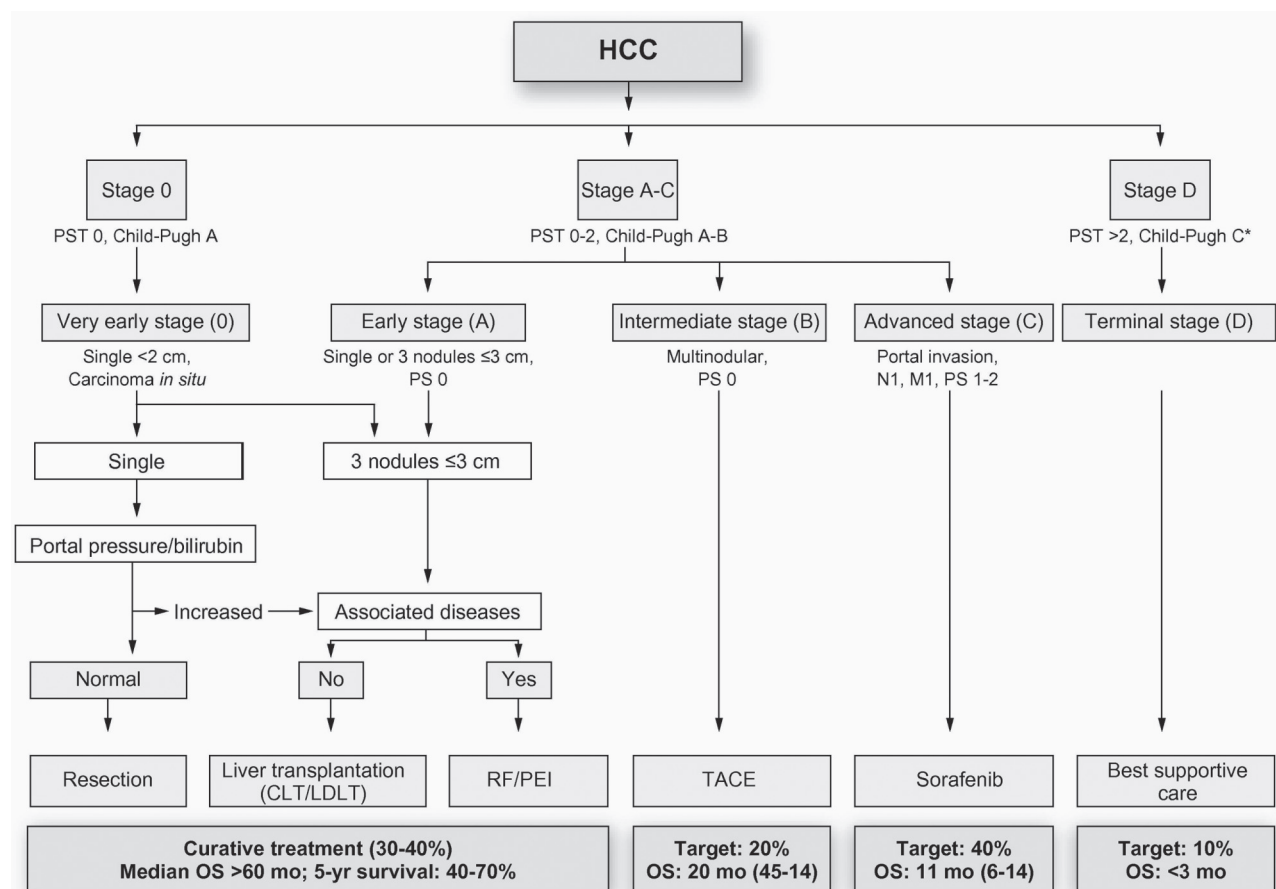

Figure 2 Barcelona Clinic Liver Cancer (BCLC) staging system for hepatocellular carcinoma (HCC). CLT, cadaveric liver transplantation. LDL, living donor liver transplantation. OS, overall survival. PEI, percutaneous ethanol injection. PST, performance status. RF, radiofrequency ablation. TACE, transarterial chemoembolization. (From EASL-EORTC Clinical Practice Guidelines: Management of hepatocellular carcinoma. *J Hepatol* 2012;56 [4]:908-43.)

Cardiopulmonary auscultation usually reveals normal clear breath sounds throughout both lung fields, an accentuated pulmonic component of the second heart sound, and a systolic murmur located along the left sternal border that is accentuated with inspiration (tricuspid regurgitation). Chest radiographs may demonstrate right ventricular enlargement and a prominent pulmonary artery.

The diagnostic workup for PPHTN should begin with transthoracic echocardiography, which provides an estimate of right ventricular and pulmonary arterial pressures and rules out left ventricular dysfunction. An estimated right ventricular systolic pressure greater than 50 mm Hg is typically used as a threshold to obtain more accurate direct hemodynamic measurements through right heart catheterization. Hemodynamic criteria used to diagnose PPHTN include mean pulmonary artery pressure (mPAP) greater than 25 mm Hg, pulmonary capillary wedge pressure less than 15 mm Hg, and pulmonary vascular resistance greater than or equal to 240 dynes $\cdot \text{cm}^{-5}$ by right heart catheterization.

Pharmacologic therapy has been extrapolated from studies performed in patients with idiopathic pulmonary arterial hypertension and includes endothelin receptor antagonists (bosentan [Tracleer]¹ and ambrisentan [Letairis]¹), phosphodiesterase inhibitors (sildenafil [Revatio]¹), and prostacyclin analogs (epoprostenol [Flolan]¹ and iloprost [Ventavis]¹).

Survival in PPHTN correlates with the severity of right ventricular dysfunction, and the safety and efficacy of liver transplantation are reliant on the severity of pulmonary arterial hypertension. Liver transplantation may be offered to selected patients with PPHTN

but is typically contraindicated in those with mPAP greater than 35 mm Hg despite medical management, particularly if right ventricular dysfunction is present, due to considerable perioperative mortality.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome (HPS) is characterized by hypoxemia due to intrapulmonary vascular dilatations with right-to-left shunting in the setting of cirrhosis and portal hypertension. Although intrapulmonary vasodilatation is encountered in over 50% of patients with cirrhosis undergoing evaluation for liver transplantation, only 15% to 30% have hypoxemia and true HPS. The most widely accepted pathophysiologic mechanism responsible for HPS is increased pulmonary synthesis of nitric oxide. Similar to PPHTN, the majority of patients with HPS are largely asymptomatic.

Clinical manifestations include dyspnea of insidious onset and two characteristic clinical findings: platypnea and orthodeoxia (worsening dyspnea and hypoxemia in upright posture, respectively). Other, more obvious but nonspecific clinical findings include spider angiomas, digital clubbing, and cyanosis. Screening for HPS relies on point-of-care oximetry indicating peripheral arterial oxygen saturation (SpO_2) less than 96% at rest and at sea level. Hypoxemia must be confirmed by arterial blood gas analysis demonstrating an arterial partial pressure of oxygen (PaO_2) less than 70 mm Hg and a widened alveolar-arterial oxygen gradient greater than or equal to 15 mm Hg (≥ 20 mm Hg for patients 65 years of age or older). Importantly, blood for arterial gas analysis should be obtained with the patient sitting upright, at rest, and breathing ambient air. After establishing a diagnosis of hypoxemia, documentation of pulmonary vascular dilatations with right-to-left

¹Not FDA approved for this indication.

blood shunting is necessary. Two-dimensional contrast-enhanced transthoracic echocardiography offers high sensitivity and is widely available. Agitated saline to produce microbubbles is injected intravenously as contrast, and under normal cardiopulmonary physiology the gas bubbles are rapidly seen in the right atrium and ventricle but then diffuse into alveoli during normal flow through the pulmonary capillaries. In patients with HPS, the presence of intrapulmonary right-to-left shunting due to vascular dilatations results in the presence of the microbubbles opacifying the left heart chambers at least three heartbeats after being seen in the right ventricle. Intracardiac right-to-left blood shunting (i.e., atrial or ventricular septal defects, patent foramen ovale) should be suspected if contrast is seen in the left heart within three heartbeats. Radionuclide lung perfusion scintigraphy using technetium-labeled macroaggregated albumin particles (^{99m}Tc -MAA scan) is less sensitive than contrast-enhanced echocardiography for diagnosis of HPS but is more specific and permits accurate quantification of the intrapulmonary shunt fraction, even in the presence of coexisting intrinsic lung disorders. Shunt fractions greater than 6% confirm the diagnosis of HPS in the appropriate clinical setting.

HPS is associated with increased mortality and diminished quality of life compared with patients with cirrhosis but no HPS. Following the diagnosis of HPS, median survival is 10.6 months; thus patients with HPS should undergo prompt liver transplantation evaluation. Under current organ allocation policies by the United Network for Organ Sharing (UNOS), patients with HPS and PaO_2 less than 60 mm Hg are eligible for standard MELD exception score of 22 points at the time of listing, regardless of their calculated (biological) MELD score, and a 10% mortality equivalent increase in points every 3 months. Liver transplantation remains the definitive therapy for HPS based on marked improvement or even resolution of hypoxemia in more than 85% of transplant recipients; however, clinically meaningful changes may be slow and take up to 1 year following transplantation.

Hepatic Hydrothorax

Hepatic hydrothorax is a transudative process leading to accumulation of more than 500 mL of fluid in the pleural space in patients with cirrhosis and portal hypertension in the absence of primary cardiopulmonary disease. Hepatic hydrothorax is thought to result from passage of ascitic fluid from the peritoneal cavity into the pleural spaces (typically on the right in up to 85% of patients) via subcentimeter defects and/or microscopic fenestrations in the tendinous portion of the diaphragm and is facilitated by negative intrathoracic pressure generated during inspiration. Clinical features include dyspnea, nonproductive cough, pleuritic chest pain, and even hypoxemia and hypotension in cases of tension hydrothorax. Fluid analysis demonstrates similar chemical characteristics than ascites: high serum-to-pleural fluid albumin gradient (> 1.1 g/dL) and low total protein concentration (< 2.5 g/dL).

Management of noninfected hepatic hydrothorax follows the same principles as those for ascites: sodium restriction, diuretics, repeated thoracenteses, and placement of TIPS for refractory cases. Importantly, indwelling pleural catheters should be avoided because of the high risk for complications including severe infections that may jeopardize possible liver transplant candidacy in the future.

In patients with fevers and worsening pleuritic chest pain, spontaneous bacterial empyema (SBEM) must be excluded. Similar to the diagnostic criteria for SBP, a diagnosis of SBEM is established by a PMN count greater than 250 cells/ μL and a positive bacterial culture in the absence of a parapneumonic effusion. In cases in which bacterial cultures are negative, a PMN count threshold of greater than 500 cells/ μL should be used to diagnose SBEM. Microorganisms responsible for this infection are also similar to those responsible for SBP; thus third-generation cephalosporins remain the antibacterial agents of choice for empiric therapy.

Liver transplantation

Liver transplantation is effective in salvaging patients with acute liver failure (ALF) and decompensated cirrhosis, as well as

selected patients with HCC (see earlier), with excellent short- and long-term outcomes. Survival after 1 and 5 years following liver transplantation is approximately 80% to 90% and 60% to 75%, respectively. Cirrhosis per se is not an indication to initiate evaluation for liver transplantation, as it is not associated with survival benefit in patients with low MELD scores. Consequently, patients should be referred for liver transplantation evaluation when the MELD score is 15 or higher or when an index complication of cirrhosis such as ascites or variceal hemorrhage occurs. Organ allocation in the United States and many other countries is based on disease severity as reflected by the MELD score for patients 12 years of age or older and the Pediatric End-Stage Liver Disease (PELD) score for patients younger than 12 years of age (includes international normalized ratio, bilirubin, albumin, and growth failure). The most recent modification of the MELD score now includes serum sodium in the mathematical equation (MELD-Na), as hyponatremia is an independent predictor of mortality in patients with cirrhosis. Some etiologies of cirrhosis result in diminished survival that is not accurately predicted by the MELD score or are associated with extremely poor quality of life; thus MELD exceptions exist. Standardized MELD exception criteria are summarized in Table 10. For patients with complications related to liver disease and associated increased morbidity and mortality not adequately reflected by the MELD score and not qualifying for standard MELD exceptions, additional points may be petitioned by the transplant center to the regional review board on a case-by-case basis with no guarantee that they will be granted. Some examples of conditions that may receive additional MELD points include recurrent bacterial cholangitis in patients with primary sclerosing cholangitis, intractable and debilitating pruritus in patients with primary biliary cholangitis, ascites refractory to maximum-tolerated doses of diuretics, hepatic encephalopathy refractory to medical therapy, and recurrent variceal hemorrhage despite adequate therapy.

Contraindications to liver transplantation continually evolve over time. Relative contraindications are usually associated with suboptimal outcomes following liver transplantation and vary widely across different transplant centers. Absolute contraindications imply that a successful outcome following liver transplantation is unlikely; thus it should not be pursued (Table 11).

TABLE 10 Medical Conditions That Qualify for Standard MELD Exception Points

CONDITIONS	REMARKS
Hepatocellular carcinoma	T2 lesions (at least 2 cm in diameter) within Milan criteria
Hepatopulmonary syndrome	$\text{PaO}_2 < 60$ mm Hg on ambient air
Portopulmonary hypertension	Mean pulmonary arterial pressure < 35 mm Hg with treatment
Familial amyloid polyneuropathy	Confirmed by DNA analysis and histology
Primary hyperoxaluria	Need simultaneous liver-kidney transplant
Cystic fibrosis	Forced expiratory volume in 1 s (FEV1) $< 40\%$
Hilar cholangiocarcinoma	Stage I or II, liver transplantation center must have a UNOS-approved protocol
Hepatic artery thrombosis	Within 14 days of liver transplantation, not meeting criteria for status 1A

Abbreviations: MELD = Model for End-Stage Liver Disease; UNOS = United Network for Organ Sharing.

TABLE 11 Absolute Contraindications to Liver Transplantation**CONTRAINDICATIONS TO LIVER TRANSPLANTATION**

Uncontrolled sepsis
Acquired immunodeficiency syndrome
Active alcohol or substance abuse
Advanced cardiac or pulmonary disease
Intrahepatic cholangiocarcinoma
Hepatic hemangiosarcoma
Hepatocellular carcinoma with metastasis
Extrahepatic malignancy
Anatomic abnormalities that preclude liver transplantation
Lack of social support
Persistent nonadherence to medical care

ALF is an uncommon but important indication for liver transplantation owing to the high mortality associated with this condition. Although a significant proportion of patients with ALF may have spontaneous recovery, its clinical course is usually unpredictable and early referral for liver transplantation is recommended, regardless of the etiology. Patients with ALF have the highest priority for organ allocation if they meet specific criteria for UNOS status 1A (Table 12).

Evaluation for liver transplantation is a multidisciplinary process carried out over multiple encounters aimed to unveil additional medical, surgical, behavioral, social, and economic issues that may affect liver transplantation candidacy and/or outcomes. Once the patient's candidacy is deemed appropriate, formal listing occurs with UNOS. Blood type (ABO) is the major determinant for organ compatibility, and appropriate size (based on body weight) must be taken into consideration.

Living-donor liver transplantation was developed as an alternative owing to ongoing shortage of deceased-donor organs; however, living donation carries important risks for the donor that must be carefully taken into consideration. The advantages and disadvantages of living-donor liver transplantation are summarized in Table 13.

Additional approaches to try to expand donor organ supply include donation after cardiac death, using grafts from hepatitis

TABLE 12 Criteria for Status 1A Designation in Patients With Acute Liver Failure

Age >18 years
Life expectancy <7 days without liver transplantation
Onset of encephalopathy within 8 weeks of first symptom of liver disease
Absence of preexisting liver disease
Admission to intensive care unit, and one of the following: <ul style="list-style-type: none"> • Ventilator dependence • Requirement of renal replacement therapy • International normalized ratio > 2
Fulminant Wilson disease
Primary graft nonfunction
Hepatic artery thrombosis

TABLE 13 Advantages and Disadvantages of Living-Donor Liver Transplantation

ADVANTAGES	DISADVANTAGES
Thorough donor screening process	Only offered in selected liver transplantation centers
Elective timing of liver transplantation permitting optimization of therapies	Donor morbidity and mortality
Diminished wait time with consequent reduction in dropout from the waiting list	Higher risk for biliary complications in the donor and recipient
Minimal cold ischemia time	

B core antibody-positive and hepatitis C-positive donors, and splitting a graft for use in adult and pediatric recipients.

Adequate long-term immunosuppression prevents graft rejection and is currently centered on the use of calcineurin inhibitors (tacrolimus [Prograf] primarily, and less often cyclosporine [Neoral]) with or without concomitant antimetabolite agents such as mycophenolic acid (Myfortic) or its prodrug mycophenolate mofetil (CellCept). Additional agents include inhibitors of the mammalian target of rapamycin (mTOR) such as sirolimus (Rapamune)¹ and everolimus (Zortress).

Long-term care of liver transplant recipients should not by any means focus exclusively on graft function and prevention of rejection, but rather be comprehensive and aimed at maintaining an overall good state of health by instituting preventive health strategies and monitoring for other complications that may ensue, such as diabetes mellitus, hypertension, dyslipidemia, renal dysfunction, obesity, and alcohol relapse, among many others.

¹Not FDA approved for this indication.

DIVERTICULA OF THE ALIMENTARY TRACT

Method of

Aaron Sinclair, MD

CURRENT DIAGNOSIS

- Endoscopy or barium swallow study may be used in the evaluation of most upper alimentary tract diverticula.
- Symptomatic small intestinal diverticula are difficult to diagnose and require a high index of suspicion and radiographic examination (nuclear medicine scans, capsule endoscopy, or computed tomography scans).
- Diverticulitis of the colon is most accurately identified and the treatment planned with computed tomography of the abdomen and pelvis.
- Diverticulitis of the colon that is slow to resolve may require additional imaging or direct visualization with endoscopy to identify an alternative diagnosis.

CURRENT THERAPY

- Most asymptomatic diverticula are identified incidentally and may only require monitoring.
- Management of symptomatic diverticula may require surgical resection.
- Early in the disease process, uncomplicated diverticulitis of the colon may be managed on an outpatient basis with a conservative no-intervention approach or oral antibiotics.
- Complicated diverticulitis of the colon should be managed in conjunction with a surgeon and in the hospital with intravenous antibiotics.

A diverticulum is an abnormal saccular protrusion from the wall of the alimentary tract. Diverticula may be classified as either true or false. The wall of the alimentary tract is composed of submucosal, mucosal, and muscular layers. A false diverticulum is a protrusion of the submucosa and mucosa through a defect in the muscular wall of the alimentary tract. A true diverticulum is a protrusion of all layers of the alimentary tract wall. Many diverticula are asymptomatic and require no treatment. Some diverticula cause symptoms depending on their anatomic location or associated pathophysiologic complications (e.g., obstruction, infection, inflammation, or bleeding). This chapter categorizes alimentary canal diverticula by their location.

Esophagus

Zenker's Diverticulum

Zenker's diverticulum is a false diverticulum that develops in the upper posterior esophagus in an area known as Killian's triangle, located between the inferior pharyngeal constrictors and the cricopharyngeal muscles. Zenker's diverticulum typically presents after age 60 and has a male predominance for reasons that are unclear. It affects only 2 per 100,000 patients per year. Though it can be asymptomatic for years before the development of symptomatology, patients may experience dysphagia, aspiration, and regurgitation of undigested food. The exact cause is unclear, but proposed mechanisms suggest a dysfunction in coordinated swallowing muscle movement and increased intraluminal pressure in the esophagus. There may be an additive component of long-term upper esophageal sphincter irritation from acid reflux.

Diagnosis is primarily made through barium swallow, though small diverticula may be missed (Figure 1). Although endoscopic direct visualization is possible, caution should be exercised owing to the risk of perforation. Small asymptomatic diverticula can be

Esophagus

Zenker's Diverticulum

Zenker's diverticulum is a false diverticulum that develops in the upper posterior esophagus in an area known as Killian's triangle, located between the inferior pharyngeal constrictors and the cricopharyngeal muscles. Zenker's diverticulum typically presents after age 60 and has a male predominance for reasons that are unclear. It affects only 2 per 100,000 patients per year. Though it can be asymptomatic for years before the development of symptomatology, patients may experience dysphagia, aspiration, and regurgitation of undigested food. The exact cause is unclear, but proposed mechanisms suggest a dysfunction in coordinated swallowing muscle movement and increased intraluminal pressure in the esophagus. There may be an additive component of long-term upper esophageal sphincter irritation from acid reflux.

Diagnosis is primarily made through barium swallow, though small diverticula may be missed (Figure 1). Although endoscopic direct visualization is possible, caution should be exercised owing to the risk of perforation. Small asymptomatic diverticula can be

Figure 1 Zenker's diverticulum. (Image courtesy of Gastrolab—The Gastrointestinal Site. Available at <http://www.gastrolab.net> [accessed August 25, 2014].)

monitored. Zenker's diverticulum greater than 2 cm in size, regardless of symptomatology, should be surgically evaluated and repair considered. Methods for closure include endoscopic diverticulostomy and myotomy or traditional surgical resection. Although most patients (> 90%) demonstrate symptom improvement, recurrence rates can be as high as 35%.

Traction Diverticulum

Traction diverticula are the only true diverticula of the esophagus. Traction diverticula are rare. Their size tends to stay below 2 cm. Owing to the proposed mechanism of formation, traction diverticula are isolated to the middle third of the esophagus. It is not fully clear how traction diverticula form. One proposed mechanism is related to a precedent pulmonary infection, most commonly tuberculosis or histoplasmosis, with resultant mediastinal lymph node formation. After the active infection subsides, resultant fibrosis and scarring between the tissues surrounding the mediastinal lymph nodes and esophagus occur. Initially, a small diverticulum develops from this fibrosis, which produces "traction" or a lack of mobility. Diverticular progression results when age-related changes from the dysfunction of coordinated swallowing muscle movement and increased intraluminal pressure in the esophagus develop. Surgical management is rarely needed unless these diverticula become symptomatic or complications, such as fistulas, occur.

Epiphrenic Diverticulum

Epiphrenic diverticula are false diverticula of the distal esophagus affecting only 0.015% of the general population. They are thought to arise secondary to mucosal injury from gastroesophageal reflux and muscle dysmotility. They occur within 10 cm of the gastroesophageal junction, and symptoms include dysphagia, spasmodic chest pain, and gastroesophageal reflux. With progression of diverticular size, obstruction can become a potential complication. Diagnostic measures start with barium swallow and may be followed with additional tests, including endoscopy, 24-hour pH probe, and esophageal manometry.

Management depends on patient symptoms and size of the diverticulum. If small (< 5 cm) and asymptomatic, routine clinical and

endoscopic surveillance is permissible. However, any symptomatology necessitates surgical evaluation and repair. Surgical options include open resection and laparoscopy. Partial fundoplication may be indicated depending on the severity of gastroesophageal reflux present as indicated by ancillary testing of a 24-hour pH probe.

Stomach

Gastric Diverticula

Gastric diverticula are rare with an endoscopic incidence of 0.01%. Most are asymptomatic and small (< 3 cm). Symptoms may include epigastric pain, dyspepsia, and emesis. Rarely, ulcerations, perforations, or bleeding can occur. Diagnosis involves endoscopy, barium swallow, or contrast-aided computed tomography scan. If symptomatic, typical treatment includes a proton pump inhibitor and monitoring for symptom improvement. Persistent symptoms may necessitate gastrectomy of the diverticulum especially if concerns for cancer exists.

Small Intestine

Duodenal Diverticula

Diverticula located in the duodenum are relatively common, affecting up to 22% of the general population (Figure 2). Duodenal diverticula may be either true or false diverticula. The most common location is the second portion of the duodenum. The size and position of the diverticula may lead to complications such as obstruction of the sphincter of Oddi and/or impingement of the hepatobiliary tree drainage. This impingement may result in jaundice, right upper quadrant pain, or infection signs/symptoms similar to cholecystitis. Although usually asymptomatic, on occasion ulcerative bleeding or perforation may occur.

Duodenal diverticula may be identified on barium swallow, contrast-enhanced computed tomography, magnetic resonance imaging, or endoscopy. Duodenal diverticula found incidentally do not require treatment. If symptoms arise, endoscopic evaluation and surgical resection should be considered. However, intervention should be considered with caution owing to a high risk (30%) of complications, in particular fistula formation and mortality.

Jejunal and Ileal Diverticula

Jejunal and ileal diverticula occur throughout the length of the small intestine in about 1% to 2% of the population. There does not appear to be any statistically significant relationship with morbidity or mortality of these types of diverticula with respect to location, gender, size, number, and so forth. These false diverticula are located predominantly where the blood vessels penetrate the muscular wall of the mesenteric side of the bowel. Most are noted

Figure 2 Duodenal diverticulum. (Image courtesy of Gastrolab—The Gastrointestinal Site. Available at <http://www.gastrolab.net> [accessed August 25, 2014].)

incidentally, but some manifest with symptoms secondary to bleeding, obstruction, or infection. These symptoms are believed to be due to bacterial overgrowth that may occur within the cavity of the diverticulum. Diagnosis can be made with capsule endoscopy or a small bowel barium contrast follow-through study, although some may be noted on computed tomography with intravenous and oral contrast. Advanced endoscopic procedures such as push enteroscopy and double balloon endoscopy can be utilized to further evaluate symptomatic diverticula.

Asymptomatic jejunal and ileal diverticula should not be resected. Bacterial overgrowth symptoms may respond to antibiotic treatment and intestinal promotility drug therapy. Surgical intervention with small bowel resection is indicated if symptomatic diverticula persist despite conservative management.

Meckel's Diverticulum

Meckel's diverticulum is a congenital anomaly that occurs owing to incomplete closure of the vitelline duct. This duct typically obliterates during the ninth week of gestational age. Owing to the embryologic origin of the diverticulum, it is almost always located within 2 feet of the ileocecal valve. Meckel's diverticulum has a prevalence of approximately 1% to 2% of the population, with a 2:1 male predominance. About 2% of all existing Meckel's diverticula will become symptomatic. Symptomatic diverticula most commonly cause nausea, vomiting, and abdominal pain. The sign most commonly associated with Meckel's diverticulum is intussusception. This occurs owing to residual fibrous attachments to the umbilicus causing a lead point for the proximal bowel to involute onto the distal bowel. It most commonly presents with bloody mucoid stools, abdominal pain, and vomiting in children under age 6 (most commonly within the first 2 years of life). However, other symptoms may occur if ectopic tissue exists in the diverticulum. Gastric ectopic tissue may cause abdominal pain and bloody stools from ulceration of the underlying ileal tissue. Duodenal and pancreatic tissues have been identified in Meckel's diverticulum but are very rare and do not typically cause symptoms.

Diagnosis in adults requires a high level of suspicion and is aided by the use of a technetium 99 m (^{99m}Tc) scan to identify ectopic gastric mucosa in those patients with bleeding and symptoms of ulceration. For children with obstructive signs or symptoms, the diagnosis may be aided by ultrasound and/or computed tomographic scans. Plain film radiographs of the abdomen have low sensitivity and specificity for the diagnosis of intussusception. The sensitivity of the Meckel scan for the pediatric population is 85% to 97% but is much lower in the adult population at 62%. The choice of imaging procedure is dictated by the experience of the radiologic personnel performing the procedure.

Symptomatic Meckel's diverticulum should be surgically resected. Up to 90% of intussusception secondary to Meckel's diverticulum may be reduced utilizing diagnostic ultrasonography in children with saline or pneumatic enema. Treatment of Meckel's diverticulum largely depends on age and symptomatology, because operating on asymptomatic Meckel's diverticulum has been shown to have a fivefold increase in complications such as postoperative bowel obstruction, leaks, ileus, and infection. Many experts have advocated that incidental, asymptomatic Meckel's diverticulum should not be resected. Some experts advocate for selective surgical resection of asymptomatic patients with an incidentally noted Meckel's diverticulum for the following: healthy young children, healthy adults younger than 50 years of age with palpable abnormalities suggestive of heterotrophic tissue, size longer than 2 cm, or a broad base wider than 2 cm.

Colon

Diverticulosis

The colon is where the majority of all diverticula occur in the alimentary tract. Owing to this predominance, this condition is commonly termed *diverticulosis* or *diverticular disease*. Diverticulum of the colon is of the false type. The incidence increases with age. The incidence of left-sided diverticulosis approaches 5% at

age 40 and increases to greater than 60% at age 80. Diverticulosis is most commonly located in the sigmoid colon.

The exact pathogenesis of diverticulosis is unclear. The proposed mechanism of colonic diverticular formation places an emphasis on intraluminal pressure buildup. The pressure across the colonic wall increases as the radius of the wall decreases. Accordingly, the radius is the smallest in the sigmoid colon and thus the most likely location of diverticulosis. Normally, pressure is constant throughout the colon. However, as diverticular disease develops, abnormal pressure segmentations occur, resulting in pressure gradient changes in the colon. With increased pressure, the integrity of collagen and elastin in the wall muscle changes, the circular muscles thicken, colonic segments shorten, and the lumen narrows, leading to propagation of the disease. Several risk factors have been associated with the development of diverticular disease: smoking, lack of physical activity, and obesity. By increasing the amount of dietary fiber, it is theorized that the resultant bulking of the stools may decrease the pressure in the colon lumen and prevent diverticular disease progression. Yet, mixed results have been noted on studies with regard to fiber intake and diverticular development and progression of disease. There is no associated risk with caffeine, alcohol, popcorn, seeds, or nuts with the development of diverticulosis, diverticular bleeding, or diverticulitis.

Colonic Diverticular Bleeding

Diverticula tend to develop where an arteriole penetrates the circular muscle layer of the colon. This results in vessels arching over the dome of the diverticulum. This leaves fragile vessels in a vulnerable position of a relatively thin mucosal layer prone to trauma and resultant diverticular bleeding. Bleeding typically manifests as hematochezia—a darkish to bright red bleeding that is typically characterized as brisk and acute in nature. Diverticulosis is attributed to 30% to 50% of all hematochezia. Fifteen percent of patients will experience at least one episode of bleeding in their lifetime, with a recurrent bleeding risk of up to 38%. Most patients presenting with diverticular bleeding are asymptomatic, but some may experience bloating or cramping.

Selection of the diagnostic modality depends largely on the degree of bleeding and the cardiovascular stability of the patient. Although new technologies are emerging with enhanced computed tomography scanning, their availability is not widespread. Endoscopy is the preferred treatment modality for stable patients owing to its potential for diagnosis and treatment options. Up to 80% of diverticular bleeding can be isolated with direct endoscopic visualization (Figure 3).

Endoscopic failure to identify or control diverticular bleeding may occur in the patient with massive or intermittent bleeding. Hemodynamically unstable patients may have a high complication risk from the bowel preparation, sedation, or the procedure. Radionuclide imaging can be considered in unstable patients, non-diagnostic endoscopy, or bleeding recurrence. Radionuclide imaging requires that bleeding be active (at least 0.05–0.1 mL/min) to accurately isolate the location of the diverticulum. Radionuclide imaging using technetium (^{99m}Tc) sulfur colloid (shorter half-life thus utilized for acute bleeding) or ^{99m}Tc pertechnetate (longer half-life more useful for intermittent bleeding)—labeled autologous red blood cells can be used to isolate the location of obscure gastrointestinal bleeding. However, numerous studies have produced highly variable sensitivities (26% to 91%). Many advocate for radionuclide imaging to be used as an ancillary test for directing more definitive treatments such as surgery or angiography-directed therapies. Angiography can be used if bleeding is active (at least 0.5 mL/min) and can isolate the bleeding location with a diagnostic yield of 40% to 78%. Angiography can be combined with embolization and/or vasopressin infusion to achieve hemostasis; however, complications may occur, including bowel infarction and contrast-induced nephrotoxicity.

Diverticulitis

Diverticulosis is largely asymptomatic. Only about 4% will develop inflammation and infection known as diverticulitis. The

Figure 3 Colonoscopy in a patient with hematochezia from the source isolated to a diverticulum (A) and hemostasis noted after placement of two hemoclips (B). (Courtesy of Janak Shah.) (From Feldman M: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*, 9th ed. Philadelphia, Elsevier, Figure 117-8.)

disease severity and complications occur along a spectrum. The proposed mechanism of diverticulitis may be a blocked diverticulum or trauma-associated mucosal injury. Colonic diverticula become filled with feces and obstruction may occur. With the resultant bacterial overgrowth, expansion of the diverticula occurs. Subsequent vascular compromise and microperforation may occur, leading to localized infection and inflammation. These microperforations are usually sequestered and may lead to small localized abscess formation. This process is generally referred to as uncomplicated diverticulitis. Complicated diverticulitis is classified when a localized abscess or infection infiltrates into adjacent organs or viscera causing macroperforations, fistulas, obstructions, or enlarged abscesses.

The clinical presentation often begins with mild left lower abdominal pain, fever, and leukocytosis. Patients who seek care later in the disease process may present with sepsis or diffuse peritonitis. Initial diagnosis should be accomplished with history, physical examination, radiographic imaging, and laboratory evaluation. Abdominal radiography may indicate severe complications of diverticulitis such as bowel perforation or bowel obstruction. Ultrasonography and magnetic resonance imaging can be used with high levels of sensitivity and specificity in centers with demonstrated expertise. Ultrasonography has sensitivities and specificities of 92% and 90% for the detection of diverticulitis, respectively. With sensitivities and specificities of 94% and 99%, respectively, computed tomography appears to be the imaging test of choice. This is especially true as an alternative diagnosis was more likely to be identified with computed tomography than with ultrasonography (50%–100% vs. 33%–78%). Those patients with a past medical history of diverticulitis may be empirically treated without imaging, although imaging may be needed if no clinical improvement is noted within 48 hours.

Recent data indicates no added benefit with antimicrobial therapy; thus uncomplicated diverticulitis may be treated without antibiotics. Until further studies are done, many experts recommend that traditional treatment should include supportive care and antibiotics for uncomplicated diverticulitis. Outpatient management is reasonable if the diagnosis is made early in the disease process. Uncomplicated diverticulitis responds to medical therapy in the majority of cases. Complicated diverticulitis occurs in 25% of all diverticulitis diagnoses, requiring a surgical evaluation and intervention. Optional antibiotic regimens for gram-negative coverage and anaerobic coverage are listed in Table 1. Inpatient management is recommended with any comorbid conditions, immunosuppression, high-grade fever, or leukocytosis and/or for elderly patients. Patient improvement

TABLE 1 Antibiotic Therapy for Diverticulitis

OPTIONAL REGIMENS	DOSAGE (ADULT)
Uncomplicated Diverticulitis	
Outpatient (10–14 Days)	
Ciprofloxacin (Cipro) and Metronidazole (Flagyl)	500 mg PO bid 500 mg PO tid
Amoxicillin-clavulanate (Augmentin) ¹	875 mg PO bid
Moxifloxacin (Avelox)	400 mg PO daily
Complicated Diverticulitis	
Inpatient Transitioning to Outpatient (10–14 Days Total)	
Piperacillin-tazobactam (Zosyn) ¹	3.375–4.5 g IV every 6 h
Ticarcillin-clavulanate (Timentin)	3.1 g IV every 4 h
Imipenem-cilastatin (Primaxin)	500 mg IV every 6 h
Levofloxacin (Levaquin) ¹ and Metronidazole	500 mg IV every 24 h 500 mg IV every 8 h
Ceftriaxone (Rocephin) and Metronidazole	1 g IV every 24 h 500 mg IV every 8 h

¹Not FDA approved for this indication.

Notes: Clindamycin (Cleocin) may be substituted in metronidazole intolerance/allergy. Antibiotics continued in complicated diverticulitis cases until negative cultures, clinical improvement, or sensitivities obtained on any surgical specimens. Abbreviations: bid = twice a day; tid = three times a day.

Modified from Jacobs DO. Clinical practice. Diverticulitis. *N Engl J Med* 2007;357:2057–2066.

should be seen within 48 hours. Those who do not improve should undergo additional evaluation such as repeat imaging or endoscopy. This is done to evaluate for underlying pathology such as cancer or inflammatory bowel disease, which would change the management strategy.

Follow-up scanning should also be considered for cases of slow-resolving diverticulitis. In up to 10% of computed tomography scans in which diverticulitis was the primary diagnosis, cancer could not be fully excluded. A colonoscopy should be performed to evaluate the extent of diverticular disease and to rule out other comorbid pathology in all patients. Colonoscopy is typically recommended within 3 to 6 weeks after diverticulitis symptoms

Figure 4 Diverticulitis. A, Computed tomography (CT) image demonstrates thickened wall of the sigmoid colon (arrows) with stranding in the adjacent fat (*) indicative of diverticulitis. Fat stranding refers to abnormally increased attenuation of fat from edema and engorgement of lymphatics. B, CT image slightly more caudal demonstrates an air-filled abscess cavity (arrows) with adjacent thickened sigmoid colon wall. (From McNally PR: *GI/Liver Secrets Plus*, 4th ed. *Noninvasive Gastrointestinal Imaging: Ultrasound, Computed Tomography, Magnetic Resonance Imaging*. Philadelphia, Mosby Elsevier, 2010, Figure 70-16.)

have resolved. Introduction of stool softeners and a high-fiber diet should begin immediately and continued indefinitely for all patients to help decrease the intraluminal pressure within the colon.

Diverticulitis that is complicated with abscess formation should be evaluated by a surgeon or radiologist for percutaneous drainage using computed tomography or ultrasonography (Figure 4). Depending on location, drainage tubes may be placed transanally for drainage. A general recommendation exists for consideration of drainage, preferably with interventional radiology localization, for any abscess measuring greater than 3 to 4 cm.

New research to prevent recurrent diverticulitis with medical management is emerging. Mesalamine (Asacol)¹ and rifaximin (Xifaxan)¹, in combination or separately, may help prevent recurrent episodes of diverticulitis. Probiotics⁷ have not been shown to prevent recurrence. Fiber may be used as a beneficial supplement for the prevention of recurrent diverticulitis. Debate exists regarding elective segmental colectomy for patients who have experienced recurrent episodes of diverticulitis. Current recommendations suggest surgical consultation with discussion of the benefits and risks of surgery compared to the risks of recurrent diverticulitis. This discussion should take into account the diverticulitis frequency and severity, the impact on the patient's lifestyle, and the patient's other comorbid conditions. This consultation should at a minimum occur after the fourth recurrence of diverticulitis in patients over age 50. There is insufficient evi-

dence to advise a patient who has experienced fewer than four recurrent cases of diverticulitis or who is younger than age 50 on the benefit of a segmental colectomy.

DYSPHAGIA AND ESOPHAGEAL OBSTRUCTION

Method of

Kumar Krishnan, MD; and John E. Pandolfino, MD

CURRENT DIAGNOSIS

- The evaluation of dysphagia begins with a careful history, though additional diagnostic testing is often required.
- Oropharyngeal dysphagia is best initially evaluated with a video fluoroscopic examination, whereas esophageal dysphagia is best evaluated with endoscopy.
- Esophageal dysphagia with negative endoscopy and biopsy should be evaluated next with esophageal physiological testing (esophageal manometry or endoscopic functional lumen imaging probe EndoFLIP).

¹Not U.S. Food and Drug Administration (FDA) approved for this indication.

⁷Available as dietary supplement.

⁷Available as dietary supplement.

CURRENT THERAPY

- Underlying neuromuscular conditions such as amyotrophic lateral sclerosis, myasthenia gravis, or Guillain-Barré syndrome should be treated accordingly.
- Endoscopic therapy with dilation (often multiple) is the mainstay of treating fibrotic esophageal strictures regardless of etiology.
- Achalasia can be treated surgically or with dilation, which are equally effective. Minimally invasive endoscopic therapy for achalasia is promising and may provide a competing approach.

Dysphagia is a symptom generated by the perceived sensation of difficulty or inability to swallow. It ranges in severity from mild difficulty with no associated clinical sequelae, to a complete inability to swallow with aspiration and severe malnutrition. Dysphagia can coexist with and must be distinguished from odynophagia, which is pain when swallowing, with associated swallowing aversion. The etiology of dysphagia is protean and includes two main categories, mechanical obstruction and motor dysfunction.

Epidemiology

Dysphagia is a common condition. A recent investigation surveyed 790 ambulatory patients who were awaiting their annual primary care visit; 22.6% of patients reported dysphagia at least several times per month. Only half of these patients had discussed their symptoms with their physician. Elderly patients and women were more likely to note symptoms of dysphagia.

Pathophysiology

Effective swallowing and transfer of food bolus into the stomach requires multiple steps. These steps can be broadly placed into two phases: the oropharyngeal phase and the esophageal phase. The oropharyngeal phase of swallowing ultimately transforms the hypopharynx from a respiratory organ to a digestive organ. It requires five main coordinated steps to occur: (1) elevation of the soft palate and closure of the nasopharynx, (2) relaxation of the upper esophageal sphincter (UES), (3) traction opening of the UES, (4) closure of the laryngeal vestibule and, hence, airway protection, and (5) propulsion of the food bolus by the tongue and pharyngeal constrictors. This process is a carefully coordinated neuromuscular phenomenon with both autonomic and volitional components.

The esophageal phase of swallowing begins when a food bolus passes through the UES. During swallowing, the rapidity of bolus transit into the stomach is accomplished primarily by gravity. Esophageal peristalsis is a secondary contributor that functions to strip the bolus and clear the esophagus. Primary peristalsis is associated with oropharyngeal swallowing and propagates down through the predominantly striated muscle esophagus via a sequential activation pattern originating from the brainstem. This continues into the smooth muscle esophagus where it also engages the intrinsic enteric nervous system to promote peristalsis through a similar but distinct mechanism. Secondary peristalsis is stimulated by distention of the proximal esophagus and will generate a propagating peristaltic contraction similar to primary peristalsis without a swallow-induced trigger. The strength, propagation velocity, and order of peristaltic contractions can be altered, and this may lead to motor abnormalities associated with dysphagia.

Diagnosis

Dysphagia is never a normal symptom and always requires additional investigation. The first step in the diagnostic evaluation of dysphagia begins with a careful history to distinguish true dysphagia from other associated conditions such as odynophagia and globus sensation. Odynophagia can coexist with dysphagia; however, the predominant symptom is pain during swallowing. Globus is a sensation of a lump in the throat. It is likely a pharyngeal

hypersensitivity that may coexist with other esophageal diseases or occur alone as a functional disorder. Unlike dysphagia, the symptoms in globus persist between swallows and may actually improve during the swallow.

After the above conditions have been ruled out, the next step focuses on distinguishing oropharyngeal dysphagia from esophageal dysphagia. Unfortunately, patients have a difficult time communicating their symptoms because localization of the point of perceived obstruction is hampered by poor discriminant capacity and may be masked by compensatory mechanisms. Localization of dysphagia to the throat or sternal notch is unreliable because the point of obstruction may be further down in the body. However, localization in the midchest or below is more reliable than the obstruction is esophageal in origin.

As a result, the most useful and underused test for distinguishing oropharyngeal and esophageal dysphagia focuses on observing the patient swallow sips of water in the office. Often this allows the distinction between oropharyngeal and esophageal dysphagia to become apparent. Patients with oropharyngeal dysphagia will have difficulty almost immediately after initiating a swallow, such as coughing, choking, and nasal regurgitation. Patients who can initiate a swallow without difficulty, but note symptoms soon after the swallow, are likely to have esophageal dysphagia. Furthermore, this exercise may be able to elicit associated odynophagia or regurgitation.

Physical examination plays a minor role in evaluating dysphagia outside of assessing the patient's baseline status to rule out malnutrition and dehydration because this will determine whether an expedited evaluation is required. A careful assessment of the oropharynx and a careful neck examination may unmask a mass lesion, and a neurologic examination should be performed if oropharyngeal dysphagia is suspected. Additionally, a skin examination and assessment of the oropharyngeal mucosa may be helpful in assessing for potential dermatologic diseases that are associated with esophageal dysphagia. Regardless of findings, most patients will ultimately be referred for diagnostic testing, and this is dependent on the anatomic zone of interest—oropharyngeal versus esophageal (Figure 1).

Diagnostic Testing

Oropharyngeal Dysphagia

Once a distinction is made that the patient is experiencing oropharyngeal dysphagia, the next step in the evaluation should be referral for a video fluoroscopic swallowing examination, also known as a modified barium study. Standard upper endoscopy is of limited value given the general inability to evaluate lesions in the hypopharynx and the upper esophageal sphincter. Video fluoroscopic swallow examinations have the added benefit of providing functional information in addition to anatomic information. They differ from a standard fluoroscopic examination (i.e., esophogram) by offering the patient various radiopaque food items of different consistency and are often performed by a speech pathologist. They can evaluate delay in initiation of pharyngeal swallowing, aspiration of solids and liquids, retrograde flow of ingested bolus, and residual pharyngeal contents.

If there is a suspicion for a malignancy or mechanical obstruction, a referral to otolaryngology is required. Direct laryngoscopy is used to evaluate for anatomic lesions in the nasopharynx and hypopharynx. In addition to anatomic abnormalities, function can be assessed by having the patient drink liquids with the nasal endoscope positioned in the hypopharynx. Oropharyngeal pooling of liquid indicates ineffective hypopharyngeal clearance and can suggest a high aspiration risk. Cross-sectional imaging is often an adjunct to the functional assessment of videoscopic imaging or direct laryngoscopy when an obstruction is noted without a clear lesion noted on direct examination.

Esophageal Dysphagia

If oropharyngeal dysphagia is excluded on history, the evaluation of dysphagia should proceed to upper endoscopy to rule out a mechanical obstruction. Although an esophogram can be used to

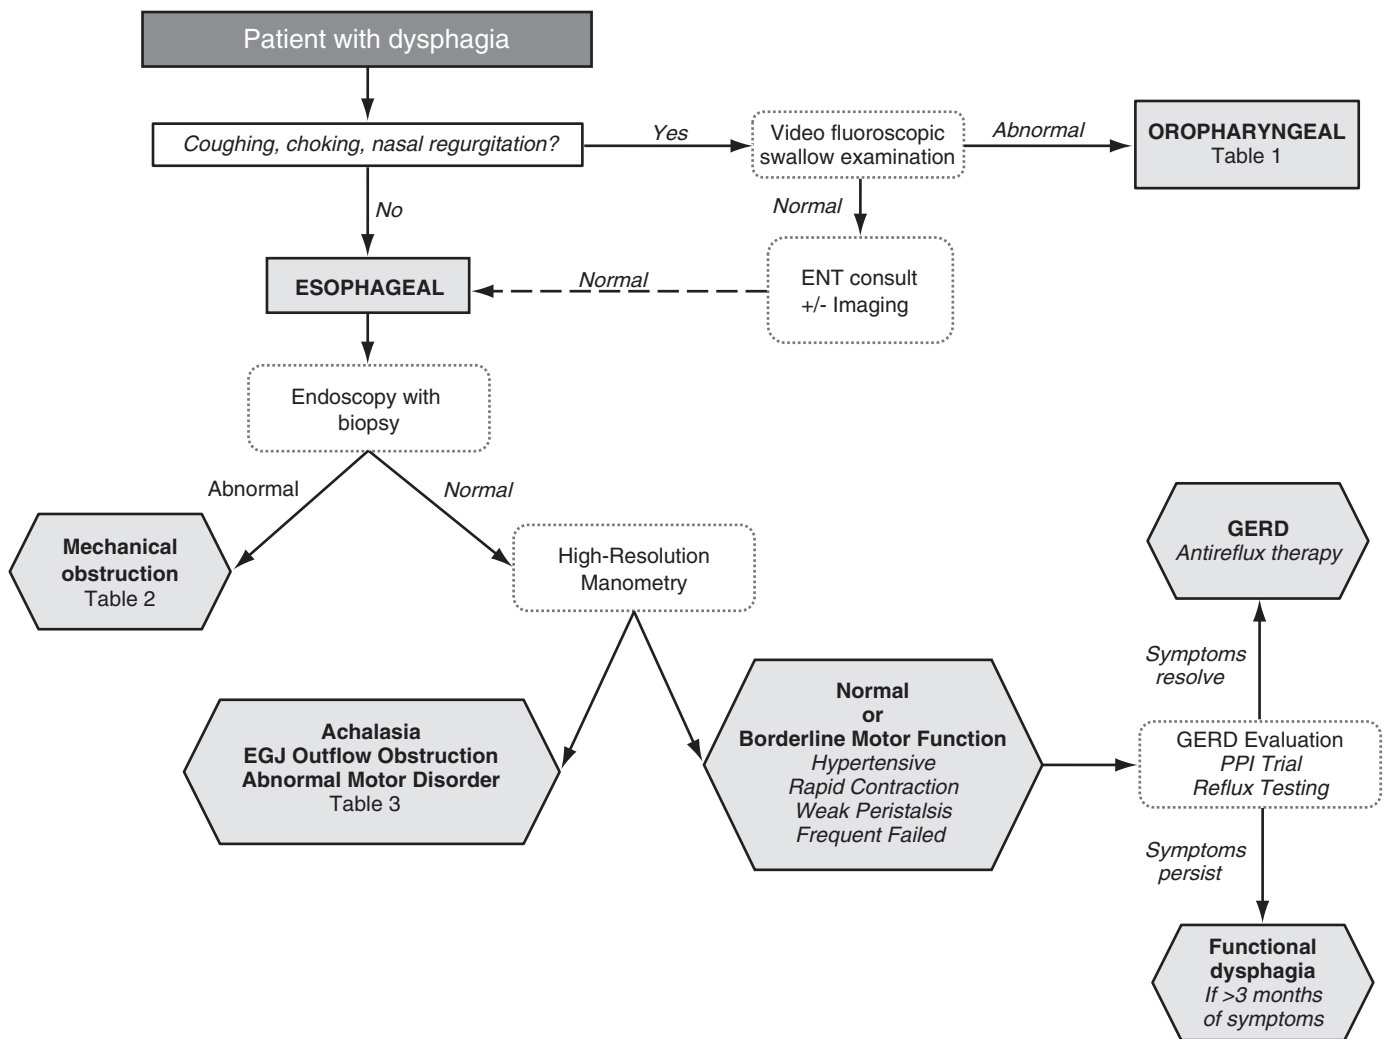

Figure 1 The workup of dysphagia and esophageal obstruction. The first step in the workup of dysphagia focuses on distinguishing oropharyngeal from esophageal dysphagia, which can be done with a history and careful assessment of swallowing during liquid swallows. The workup once this distinction is made is very different. Oropharyngeal dysphagia is typically evaluated by speech pathology and otolaryngology (ENT) based on the results of a video fluoroscopic swallow evaluation. Esophageal dysphagia is evaluated primarily with endoscopy because biopsies and interventions are often required. The primary indication for manometry is to rule out a major motor disorder in patients with a negative endoscopy. Alternatively, the functional lumen imaging probe (FLIP) can be utilized at the time of endoscopy to assess for a primary motor disorder. If a major motor abnormality is not seen on manometry or FLIP, a diagnosis of functional dysphagia should be considered; however, underlying GERD must also be addressed.

assess for obstruction, most patients will eventually require endoscopy to obtain biopsies to rule out malignancy or eosinophilic esophagitis. Additionally, endoscopy has the added benefit of being therapeutic in some circumstances, and thus it is more cost-effective to begin the evaluation with endoscopy. If the endoscopy is negative, the next step is to evaluate for an underlying esophageal motor disorder. This is traditionally done by performing esophageal manometry. Recently, a novel method of assessing esophageal motor function has been developed. The functional lumen imaging probe (FLIP) is a catheter that can be placed at the time of endoscopy. Using a variety of sensors positioned along the length of the probe, it measures diameter and pressure along the esophagus. This information can be used to evaluate for contractility of the esophageal body and esophageal distensibility at the EGJ, thus providing a comprehensive assessment of esophageal motility (Carlson DA AJG). If these studies are negative, a careful evaluation for the presence of gastroesophageal reflux disease (GERD) should be performed and if suspected, the patient may benefit from ambulatory reflux testing or an empiric trial of proton pump inhibitors. Patients with no evidence of obstruction, abnormal esophageal motor function, or evidence of GERD may be classified as having functional dysphagia if the symptoms fulfill the Rome III

consensus (onset greater than 6 months before presentation with 3 months of symptoms).

Oropharyngeal Dysphagia Differential Diagnosis

The etiology of oropharyngeal dysphagia can be broadly separated based on neuromuscular causes and anatomic causes (Table 1). The most common neurologic cause is cerebrovascular accident (CVA), with an incidence reported between 20% and 80%. CVAs involving the cerebrum, cerebellum, and brainstem can each lead to swallow dysfunction. Cerebral CVA can lead to impairment in mastication and the oral phase of swallowing and can interrupt normal pharyngeal peristalsis. CVA involving the brainstem can lead to disruption of the sensory afferents in the pharynx that help trigger pharyngeal swallow, and can also lead to motor dysfunction of laryngeal elevation, glottic closure, and cricopharyngeal relaxation/opening. Tumors in these areas can also produce similar effects.

A variety of neuromuscular disease can lead to bulbar symptoms, which manifest as dysphagia. This includes myasthenia gravis, amyotrophic lateral sclerosis (ALS), and Guillain-Barré syndrome (GBS). Clinicians need to be able to identify systemic

TABLE 1 Oropharyngeal Dysphagia**Iatrogenic**

Structural

- Cricopharyngeal bar
- Zenker's diverticulum
- Cervical webs
- Oropharyngeal tumors
- Osteophytes and skeletal abnormalities
- Congenital abnormalities (cleft palate, diverticula, pouches, etc.)

manifestations of these conditions because dysphagia can often be the first manifestation of neuromuscular disorders.

The most common structural abnormalities of the hypopharynx associated with dysphagia are hypopharyngeal diverticula and cricopharyngeal bars. Acquired hypopharyngeal diverticula are most common in men after age 60 and typically present with symptoms of dysphagia, halitosis, post-swallow regurgitation, or even aspiration of material from the pharyngeal pouch. Hypopharyngeal diverticula are the result of a restrictive myopathy associated with diminished compliance of the cricopharyngeus muscle. The treatment of hypopharyngeal diverticula is cricopharyngeal myotomy with or without a diverticulectomy. Good or excellent results can be expected in 80% to 100% of Zenker's patients treated by transcervical myotomy combined with diverticulectomy or diverticulopexy. Small diverticula may spontaneously disappear following myotomy.

Other anatomic causes associated with oropharyngeal dysphagia that should be considered are cervical osteophytes and head and neck cancers. Cervical osteophytes are associated with cervical spine arthritis and may be confused with a cricopharyngeal bar because the dysphagia is structural and localized to the area of the upper esophageal sphincter. It is easily differentiated on contrast studies because the cervical osteophyte can be seen impinging on the upper sphincter. Additionally, head and neck lesions of the larynx, tonsil, tongue, oral cavity, vocal cord, and nasopharynx may also impair bolus transit into the esophagus. Rapid weight loss in a patient with oropharyngeal dysphagia warrants further evaluation for malignancy; however, it is often difficult to distinguish weight loss resulting from malignancy from weight loss secondary to dysphagia. Constitutional symptoms (night sweats, fever, etc.) associated with oropharyngeal dysphagia should raise the suspicion for lymphoma.

Management

The management of oropharyngeal dysphagia is dependent on the underlying cause. Neuromuscular conditions such as stroke may respond to speech therapy and rehabilitation. Systemic neuromuscular dysfunction from conditions such as myasthenia gravis, GBS, or ALS will require treatment of the underlying condition. Patients who cannot safely take oral nutrition may need a temporary enteral feeding tube until swallow function is intact.

Management of dysphagia in patients with head and neck cancers requires a multidisciplinary approach and treatment of the underlying malignancy. Some patients are able to take adequate nutrition with dietary modification (soft or full liquid diet) while undergoing therapy. Patients who are losing weight, are dehydrated, or are unable to meet nutritional requirement by dietary modification alone may require enteral nutrition in the form of a gastrostomy tube. Although endoscopic gastrostomy tube placement is typically safe, and routinely performed in patients with head and neck cancer, there are reports of seeding the gastrostomy tube tract with malignant cells from the pharynx. In such circumstances, a direct gastrostomy tube placed by a radiologist may be preferable.

Esophageal Dysphagia

Esophageal dysphagia can be easily separated into mechanical causes and motor abnormalities after upper endoscopy is performed. Mechanical causes can be further separated into malignant and benign causes of dysphagia, and motor disorders can be conceptualized as primary motor abnormalities versus borderline motor abnormalities. Patients who have symptoms in the context of a normal endoscopy (negative biopsies for eosinophilic esophagitis) and no evidence of a primary motor disorder may also have underlying GERD or functional dysphagia (see [Figure 1](#)).

Differential Diagnosis: Mechanical Obstruction (Table 2)**Stricture**

Fibrotic esophageal strictures are common and can be caused by erosive esophagitis (peptic stricture), radiation therapy, surgical anastomosis, eosinophilic esophagitis, and desquamating lesions (pemphigus, lichen planus, etc.). Peptic strictures are common and are the result of long-standing erosive esophagitis. They typically occur in the distal esophagus. Such patients often have underlying physiologic derangements that favor aggressive reflux (weak lower esophageal sphincter, hiatal hernia, poor esophageal clearance). Postsurgical anastomotic strictures are an unfortunate consequence of surgical therapy for esophageal disease, but these lesions are often amenable to endoscopic therapy.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) requires some focused discussion because its prevalence in patients presenting with dysphagia is increasing. EoE is a condition characterized by marked eosinophilic infiltrate within the esophageal epithelium. This infiltrate results in characteristic endoscopic findings of esophageal rings, furrows, exudate, and eventually stricture formation. The most

TABLE 2 Esophageal Dysphagia (Mechanical)

Tumors (lymph nodes, lung cancer)
Infection (histoplasmosis, tuberculosis)
Vascular compression
Dysphagia lusoria
Dysphagia aortica

common symptom in patients with EoE is dysphagia, which often leads to food bolus impaction. Patients are typically young Caucasians and there is a clear male predominance. Atopic conditions are more prevalent in patients with EoE. Patients should initially be treated with proton pump inhibitor (PPI) therapy because there is an overlap between GERD and EoE. Patients with persistent eosinophilia on PPI therapy can be treated by swallowing inhaled formulations of steroids (fluticasone [Flovent],¹ budesonide [Pulmicort]¹) or a food elimination diet (avoid: soy, nuts, wheat, eggs, dairy, seafood) to reduce the inflammatory component of the disease. Additional therapy with dilation will be required in many patients because histologic improvement does not always result in regression of fibrotic strictures. The esophageal body is more prone to fracture in EoE, and deep mucosal tears are often associated with dilation therapy; thus these lesions may require a more gradual and careful dilation protocol.

Rings/Webs

Esophageal webs can exist along the length of the esophagus and lead to dysphagia. The classic triad of proximal esophageal web, iron deficiency anemia, and dysphagia is Plummer-Vinson syndrome. The etiology of this condition is not entirely known; however, it is thought that iron deficiency leads to a decrease in iron-dependent oxidative enzymes, which results in degradation of esophageal tissue, resulting in web formation. Interestingly, iron supplementation alone may result in resolution of symptoms. Whereas Plummer-Vinson syndrome is a rare condition, esophageal webs are relatively common and should prompt an evaluation for caustic pill injury if localized to the transition zone along the aortic impression or distal esophagus. Medications that can be associated with pill esophagitis include NSAIDs, tetracycline, iron, bisphosphonates, potassium, and quinidine.

Malignancy

Dysphagia is often the presenting symptom in a patient with esophageal cancer. There are two subtypes of mucosal cancer in the esophagus, squamous cell and adenocarcinoma. In general, esophageal cancer has a male predominance and is slightly more prevalent among African Americans. The racial disparity is largely due to squamous cell carcinoma, which has noted a sharp decline since the 1960s. Adenocarcinoma tends to be a disease of white men (SEER database). Squamous cell carcinoma typically occurs in the mid esophagus, whereas adenocarcinoma is localized to the distal esophagus where it is associated with intestinal metaplasia (Barrett's esophagus).

Management for Esophageal Obstruction

Endoscopic dilation therapy is the most common therapeutic intervention for patients with nonmalignant mechanical dysphagia. This can be done with a single, large-diameter dilating balloon or semirigid bougie over a guide wire. There has not been any convincing data to demonstrate superiority of balloon dilators over bougie dilators. In cases of membranous webs or Schatzki rings, the goal of endoscopic therapy is to tear the lesion with a single, large-diameter dilation. In the case of a Schatzki ring, postdilation PPI therapy is associated with decreased recurrence rates.

When treating fibrotic strictures (peptic, anastomotic, radiation, EoE), the goal should be gradual stretching of the stricture. The choice of initial dilation size is based on an estimate of the diameter of the stricture. The extent to which a stricture can be dilated is expressed by the endoscopic axiom of the "rule of threes." This refers to the approach whereby the diameter of the stricture is approximated, and no more than three subsequent dilations are performed at 1-mm intervals once resistance is noted. Although there is no controlled trial for support, this approach is used to minimize the most serious risks of dilation therapy, perforation, and bleeding.

In patients with refractory strictures despite dilation therapy, several therapies have been attempted with variable efficacy. Temporary self-expanding stents have been placed to maintain lumen patency. When placed across a stricture, stents serve two purposes. First, they relieve symptoms of dysphagia by maintaining a patent lumen. In addition, the self-expanding nature of the stent provides ongoing radial force, which gradually stretches the lumen. The main disadvantage of stents is their tendency to migrate. Plastic and biodegradable stents are currently not available, but may be promising in the future.

An alternative endoscopic approach is incisional therapy with an electrocautery knife. This is used to make incisions in the mucosa and fibrotic submucosa. This approach has been best studied in the setting of refractory anastomotic strictures; however, no head-to-head comparisons have been made between incisional therapy and other modalities.

Treatment of malignant etiologies for dysphagia will ultimately depend on the tumor type and extent of disease. Benign tumors and early-stage lesions can be treated with endoscopic resection or surgery. Endoscopic therapy using stents is also an important component of the treatment of malignancy and may be used during the treatment phase of malignant disorders or as a palliative technique for later-stage disease.

Differential Diagnosis: Motility Disorders (Table 3)

Esophageal motor disorders are defined based on patterns of contractile vigor, propagation, and the presence of deglutitive relaxation. Multiple classifications have been proposed; however, a new technique using a more advanced high-resolution manometric system that provides greater detail and accuracy has become available. This classification scheme is based on previous conventional schemes with modifications based on refining disorders into clinically relevant phenotypes.

Achalasia

The diagnosis of achalasia is made by esophageal manometry and requires two main manometric criteria: (1) inability of the lower esophageal sphincter to relax and (2) absence of peristalsis. Recently achalasia has been subdivided into three different

TABLE 3 Esophageal Dysphagia (Abnormal Motor Function)

phenotypes using high-resolution manometry, which are associated with varying clinical outcomes. Patients typically describe both solid and liquid dysphagia. Other common symptoms are regurgitation (especially nocturnal), chest pain, and aspiration. Weight loss and malnutrition may be dominant symptoms as the disease progresses. Given that there is no treatment to reverse absent peristalsis, the treatment is focused on improving esophago-gastric junction (EGJ) opening by disrupting the poorly relaxing lower esophageal sphincter. This can be accomplished using pneumatic dilation with rigid balloons ranging in size from 3 to 4 cm or surgical myotomy. It appears that the two treatment approaches are associated with good outcomes with surgery having a more durable single intervention success rate and pneumatic dilation typically requiring multiple sessions. Botulinum toxin type A (Botox)¹ injected into the lower esophageal sphincter has been shown to reduce EGJ pressure and improve symptoms; however, this treatment only provides temporary relief and should only be reserved for poor surgical candidates or patients unwilling to undergo surgery or dilation. Occasionally, esophageal dilatation may progress to a point where treatment with pneumatic dilation and myotomy are not adequate and esophagectomy must be performed to prevent severe complications, such as aspiration and severe malnutrition.

Esophagogastric Junction Outflow Obstruction

This pattern of motor disturbance is associated with preserved peristalsis and evidence of high pressures through the EGJ during swallowing. This may be an achalasia variant or could be associated with a subtle obstruction at the distal esophagus not evident on endoscopy. Thus recognition of this pattern should prompt an evaluation for an infiltrating tumor or other potential etiology of obstruction. Treatment is focused on the underlying cause of the obstruction.

Absent Peristalsis

Absent peristalsis is defined as complete absence of contractile activity on all swallows in the context of a normal or low EGJ relaxation pressure. This pattern was previously categorized as scleroderma esophagus if it was found in the context of a hypotensive lower esophageal sphincter; however, this has been abandoned because this pattern may be found in patients with severe GERD without scleroderma. Treatment is focused on aggressive antireflux therapy and lifestyle modifications to reduce dysphagia and caustic injury to the esophagus.

Distal Esophageal Spasm

Distal esophageal spasm is a rare primary motor disorder that may present with dysphagia and chest pain. It is associated with impaired deglutitive inhibition of the esophageal body and results in unopposed activation of the cholinergic intrinsic neurons resulting in premature contractions associated with a rapid contractile velocity. The premature contraction is the most important aspect of this disorder and this has replaced an emphasis on peristaltic velocity because high-resolution manometry has shown that rapid contractions are usually associated with weak contractions. Treatment for this disorder is extremely difficult and focuses on medical management with smooth muscle relaxants, such as calcium channel blockers,¹ nitrates,¹ and 5-phosphodiesterase inhibitors.¹

Jackhammer

Jackhammer esophagus is an extreme form of nutcracker esophagus associated with contractile vigor not encountered in asymptomatic controls or under normal conditions. Previous definitions for hypertensive esophagus had a significant overlap with data from cohorts of asymptomatic controls, and thus the clinical significance of these disorders was unclear. This pattern is associated with dysphagia and chest pain and is typically treated similar to distal esophageal spasm. This motor pattern can also be seen with distal esophageal obstruction, and this should be considered in the

differential diagnosis because it would alter management to focus on the obstruction.

Borderline Motor Abnormalities

Borderline motor abnormalities are those associated with ineffective esophageal motility and mild abnormalities of peristaltic propagation (rapid contraction) or hypertensive contraction. These disorders are not considered to be primary motor disorders, and secondary cause for symptoms, such as GERD and visceral sensitivity, should be considered and treated.

Monitoring

Patients with dysphagia or esophageal obstruction should be monitored for three important complications:

- Evidence of aspiration and nocturnal regurgitation because these can be associated with severe complications, such as chemical pneumonitis and aspiration pneumonia.
- Malnutrition and dehydration because this may prompt more aggressive therapy or consideration of non-oral feeding methods.
- Progressive symptoms because this could lead to progression of the disease and early therapy may avoid the above complications.

phenotypes using high-resolution manometry, which are associated with varying clinical outcomes. Patients typically describe both solid and liquid dysphagia. Other common symptoms are regurgitation (especially nocturnal), chest pain, and aspiration. Weight loss and malnutrition may be dominant symptoms as the disease progresses. Given that there is no treatment to reverse absent peristalsis, the treatment is focused on improving esophago-gastric junction (EGJ) opening by disrupting the poorly relaxing lower esophageal sphincter. This can be accomplished using pneumatic dilation with rigid balloons ranging in size from 3 to 4 cm or surgical myotomy. It appears that the two treatment approaches are associated with good outcomes with surgery having a more durable single intervention success rate and pneumatic dilation typically requiring multiple sessions. Botulinum toxin type A (Botox)¹ injected into the lower esophageal sphincter has been shown to reduce EGJ pressure and improve symptoms; however, this treatment only provides temporary relief and should only be reserved for poor surgical candidates or patients unwilling to undergo surgery or dilation. Occasionally, esophageal dilatation may progress to a point where treatment with pneumatic dilation and myotomy are not adequate and esophagectomy must be performed to prevent severe complications, such as aspiration and severe malnutrition.

Esophagogastric Junction Outflow Obstruction

This pattern of motor disturbance is associated with preserved peristalsis and evidence of high pressures through the EGJ during swallowing. This may be an achalasia variant or could be associated with a subtle obstruction at the distal esophagus not evident on endoscopy. Thus recognition of this pattern should prompt an evaluation for an infiltrating tumor or other potential etiology of obstruction. Treatment is focused on the underlying cause of the obstruction.

Absent Peristalsis

Absent peristalsis is defined as complete absence of contractile activity on all swallows in the context of a normal or low EGJ relaxation pressure. This pattern was previously categorized as scleroderma esophagus if it was found in the context of a hypotensive lower esophageal sphincter; however, this has been abandoned because this pattern may be found in patients with severe GERD without scleroderma. Treatment is focused on aggressive antireflux therapy and lifestyle modifications to reduce dysphagia and caustic injury to the esophagus.

Distal Esophageal Spasm

Distal esophageal spasm is a rare primary motor disorder that may present with dysphagia and chest pain. It is associated with impaired deglutitive inhibition of the esophageal body and results in unopposed activation of the cholinergic intrinsic neurons resulting in premature contractions associated with a rapid contractile velocity. The premature contraction is the most important aspect of this disorder and this has replaced an emphasis on peristaltic velocity because high-resolution manometry has shown that rapid contractions are usually associated with weak contractions. Treatment for this disorder is extremely difficult and focuses on medical management with smooth muscle relaxants, such as calcium channel blockers,¹ nitrates,¹ and 5-phosphodiesterase inhibitors.¹

Jackhammer

Jackhammer esophagus is an extreme form of nutcracker esophagus associated with contractile vigor not encountered in asymptomatic controls or under normal conditions. Previous definitions for hypertensive esophagus had a significant overlap with data from cohorts of asymptomatic controls, and thus the clinical significance of these disorders was unclear. This pattern is associated with dysphagia and chest pain and is typically treated similar to distal esophageal spasm. This motor pattern can also be seen with distal esophageal obstruction, and this should be considered in the

differential diagnosis because it would alter management to focus on the obstruction.

Borderline Motor Abnormalities

Borderline motor abnormalities are those associated with ineffective esophageal motility and mild abnormalities of peristaltic propagation (rapid contraction) or hypertensive contraction. These disorders are not considered to be primary motor disorders, and secondary cause for symptoms, such as GERD and visceral sensitivity, should be considered and treated.

Monitoring

Patients with dysphagia or esophageal obstruction should be monitored for three important complications:

- Evidence of aspiration and nocturnal regurgitation because these can be associated with severe complications, such as chemical pneumonitis and aspiration pneumonia.
- Malnutrition and dehydration because this may prompt more aggressive therapy or consideration of non-oral feeding methods.
- Progressive symptoms because this could lead to progression of the disease and early therapy may avoid the above complications.

GASTRITIS AND PEPTIC ULCER DISEASE

Method of

Kyle Vincent, MD

CURRENT DIAGNOSIS

- Diagnosis of gastritis and peptic ulcer disease (PUD) is based on history of dyspepsia and elimination of other conditions.
- *Helicobacter pylori* (*H. pylori*) and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most common cause of ulcer disease. Hypersecretory conditions such as Zollinger-Ellison syndrome are rare.
- If testing for *H. pylori* is indicated (test and treat strategy), IgG antibody, urea breath test, and fecal antigen test are available.

¹Not FDA approved for this indication.

- Young patients with no “warning signs” can usually be managed on an outpatient basis without immediate endoscopy.
- Patients older than 55 with bleeding, anemia, loss of more than 10% of body weight, dysphagia, odynophagia, early satiety, history of previous malignancy, lymphadenopathy, abdominal mass, or a previously documented ulcer should undergo upper endoscopy promptly.

CURRENT TREATMENT

- The two principal strategies are empiric treatment or test and treat.
- In areas with an *H. pylori* infection rate of less than 10% a 4–8 week course of proton-pump inhibitors (PPIs) given empirically is appropriate.
- In patients who fail empiric PPI treatment or in areas with an *H. pylori* infection rate of greater than 10%, a test and treat strategy should be employed. A verified noninvasive *H. pylori* test should be used.
- First-line treatment of *H. pylori* consists of a PPI, clarithromycin (Biaxin), and amoxicillin (Amoxil) all taken twice a day for 14 days.
- Test of cure should be undertaken in any patient treated for *H. pylori*.
- NSAIDs should be discontinued or standard dose PPI for ulcer prophylaxis used to treat any dyspepsia.

Epidemiology

An estimated four million Americans have active gastric ulcers with 350,000 new cases diagnosed each year. The lifetime prevalence of this condition is around 10%. The incidence was previously higher in men but is currently equal in men and women. Familial clustering is now believed to result from transmission of *Helicobacter pylori* (*H. pylori*) from person to person or a genetic predisposition to infection with *H. pylori* rather than a genetic predisposition to gastric ulcers.

Risk Factors

Most gastric and duodenal ulcers can be attributed to *H. pylori*, NSAID use, severe physiologic stress, or hypersecretory conditions. In America, 10% of young adults harbor *H. pylori* infections, and this incidence increases with age. Lower socioeconomic status and recent immigration from areas with high rates of infection also increase the incidence of *H. pylori* infection. Hypersecretory conditions such as Zollinger-Ellison syndrome are rare, estimated to be responsible for only 0.1% of all ulcers. These conditions should not be routinely considered except in refractory or recurrent cases or in patients who have multiple ulcers.

Pathophysiology

The low pH of gastric acid is required to kill ingested bacteria and to promote proteolysis and activation of pepsin. Postprandial gastric acid production is stimulated by expression of gastrin from G cells and is inhibited in a negative feedback loop by somatostatin from antral D cells. Contrary to previous beliefs, peptic ulcer disease is not simply due to excessive acid production. Almost all patients with gastric ulcer have normal acid production and only one-third of patients with duodenal ulcer have evidence of increased acid production. The protective mechanisms of the mucosa play an important role in maintaining mucosal integrity.

The gastric and duodenal mucosa forms a gelatinous layer that is impermeable to gastric acid and pepsin. Mucosal blood flow as well as the production of mucus and bicarbonate secretion are largely regulated by E type prostaglandins (PGE). Anything that can disrupt the balance between acid production and the protective barrier has the potential to cause loss of mucosal integrity and

tissue exposure to gastric acid and pepsin with subsequent inflammation and potential ulceration.

Two major mechanisms contribute to gastritis and/or ulcer formation. *H. pylori* is a gram-negative curved rod that produces ammonia to control the surrounding pH. Ammonia is toxic to epithelial cells, causing gastritis or duodenitis and damaging mucosal integrity. Many patients with gastritis also have a marked decrease in the number of somatostatin secreting antral D cells, leading to diminished feedback to control acid secretion during gastrin stimulation.

Prevention

The United States Preventative Task Force does not currently recommend routine screening for *H. pylori* in asymptomatic individuals. Prevention is based on avoidance or minimization of risk factors. Long-term NSAID use should be avoided. Prophylactic antisecretory medication should be considered when prolonged NSAID use is necessary. Proton pump inhibitors (PPIs) have better protective efficacy than histamine receptor antagonists (H2RAs) when prolonged NSAID use is necessary. Patients with a previous history of ulcer disease who use steroids or are older than 65 years of age should strongly be considered for prophylaxis with an antisecretory medication. Because of the high risk of gastric ulceration, prophylaxis is recommended for patients experiencing severe physiologic stress such as mechanical ventilation for longer than 48 hours, hypoperfusion, high dose corticosteroids, and large surface area burns (>35% total body surface). Histamine receptor antagonists such as famotidine (Pepcid),¹ cimetidine (Tagamet),¹ and ranitidine (Zantac)¹ or PPIs are recommended. No agent has shown to be clearly superior for prophylaxis in patients on steroids or undergoing physiologic stress.

No immunization against *H. pylori* is currently available but early stage animal trials are in progress.

Clinical Manifestations

Dyspepsia is defined by the American College of Gastroenterology as chronic or recurrent pain or discomfort centered in the upper abdomen. Discomfort is defined as a subjective negative feeling that is not painful. Discomfort can incorporate a variety of symptoms including early satiety or upper abdominal fullness. A thorough history alone is usually sufficient to establish the diagnosis and to differentiate gastritis and peptic ulcers from other common conditions, though gastritis and peptic ulcer disease are difficult to differentiate from each other. Patients with peptic ulcer disease tend to have symptoms more pronounced with food intake. A patient with a duodenal ulcer usually reports increased pain 2–3 hours after a meal; conversely, a patient with a gastric ulcer tends to have pain precipitated or exacerbated by food intake. However, these classical findings are not reliable diagnostic indicators. Physical examination is important to rule out serious complications from peptic ulcer disease. Patient with a rigid abdomen, rebound tenderness, or guarding should be evaluated with imaging and by a surgeon to rule out perforation. The most common physical finding in peptic ulcer disease is tenderness in the epigastrium.

Differential Diagnosis

The differential diagnosis for gastritis and peptic ulcer disease is broad given its nonspecific nature, but can be narrowed down fairly quickly by a good initial history. The differential diagnosis includes gastroesophageal reflux disease (GERD), cardiac disease, gastric cancer, pancreatitis, pancreatic neoplasm, biliary disease including cholelithiasis or cholecystitis, delayed gastric emptying, or bowel ischemia. Patients presenting with a predominant complaint of heartburn or abdominal pain with heartburn more than once per week should be considered to have GERD until proven otherwise. Any symptoms associated with dyspnea or chest pressure should raise concern for a cardiac etiology. Biliary pain often radiates to the right shoulder and is associated with fatty or greasy

¹Not FDA approved for this indication.

foods. Patients with pancreatitis usually describe a severe boring type pain in the epigastrium. They may also get relief from leaning forward.

Diagnosis

While most dyspepsia symptoms can be treated on a nonurgent basis, specific “warning signs” should prompt referral or performance of upper endoscopy. These include age 55 or older, bleeding, anemia, loss of more than 10% of body weight, dysphagia, odynophagia, early satiety, history of previous malignancy, lymphadenopathy, abdominal mass, or a previously documented ulcer.

H. pylori testing is a cornerstone of managing dyspepsia. However, most other laboratory studies are usually not helpful in establishing the diagnosis in uncomplicated peptic ulcer disease or gastritis but may be helpful in eliminating other conditions in the differential diagnosis.

Noninvasive Testing

Antibody Test—Serum IgG antibodies are typically present at 21 days after the onset of *H. pylori* infection but can persist long after active infection. Antibody testing has a sensitivity of 85% and specificity of 79%. The positive predictive value is greatly influenced by the prevalence of the organism in the community and therefore it is less useful in areas with lower rates of *H. pylori* infection. The excellent negative predictive value makes IgG testing a good screening test. However, given that the IgG antibodies can persist for up to a year or longer after infection, it is not as helpful in the acute phase.

Urea Breath Test—This test identifies infection through urease activity. The patient ingests urea labeled with either ^{13}C or ^{14}C . In the presence of *H. pylori*, urease activity produces labeled CO_2 that is expired and can be collected and measured. Sensitivities and specificities of this test exceed 95%. It maintains a strong positive and negative predictive value despite the prevalence of *H. pylori*, but the test is not universally available.

Fecal Antigen Test—This assay uses either polyclonal or monoclonal antibodies to identify *H. pylori* antigens in the stool. The sensitivity and specificity exceed 90% in most studies. Like the breath test, it is unaffected by prevalence, however, both tests are affected by previous exposure to bismuth, antibiotics, and PPIs.

Treatment

The treatment of dyspepsia was revolutionized in the 1990s following the discovery of the role of *H. pylori* in pathogenesis. For patients who present with dyspepsia but no “warning signs,” two separate and approximately equivalent treatment strategies are recommended. The “test and treat” option recommends using a validated noninvasive test for *H. pylori* and treatment of positive tests. The “empiric” acid suppression option recommends treating with a PPI for 4–8 weeks without testing for *H. pylori*. The test and treat strategy is recommended for populations where the *H. pylori* infection rate is higher than 10%, in patients with active or past PUD, low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphoma, or history of endoscopic resection of early gastric cancer. As the US prevalence varies from 10% to 40% in different communities, either strategy may be appropriate. The test and treat strategy is more appropriate for most urban areas and in communities with a high immigrant population or known high rates of *H. pylori* infection. In populations with low *H. pylori* prevalence, such as high socioeconomic areas, empiric acid suppression is an appropriate first strategy, followed by *H. pylori* testing in those patients who have continued symptoms (Figure 1).

The recommendations for eradication of *H. pylori* were updated by the American College of Gastroenterology in 2017. Previous regimens had focused on specific PPI medications. This has been replaced with a general recommendation for standard or double dose PPI of choice. There are two key considerations for selection for initial treatment: (1) Is there a penicillin allergy? and (2) Has there been any previous macrolide exposure for any reason? Current first-line treatment is the so-called triple therapy with standard

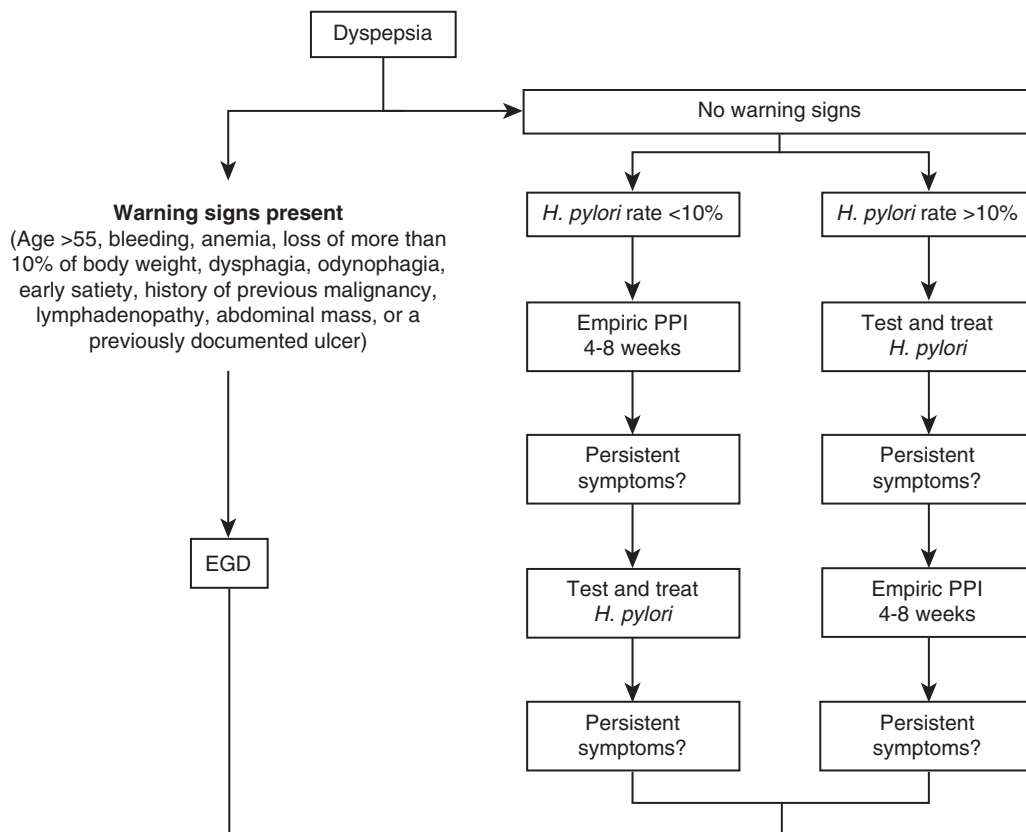

Figure 1 The treatment of dyspepsia.

or double dose PPI, clarithromycin (Biaxin), and amoxicillin (Amoxil) for 14 days. This regimen has an eradication rate of 70% to 85%. Studies show no statistical difference between 7- and 10-day treatment regimens; however, there were trends toward higher eradication rates with the longer regimen. In addition, these studies have not been duplicated in the U.S. population where 7-day regimens have shown efficacy rates below 80%. Therefore, regimens less than 10 days are not recommended and 14-day treatment should be considered. In patients who are penicillin allergic, metronidazole (Flagyl)¹ may be substituted for amoxicillin, but resistance rates for metronidazole are more than double those for amoxicillin. Second-line therapy for those with previous macrolide exposure or penicillin allergy is the so-called quadruple therapy. This consists of standard dose PPI, bismuth subcitrate,² tetracycline (Sumycin),¹ and metronidazole (Flagyl).¹ Bismuth subcitrate, metronidazole, and tetracycline are available as a combination product, Pylera, which is approved to use with omeprazole for the treatment of patients with *H. pylori* infection and duodenal ulcer disease. There are multiple other regimens with similar eradication rates in European studies that have not been well validated in North America. Nonetheless, they are recommended by the American College of Gastroenterology and can be used for patients who are having difficulty with intolerance to the more common regimens. They are listed in Table 1.

Monitoring

The recommendations for routine testing for eradication of *H. pylori* were updated in 2017. Although strong evidence is lacking, expert consensus supports testing for eradication in most cases. There is clear benefit in testing patients who have persistent symptoms despite the test and treat strategy, any patient with an *H. pylori*-associated ulcer, any patient who has had a resection of any early gastric cancer, or those with an *H. pylori*-associated

MALT lymphoma. In these patients, testing should be done no sooner than 4 weeks after the completion of eradication treatment. Patients requiring follow-up endoscopy, such as for an ulcer or MALT lymphoma, should undergo endoscopic testing for eradication. Patients who are not undergoing endoscopy can be tested for eradication with fecal antigen or urea breath testing. The serum antibody test is unreliable for follow-up as it can remain positive for quite some time after successful treatment.

The most common causes of treatment failure are poor compliance with the medications and antibiotic resistance by the organism. Patients should be counseled on the side effects of their regimen and the importance of compliance. About 10% of patients report headaches and diarrhea with PPI use. Clarithromycin (Biaxin) can cause diarrhea, gastrointestinal upset, and altered taste. Similar effects can be seen with amoxicillin and metronidazole. Metronidazole also has disulfiram-like effects if taken with alcohol. Bacterial resistance is relatively rare, with multicenter U. S. data showing resistance rates to be 37% for metronidazole, 10% for clarithromycin, 3.9% for both antibiotics, and 1.4% for amoxicillin. For patients with persistent *H. pylori* infections, a new regimen should be attempted that does not include previously used antibiotics.

Patients who continue to have dyspepsia after successful eradication of *H. pylori* or who have persistent symptoms after a negative test and acid suppression should be considered for upper endoscopy.

Complications

Peptic ulcer disease can have severe complications, almost always requiring hospital admission. The most significant complications are gastric bleeding, perforation, or outlet obstruction.

Gastrointestinal bleeding is the most common cause of death in patients with peptic ulcer disease. Most cases of massive hemorrhage are due to erosion of a posterior ulcer into the gastroduodenal artery. Although the most common site of such hemorrhage is proximal to the ligament of Trietz, profuse bleeding can result in bright red blood from the rectum.

TABLE 1 *H. pylori* Regimens

REGIMEN	ANTIBIOTIC			ANTACID	DURATION
Clarithromycin Triple Therapy	Clarithromycin (Biaxin) 500 mg BID	Amoxicillin (Amoxil) 1 g BID ^a		PPI (Standard or double dose)	14 days ^b
Bismuth Quadruple Therapy ^c	Tetracycline (Sumycin) ¹ 500 mg QID	Metronidazole (Flagyl) ¹ 500 mg QID	Bismuth subcitrate ² or subsalicylate (Pepto-Bismol) 300 mg QID	PPI (Standard dose)	10-14 days ^b
Concomitant ^c	Clarithromycin (Biaxin) 500 mg BID	Amoxicillin (Amoxil) 1 g BID	Metronidazole (Flagyl) ¹ 500 mg BID	PPI (Standard dose)	10-14 days ^b
Sequential ^c	Amoxicillin (Amoxil) 1 g BID and PPI (Standard dose)		Clarithromycin (Biaxin) 500 mg BID and metronidazole (Flagyl) 500 mg BID and PPI (Standard dose)		5-7 days
Hybrid ^c	Amoxicillin (Amoxil) 1 g BID and PPI (Standard dose)		Amoxicillin (Amoxil) 1 g BID, PPI (Standard dose), clarithromycin (Biaxin) 500 mg BID, and metronidazole (Flagyl) ¹ 500 mg BID		5-7 days
Levofloxacin triple ^c	Amoxicillin (Amoxil) 1 g BID	Levofloxacin (Levaquin) ¹ 500 mg daily		PPI (Standard dose)	10-14 days ^b
Levofloxacin sequential ^c	Amoxicillin (Amoxil) 1 g BID and PPI (Standard dose)	Amoxicillin (Amoxil) 1 g BID, PPI (Standard dose), levofloxacin 500 mg daily, and metronidazole (Flagyl) 500 mg BID		PPI (Standard or double dose)	5-7 days
LOAD ^c	Levofloxacin (Levaquin) 250 mg daily	Doxycycline (Vibramycin) ¹ 100 mg daily	Nitazoxanide (Alinia) ¹ 500 mg BID	PPI (Double dose)	7-10 days

^aIn patients with penicillin allergy, metronidazole (Flagyl) 500 mg TID can be substituted, although not FDA approved.

^b14-day courses should be considered secondary to increased eradication rates.

^cNot FDA approved for this treatment regimen.

¹Not FDA approved for this indication.

²Not available in the United States.

Approximately 5% of peptic ulcers cause perforation. This usually occurs anteriorly through the duodenum or lesser curve of the stomach. These patients often present in extremis with fever, tachycardia, dehydration, and abdominal findings of rigidity and rebound due to chemical peritonitis. Free air is commonly present under the diaphragm. Perforation almost always requires surgical management.

Gastric outlet obstruction can occur acutely due to inflammation from peptic ulcer disease or more chronically secondary to inflammation and healing that lead to scarring and fibrosis of the duodenum. These patients can present with severe hypochloremic hypokalemic alkalosis due to the loss of hydrogen, potassium, and chloride from gastric secretions. Electrolyte derangements must be corrected prior to any attempted surgery. Initial treatment with balloon dilation can be attempted, especially in cases with newly diagnosed *H. pylori*. If the patient is negative for *H. pylori* or has successfully eradicated the organism, the long-term outcomes of dilation do not compare well to surgery.

GASTROESOPHAGEAL REFLUX DISEASE (GERD)

Method of

Mustafa Abdul-Hussein, MD MSCR; and Donald O. Castell, MD

Gastroesophageal reflux disease (GERD) is a motility disorder of the lower esophageal sphincter (LES). The definition of this disease has evolved over time, reflecting better understanding of the roles that transient LES relaxations and acid/pepsin contact with esophageal mucosa play, as well as the ability to identify these events. The diagnosis of GERD has changed from identification of a hiatal hernia, to identification of erosive esophagitis, to the currently accepted patient-centered definition: any symptom or injury to esophageal mucosa resulting from reflux of gastric contents into the esophagus. GERD should not be confused with physiologic gastroesophageal reflux, which is not associated with symptoms or esophageal mucosal injury.

The prevalence of GERD is difficult to ascertain, although several studies have indicated it to be as high as 50% of adults in Western countries, with 10% to 18% experiencing heartburn on a daily basis. Studies using health care utilization data may underestimate the prevalence because of self-treatment by individuals in the community, whereas population surveys may overestimate it because of inaccurate assessment of symptoms and absence of objective data. Regardless of the real number, the management of this disease costs more than \$10 billion annually in the United States. GERD has been called a disease of white males, although recent data suggest increasing prevalence in Asia and Pacific regions.

Pathophysiology

GERD is a motility disorder of the LES characterized by inappropriate or transient relaxations that allow gastric contents to reflux into the esophagus. The LES is a tonically contracted ring of smooth muscle fibers innervated by the vagus nerve. Vagal

stimulation during swallowing produces physiologic LES relaxation and is a likely source for transient LES relaxations. Gastroesophageal reflux occurs most frequently during postprandial periods, at a rate of six reflux episodes per hour, but averages two episodes per hour over the entire day. Increasing frequency of reflux in the postprandial period results from gastric distention after a meal and stimulation of tension receptors in the proximal stomach leading to transient LES relaxations (Box 1). A chronically hypotensive LES is not a major mechanism for GERD in most patients but can be seen in cases of severe erosive esophagitis.

Reflux of acidic gastric contents can lead to injury of the esophageal mucosa, including inflammation, ulceration, stricturing, Barrett's metaplasia, and adenocarcinoma. Peristaltic clearance, tissue resistance, and salivary bicarbonate make up host defense mechanisms that work by clearing reflux and neutralizing the acid residue on the mucosa. Erosive esophagitis or strictures result in the most severe form of GERD, which includes nocturnal reflux with longer acid contact times, decreased salivary production, and lower frequency of swallowing during sleep.

Complications

Acid reflux can lead to significant morbidity if it is not recognized and treated appropriately. Habitual contact of acid and activated pepsin with the stratified squamous epithelium, along with impaired defense mechanisms, results in tissue injury (Box 2). The end result of this process can be ulceration, fibrosis with stricture formation, Barrett's esophagus, or adenocarcinoma. These complications can produce alarm symptoms (Box 3). Patients presenting with alarm symptoms should undergo immediate diagnostic evaluation with an esophagogastroduodenoscopy (EGD).

GASTROESOPHAGEAL REFLUX DISEASE (GERD)

Method of

Mustafa Abdul-Hussein, MD MSCR; and Donald O. Castell, MD

Gastroesophageal reflux disease (GERD) is a motility disorder of the lower esophageal sphincter (LES). The definition of this disease has evolved over time, reflecting better understanding of the roles that transient LES relaxations and acid/pepsin contact with esophageal mucosa play, as well as the ability to identify these events. The diagnosis of GERD has changed from identification of a hiatal hernia, to identification of erosive esophagitis, to the currently accepted patient-centered definition: any symptom or injury to esophageal mucosa resulting from reflux of gastric contents into the esophagus. GERD should not be confused with physiologic gastroesophageal reflux, which is not associated with symptoms or esophageal mucosal injury.

The prevalence of GERD is difficult to ascertain, although several studies have indicated it to be as high as 50% of adults in Western countries, with 10% to 18% experiencing heartburn on a daily basis. Studies using health care utilization data may underestimate the prevalence because of self-treatment by individuals in the community, whereas population surveys may overestimate it because of inaccurate assessment of symptoms and absence of objective data. Regardless of the real number, the management of this disease costs more than \$10 billion annually in the United States. GERD has been called a disease of white males, although recent data suggest increasing prevalence in Asia and Pacific regions.

Pathophysiology

GERD is a motility disorder of the LES characterized by inappropriate or transient relaxations that allow gastric contents to reflux into the esophagus. The LES is a tonically contracted ring of smooth muscle fibers innervated by the vagus nerve. Vagal

stimulation during swallowing produces physiologic LES relaxation and is a likely source for transient LES relaxations. Gastroesophageal reflux occurs most frequently during postprandial periods, at a rate of six reflux episodes per hour, but averages two episodes per hour over the entire day. Increasing frequency of reflux in the postprandial period results from gastric distention after a meal and stimulation of tension receptors in the proximal stomach leading to transient LES relaxations (Box 1). A chronically hypotensive LES is not a major mechanism for GERD in most patients but can be seen in cases of severe erosive esophagitis.

Reflux of acidic gastric contents can lead to injury of the esophageal mucosa, including inflammation, ulceration, stricturing, Barrett's metaplasia, and adenocarcinoma. Peristaltic clearance, tissue resistance, and salivary bicarbonate make up host defense mechanisms that work by clearing reflux and neutralizing the acid residue on the mucosa. Erosive esophagitis or strictures result in the most severe form of GERD, which includes nocturnal reflux with longer acid contact times, decreased salivary production, and lower frequency of swallowing during sleep.

Complications

Acid reflux can lead to significant morbidity if it is not recognized and treated appropriately. Habitual contact of acid and activated pepsin with the stratified squamous epithelium, along with impaired defense mechanisms, results in tissue injury (Box 2). The end result of this process can be ulceration, fibrosis with stricture formation, Barrett's esophagus, or adenocarcinoma. These complications can produce alarm symptoms (Box 3). Patients presenting with alarm symptoms should undergo immediate diagnostic evaluation with an esophagogastroduodenoscopy (EGD).

Postepithelial

- Blood flow
- Tissue acid-base status

Presence of any of the following symptoms requires immediate evaluation:

- Dysphagia
- Odynophagia
- Weight loss
- Spontaneous resolution of GERD symptoms
- Iron deficiency anemia
- Gastrointestinal bleeding

Erosive Esophagitis

The endoscopic finding of erosive esophagitis is seen in fewer than 50% of patients with heartburn. The severity is stratified according to the Los Angeles Classification of Esophagitis. Treatment with a proton pump inhibitor (PPI) for 4 to 12 weeks heals erosive esophagitis in 78% to 95% of cases. The healing effect of antisecretory therapy, and particularly PPIs, demonstrates the important role of acid reflux in causing tissue injury. The recurrence rates for erosive esophagitis are high after discontinuation of PPI maintenance therapy (75%–92%), necessitating continuation of gastric acid suppression.

Strictures

Most strictures caused by GERD are peptic in origin and are located at the squamocolumnar junction. Patients with GERD and strictures, compared to those without strictures, are more likely to have a hypotensive LES, abnormal peristalsis, and prolonged acid clearance time. Stricture formation decreases the luminal diameter, resulting in solid food dysphagia. Dysphagia in these patients is often a combination of decreased luminal diameter and dysmotility of the distal esophageal body with low-amplitude peristalsis. Patients with GERD who develop dysphagia should have immediate barium radiography and an endoscopic evaluation.

Barrett's Esophagus

Barrett's esophagus (BE) is a premalignant condition that may evolve into esophageal adenocarcinoma. The histologic abnormality involves intestinal-like metaplasia of the stratified squamous epithelium. Epidemiologic studies show Barrett's to be more common among Caucasians, males, and the elderly (mean age, 60 years). The relative risk of esophageal adenocarcinoma (EAC) in BE patients was thought to be 30- to 125-fold with an incidence of 0.5% per patient year; however, recent population studies have shown a lower incidence of 0.12% to 0.13%. Despite the prevalent use of PPIs in the treatment of GERD, the incidence of adenocarcinoma has been increasing. Current guidelines encourage endoscopic surveillance for patients with Barrett's esophagus, yet there are sparse data showing the cost-effectiveness or mortality benefit of this strategy.

Adenocarcinoma

Approximately 50% of esophageal cancers are adenocarcinomas. Since the 1970s, the incidence has been rising for reasons that are still unknown. GERD is a risk factor for esophageal adenocarcinoma, and the risk increases with the duration and severity of GERD symptoms. There is a suggestion that cagA strains of *Helicobacter pylori* are protective against development of Barrett's esophagus and adenocarcinoma. The declining incidence of *H. pylori* may be a possible explanation for the rising incidence of adenocarcinoma.

Diagnosis

GERD is largely a clinical diagnosis under the current definition (i.e., any symptom or tissue injury resulting from reflux of gastric contents into the esophagus). Patients with the typical symptoms of heartburn and regurgitation most often associated with meals have

a high pretest probability of having GERD. A well-obtained history and symptom questionnaire are usually sufficient to form a presumptive diagnosis and are more cost-effective than ambulatory reflux testing or EGD. An empiric trial of PPI therapy that leads to a significant reduction or resolution of symptoms likely confirms the diagnosis.

The pathophysiology of GERD is much more complex than previously thought. It involves more than acid reflux, because nonacid reflux with a pH greater than 4 can be a common source of symptoms. This entity is unmasked when PPI therapy is found to control gastric acid secretion and impedance-pH testing identifies a temporal relationship between symptoms and episodes of nonacid reflux.

Direct-to-consumer marketing and the availability of over-the-counter PPI medications (e.g., Prilosec OTC) have led to self-treatment of GERD-type symptoms and a consequent change in the type of patients seeking medical care for their symptoms. Patients with typical GERD symptoms that do not completely respond to therapy with PPIs, including over-the-counter and prescription PPIs, warrant a more detailed evaluation of their symptoms. A separate population requiring earlier diagnostic evaluation includes patients with exclusively atypical GERD symptoms such as cough, hoarseness, throat clearing, asthma attacks, and chest pain. Less commonly, patients presenting with signs or symptoms of tissue injury, such as solid food dysphagia, should also be more rigorously tested for GERD (Box 4).

Patients who have symptoms associated with GERD, whether typical or atypical, are frequently treated empirically with PPI therapy. With a lack of discrimination regarding symptom types, this population is very heterogeneous and comprises patients with symptoms that are truly associated with GERD, not at all associated with GERD, and a combination of both. The pretest probability of GERD in this group is diluted, and nonresponders to empiric therapy are numerous. Partial responders and nonresponders to PPI therapy should undergo ambulatory reflux testing using combined multichannel intraluminal impedance (MII)-pH or standard pH. MII-pH catheters measure both esophageal pH changes and impedance changes that occur as an ion-rich refluxate passes a pair of ring electrodes, resulting in a drop in the resistance to a low-voltage current between the electrodes. The change in impedance can detect gastroesophageal reflux regardless of the acid content and can distinguish reflux types as liquid, gas, or mixed.

The goals of ambulatory reflux testing are to determine whether the esophageal acid contact time is abnormal, whether there are an

abnormal number of reflux episodes, and whether a relationship between reflux and symptoms exists. The advantage of combined MII-pH is its ability to identify both acid and nonacid reflux, so that testing can be done while the patient is on acid-suppression therapy and the artifact of acidic food or beverage ingestion is eliminated; pH-only testing is affected by both of these conditions. The major disadvantage is that MII-pH testing is less available than conventional pH testing.

EGD is specific for detecting reflux-related tissue injury but is not sensitive, because fewer than 50% of patients with GERD-related heartburn have endoscopic findings of reflux. If erosive esophagitis or Barrett's esophagus is found on endoscopy, aggressive antisecretory therapy with a PPI is warranted.

A barium esophagram is unlikely to add useful diagnostic information in patients with GERD symptoms without dysphagia. It is a useful tool in distinguishing obstructive from nonobstructive dysphagia and may even be more sensitive than EGD in detecting causes of obstructive dysphagia. Achalasia is often mistaken for GERD during the onset of symptoms, and early use of esophagography may help make this diagnosis.

Management

GERD is predominantly a postprandial event involving transient LES relaxations. The primary focus in management of this disease is to eliminate or improve symptoms and prevent tissue injury. In most patients with recurrent GERD symptoms, this can be accomplished by controlling gastric acid secretion with antisecretory therapy. PPIs are the most effective pharmacologic therapy for improving symptoms and preventing tissue injury from acid reflux. Individuals with only occasional heartburn may successfully treat symptoms with a combination of lifestyle modifications and over-the-counter antacids, histamine 2 receptor antagonists, or a PPI.

Patients presenting with typical symptoms and a history consistent with GERD should be given a trial of PPI once daily for at least 4 weeks. A validated GERD symptom assessment questionnaire such as the Reflux Disease Questionnaire should be used as an initial screening tool, because symptom response is the primary outcome measure, and subsequent questionnaire responses are useful in comparison with the initial responses for measuring treatment efficacy. If symptoms have not responded or have responded only partially after this trial, then the dosing or frequency of the PPI should be increased over another 4-week period. If the response is still unsatisfactory, diagnostic testing with ambulatory combined MII-pH or pH-only monitoring is indicated.

PPIs are an effective maintenance therapy for most patients with GERD and may be stepped down or used on demand, but GERD is a chronic condition with a high recurrence rate of symptoms without some form of maintenance therapy. This creates a large population of patients on antisecretory therapy for a disease with a low mortality rate, which raises the question of drug safety. There are insufficient data available that would warrant a recommendation against long-term PPI therapy. Clinical judgment in specific patient populations should be used to determine the optimal PPI regimen.

At present, pharmacologic reflux reduction therapy consists solely of the use of baclofen (Lioresal),¹ which has been shown to reduce transient LES relaxations and associated gastroesophageal reflux. The drawback of this medication is its unwanted side effects, which include somnolence and dizziness, limiting its tolerability and clinical utility as a stand-alone therapy.

Antireflux surgery is another alternative that is effective in limiting GERD symptoms in patients with a positive reflux-symptom relationship. Candidates for surgery include younger patients who do not want to continue chronic PPI therapy and patients with symptomatic nonacid reflux. Today, most antireflux surgery is performed laparoscopically with a 360-degree Nissen fundoplication. The associated mortality rate is small (0.5%–1%), and this approach is preferred to open laparotomy. Traditional predictors for surgical success have included the presence of typical symptoms

(heartburn and regurgitation), symptom response to a trial of PPIs, and an abnormal ambulatory pH study. These criteria exclude the important group of patients with atypical symptoms or symptoms related to nonacid reflux. However, such patients should be considered candidates for antireflux surgery if a positive reflux-symptom relationship can be demonstrated.

In recent years, several endoscopic therapeutic procedures have been developed for treatment of GERD. Among these procedures, transoral incisionless fundoplication (TIF) and Stretta are well studied and viable options. Stretta is the delivery of radiofrequency energy to the gastro-esophageal junction (GEJ). Stretta efficacy lays in increasing thickness of LES, decreasing compliance of GEJ without fibrosis, and decreased transient lower esophageal sphincter relaxations. Randomized trials showed improvement in GERD symptoms compared to sham procedure, though follow-up periods in these trials were only 6–12 months. A meta-analysis of 18 studies and 1441 patients concluded that Stretta is safe, well tolerated, effective in GERD symptom relief, and significantly reduces acid exposure to the esophagus, though it did not consistently normalize pH. In a recent meta analysis of 28 studies of 2468 patients with mean follow-up time of 25.4 months, Stretta improved quality-of-life scores and heartburn scores. However, 49% of the patients were still using PPIs at follow-up.

Patients with alarm symptoms and those who are partial responders to PPI therapy should also undergo EGD to aid in determining the cause of the symptoms, such as obstructive dysphagia from peptic strictures, adenocarcinoma, and bleeding esophageal ulcers (which can cause anemia). EGD findings that suggest GERD are a result of acid reflux. However, the incidence of these findings has declined with the use of PPIs.

Nonerosive reflux disease is increasingly common as more patients are converted from acid refluxers to nonacid refluxers with PPI therapy. By definition, these patients have no findings on endoscopy to suggest ongoing GERD. Absence of endoscopic findings does not exclude GERD, however, because tissue injury can occur at the microscopic as well as the macroscopic level. Patients with either erosive esophagitis or nonerosive reflux disease have dilated intercellular spaces on electron microscopy.

As previously discussed, patients with GERD may develop Barrett's esophagus. The metaplastic transformation from normal stratified squamous epithelium to an intestinal-type, columnar-lined epithelium creates a premalignant lesion with a 0.5% per year risk of progression to adenocarcinoma. Screening for Barrett's esophagus remains controversial. There is no evidence that screening results in a mortality benefit due to early detection of esophageal adenocarcinoma. Screening of all patients with GERD for Barrett's esophagus is clearly not cost-effective, but it is reasonable to target the highest-risk populations, such as Caucasian men older than 50 years of age with chronic reflux symptoms. Current American College of Gastroenterology guidelines recommend surveillance endoscopy in patients with known Barrett's esophagus at intervals determined by the degree of dysplasia. Because there have been no long-term, controlled studies, it is a grade C recommendation.

HEMORRHOIDS, ANAL FISSURE, AND ANORECTAL ABSCESS AND FISTULA

Method of

Genevieve B. Melton-Meaux, MD; and Mary R. Kwaan, MD, MPH

CURRENT DIAGNOSIS

- While most anorectal complaints are caused by a benign process, it is important to be mindful that the etiology can be a malignancy or other serious medical condition, such as anorectal Crohn's disease.
- A thorough, focused history is often the most helpful diagnostic tool for patients with anorectal complaints.
- In patients where no etiology for bleeding is found or where there has been a change in bowel movements, a further diagnostic work-up should be performed.
- Pain is the predominant symptom with anal fissure, thrombosed external hemorrhoids, and anorectal abscess but is not prominently featured with internal hemorrhoids.

CURRENT THERAPY

- External thrombosed hemorrhoids are treated with evacuation in their early development (<72 hours) but with expectant, supportive management only in their subacute phase.
- Most internal hemorrhoids can be treated with outpatient treatments, including measures to normalize bowel movements and hemorrhoidal banding or injection therapy.
- Anal fissures are treated conservatively with medical therapy but require operative therapy in a minority of cases.
- Anal fistula repair techniques have variable success rates; it may require multiple procedures to treat anal fistula effectively.

A number of conditions cause anorectal symptoms, but the majority of patients present with a complaint of “hemorrhoids.” Most anorectal conditions can be diagnosed with a focused history and physical examination. Treatment is aimed at the relief of symptoms, education of the patient, and prevention of further symptoms. Although most anorectal complaints are caused by a benign process, it is important for clinicians to be mindful that in some cases the etiology can be a malignancy or other serious medical conditions, such as anorectal Crohn's disease.

History

A thorough, focused history is often the most helpful diagnostic tool for patients with anorectal complaints. Clinicians should inquire about pain, itching, discharge, extra tissue or a lump, and bleeding. It is particularly important to understand the patient's bowel habits with respect to constipation or diarrhea as well as any change in defecatory habits. Other relevant history items include previous anorectal procedures and related medical conditions such as Crohn's disease, malignancy, sexually transmitted diseases, or immunosuppression.

Pain is an important symptom to elicit from patients. In most cases, pain is the predominant symptom with anal fissure, thrombosed external hemorrhoids, and anorectal abscess. Although discomfort from internal hemorrhoids can cause aching, soreness, or itching in the setting of tissue prolapse, internal hemorrhoid disease is most often painless. In contrast, external hemorrhoids that are acutely thrombosed cause pain that is acute in onset, severe, and constant. Fissure pain is often described as a tearing sensation or the feeling of “razor blades” during bowel movements that can continue for more than an hour following defecation. Patients with anal fissures might also express a fear of having bowel movements because of pain. Anorectal abscess is often associated with pain, and patients can also present with an acute lump and sometimes fever.

Anal discharge and difficulty with anorectal hygiene are also common complaints. The discharge associated with prolapsing internal hemorrhoids might contain mucus or small amounts of stool. In contrast, an anorectal fistula or abscess can spontaneously drain with associated purulent and blood-tinged output.

When a patient has bleeding, specific details to inquire about include color (bright red versus dark blood), amount, frequency, and length of time. When no etiology for bleeding is found, further screening should be performed. Patients who are younger than 50 years and who have no other risk factors should undergo flexible sigmoidoscopy. A colonoscopy should be done when patients are 50 years of age or older who have abdominal pain, anemia, change in bowel habits, a family history of polyps or colon cancer, or a personal history of polyps or colon cancer.

Diagnosis

Although the prone jack-knife position allows the greatest exposure, the left lateral decubitus position with the knees up is preferred by patients and usually allows adequate exposure for the anorectal examination. It is critically important to have sufficient lighting with a self-lighted anoscope or a headlight as well as adequate instrumentation to perform the anoscopy. An adjunctive test that can also be helpful in patients where mucosal (hemorrhoidal) or full-thickness rectal prolapse is suspected is to have patients bear down on the commode and then to examine externally.

The perianal skin is the skin immediately surrounding the anal verge (Figure 1). Perianal inspection includes careful examination of the surrounding skin for excoriation, an external draining orifice in the case of an anorectal fistula, lichenified skin with chronic irritation, other dermatitis, and the presence of perianal lesions. The anal verge is the entrance to the anal canal and is defined by the intersphincteric groove. There is frequently a clear demarcation between hair-bearing and non-hair-bearing skin in this location. Careful retraction of the buttocks can help to visualize an anal fissure located at the anal verge and extending into the anal canal.

A digital rectal examination is helpful for assessing resting and squeeze anorectal tone, palpating the prostate in men, assessing for rectocele in women, detecting any palpable anorectal lesions, and evaluating for tenderness within the anal canal or at the level of the levator ani muscles at the anorectal ring. Anoscopy is used to visually examine the anal canal, which is between 4 and 5 cm in length starting at the anal verge and extending to the top of the anorectal ring (top of external sphincter and levator ani muscles). Within the anal canal is the dentate line, which acts as a landmark anatomically and is located approximately 2 cm from the anal verge. The dentate line represents the transition from squamous

A colonoscopy should be done when patients are 50 years of age or older who have abdominal pain, anemia, change in bowel habits, a family history of polyps or colon cancer, or a personal history of polyps or colon cancer.

Diagnosis

Although the prone jack-knife position allows the greatest exposure, the left lateral decubitus position with the knees up is preferred by patients and usually allows adequate exposure for the anorectal examination. It is critically important to have sufficient lighting with a self-lighted anoscope or a headlight as well as adequate instrumentation to perform the anoscopy. An adjunctive test that can also be helpful in patients where mucosal (hemorrhoidal) or full-thickness rectal prolapse is suspected is to have patients bear down on the commode and then to examine externally.

The perianal skin is the skin immediately surrounding the anal verge (Figure 1). Perianal inspection includes careful examination of the surrounding skin for excoriation, an external draining orifice in the case of an anorectal fistula, lichenified skin with chronic irritation, other dermatitis, and the presence of perianal lesions. The anal verge is the entrance to the anal canal and is defined by the intersphincteric groove. There is frequently a clear demarcation between hair-bearing and non-hair-bearing skin in this location. Careful retraction of the buttocks can help to visualize an anal fissure located at the anal verge and extending into the anal canal.

A digital rectal examination is helpful for assessing resting and squeeze anorectal tone, palpating the prostate in men, assessing for rectocele in women, detecting any palpable anorectal lesions, and evaluating for tenderness within the anal canal or at the level of the levator ani muscles at the anorectal ring. Anoscopy is used to visually examine the anal canal, which is between 4 and 5 cm in length starting at the anal verge and extending to the top of the anorectal ring (top of external sphincter and levator ani muscles). Within the anal canal is the dentate line, which acts as a landmark anatomically and is located approximately 2 cm from the anal verge. The dentate line represents the transition from squamous

Figure 1 Anatomy of the anal canal.

epithelial lining of the anus to the columnar epithelial lining of the rectum. Sensation above the dentate line is mediated by autonomic fibers and results in a relative lack of sensation in comparison to the highly sensitive, somatically innervated tissue below the dentate line. The dentate line is also the location of the crypt anal glands from which anorectal abscesses and fistulas originate.

Hemorrhoids

Hemorrhoids are the anal vascular cushions that are present as normal structures in everyone. In the case of internal hemorrhoids, these cushions are arteriovenous channels that have overlying mucosa, submucosal smooth muscle, and supportive fibroelastic connective tissue. It is believed that internal hemorrhoids function by aiding with fine control of fecal continence of liquids and gases. Internal hemorrhoids enlarge and become symptomatic as fixation by submucosal smooth muscle and connective tissue becomes disrupted and loosens. This results in a sliding or prolapsing of the anal canal lining and further engorgement of the internal hemorrhoid tissues. Common exacerbating factors include constipation, diarrhea, aging, and increased abdominal pressure that can occur with chronic straining, pregnancy, heavy lifting, and decreased venous return. Internal hemorrhoids are typically staged on a scale from I to IV based upon the extent of prolapse ([Table 1](#)).

Internal hemorrhoids, when symptomatic, most commonly present with painless bright red bleeding or prolapsing tissue ([Figure 2](#)). Patients describe bleeding with or after bowel movements. Other symptoms include itching and leakage of mucus in the setting of tissue prolapse. Pain is rarely a prominent symptom except in the case of mixed hemorrhoid disease, when there is a thrombosed external component, or in the case of stage IV incarcerated hemorrhoids.

The central principles for conservative treatment of internal hemorrhoids and for long-term prevention of worsening symptoms are the normalization of bowel habits and avoidance of straining. Ideal bowel habits include having regular, soft, and formed stool resulting in minimal straining with elimination. An ideal diet should have high fiber content along with sufficient fluid intake.

Figure 2 Prolapsing (grade III) hemorrhoids, with a prominent external component on the right and two sites of recent bleeding seen on the left.

A total of at least 30 g of fiber per day is generally recommended. For the majority of patients, this is most easily achieved with the addition of a fiber supplement such as psyllium. Other medical treatment of hemorrhoids includes local anesthetic topical ointments, which relieve symptoms but do not improve the hemorrhoids, and steroid ointments, which symptomatically improve itching and irritation but also thin and atrophy the overlying tissue if used regularly.

Internal hemorrhoids might benefit from further treatment in the setting of persistent prolapse or bleeding. Injection sclerotherapy works through shrinking and scarring the internal hemorrhoid by injecting a sclerosing agent (most commonly phenol in olive oil). Alternatively, infrared coagulation may be administered at the apex of the hemorrhoid. Both procedures have moderate effectiveness but are considered to be less effective than rubber-band ligation, which is widely used in the office setting, with good results.

Rubber-band ligation requires the use of a rubber-band ligator (either suction type or ligator with clamp) and is performed by placing a rubber band around excess hemorrhoidal tissue at the apex of the hemorrhoid. Rubber-band ligation works by strangulating and cutting off blood flow to the hemorrhoid and by creating a scar that helps to fix tissue into place. The band must be placed well above the dentate line to prevent pain. Most patients experience a sensation of pressure with the procedure. Rarely, this procedure can cause significant pain, bleeding, or a vasovagal reaction. In general, only one or two band applications are performed in the same setting to prevent excessive pain or a vasovagal reaction.

Surgical treatment for hemorrhoidal disease should be considered in patients with stage III or IV internal hemorrhoids. Surgery is also a consideration in cases where office procedures and conservative treatment have been ineffective or when internal hemorrhoids are circumferential. In the United States, most hemorrhoidectomies continue to be performed using a closed technique, where the hemorrhoid is excised and the defect sutured closed. More recently, stapled hemorrhoidectomy (sometimes called hemorrhoidopexy) has been introduced. The stapled technique appears to work best in cases where patients have more circumferential disease and is performed by excising the rectal mucosa and disrupting blood flow, thereby shrinking hemorrhoidal tissue and lifting the prolapsing tissue into the anal canal. Although stapled hemorrhoidectomy has been demonstrated to be effective and on average less painful, it does not address any external hemorrhoidal component, costs significantly more money, and has been associated with rare but severe complications, including pelvic sepsis.

External hemorrhoids are generally painless, except in the case of thrombosis, and normally appear as more prominent external perianal tissue or painless skin tags. Thrombosed external

TABLE 1 Staging of Hemorrhoidal Disease

GRADE	DESCRIPTION

II	Protrude during defecation; reduce spontaneously
III	Protrude during defecation; require manual reduction
IV	Permanently prolapsed and irreducible

Figure 3 Incision and evacuation of an external thrombosed hemorrhoid. **A**, A local anesthetic is injected into the subcutaneous surrounding tissue and at the base of the hemorrhoid. **B**, The skin over the hemorrhoid is lifted and a small elliptical excision of skin is made. **C**, The thrombotic clot is evacuated. Additional dissection is sometimes needed in the subcutaneous tissue to extract the clot. **D**, The appearance of the evacuated area. The incision is left open and the skin heals by secondary intention.

hemorrhoids, in contrast, are associated with severe pain and a prominent external lump but not with bleeding or fever. On examination, an external thrombosed hemorrhoid appears as a prominent, blue, and firm perianal lump. It is also not uncommon for multiple hemorrhoids to thrombose. Patients who present within 72 hours of the onset of symptoms benefit from an evacuation of the thrombosed clot using local anesthetic (Figure 3). In contrast, patients who present after 72 hours should be treated expectantly with conservative supportive care, including sitz baths, normalization of bowel habits with fiber or stool softener, and pain management. The natural history in these cases is for the thrombosed clot to gradually be reabsorbed within several weeks.

Anal Fissure

An anal fissure is a tear in the anoderm extending proximally into the anal canal and initially resulting from a traumatic bowel movement. Fissures typically occur in the setting of constipation or frequent bowel movements. Although most superficial fissures resulting from trauma to the anorectal region will heal, some patients have prolonged symptoms, causing them to seek medical attention. The pathophysiology of anal fissures is still not completely understood but is related to local ischemia caused by hypertonia of the internal sphincter. The great majority of anal fissures are located at the posterior midline; some also occur at the anterior midline (Figure 4). Lateral fissures are rare and can be associated with anal malignancy, anorectal Crohn's disease, HIV, syphilis, or tuberculosis. In these cases, a biopsy should be strongly considered to confirm the diagnosis.

Patients who present with anal fissure most often have a tearing pain that is associated with bowel movements and that continues after defecation and bright red bleeding with bowel movements. Physical examination demonstrates a tear in the anoderm with exposed internal sphincter upon retraction of the buttocks. Chronic cases also demonstrate a sentinel tag overlying the distal aspect of the fissure.

Conservative treatment for acute anal fissures includes the normalization of bowel habits to minimize recurrent trauma to the anoderm and sitz baths for comfort. In cases in which the fissure is chronic or unresponsive to conservative treatment, topical therapy

Figure 4 Distribution of the location of anal fissures.

to relax the internal sphincter (i.e., a “chemical sphincterotomy”) is prescribed. Classically, nitroglycerin ointment (0.2%–0.4%)^{1,2} has been used but is associated with significant headaches and light-headedness. Diltiazem ointment (2%)¹ is a commonly used alternative without associated side effects. Either ointment can be applied topically two to three times per day for approximately 8 weeks. Reported healing rates are similar and range from 40% to 100%. An alternative agent that can be used for chemical sphincterotomy is botulinum toxin A (Botox), which can be injected in the office or operating room with a single application into the internal sphincter. Although botulinum toxin A appears to be as effective as topical therapy, it is significantly more expensive.

¹Not FDA approved for this indication.

²May be compounded by pharmacists.

Surgical internal sphincterotomy is the most effective treatment for resolution of anal fissures but is associated with a risk of fecal incontinence, particularly in women, elderly patients, or others at risk for impaired continence. This procedure is performed in the outpatient setting and should be considered in cases where more-conservative dietary and medical treatments have failed. Internal sphincterotomy is performed by dividing the internal sphincter laterally, which prevents the formation of a keyhole defect with stool leakage, which can occur with the posterior division of the internal sphincter muscle. This procedure can be performed with an open approach (incising mucosa and exposing muscle) or a closed approach (using landmarks and then blindly dividing muscle) and can be full thickness (entire internal sphincter) or tailored (partial thickness and length). Most surgeons perform a tailored sphincterotomy from the level of the top of the fissure distally, with partial division of the internal sphincter muscle to decrease the risk of postoperative fecal incontinence.

Anorectal Abscess and Fistula

Anorectal abscess is most commonly a self-limited process thought to result from obstruction and infection of anal glands located in the crypts along the dentate line. Clinicians should be aware that perianal Crohn's disease, trauma, and malignancy can cause anorectal abscess or fistula. Anorectal abscesses typically manifest with acute pain in the perianal area, acutely painful defecation, an indurated painful area, or fever. Most anorectal abscesses manifest with pain and swelling either superficially at the anal verge or deeper within the ischioanal fossa. These patients have obvious tenderness, induration, or fluctuance on external and/or digital examination. In contrast, patients with intersphincteric abscesses have severe pain but minimal findings on external examination and are only suspected on digital rectal examination.

The mainstay of therapy is surgical drainage. Superficial abscesses can be drained using local anesthesia, but more-extensive infections typically require general anesthesia. When the abscess is fluctuant and appears easily accessible, an incision and drainage with a local anesthetic can be considered in a motivated patient. Important principles in draining an anorectal abscess include keeping the patient comfortable, using aspiration with a large-bore (14- or 16-gauge) needle to help in the event of difficult localization, using a cruciate incision to ensure adequate drainage, and keeping the incision near the anus to keep any potential fistula tract as short as possible. After the abscess is drained, the area is allowed to heal by secondary intention. Patients are given analgesics and encouraged to take sitz baths. When the abscess is large and extensive, sometimes drainage tubes, débridement, or additional dressing changes are required.

In a majority of patients, drainage of the anorectal abscess is sufficient. However, in one-third of patients, these do not heal and form a fistula with the external opening beyond the anal verge and the internal opening within an infected crypt gland at the dentate line. These continue to drain purulent material from the external opening, and some patients continue to have signs and symptoms of infection. The tract of the fistula is most often predicted with Goodsall's rule. Goodsall's rule states that an anterior fistula follows a radial tract to the internal opening, typically at the anterior midline. In contrast, a posterior fistula follows a curvilinear path to the internal opening at the posterior midline. Anorectal fistulas are defined by their anatomy and path relative to the sphincter muscles and are classified typically as superficial, intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric, as classically described by Parks (Figure 5). In most cases, patients can proceed directly to the operating room for initial definition of the anatomy and placement of a seton (a length of suture or other material that is looped through the fistula), which helps to allow drainage of infection within the tract, prevents recurrent infection, and allows the fistula to mature. Recurrent and complex fistulas may be better defined anatomically with the use of magnetic resonance imaging or endorectal ultrasound.

Superficial, intersphincteric, or low transsphincteric fistulas can be treated with simple fistulotomy, which opens up the fistula tract

Figure 5 Classification of anal fistulas. Abbreviations: ES = extrasphincteric; IS = intersphincteric; S = superficial; SS = suprasphincteric; TS = transsphincteric.

and allows the tissue to heal by secondary intention. This, however, can result in impaired fecal continence, particularly if the fistula involves a significant amount of sphincter muscle.

Following this, a variety of methods can be used to repair the fistula. One classic technique is the use of a cutting seton, where a taut seton is progressively tightened over several weeks or months to form a scar in place of the fistula and muscle. A cutting seton may be painful, and the scar is associated with impaired continence in some cases. Fibrin glue has been proposed as a method to repair a fistula, but the long-term recurrence rate is high (>85%). Fistula plugs have also been proposed as a method to heal the fistula tract by repairing the internal opening and providing a scaffolding for fibrosis to occur. Although short- and medium-term success is reported to be approximately 30%, long-term results are not known.

Endorectal advancement flaps are the most well-established method to repair an anal fistula. With this technique, the internal orifice is closed and healthy tissue is brought down over the internal fistula opening to allow the area to heal. This procedure can be technically difficult: failure most commonly results from ischemia of the flap, and repeat flap procedures are often not anatomically feasible owing to scarring and fibrosis. Success rates have been reported between 50% and 80%.

A new procedure has been developed for transsphincteric and suprasphincteric fistulas called ligation of intersphincteric fistula tract. This has been reported in about a dozen centers as a method to treat transsphincteric fistulas and is performed by closing the internal opening and ligating and removing the intersphincteric portion of the fistula tract through an intersphincteric approach. Although long-term results are still unknown, reports are favorable (on the order of 80%) for the short-term success of this technique; a multicenter trial is ongoing.

CURRENT DIAGNOSIS

Hepatitis A

- Typical prodromal symptoms are nonspecific (i.e., fever, anorexia, nausea, vomiting, diarrhea, abdominal pain, and weight loss). In about half of patients, prodromal symptoms are followed by icterus (i.e., jaundice, pruritus, and dark urine) lasting 2 weeks.
- Serum aminotransferase levels increase to 10 to 20 times the upper limit of normal during the prodromal phase. Total serum bilirubin rises but rarely exceeds 10 mg/dL during the icteric phase. Biochemical recovery usually occurs within 3 months.
- Acute hepatitis A virus (HAV) infection is diagnosed by the presence of anti-HAV immunoglobulin M (IgM). Anti-HAV IgG appears in the convalescent phase and remains detectable for life. Anti-HAV IgG positivity with the absence of anti-HAV IgM antibodies reflects past exposure or vaccination. The antibody test for HAV usually includes total antibodies (IgM and IgG); thus, diagnosis of acute hepatitis A requires specific anti-HAV IgM testing.

Hepatitis B

- Acute hepatitis B virus (HBV) infection may be asymptomatic or present with nonspecific symptoms of anorexia, nausea, and fever with development of icterus, pruritus, right upper quadrant pain, or, rarely, acute liver failure. Globally, it is a major cause of chronic hepatitis.
- Serum alanine aminotransferase (ALT) levels peak with the onset of symptoms.
- Suspected acute HBV infection is diagnosed by the detection of hepatitis B surface antigen (HBsAg), hepatitis B e-antigen (HBeAg), IgM antibody to hepatitis B core antigen (anti-HBc), and HBV DNA in serum in the appropriate clinical setting. Anti-HBc IgM is detected during acute HBV infection and may be detected during reactivation of chronic HBV infection.
- Chronic infection is defined as the persistence of serum HBsAg for greater than 6 months. If HBsAg is present, serum HBeAg, antibody to hepatitis B e-antigen (anti-HBe), HBV DNA, and serum ALT are used to determine the four phases of chronic infection (immune tolerant, HBeAg-positive and HBeAg-negative immune active, and inactive carrier).

CURRENT THERAPY

Hepatitis A

- Treatment is predominately supportive. Avoid hepatotoxic medications and drugs metabolized by the liver. Acute liver failure with encephalopathy and impaired synthetic function occurs rarely and is more common in patients older than 50 years of age and/or those who have coexisting chronic HBV or hepatitis C virus (HCV) infections.
- Prevention includes administration of the inactivated or attenuated vaccine for children at age 1 year or older and for at-risk populations (e.g., intravenous drug users, travelers to regions with high or intermediate HAV rates, men who have sex with men, patients with chronic liver disease or clotting factor disorders).
- Preexposure passive immunization with pooled human anti-HAV immunoglobulin may be used for those at high or intermediate risk of hepatitis A virus exposure.

- Postexposure passive immunization with pooled human anti-HAV immunoglobulin may be used for close personal contacts of an individual with laboratory-confirmed HAV infection, staff and attendees of child care centers if one or more children and/or staff are diagnosed with HAV infection, and food handlers during a common-source exposure. Concurrent immunization with inactivated or attenuated vaccines for these at-risk contacts is also warranted.

Hepatitis B

- Acute HBV infection in an adult generally only requires supportive care owing to high rates of spontaneous recovery. For people with evidence of acute liver failure, prompt institution of antiviral therapy with a potent nucleos(t)ide analog and referral to a transplant center is recommended. Peginterferon alfa-2a (Pegasys)¹ is contraindicated in persons with acute liver failure.
- Chronic HBV treatment goals are sustained suppression of HBV DNA to prevent the development of cirrhosis, hepatocellular carcinoma, and liver-related mortality. Cure of chronic HBV infection is currently not possible. Treatment recommendations for chronic HBV differ depending on the phase of infection but is generally indicated for immune active HBeAg-positive subjects with confirmed HBV DNA greater than 2000 to 20,000 IU/mL and serum ALT two or more times the upper limit of normal, and for immune active HBeAg-negative patients with HBV DNA greater than or equal to 2000 IU/mL with serum ALT two or more times the upper limit of normal and patients with liver biopsy-proven moderate to severe inflammation and/or moderate fibrosis. Treatment decisions outside these parameters should be individualized based on the risk for complications (e.g., older age [>40 years], family history of cirrhosis or hepatocellular carcinoma, presence of cirrhosis) and the risk of therapy (e.g., chronic kidney disease, previous treatment history). Four agents are considered first line—peginterferon alfa-2a (Pegasys), entecavir (Baraclude), tenofovir (Viread), and tenofovir alafenamide (Vemlidy)—based on their safety, effectiveness, and low rates of antiviral resistance. Peginterferon is generally recommended for those who prefer a finite course of treatment and who have clinical and laboratory features predictive of a response to peginterferon (high ALT, low HBV DNA, young age, female gender, and HBV genotype A or B). Peginterferon is contraindicated in persons with decompensated cirrhosis, autoimmune illnesses, or active psychiatric illness. Nucleos(t)ide analogs are more potent inhibitors of HBV DNA replication, generally better tolerated than peginterferon, and usually administered long term. The ideal endpoint of treatment is loss of HBsAg, though it is rarely observed with any therapy.
- Prevention includes completion of a two-three-dose HBV vaccination series for all children by 18 months of age with the first dose administered within 24 hours of birth. Infants whose mothers are HBsAg positive or whose HBsAg status is unknown should receive the last dose by 6 months of age.
- Hepatitis B immune globulin (HyperHEP B) and HBV vaccination are recommended at birth for infants whose mothers are HBsAg positive. In mothers with viral loads greater than 200,000 IU/mL, antiviral therapy with tenofovir (Viread), telbivudine (Tyzeka), or lamivudine (Epivir HBV) in the third trimester of pregnancy (gestation weeks 28-32) can be considered.

¹Not FDA approved for this indication.

Five viruses hepatitis A through E account for the majority of cases of acute and chronic viral hepatitis. Chronic hepatitis is arbitrarily defined as the persistence of elevated serum aminotransferase levels for 6 months or more. Complications of chronic hepatitis (predominantly cirrhosis and hepatocellular carcinoma) account for the majority of morbidity and mortality due to viral hepatitis. Effective vaccines are available for the prevention of hepatitis A, B, and D

infections. In addition, safe and effective therapy is available for treatment of chronic hepatitis B and C. Therefore it is important to screen individuals who are at high risk for chronic viral hepatitis to provide them access to care, reduce complications, and offer counseling to prevent transmission of infection.

Hepatitis A Virus

Introduction

HAV is a positive-sense, single-stranded RNA virus of the *Hepatitisvirus* genus belonging to the Picornaviridae family. Its genome encodes four structural and seven nonstructural proteins. Four genotypes have been identified, but there is only one serotype. Therefore exposure to one HAV genotype confers immunity to all genotypes.

Natural History

HAV is a cause of acute hepatitis and acute liver failure but not chronic hepatitis (Table 1). In ~5% of cases, a prolonged cholestasis lasting more than 3 months may occur, and in ~10% of patients, a relapsing hepatitis has been observed up to 6 months after the acute illness with recrudescence of symptoms and flare of hepatitis. Cases of relapsing hepatitis continue to remain infectious with fecal shedding of the virus. These atypical presentations of acute hepatitis A should not be mistaken for evolution to chronic hepatitis, as resolution is the rule. Recovery of HAV is associated with development of lifelong immunity.

HAV replication occurs in hepatocytes, and the virus is shed into the intestine via the biliary system. Viral levels peak during the asymptomatic period, and virus shedding continues until around 2 weeks into the icteric phase. HAV is detectable in the blood, but levels are 1000-fold higher in the feces. Children may shed the virus longer than adults.

The incubation period usually lasts 14 to 28 days. This is followed by the onset of symptoms. The presence and severity of symptoms are variable and age related. Generally, more than 70% of adult patients have a symptomatic illness, compared with only 10% of children younger than the age of 10 years. Typical symptoms are nonspecific and include fever, anorexia, nausea, vomiting, diarrhea, abdominal pain, and weight loss. This prodromal phase is followed by an icteric phase in 40% to 70% of patients with jaundice, pruritus, and dark urine. Physical examination findings are usually unremarkable, but hepatomegaly may be observed. Extrahepatic manifestations are uncommon and may include an evanescent rash and arthralgias.

Laboratory studies during the prodromal phase reveal elevated serum aminotransferase levels greater than 10 to 20 times the

upper limit of normal. During the icteric phase, total serum bilirubin rises but generally does not exceed 10 mg/dL. In most patients, jaundice lasts 2 weeks and a complete clinical and biochemical recovery can be expected in 2 to 3 months.

Epidemiology

Hepatitis A occurs throughout the world (Figure 1), either sporadically or in epidemics. The prevalence of HAV correlates with the level of sanitation and hygiene of a region. In developing countries, more than 90% of children are infected before the age of 10. In developed countries, including the United States, infection rates are low. Lack of exposure at a young age leads to higher susceptibility in certain high-risk adults including travelers to endemic areas, injection drug users, and men who have sex with men.

In the United States, HAV infection rates have declined by 95% since the introduction of mandatory childhood vaccination in 1995. The overall incidence rate in 2016 was 0.6% per 100,000 persons, representing a 44% increase in cases between 2015 and 2016 due to outbreaks related to imported foods, in homeless persons, and persons who use injection drugs. HAV is spread primarily by the fecal-oral route through the ingestion of contaminated food or water. Humans are the only known reservoir of the virus.

Diagnosis

Serologic testing for antibody to HAV can confirm the diagnosis of acute infection, past exposure, and immunity to the virus. Acute HAV infection is diagnosed by the presence of anti-HAV IgM. Anti-HAV IgG appears in the convalescent phase of infection and remains detectable for life. Past exposure or vaccination confers immunity and is reflected by anti-HAV IgG positivity with the absence of anti-HAV IgM antibodies. The antibody test for HAV usually includes total antibodies (IgM and IgG). Thus, to diagnose acute hepatitis A, it is important to order anti-HAV IgM.

Treatment

Given the self-limiting nature of acute hepatitis A, treatment is predominantly supportive. Caution should be taken when using hepatotoxic medications or medications metabolized predominantly in the liver. Rarely, acute liver failure with encephalopathy and impaired synthetic function can occur. The patients at highest risk for this complication are generally older than 50 years of age and may have coexisting chronic HBV or HCV infections. Individuals presenting with acute liver failure are more appropriately managed at a liver transplant center.

TABLE 1 Hepatitis A, B, D, and E Characteristics

	HEPATITIS A	HEPATITIS B	HEPATITIS D	HEPATITIS E
Classification	Picornavirus, ssRNA(+)	Hepadnavirus, dsDNA	Deltavirus, ssRNA(-)	Hepevirus, ssRNA(+)
Source	Stool	Blood	Blood	Stool
Transmission	Enteric	Percutaneous/permucosal	Percutaneous/permucosal	Enteric
Acute infections (per 1000/year) in U.S.	125-200	140-320	6-13	unknown

Abbreviation: HCC = hepatocellular carcinoma.

*Not available in United States

[#]Higher in pregnancy at 5-20%

Figure 1 Global prevalence of hepatitis A and infection risk. Hepatitis A has a worldwide prevalence. Prevalence is related to the regional income, sanitation, and hygiene. High-income areas (e.g., North America, Western Europe, Australia, New Zealand, Japan, the Republic of Korea, and Singapore) have low levels of hepatitis A virus (HAV) endemicity and subsequently a high proportion of susceptible adults. Low-income regions (Sub-Saharan Africa and parts of South Asia) have high endemicity levels and very few susceptible adolescents and adults. Middle-income regions have a mix of intermediate and low endemicity levels.

Prevention

Both inactivated and attenuated vaccines have been licensed against HAV. Inactivated vaccines include HAVRIX (GlaxoSmithKline), VAQTA (Merck), TWINRIX (a combined hepatitis A and B vaccine from GlaxoSmithKline), AVAXIM (Sanofi Pasteur),² EPAXAL (Crucell),² and HEALIVE (Sinovac).² The only live attenuated vaccine is BIOVAC-A (Pukang).² The World Health Organization (WHO) recommends routine childhood vaccination for HAV in areas with intermediate infection rates. In the United States, the Advisory Committee on Immunization Practices recommends that all children at age 1 year be vaccinated. Other at-risk populations for whom vaccination is recommended include intravenous drug users, travelers to regions with high or intermediate HAV rates, men who have sex with men, persons in close contact with new adoptees from countries of high or intermediate hepatitis A endemicity, and patients with chronic liver disease or clotting factor disorders.

Passive immunization with immunoglobulin may also be used for preexposure protection among individuals who are at high or intermediate risk of HAV exposure. Pooled human anti-HAV immunoglobulins (GamaSTAN [IGIM]) decrease the HAV infection risk by 90% for up to 3 months. Passive immunization is also recommended for postexposure protection in cases of close personal contacts to an individual with laboratory-confirmed HAV infection, to staff and attendees of child care centers if one or more children and/or staff are diagnosed with HAV infection, and to food handlers during a common-source exposure. Concurrent immunization for HAV in these at-risk contacts is also warranted.

Hepatitis E

Introduction

Hepatitis E virus (HEV) is a nonenveloped, single-stranded, positive-sense RNA virus of ~7300 bases in length and the sole member of the Hepeviridae family. Its genome contains three overlapping open reading frames. ORF1 encodes four nonstructural proteins, ORF2 encodes the capsid protein, and ORF3 a protein

of unknown function. Four genotypes are known to infect humans, but similar to HAV, only one serotype exists and infection with one strain confers immunity to all others. HEV is likely a zoonosis with multiple nonhuman vectors.

Natural History

HEV is a cause of acute hepatitis and acute liver failure (see Table 1). It can cause chronic hepatitis in immunocompromised individuals. The majority of acute HEV infections are asymptomatic or minimally symptomatic. The incubation period is between 15 and 60 days, and if symptoms arise, they generally consist of anorexia, nausea, vomiting, diarrhea, and abdominal pain. Acute HEV infection rarely causes jaundice, and most symptoms resolve within 6 weeks from onset. A notable exception to the generally favorable outcome is an increased risk of acute liver failure among pregnant women during the second and third trimesters in endemic regions. This leads to a high maternal mortality rate of 15% to 25% and worse maternofetal outcomes in third-trimester infections. Acute HEV infection may also be associated with a lymphocytic destructive cholangitis.

Chronic HEV infection is defined as the presence of HEV RNA in the serum or stool for more than 6 months. It is uncommon and has been observed in solid-organ transplant recipients, HIV-positive subjects, and other immunocompromised hosts. Chronic HEV infection has only been reported with HEV genotype 3 infections. It is unknown if other HEV genotypes can cause chronic HEV infection. Development of cirrhosis has been described as a consequence of chronic infection.

Epidemiology

HEV is found worldwide and can be divided into three distinct geographical patterns: highly endemic, endemic, and nonendemic (sporadic) (Figure 2). Large waterborne epidemics in highly endemic regions are due to infection with HEV genotypes 1 and 2 in Central America, Africa, and Asia. Sporadic cases of HEV in developed countries (Europe, North America, and Far East Asia) are due to HEV genotypes 3 and 4. The reservoir for autochthonous HEV is unknown but thought to be domestic swine. Sporadic cases may occur in travelers to endemic areas. Interestingly, males

²Not available in the United States.

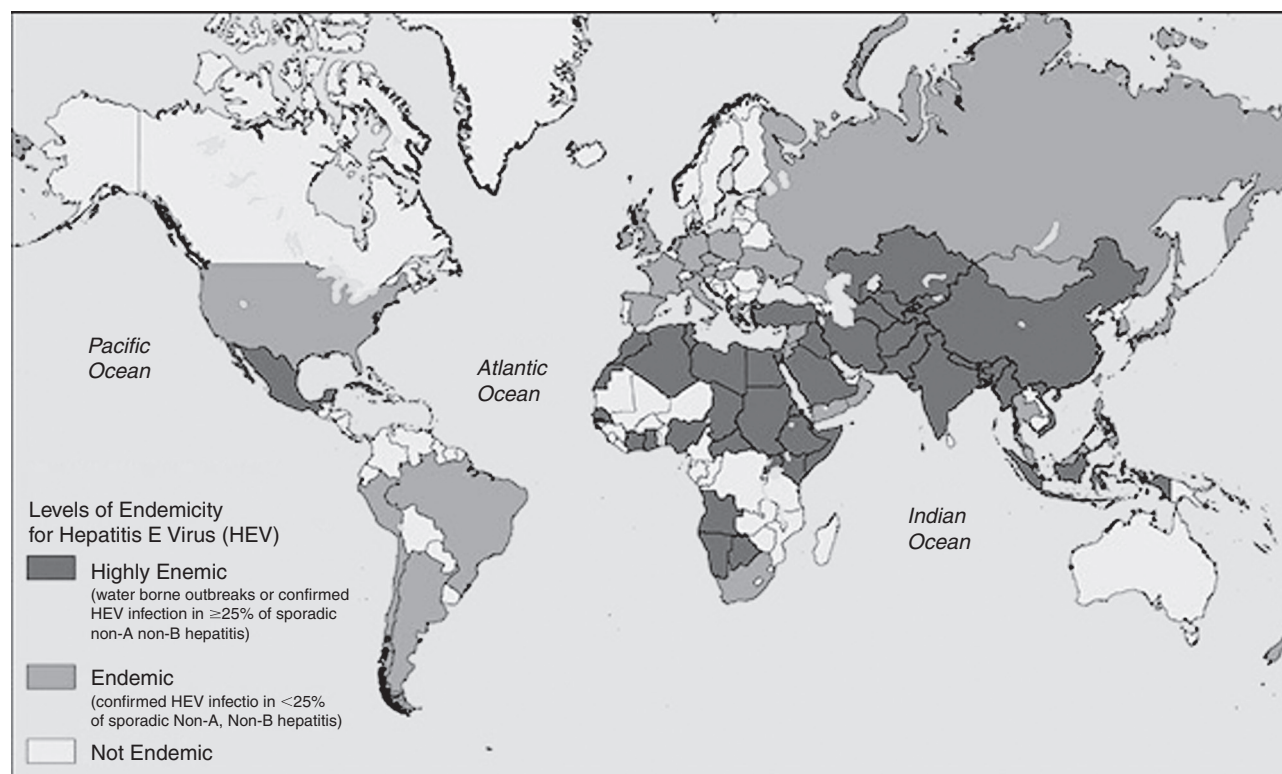

Figure 2 Global prevalence of hepatitis E virus. Hepatitis E is found worldwide. High endemic areas, defined by greater than or equal to 25% prevalence of sporadic non-A, non-B hepatitis, include parts of Central America and Mexico, Africa, the Middle East, and most of Asia. Endemic areas, defined as less than 25% prevalence of sporadic non-A, non-B hepatitis, include the United States, Europe, Russia, and parts of South America. Remaining regions are regarded as nonendemic.

are more affected than females in sporadic infections, but this gender bias is not observed during epidemics. HEV is spread by the fecal-oral route, usually through ingestion of contaminated water.

Diagnosis

There are no commercially licensed tests for HEV detection in the United States. Testing is limited to research laboratories and can be obtained through the Centers for Disease Control and Prevention.

The diagnosis of acute HEV is made by detection of anti-HEV IgM in serum or HEV RNA in stool or serum. Anti-HEV IgG has limited utility in diagnosis of HEV infections and may be a serologic marker for past infection. In immunocompromised patients, antibody testing can be falsely negative, making HEV RNA the more reliable marker of acute and chronic infection. Chronic HEV is diagnosed when HEV RNA is present in sera or stool for more than 6 months in suspected cases.

Treatment

Since most acute HEV infections are mild, the treatment is generally supportive. Patients who develop acute liver failure should be managed at a liver transplant center. The initial approach to management of chronic HEV infection in posttransplant recipients is to reduce the level of immunosuppression. If this is unsuccessful, then off-label use of antiviral therapy with peginterferon (Pegasys)¹ or ribavirin (Rebetol)¹ may be considered. In immunocompromised individuals therapy with peginterferon¹ or ribavirin¹ may be considered.

Prevention

Prevention of hepatitis E relies principally on good sanitation and the availability of clean drinking water. Prevention of transmission in travelers to endemic areas includes avoidance of tap water and consumption of street foods, raw vegetables, or raw or

undercooked meats such as pork and seafood. A commercially available vaccine for HEV, HECOLIN² (Xiamen Innovax Biotech), has been available in China since 2012.

Hepatitis B

Introduction

HBV is a partially double-stranded DNA virus of ~3200 bases belonging to the Hepadnaviridae family. HBV consists of an outer lipid shell that surrounds a nucleocapsid consisting of the viral DNA and the polymerase. HBV has four overlapping reading frames (core, surface, polymerase, and x), which encode for seven viral proteins. HBsAg is the marker of infection and HBeAg is a marker of high viral replication and infectivity. The virus is classified into 10 major genotypes (A through J) that have a distinct geographical distribution. Four major serotypes have been described. Humans and old world primates (e.g., chimpanzees) are the only known hosts.

Natural History

Hepatitis B virus is a cause of acute hepatitis and acute liver failure (see Table 1). Globally, it is a major cause of chronic hepatitis. Infection with HBV is notable for a long incubation period ranging from 1 to 6 months. The majority (two-thirds) of persons with acute HBV infection are asymptomatic, one-third have an icteric presentation, and less than 1% present with acute liver failure. Symptoms of acute HBV are nonspecific and include anorexia, nausea, pruritus, and right upper quadrant pain. Symptoms usually resolve in ~1 to 3 months. Serum ALT levels peak with the onset of symptoms. The outcome of acute hepatitis B is strongly influenced by age at exposure. Resolution of acute infection occurs in 95% of persons exposed as adults, but chronic infection ensues in more than 90% of persons exposed as infants.

¹Not FDA approved for this indication.

²Not available in the United States.

Figure 3 Phases of chronic hepatitis B virus (HBV) infection. Chronic hepatitis B can be viewed in phases defined by HBeAg status and serum HBV DNA and ALT levels. The initial phase is the immune-tolerant phase, characterized by HBeAg positivity, high HBV DNA level ($> 10^7$ IU/mL), and persistently normal ALT levels. This is seen only in persons who acquire the infection at birth or infancy and that persists for two to three decades of life. The next phase is the immune-active phase, defined by continued HBeAg positivity, high HBV viral load ($> 10^5$ IU/mL), and elevated ALT levels. The next phase is characterized by loss of HBeAg and development of anti-HBe and heralds a transition from a phase of high viral replication to one of low replication. The viral load is typically less than 10^3 IU/mL and serum ALT is normal. This phase is termed the inactive carrier phase. A proportion of individuals develop raised HBV DNA and ALT levels after HBeAg seroconversion. These persons are said to have transitioned to the immune-escape or HBeAg-negative immune-active phase.

The natural history of chronic HBV infection depends on a complex interplay between the virus and the host immune response. Chronic HBV infection is often viewed in four phases (immune tolerant, HBeAg-positive and HBeAg-negative immune active, and inactive carrier) based on HBeAg status and serum HBV DNA and ALT levels (Figure 3). This classification is useful for providing advice on prognosis and need for treatment. Approximately 25% to 40% of persons with chronic infection will be at risk for development of cirrhosis. The 5-year cumulative incidence of cirrhosis in untreated chronic HBV infection is 8% to 20%. Once cirrhosis develops, the 5-year cumulative incidence of decompensated liver disease (ascites, variceal hemorrhage, hepatic encephalopathy) is approximately 20%, and the annual risk of hepatocellular carcinoma is 2% to 5%. Persons who have resolved chronic infection (cleared HBsAg) should be counseled of the risk for viral reactivation with use of chemotherapy or other immunosuppressive therapies.

Epidemiology

An estimated 2 billion people worldwide have evidence of past HBV infection, and of these an estimated 257 million have chronic HBV infection. The prevalence of HBV infection is declining worldwide owing to the availability of an effective vaccine and implementation of successful vaccination programs. The prevalence of HBsAg, the serologic marker of chronic infection, is highest in Sub-Saharan Africa and Central Asia ($\geq 8\%$) (see Figure 2) and lowest ($< 2\%$) in Western Europe, Australia, Canada, and the United States (except Alaska) (Figure 4). HBV is transmitted vertically, sexually, or through percutaneous routes and is more infectious than human immunodeficiency virus or hepatitis C virus. Individuals considered at high risk for acquiring HBV infection should be screened for chronic hepatitis B by testing for HBsAg (Table 2).

Diagnosis

A number of serologic markers (viral antigens and antibodies to the viral antigens) and nucleic acid testing are available to diagnose

acute and chronic HBV infection. Cases of suspected acute HBV infection are diagnosed by the detection of HBsAg, HBeAg, IgM anti-HBc, and HBV DNA in serum in the appropriate clinical setting. Although anti-HBc IgM is detected during acute HBV infection, it is not specific for acute hepatitis B and may be seen during reactivation of chronic HBV infection.

Chronic infection is defined as persistence of HBsAg for greater than 6 months in serum. If HBsAg is present, it is advised to check HBeAg, anti-HBe, HBV DNA, and serum ALT to determine the phase of infection.

Treatment

Acute HBV infection in an adult is associated with a high rate of spontaneous recovery, and antiviral treatment is rarely required. Supportive care is advised. For persons with evidence of acute liver failure, prompt institution of antiviral therapy with a potent nucleos(t)ide analog and referral to a transplant center is recommended. Peginterferon alfa-2a (Pegasis)¹ is contraindicated in persons with acute liver failure.

The goals of treatment of chronic HBV are sustained suppression of HBV DNA to prevent the development of cirrhosis, hepatocellular carcinoma, and liver-related mortality. Cure of chronic HBV infection is currently not possible because of persistence of covalently closed circular DNA within the hepatocyte nucleus. Treatment recommendations differ among regional guidelines, but treatment is generally indicated for HBeAg-positive subjects with confirmed HBV DNA greater than 2,000 to 20,000 IU/mL and serum ALT two or more times the upper limit of normal, and for HBeAg-negative patients with HBV DNA greater than or equal to 2000 IU/mL with serum ALT two or more times the upper limit of normal and/or liver biopsy-proven moderate to severe inflammation and/or moderate fibrosis. The decision to treat persons outside these parameters should be individualized based on their risk

¹Not FDA approved for this indication.

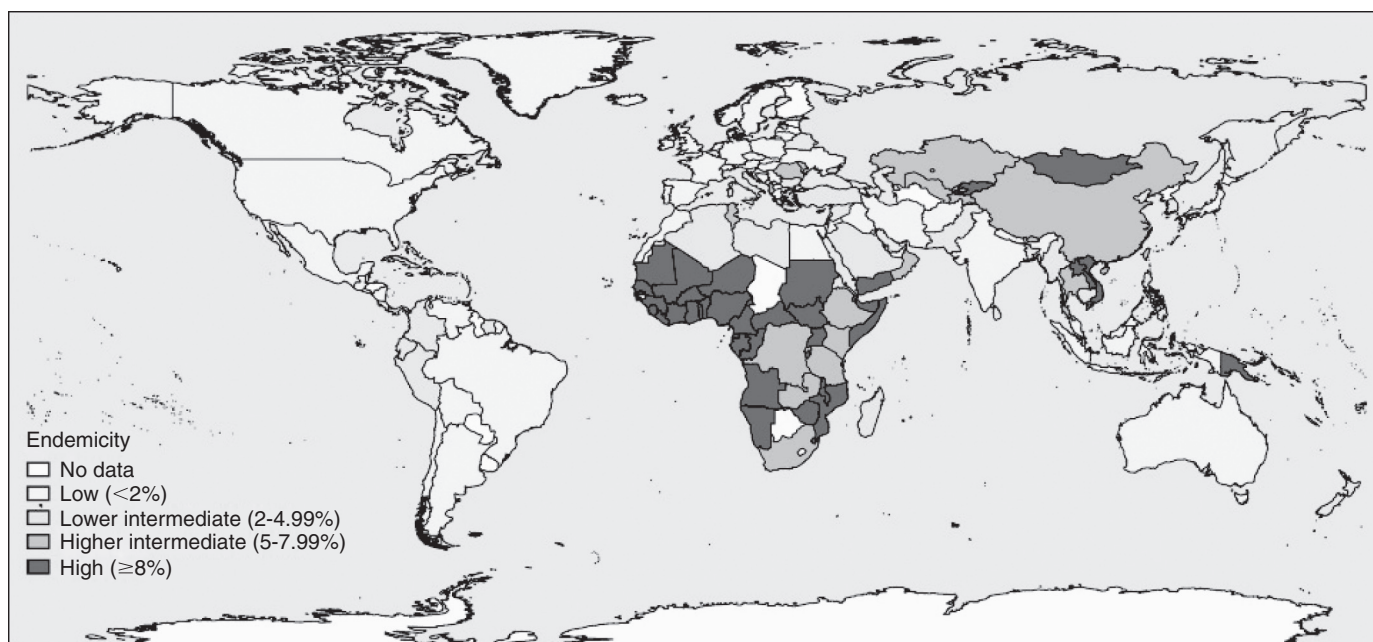

Figure 4 Global prevalence of chronic hepatitis B virus (HBV). Hepatitis B is found worldwide with varying geographical prevalence. High-prevalence areas defined as a prevalence of HBsAg greater than or equal to 8% include West Sub-Saharan Africa and Mongolia. Regions of high intermediate prevalence, defined as HBsAg prevalence of 5% to 7%, include China, Southeast Asia, and the remainder of Sub-Saharan Africa. Regions of low to intermediate prevalence, defined as HBsAg prevalence of 2% to 4%, include the Mediterranean region, India, the Middle East, Australia, and Japan. Regions with low prevalence, defined as HBsAg prevalence of less than or equal to 2%, include North America and Western Europe. Overall, the prevalence of HBV is declining worldwide.

TABLE 2 Centers for Disease Control and Prevention Guidelines for Hepatitis B Virus (HBV) Screening

Populations recommended or required for routine testing for chronic HBV infections
Persons born in regions of high and intermediate HBV endemicity (HBsAg prevalence $\geq 2\%$)
U.S.-born persons not vaccinated as infants whose parents were born in regions with high HBV endemicity ($\geq 8\%$)
Injection drug users
Men who have sex with men
Persons with elevated alanine aminotransferase/aspartate aminotransferase of unknown etiology
Donors of blood, plasma, organs, tissues, or semen
Hemodialysis patients
All pregnant women
Persons needing immunosuppressive therapy
Infants born to HBsAg-positive mothers
Household, needle-sharing, or sex contacts of persons known to be HBsAg positive
HIV-positive persons
Persons who are the sources of blood or body fluids for exposures the might require postexposure prophylaxis (e.g., needlestick, sexual assault)

Modified from Centers for Disease Control and Prevention. Recommendations for Identification and Public Health Management of Persons with Chronic Hepatitis B Virus Infection.

for complications and risk of therapy. Eight agents are approved for the treatment of chronic HBV infection: two interferon preparations, interferon alfa-2b (Intron A) and peginterferon alfa-2a (Pegasys), and six nucleos(t)ide analogs: lamivudine (Epivir

HBV), adefovir (Hepsera), entecavir (Baraclude), telbivudine (Tyzeka), tenofovir disoproxil fumarate (Viread), and tenofovir alafenamide (Vemlidy). Four agents are considered first line—peginterferon, entecavir, tenofovir, and tenofovir alafenamide—based on their safety, effectiveness, and low rates of antiviral resistance. Peginterferon is generally recommended in persons who would prefer a finite course of treatment and who have clinical and laboratory features predictive of a response to peginterferon (high ALT, low HBV DNA, young age, female gender, and HBV genotype A or B). Peginterferon is contraindicated in persons with decompensated cirrhosis, autoimmune illnesses, or active psychiatric illness. Nucleos(t)ide analogs are more potent inhibitors of HBV DNA replication and generally better tolerated than peginterferon. They are usually administered long term. The ideal endpoint of treatment is HBsAg loss, but this is rarely observed with any therapy ($< 10\%$ with interferon and after 5 years of therapy with nucleos(t)ide analogs).

Prevention

- Vaccination is the primary method of prevention. An effective vaccine against HBV has been available since 1981. In the United States, the Advisory Committee on Immunization Practices has recommended that all children complete the series of three vaccinations by 18 months of age with the first dose administered within 24 hours of birth. Infants whose mothers are HBsAg positive or whose HBsAg status is unknown should receive the last dose by 6 months of age. Hepatitis B immune globulin (HyperHEP B) and HBV vaccination is recommended at birth for infants whose mothers are HBsAg positive to prevent maternal-infant transmission of HBV. In mothers with viral loads greater than 200,000 IU/mL, antiviral therapy with tenofovir, telbivudine (Tyzeka), or lamivudine (Epivir HBV) in the third trimester of pregnancy (gestation weeks 28-32) can be considered. Postexposure prophylaxis is recommended for anyone who is exposed to HBV and is considered susceptible to HBV infection and consists of hepatitis B vaccination and/or hepatitis B immune globulin depending on the HBsAg status of the exposure source.

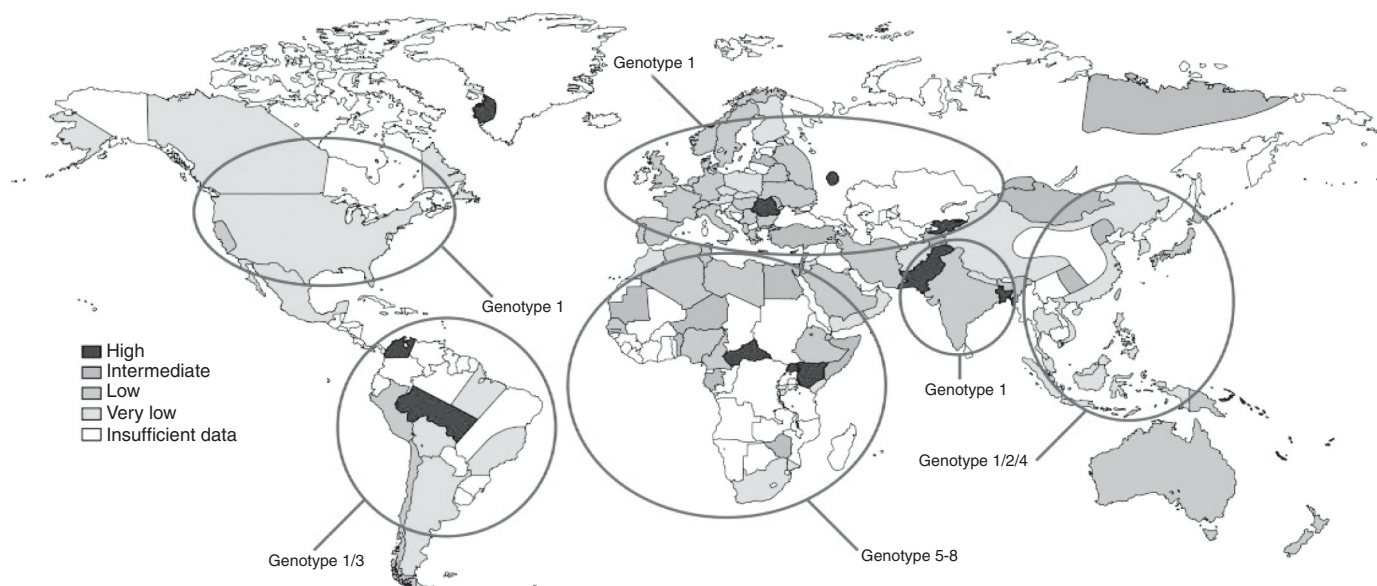

Figure 5 Global prevalence of hepatitis D virus. Hepatitis D is found globally, but prevalence varies among geographic regions. The highest prevalence is observed in Central Africa, Central Asia, and the Amazon. Intermediate-prevalence regions include West Africa and Eastern Europe. Low-prevalence regions include North America, most of Western Europe, and Australia.

Hepatitis D

Introduction

Hepatitis D virus (HDV) is a viroid that is dependent on HBV for its lifecycle. The genome consists of a negative-sense, single-stranded circular RNA virus of ~1600 bases. The virus has an outer lipoprotein envelope HBsAg derived from HBV and is attached to a single structural protein, the HDV antigen (HDAg). There are eight known genotypes. Immunity to HBV prevents HDV infection.

Natural History

Hepatitis D virus is a cause of acute hepatitis, acute liver failure, and chronic hepatitis (see [Table 1](#)). Hepatitis D virus infection can occur either simultaneously with HBV (referred to as coinfection) or as an infection in a patient with chronic HBV infection (referred to as superinfection). The outcome of HBV/HDV coinfection depends on the course of acute hepatitis B infection and is generally self-limiting with a low risk of chronicity (~5%). In contrast, HDV superinfection of a chronic HBV carrier results in chronic HDV infection in more than 90% of cases. Acute liver failure is observed more commonly with coinfection than with superinfection. Chronic HDV infection has a variable course, from an asymptomatic carrier to cirrhosis and decompensated liver disease. In general, HDV infection is associated with more rapid progression to cirrhosis and decompensated liver disease and a higher rate of hepatocellular carcinoma as compared with HBV monoinfection.

Epidemiology

In developed countries, the prevalence of HDV has declined as a consequence of widespread vaccination against hepatitis B. Chronic HDV infection is predominately seen in intravenous drug users or hemophiliacs requiring frequent transfusions. HDV is prevalent in the Amazon basin, Africa, the Mediterranean basin, Central Asia, Mongolia, and Russia ([Figure 5](#)). HDV genotype 1 can be found worldwide, but all other genotypes are restricted to specific geographic areas.

HDV is spread by the same routes as HBV infection and is efficiently transmitted by parenteral and sexual exposure. In contrast to HBV, vertical transmission is not a common mode of transmission. Transmission cannot occur in the absence of HBsAg.

Diagnosis

Testing for hepatitis D should be considered in persons presenting with acute hepatitis B who have additional risk factors for HDV, including a history of injection drug use; persons from endemic regions who present with a severe or protracted hepatitis; patients with chronic hepatitis B who develop an acute hepatitis of undetermined origin; and persons with HBsAg-positive chronic hepatitis B from endemic regions. Total anti-HDV (IgM and IgG) and anti-HDV IgM are the only commercially available assays in the United States. Initial testing for HDV should be with total anti-HDV. Chronic infection should be confirmed by a reverse transcriptase polymerase chain reaction assay for HDV RNA.

Treatment

The goals of treatment are long-term suppression of both HDV and HBV to prevent the development of cirrhosis, hepatocellular carcinoma, and liver-related death. There is no effective treatment for HDV. Interferon alfa (Intron A)¹ has been used for treatment of HDV. The most effective dose and duration of treatment have not been established. Peginterferon alfa-2a (Pegasys)¹ administered for 48 to 72 weeks results in sustained HDV RNA suppression after 6 months off therapy in 17% to 43% of patients. Liver transplantation with the use of hepatitis B immune globulin¹ is an option for patients with decompensated liver disease. Novel agents blocking viral entry and posttranslational prenylation are currently being investigated in clinical studies.

HEPATITIS C

Method of

Arthur Y. Kim, MD

CURRENT DIAGNOSIS

- Hepatitis C virus (HCV) is a common infection in the United States with major morbidity and mortality.
- Incidence of HCV is rising, linked to the opioid epidemic.
- Given the asymptomatic presentation and long period before complications, screening is warranted: undiagnosed persons born between 1945 and 1965 with no previous history of antibody testing, and people who inject drugs (Table 1).
- Diagnosis is made with two-stage testing: initial screening for anti-HCV antibodies followed by HCV RNA testing to confirm the presence of virus.

CURRENT THERAPY

- Novel therapeutic approaches that are safe and highly effective have revolutionized the care of HCV.
- The goal of therapy is cure of virus, which prevents liver-related complications and further transmission.
- Regimens of combination antivirals typically given for 12 weeks can cure over 95% of those living with HCV infection.

The diagnosis, management, and therapeutic approaches for patients living with HCV have dramatically transformed in recent years. Most people (over 95%) living with HCV infection can be

cured after 8 to 12 weeks of safe oral regimens combining antiviral agents. The availability of novel therapies enhances the effectiveness of screening patients for HCV infection who may otherwise be unaware of infection owing to its asymptomatic presentation.

Virology, Pathogenesis, and Natural History

HCV is a single-strand RNA virus whose genome encodes several viral proteins, including nonstructural proteins (NS3/4A, termed protease; NS5A, and NS5B, termed polymerase) that may each be specifically targeted by medications. There are seven known families of virus, commonly known as genotypes 1 through 7, many with subtypes (e.g., genotype 1a or 1b).

After acute infection, in the majority of individuals the virus establishes a chronic lifelong infection characterized by high levels of viremia easily detected in plasma; in a minority the virus is spontaneously cleared. In the latter scenario, HCV is permanently eradicated as the polymerase is an RNA-RNA polymerase and there is no DNA intermediate to establish latency in the host. Those who achieve clearance of virus, whether spontaneously or via treatment, are susceptible to reinfection if exposed again.

Both the acute and chronic phases of HCV infection are largely asymptomatic. A minority of those with acute infection may present with nonspecific symptoms such as abdominal pain and malaise, with less than 10% presenting with jaundice. Rarely, those with chronic infection may experience extrahepatic manifestations of HCV infection, such as cryoglobulinemic vasculitis, proteinuria or glomerulonephritis, or lymphoma. Otherwise, alanine transaminase (ALT) levels may be persistently or intermittently elevated, but may also be within normal range in up to 20% of infected individuals; thus, ALT is considered an imperfect screening test for HCV.

After establishment of chronic HCV infection, fibrosis occurs at a variable rate and may progress to cirrhosis in about 15% to 20% over a 20-year period. Fibrosis may be accelerated by other liver insults, such as alcohol use, nonalcoholic steatohepatitis, and coinfection with HIV or hepatitis B virus (HBV). Those with HCV-related cirrhosis may experience significant morbidity and mortality from various complications; screening for varices and hepatocellular carcinoma is recommended (see chapter on cirrhosis).

Epidemiology

HCV is estimated to infect at least 100 million people worldwide. In the United States, it is the leading bloodborne pathogen and infects over 3 million Americans. The highest-risk groups are those born between 1945 and 1965 (so-called baby boomers), people who inject drugs, and HIV-positive men who have sex with men. In the United States, the incidence reached a peak in the 1970s and 1980s and then steeply declined; in the past decade there has been a resurgence of new incident cases linked to a widespread opioid epidemic.

Owing to the high number of infections that occurred decades ago, a large number of Americans within the baby-boomer cohort are now at risk for unidentified long-standing HCV infection, cirrhosis, and death; at present the mortality related to HCV exceeds that related to all other notifiable infectious diseases in the United States. HCV remains the leading indication for liver transplantation.

Risk Factors

HCV is most efficiently transmitted via exposure to contaminated blood or its components. In the United States, injection drug use (IDU) is the most common mode of transmission. Nosocomial exposure to contaminated blood or blood products and poorly sterilized or reused contaminated medical equipment remains an important risk, especially if strict universal precautions are not instituted. Mother-to-child transmission is not efficient, as about 5% of children born to HCV-infected women are infected, with higher rates if HIV/HCV coinfection is present. Sexual transmission is considered very rare in the context of heterosexual relationships but does occur at higher rates in men who have sex with men, particularly with HIV and/or practices that result in bloody exposures.

TABLE 1 Recommendations for One-Time Screening

Persons born between 1945 and 1965, without prior ascertainment of risk

Risk factor–based screening

Risk behaviors

- Injection drug use (current or ever, including those who injected once)
- Intranasal drug use

Risk exposures

- Persons on long-term hemodialysis (ever)
- Persons with percutaneous/parenteral exposures in an unregulated setting
- Health care, emergency medical, and public safety workers after needlesticks, sharps, or mucosal exposures to HCV-infected blood
- Children born to HCV-infected women
- Prior recipients of transfusions or organ transplants, including persons who:
 - Were notified that they received blood from a donor who later tested positive for HCV infection
 - Received a transfusion of blood or blood components or underwent an organ transplant before July 1992
 - Received clotting factor concentrates produced before 1987
- Persons who were ever incarcerated

Other considerations

- HIV infection
- Sexually active persons about to start preexposure prophylaxis for HIV
- Unexplained chronic liver disease and/or chronic hepatitis including elevated alanine aminotransferase levels
- Solid-organ donors (deceased and living)

Abbreviation: HCV = hepatitis C virus.
Modified from <http://hcvguidelines.org>.

Diagnosis

There are two tests utilized for the diagnosis of HCV infection: testing for anti-HCV antibodies and measuring HCV RNA. The suggested algorithm is initial serologic testing to assess exposure followed by HCV RNA testing to determine current or cleared infection. Currently available anti-HCV testing is highly sensitive (> 99%) but may be falsely negative in the earliest stages of infection (typically the first 4–12 weeks) or in the setting of immunosuppression (such as dialysis or HIV if CD4 counts are below 200 cells/mm³). HCV RNA testing may be utilized to confirm current HCV RNA infection after an initial positive anti-HCV test or in settings when anti-HCV may be falsely negative. There are two types of HCV RNA tests: qualitative HCV RNA tests that do not quantify the level of viral replication and quantitative HCV RNA tests. Quantitative testing has improved in recent years and exhibits sensitivity similar to qualitative testing; therefore, it is preferred in most situations.

Those with confirmed current HCV infection (positive HCV RNA) should also be tested for HIV and HBV (the latter typically by HBsAg). Follow-up evaluation includes HCV genotype, which defines therapeutic options. Discovery of advanced fibrosis or cirrhosis may affect the specifics of recommended antiviral regimens but also has prognostic implications. The likelihood of cirrhosis is dependent on various factors, including advancing patient age, duration of infection, and cofactors such as significant alcohol use or HIV. Noninvasive assessment with serologic testing (such as Fibrosure) or with novel imaging technologies (such as transient elastography) has largely replaced liver biopsies.

Prevention

Prevention of HCV infection should be targeted to the highest-risk groups. For people who inject drugs, clean injecting equipment, including needles, syringes, and other components of drug preparation, is paramount. Risk reduction should also be achieved after viral clearance to prevent reinfection.

Prevention of fibrosis progression includes minimization or abstinence from regular alcohol use, avoidance of fatty liver, and avoidance of primary infection with or control of coexisting viruses (HIV or HBV). If not immune, vaccines against hepatitis A virus and HBV are recommended. Patients with coexisting substance use disorder should be referred for appropriate care.

Therapy

Antiviral treatments for hepatitis C have been revolutionized with combination regimens of direct-acting antivirals (DAAs). These new drugs are used in combination with the goal to eradicate HCV. Cure is known as a sustained virologic response (SVR), defined as a negative HCV RNA test 12 or more weeks after cessation of therapy. This definition represents a durable cure in the absence of reinfection. Benefits of SVR include a significant reduction in future liver-related events, especially for those with advanced fibrosis or cirrhosis. Additional benefits include abrogation of further HCV transmission, amelioration of extrahepatic manifestations (if present), and improvement in quality of life. Virtually all patients with current HCV infection are candidates for therapy.

Available agents may be classified by the viral protein they target: NS3/4A protease inhibitors: simeprevir, paritaprevir (which requires pharmacologic boosting with ritonavir), glecaprevir and grazoprevir; NS5A inhibitors: daclatasvir, elbasvir, ledipasvir, ombitasvir and pibrentasvir; the NS5A nonnucleoside inhibitor dasabuvir; and the NS5B nucleotide polymerase inhibitor sofosbuvir. Simeprevir (Olysio), daclatasvir (Daklinza), and sofosbuvir (Sovaldi) are available as single agents, but the majority are parts of combination regimens, as described in Table 2. The Infectious Diseases Society of America (IDSA) and American Association for the Study of Liver Diseases (AASLD) maintain guidelines for providers at <http://www.hcvguidelines.org>, which provides updates with approval of novel agents and as new data become available.

TABLE 2 First-Line Combination Antiviral Regimens for Chronic Hepatitis C as of August 2018, Genotypes 1–4

GENOTYPE	COMBINATION	USE OF RIBAVIRIN (RBV)	DURATION (WEEKS)	NOTES
1	Elbasvir 50 mg/grazoprevir 100 mg FDC (Zepatier) once daily	Add RBV and extend to 16 weeks if baseline NS5A RASs present (genotype 1a only)	12–16	Safety in advanced chronic kidney disease; not recommended in decompensated cirrhosis
	Glecaprevir 300 mg/pibrentasvir 120 mg FDC (Mavyret) once daily	Not proven	8–16	8 weeks for treatment naïve; 12–16 weeks for cirrhosis/certain treatment experience
	Ledipasvir 90 mg/sofosbuvir 400 mg FDC (Harvoni) once daily	Add RBV if both interferon-experienced and cirrhosis (12 weeks)	8–24	Antacids reduce absorption; 8 weeks consideration only for naïve patients with F0-2 and HCV RNA less than 6M IU/mL
	Sofosbuvir 400 mg/velpatasvir 100 mg FDC (Epclusa) once daily	Consider in select circumstances	12–24	Antacids reduce absorption
2	Glecaprevir 300 mg/pibrentasvir 120 mg FDC (Mavyret) once daily	Not proven	8–12	8 weeks for treatment naïve; 12 weeks for cirrhosis/certain treatment experience
	Sofosbuvir/velpatasvir FDC (Epclusa) once daily	Consider in select circumstances	12	Antacids reduce absorption
3	Glecaprevir 300 mg/pibrentasvir 120 mg FDC (Mavyret) once daily	Not proven	8–16	8 weeks for treatment naïve; 12–16 weeks for cirrhosis/certain treatment experience
	Sofosbuvir/velpatasvir FDC (Epclusa) once daily	Consider in select circumstances	12–24	Antacids reduce absorption

Continued

TABLE 2 First-Line Combination Antiviral Regimens for Chronic Hepatitis C as of August 2018, Genotypes 1–4—cont'd

GENOTYPE	COMBINATION	USE OF RIBAVIRIN (RBV)	DURATION (WEEKS)	NOTES
4	Elbasvir/grazoprevir (Zepatier) once daily	Consider adding RBV for cirrhosis, prior nonresponder	12–16	
	Ledipasvir/sofosbuvir FDC (Harvoni) once daily	Consider for previous SOF failure	12	
	Glecaprevir 300 mg/pibrentasvir 120 mg FDC (Mavyret) once daily	Not proven	12	8 weeks for treatment naïve; 12 weeks for cirrhosis/interferon experienced
	Sofosbuvir/velpatasvir FDC (Epclusa) once daily	Consider in select circumstances	12	Antacids reduce absorption

Abbreviations: FDC = fixed-dose combination; NS5A = nonstructural protein 5A; RASs = resistance-associated substitutions; RBV = ribavirin; SOF = sofosbuvir. Daclatasvir may need dose adjustments with certain medications with cytochrome P450 interactions.

One major consideration in choosing a regimen is the genotype of the virus, although certain regimens are able to treat all genotypes (termed pan-genotypic). Other potential influences include presence of cirrhosis, the potential for concomitant drug interactions (including those with HIV coinfection on antiretrovirals), prior treatment experience, and adherence to therapy. Certain regimens have been tested for those with advanced renal impairment. Insurance formulary preferences may also dictate the choice. One regimen in particular, elbasvir/grazoprevir (Zepatier), requires testing of genotype 1a virus for resistance-associated substitutions (RASs) that are associated with decreased response; if present the duration should be increased and ribavirin (Ribasphere) added. In general, almost all patient groups can be offered a regimen with a rate of SVR at or above 95%.

These combinations have favorable safety profiles, with phase III trials reporting very low discontinuation rates. The most common side effects of these regimens are headache and fatigue. At times, ribavirin may be added to the regimen, particularly in the cases of relapse after previous treatment and/or cirrhosis (especially if decompensated or previously decompensated).

Drug–drug interactions are also potentially problematic. Sofosbuvir-containing regimens should not be coadministered with amiodarone (Cordarone), owing to reports of symptomatic bradycardia with poor outcomes. Medications may significantly decrease absorption of HCV antivirals, especially rifampin (Rifadin), carbamazepine (Tegretol), oxcarbazepine (Trileptal), and St. John's wort.⁷ For the combinations of ledipasvir/sofosbuvir (Harvoni) and sofosbuvir/velpatasvir (Epclusa), care must be taken if coadministered with medications that decrease gastric pH. Involvement of clinical pharmacists may be very useful, along with resources such as the website maintained at the University of Liverpool: <http://hep-druginteractions.org>.

Monitoring

Compared with previous regimens that were associated with more side effects and complications, current treatments are far more tolerable. Clinical visits or phone calls to monitor for side effects and to promote adherence are often performed monthly while on treatment. A negative HCV RNA at approximately week 4 into therapy confirms adherence. Certain regimens may require more intensive monitoring in the presence of cirrhosis, as cases of decompensation have been reported. Those with active HBV replication who are untreated are at risk for reactivation of this virus once HCV is suppressed, with rare cases of liver failure reported; cotreatment of both viruses or very close monitoring is recommended for this subgroup. At this time there are no data for the use of these agents in pregnancy or breastfeeding.

⁷Available as dietary supplement.

INFLAMMATORY BOWEL DISEASE: CROHN'S DISEASE AND ULCERATIVE COLITIS

Method of

Prabhakar P. Swaroop, MD

CURRENT DIAGNOSIS

- The most common clinical symptom of ulcerative colitis (UC) is bloody diarrhea, which is often associated with cramping abdominal pain.
- Clinical manifestations of Crohn's disease (CD) are highly variable, but the most common constellation is right lower quadrant abdominal pain and nonbloody diarrhea, often accompanied by weight loss and other constitutional symptoms.
- The hallmarks of CD are transmural inflammation, fistula formation, small-bowel fibrosis, and patchy inflammation; these may affect any segment of the gastrointestinal tract (with terminal ileal involvement in two thirds of patients). In contrast, inflammation in UC is limited to mucosa and submucosa and is diffuse, with the rectum most commonly involved. Inflammation extends proximally to varying degrees among patients.
- There is no single diagnostic test for inflammatory bowel disease; instead, the diagnosis is made based on several corroborative features.
- Potential infectious causes of symptoms should be ruled out.
- Endoscopic examination is valuable in establishing the extent of inflammation, obtaining mucosal biopsy specimens, and excluding certain infectious agents.
- Serology studies, such as anti-*Saccharomyces cerevisiae* antibodies (ASCA), perinuclear antineutrophilic cytoplasmic antibody (pANCA), anti-porin antibody (OmpC), and anti-flagellin antibody (CBir1), are occasionally useful to predict disease behavior.
- Lactoferrin and Calprotectin, which are inflammatory markers found in stool, can be used to assess for postoperative recurrence in patients with Crohn's disease. A few studies have

TABLE 2 First-Line Combination Antiviral Regimens for Chronic Hepatitis C as of August 2018, Genotypes 1–4—cont'd

INFLAMMATORY BOWEL DISEASE: CROHN'S DISEASE AND ULCERATIVE COLITIS

Method of

Prabhakar P. Swaroop, MD

CURRENT DIAGNOSIS

- The most common clinical symptom of ulcerative colitis (UC) is bloody diarrhea, which is often associated with cramping abdominal pain.
- Clinical manifestations of Crohn's disease (CD) are highly variable, but the most common constellation is right lower quadrant abdominal pain and nonbloody diarrhea, often accompanied by weight loss and other constitutional symptoms.
- The hallmarks of CD are transmural inflammation, fistula formation, small-bowel fibrosis, and patchy inflammation; these may affect any segment of the gastrointestinal tract (with terminal ileal involvement in two thirds of patients). In contrast, inflammation in UC is limited to mucosa and submucosa and is diffuse, with the rectum most commonly involved. Inflammation extends proximally to varying degrees among patients.
- There is no single diagnostic test for inflammatory bowel disease; instead, the diagnosis is made based on several corroborative features.
- Potential infectious causes of symptoms should be ruled out.
- Endoscopic examination is valuable in establishing the extent of inflammation, obtaining mucosal biopsy specimens, and excluding certain infectious agents.
- Serology studies, such as anti-*Saccharomyces cerevisiae* antibodies (ASCA), perinuclear antineutrophilic cytoplasmic antibody (pANCA), anti-porin antibody (OmpC), and anti-flagellin antibody (CBir1), are occasionally useful to predict disease behavior.
- Lactoferrin and Calprotectin, which are inflammatory markers found in stool, can be used to assess for postoperative recurrence in patients with Crohn's disease. A few studies have

demonstrated the utility of elevated inflammatory markers in predicting future clinical flares.

- Computed tomographic enterography can help distinguish inflammatory component from fibrosis.
- Rectal magnetic resonance imaging, endoscopic ultrasound, or examination under anesthesia can be used to fully delineate perianal fistulizing disease.
- In centers with available expertise, limited right lower quadrant ultrasound with doppler can be used for evaluation of ileal Crohn's disease.

CURRENT THERAPY

- Mesalamine products in adequate dosage and appropriate formulation can be effective therapy for mild to moderately active ulcerative colitis (UC) and in maintaining remission.
- Mesalamine products may be effective in mild Crohn's disease (CD), and the formulation selected should be determined by disease location.
- Steroids are useful in patients with moderate to severe CD or UC, but their use should be limited as much as possible because of frequent side effects and complications.
- Immunomodulators such as Azathioprine (Imuran)¹ and 6-mercaptopurine (Purinethol)¹ may be used as an adjunct therapy to minimize steroid use in patients who are steroid dependent and to minimize formation of neutralizing antibodies in patients receiving antibody-based biologic agents.
- Anti-tumor necrosis factor (anti-TNF) biologic agents such as infliximab (Remicade) and adalimumab (Humira) are effective in patients with moderate to severe inflammatory CD or UC that is unresponsive to conventional treatments. Golimumab (Simponi), which is another anti-TNF agent, recently has been approved for induction and maintenance of remission in ulcerative colitis. It has been demonstrated to result in improvement of endoscopic appearance of colonic mucosa. Certolizumab pegol (Cimzia) may be used to maintain response. Immunomodulators and biologic agents may be used independently or in combination for treatment of inflammatory bowel disease and for maintaining surgically induced remission in CD.
- Risks of opportunistic infections, hematologic and cutaneous malignancies, and neurologic complications, in addition to other adverse effects of biologic therapy with or without immunomodulators, should be discussed with the patient.
- The proven role of antibiotics is limited to septic complications, perianal disease, small intestinal bacterial overgrowth, and pouchitis.
- Natalizumab (Tysabri), an anti- α_4 agent, is effective in some patients with refractory CD, including those for whom anti-TNF therapy has failed.
- Another Integrin inhibitor, Vedolizumab (Entyvio) has been recently approved by FDA for induction and maintenance of remission and response in both Crohn's disease and ulcerative colitis.

¹Not FDA approved for this indication.

Clinical Manifestations

The cardinal symptom of ulcerative colitis (UC) is bloody diarrhea. Symptoms of tenesmus and the sensation of incomplete evacuation may dominate in patients who have disease limited to the rectum. Although cramping abdominal pain is often present, it is a more prominent symptom in patients with Crohn's disease (CD).

Physical examination of patients with UC may detect left lower quadrant and left upper quadrant tenderness, and occasionally the extent of colonic involvement may be deduced by careful physical examination. Rebound tenderness, distention, or

guarding suggests the development of the dreaded complication of toxic megacolon, which may supervene in patients with severe UC.

Patients with CD have more widely varying symptoms as a result of the highly variable sites of involvement and the range of phenotypic forms. Disease manifestations may be dominated by inflammatory activity per se, by fistula formation (fistulizing or perforating disease), or by stricture formation (stricturing disease). Perianal fistulas can be a distressing manifestation and may parallel clinical flares. The symptom complex of right lower quadrant pain, nonbloody diarrhea, and weight loss is most common because of the frequent involvement of the ileum. However, in CD with colonic involvement (with or without more proximal disease), symptoms may be indistinguishable from those of UC. Intestinal narrowing may be caused by edema due to inflammation, fibrosis from chronic inflammation, or a combination of these factors. The presence of a mass in the right lower quadrant suggests inflammatory ileal disease (and probably abscess formation), whereas right lower quadrant pain in conjunction with obstructive symptoms in the absence of a mass may be suggestive of stricture formation. Fistula disease can manifest with especially variable symptoms because of the many anatomic structures that can be involved (e.g., fecaluria and pneumaturia in those with fistulas to the bladder). Rectovaginal fistulas may lead to passage of air from the vagina. Patients with upper gastrointestinal CD may present with dysphagia, early satiety, and fear of food leading to weight loss.

Diarrhea is common but not universal in CD. Inflammation of the ileum or of the colon can cause diarrhea. Occasionally, diarrhea is caused by small intestinal bacterial overgrowth, especially in patients with fistulizing disease, or it may be induced by bile salts in those with ileal disease (or after ileal resection).

Diagnosis

Diagnosis of inflammatory bowel disease (IBD) is based on the combination of clinical features, laboratory abnormalities, imaging studies (e.g., upper gastrointestinal series with small bowel follow-through and abdominal computed tomography or magnetic resonance imaging or both), and endoscopic findings including examination of mucosal biopsies. None of these tests alone is diagnostic of IBD. In a patient with new symptoms and in those patients with flares if appropriate, infectious agents should be ruled out. Common pathogens that can mimic IBD are *Salmonella*, *Shigella*, *Aeromonas*, *Campylobacter*, *Yersinia*, *Clostridium difficile*, *Plesiomonas*, and parasites such as *Giardia lamblia* and *Entamoeba*; these should be ruled out. In an immunocompromised host (including patients with established IBD receiving immunosuppressive therapy), viral infections such as cytomegalovirus and herpes simplex virus may cause ulcers suggestive of IBD. Endoscopic imaging is often very useful. The constellation of findings in endoscopy and other studies, together with the histologic and clinical features, usually allows a reliable distinction between UC and CD. However, in as many as 10% of patients, it may not be possible to make the distinction with confidence, and such patients are said to have indeterminate colitis. The distinguishing features of UC and CD are presented in Table 1.

Hematologic abnormalities include evidence of microcytic anemia, elevated white blood cell count in peripheral blood, and thrombocytosis. Markers of inflammation such as erythrocyte sedimentation rate (ESR) and high-sensitivity C-reactive protein (hsCRP) may also be elevated, the latter more commonly in CD than in UC. Very high hsCRP may be associated with infections such as cytomegalovirus or *Clostridium difficile*.

Serologic measurements of perinuclear antineutrophilic cytoplasmic antibody (pANCA), anti-*Saccharomyces cerevisiae* antibodies (ASCA—immunoglobulin G and immunoglobulin A), anti-porin antibody (OmpC), and anti-flagellin antibody (CBir1) are occasionally helpful as corroborative evidence and to help identify patients who are at higher risk for complicating events. They may also be useful in differentiating between CD and UC in patients for whom colectomy is being considered when diagnostic ambiguity remains.

TABLE 1 Distinguishing Features: Crohn's Disease and Ulcerative Colitis

FEATURES	CROHN'S DISEASE	ULCERATIVE COLITIS
Location	Any part of gastrointestinal tract	Colonic
Inflammation	Transmural	Mucosal/submucosal
Smoking	Smokers higher than expected	Appears to be protective
Risk of colorectal cancer	Elevated in colonic Crohn's	Elevated
Risk of intestinal cancer	Elevated in small-bowel Crohn's disease	NA
hsCRP	Elevation common	Elevation not common
Serology	ASCA, OmpC, CBir1	pANCA
Surgery	Recurrence common	Total proctocolectomy may be curative
Fistulas	Common	Very rare
FDA-approved biologic agents	Infliximab (Remicade), adalimumab (Humira), certolizumab pegol (Cimzia), natalizumab (Tysabri), vedolizumab (Entyvio)	Infliximab, adalimumab, golimumab, vedolizumab (Entyvio)
Immunomodulator therapy	Azathioprine (AZA, Imuran), ¹ 6-mercaptopurine (6MP, Purinethol), ¹ methotrexate (MTX, Trexall) ¹	AZA, 6MP, cyclosporine (Sandimmune, Neoral) ¹
Endoscopic features	Skip lesions	Contiguous involvement
Strictures	Common	Colorectal cancer unless proven otherwise
Genetic markers*	NOD2, ATG16L1, IRGM, IL23R, IL12B, STAT3, NKX2-3	IL12B, STAT3, NKX2-3

Abbreviations: ASCA = anti-*Saccharomyces cerevisiae* antibodies; CBir1 = anti-flagellin antibody; FDA = U.S. Food and Drug Administration; hsCRP = high-sensitivity C-reactive protein; NA = not applicable; OmpC = anti-porin antibody; pANCA = perinuclear antineutrophilic cytoplasmic antibody.

¹Not FDA approved for this indication.

*Not approved for diagnosis. More than 50 genes have been associated with susceptibility to IBD.

Hypoalbuminemia can be a sign of poor nutritional status, and these patients should be considered for total parenteral nutrition, particularly if surgery is being planned.

Among the imaging modalities commonly used in diagnosis and management of IBD, computed tomography of the abdomen and pelvis can alert physicians to perforation, bowel obstruction, and extent of inflammation. Computed tomographic enterography can be used to evaluate the degree and extent of inflammation in the small bowel (Figure 1). In cases of stenotic lesions of the small bowel, it can be especially helpful in identifying the inflammatory component, as evidenced by mural stranding. Lack of mural stranding in stenotic portions of small bowel suggests fibrosis, and if there is evidence of proximal dilation in a symptomatic patient, resection or strictureplasty should be considered. Ultrasound scanning of the right lower quadrant can be an effective imaging modality in select patient populations to assess for postoperative recurrence, disease activity, and response to therapy.

Magnetic resonance imaging can be a helpful adjunct, along with examination under anesthesia and rectal endoscopic ultrasonography, in cases of perianal fistulizing disease.

Endoscopic examination is helpful to establish the extent of disease and obtain tissue for histologic examination. Esophagogastroduodenoscopy should be done if upper gastrointestinal CD is suspected. Single-balloon and double-balloon enteroscopy have allowed gastroenterologists to obtain tissue samples from jejunum and proximal ileum. Capsule endoscopy can be a useful alternative, although it does not allow tissue sampling and should not be used if even limited obstruction is suspected. Colonoscopy is helpful in diagnosis and during follow-up to assess response to various therapeutic modalities. It can also be used to obtain biopsy specimens from the colon and terminal ileum to be examined for findings of IBD or potentially confounding processes, including some infections. Stool Calprotectin can be a valuable tool to assess efficacy of therapies, monitor for postsurgical recurrence in patients with Crohn's disease, and differentiate between inflammatory and non-inflammatory etiologies of diarrhea in patients with IBD.

Figure 1 Computed tomographic enterography. Mural stratification; ileal wall thickening (arrow) suggestive of active inflammation; dilated loops of small bowel (double arrow) consistent with partial obstruction; and diffuse increased density of the subcutaneous and intraperitoneal fat compatible with anasarca are seen in this image. (Courtesy Dr. Cecelia Brewhington, MD.)

Treatment

Once the diagnosis is confirmed, the treatment of IBD is based on manifestation, location, patient history, and severity of symptoms.

Treatment algorithms for IBD are usually divided into management of mild, moderate, and severe disease. The roles of various agents have evolved, and as more data are being accumulated,

patients are treated earlier with agents that had been reserved for more severe disease in the past. Treatment goals for these patients are:

- Improving quality of life to as close to normal as possible
- Maintaining remission
- Avoiding surgery
- Minimizing the risk of steroid dependence
- Minimizing the risk of treatment-associated complications

Ulcerative Colitis

In the initial evaluation of UC patients, it is important to establish the extent and degree of inflammation and the concomitant presence of extraintestinal manifestations. Extent and severity of UC are judged on clinical symptoms, basic laboratory parameters (complete blood count and albumin level), and colonoscopic findings. Disease limited to the rectum and distal colon may be treated with local mesalamine therapy, in a suppository (Canasa), foam (Salofalk),² or enema (Rowasa) formulation. Newly diagnosed patients with mild to moderate disease activity should be given an appropriate oral formulation of mesalamine (Asacol). Mesalamine formulation as Asacol has been discontinued in the United States. Patients who are on Asacol can be switched to alternate mesalamine formulations, keeping in mind that the replacement agent should deliver an equivalent amount of mesalamine to the colon. One of the substitute mesalamine preparations is Delzicol, which delivers 400 mg of mesalamine per capsule. Antidiarrheal agents may provide symptomatic relief once infectious causes of colitis have been excluded. Colonic release budesonide (Uceris) recently has been approved for short-term (up to 16 weeks) therapy of mild to moderate ulcerative colitis.

If remission is achieved with a mesalamine formulation, the same dose of mesalamine is continued for maintenance of remission. For an occasional flareup suggested by symptoms of recurrence and documented by sigmoidoscopy or colonoscopy, steroids may be used. For patients who have frequent flareups (more than two per year), initiation of therapy with a conventional immunomodulator or biologic agent (infliximab, adalimumab, or golimumab) should be considered. Colonic release budesonide formulation utilizing MMX technology, marketed as Uceris, has been shown to be an effective but probably short-term (up to 16 weeks) therapy for active mild to moderate ulcerative colitis.

For patients with moderate disease unresponsiveness to mesalamine or severe disease, a topical, oral, or intravenous corticosteroid (depending on extent and severity) may be necessary, but it should be used for as short a period as possible, and, if it is not possible to taper and discontinue the steroid within 6 weeks, an immunomodulator should be added.

Surgical intervention should be considered for patients who have not responded to therapy with biologic agents, steroids, or cyclosporine (Neoral).¹ Patients who have high-grade dysplasia or colorectal cancer are also candidates for surgery.

Crohn's Disease

Optimal treatment of CD is based on many factors, including location, severity, specific clinical manifestation and complications, prior clinical course intervention, whether fistulas are present, potential fibrostenotic strictures, history of steroid dependence, history of failure with other agents, and contraindications (e.g., malignancy, opportunistic infections, tuberculosis, intolerance to medications). Before deciding on treatment options, it is important to delineate behavior (fistulizing, stricturing, or inflammatory), location (ileal, colonic, or ileocolonic), and severity and to assess for the presence of extraintestinal complications and nutritional deficiencies.

In patients with mildly active, localized ileocecal disease, treatment has historically begun with a suitable mesalamine product (although the effectiveness of this approach remains uncertain).¹

More recently, oral budesonide (Entocort EC, a steroid targeted to the ileum that undergoes extensive first-pass metabolism to minimize systemic steroid effects) has been used. For those with more extensive or severe disease, conventional systemic steroids (prednisone) may be used, but if it is not possible to wean the patient off steroids within 6 weeks, an immunodulatory agent should be started, typically 6-mercaptopurine (Purinethol)¹/azathioprine (Imuran)¹ or, in those unable to tolerate these agents, low-dose methotrexate (Trexall).¹ For patients with moderate to severe disease, treatment should include an anti-tumor necrosis factor (anti-TNF) agent with or without immunomodulator therapy. Natalizumab (Tysabri), an anti- α_4 integrin, is an alternative and may be used if anti-TNF therapy fails.

Before starting therapy with a biologic agent, patients should have a purified protein derivative (PPD) test and a hepatitis B surface antibody determination. Once biologic therapy begins, patients should continue to have an annual PPD test. QuantiFERON-TB Gold testing is a possible alternative to PPD for testing. This requires patients to come for testing once, as opposed to twice for PPD. We recommend checking for John Cunningham (JC) virus antibody before starting therapy with natalizumab. JC virus is a polyomavirus that is responsible for progressive multifocal leukoencephalopathy. Those testing positive should not be started on natalizumab. Patients who test negative should be tested for exposure at least twice a year.

Plans for alternative therapies should be made for patients who have not responded to a biologic agent within 12 weeks.

Perianal fistulizing disease, in the absence of abscess, can be treated with a combination of antibiotics, seton placement, immunomodulator therapy, and biologic agents. Complex perianal fistulizing disease may require a diverting ostomy.

Therapeutic Options

Mesalamine Preparations

Aminosalicylate preparations have been used for the treatment of UC and CD. Some data suggest that mesalamine has limited efficacy in patients with CD.

In patients with limited distal UC (e.g., proctitis), treatment may be begun with a mesalamine enema (Rowasa) or suppository (Canasa). For more extensive disease, oral therapy (Asacol) or an appropriate substitute mesalamine product should be used.

Combination therapy (oral administration, as well as enemas/suppositories) has been shown to be more effective in inducing remission than either modality alone. In general, the dosage that induces remission is used for maintenance of remission (Table 2).

Steroids

The National Co-operative Crohn's Disease Study and the European Co-operative Crohn's Disease Study demonstrated that steroids are efficacious in inducing remission but ineffective in maintaining remission. Among patients who have received steroids, about 26% will have a partial response, and 16% will have no response; among those who have had a complete or partial response, about 28% will become steroid dependent. The requirement for surgery is high in the latter group of patients; about 38% require surgery by the end of 1 year.

The adverse effects of steroids are many and varied and can be classified as early effects and delayed effects associated with prolonged use (>12 weeks). Acne, moon facies, mood changes, sleep disturbances, gastrointestinal intolerance, hyperglycemia, hypertension, weight gain, and ulcers of the gastrointestinal tract can be seen early. Formation of cataracts, aseptic necrosis, suppression of the hypothalamic-pituitary axis, and myopathy are associated with prolonged use. Loss of bone density, previously thought to occur only with long-term use, may be evident in bone density studies after as little as 2 weeks of therapy.

Budesonide (Entocort EC) is used for ileal inflammatory and right-sided colonic CD, with lower expected incidences of acne,

TABLE 2 Mesalamine Products Indicated for Ulcerative Colitis

AMINOSALICYLATE PRODUCT	DAILY DOSAGE	FREQUENCY
Azulfidine (sulfasalazine tablet)	0.5 g–4 g	qid
Delzicol	2.4 g	tid
Pentasa (mesalamine controlled-release tablet)	2–4 g	qid
Colazal (balsalazide capsule)	6.75 g	tid
Dipentum (olsalazine capsule)	1 g	bid
Lialda (mesalamine delayed-release tablet)	2.4–4.8 g	qd
Canasa (mesalamine rectal suppository)*	1 g	qd
Rowasa (mesalamine rectal enema) [†]	4 g	qd
Apriso (mesalamine delayed and extended-release capsule)	1.5 g	qd

*Indicated for ulcerative proctitis.

[†]Indicated for distal ulcerative colitis.

moon facies, adrenal suppression, and loss of bone mineral density. Alternative therapies (immunomodulators, biologic agents) should be discussed with the patient if there has been no response to steroids in a few weeks.

Immunomodulatory Therapy

Azathioprine¹ and 6-mercaptopurine¹ are immunomodulators used as steroid-sparing agents for both CD and UC. Immunomodulators have been shown to modestly reduce the incidence of post-surgical recurrence in CD. The onset of action of these agents is slow, up to 3 to 4 months. Some toxicities are associated with genetic variants in the enzymes responsible for catabolism of azathioprine and 6-mercaptopurine, most notably thiopurine methyltransferase (TPMT). Most (89%) patients have wild-type TPMT (full TPMT enzyme activity), 11% have intermediate enzyme activity, and 0.3% have none. In patients with full TPMT enzyme activity, therapy should be started with 1.5 mg/kg/day of 6-mercaptopurine or 2.5 mg/kg/day of azathioprine; those with intermediate activity should have the dosage reduced by half. Those who do not have any TPMT expression should not be started on these agents because of the high risk of bone marrow toxicity.

Some complications, including pancreatitis, hepatotoxicity, and serum sickness–like syndrome, cannot be predicted. It is recommended that patients starting these medications have a complete blood count and liver function tests performed every other week while their medications are being adjusted. Once they are on a stable dosage, these tests should be done every 2 to 3 months.

Parenteral methotrexate¹ 15 to 25 mg/week can be used to induce remission in patients with CD that has not responded to conventional agents. Once remission has been achieved, oral methotrexate¹ 15 mg can be used to maintain remission. Methotrexate is absolutely contraindicated in pregnancy. Leukopenia, hepatic fibrosis, nausea and vomiting, and hypersensitivity reactions are potential side effects. Risk of hepatic fibrosis is associated with a cumulative dose of more than 1.5 g, diabetes, and concomitant use of alcohol.

Cyclosporine

In patients with severe UC, intravenous cyclosporine (Sandimmune)¹ at a dose of 2 to 4 mg/kg/day has been shown to be effective in inducing remission. A significant proportion of these patients may still require colectomy within 1 year. Those patients who

have achieved response and remission on intravenous cyclosporine should be started on oral cyclosporine (Neoral)¹ for a few months, together with prophylaxis against *Pneumocystis*. 6-Mercaptopurine or azathioprine can also be used as maintenance agents.

Side effects commonly seen with cyclosporine include renal dysfunction, seizures (particularly in patients with hypocholesterolemia), hypertension, gingival hyperplasia, electrolyte abnormalities, and hirsutism.

Biologic Agents

Infliximab is a chimeric (murine-human) monoclonal anti-TNF antibody that has been approved for induction and maintenance of remission in both CD and UC. It was initially approved for the treatment of fistulizing CD, and subsequent studies showed it to be effective in maintenance therapy as well. In several other studies, it was found to be efficacious in reducing steroid use, length of hospital stay, and surgical intervention and achieving mucosal healing. Infliximab is administered intravenously with or without premedication to avoid allergic reactions.

For induction, infliximab 5 mg/kg is administered at weeks 0, 2, and 6, and maintenance is begun at 5 mg/kg every 8 weeks. Some patients require dose escalation because of diminution of response or failure to maintain remission. In these patients, depending on the clinical scenario, the dose should be increased to 10 mg/kg or the interval reduced to every 6 weeks. In the past, infliximab was routinely used with concomitant immunomodulator therapy to reduce the possibility of infliximab antibodies, but this practice has been associated with a higher risk for a rare hepatosplenic T-cell lymphoma (predominantly in the pediatric population), leading to reconsideration of the need for concomitant immunomodulators in some patients. However, results from the recently released Study of Biologic and Immunomodulator Naïve Patients in Crohn's Disease (SONIC) trial demonstrated the superiority of combination therapy over either immunomodulator or infliximab alone, especially in patients with elevated C-reactive protein and ulcers in their baseline colonoscopy. Because reactivation of latent tuberculosis has been reported, patients should undergo a PPD test or QuantiFERON-TB gold and chest radiography before beginning therapy. Available data, although limited, suggests that biologic agents (Infliximab, Adalimumab, Certolizumab and Tysabri) are safe for conception and pregnancy, as well as breast feeding.

Other Anti-Tumor Necrosis Factor Antibodies

Adalimumab

Recently, adalimumab (Humira), a recombinant fully human immunoglobulin targeting TNF, was approved for use in CD. In the CLASSIC and CHARM trials, adalimumab was demonstrated to be an effective agent in inducing and maintaining remission. It has also been shown to be effective in patients who have lost response to infliximab or are intolerant to it, but it has not yet been approved for treatment of UC. Serious reactions, reactivation of tuberculosis, allergic reactions, lupus-like reactions, and demyelinating diseases are some of the concerns.

For induction, adalimumab 160 mg is given subcutaneously at week 0, 80 mg at week 2, and then, for maintenance of remission, 40 mg every other week.

Certolizumab

Certolizumab (Cimzia) is a polyethylene-glycolated Fab fragment of humanized anti-TNF monoclonal antibody approved for use in CD. In the PRECISE 1 and 2 studies, certolizumab was shown to result in modest improvement in response but no clinically significant improvement in remission.

Golimumab

Golimumab (Simponi) is another monoclonal TNF antibody that has been approved for the treatment of moderate to severe

¹Not FDA approved for this indication.¹Not FDA approved for this indication.

Ulcerative Colitis
Proctitis

- Initial treatment choices
 - Mesalamine suppositories (Canasa) or enemas (Rowasa) to induce remission
 - Steroid foam enemas (Cortifoam) to induce remission
 - Mesalamine suppositories or enemas to maintain remission
- Second-line treatment choices
 - Oral mesalamine in combination with local therapy
 - Adjunctive treatment with antibiotics: ciprofloxacin (Cipro),¹ metronidazole (Flagyl),¹ or rifaximin (Xifaxan)¹
 - Probiotics

Left-Sided Colitis

- Initial treatment choices
 - Oral mesalamine product with or without local therapy
- Second-line treatment choices
 - Oral or intravenous steroids budesonide (Uceris)
 - Immunomodulator therapy
 - Infliximab (IFX, Remicade), adalimumab (Humira), golimumab (Simponi)
 - Cyclosporine (Sandimmune)¹ on an inpatient basis (avoid cyclosporine after IFX therapy due to risk of severe immunosuppression)

Pancolitis

- Initial treatment choices
 - Oral mesalamine with a short course of oral or intravenous steroids including colonic-release budesonide
- Second-line treatment choices
 - Immunomodulator therapy
 - Infliximab, adalimumab, golimumab
 - Cyclosporine on an inpatient basis (avoid cyclosporine after IFX therapy due to risk of severe immunosuppression)

Crohn's Disease
Ileocecal Inflammatory Crohn's Disease

- First-line treatment
 - Oral mesalamine (ileo-colonic release mesalamine product for ileal disease; Pentasa for more proximal small-bowel disease)¹
 - Budesonide (Entocort EC) 9 mg PO qd
 - Immunomodulator therapy
 - Biologic agents with or without concomitant immunomodulators

Ileal Stricturing Disease

- No proximal dilation
 - Trial with budesonide or biologic agents (patients with elevated hsCRP are more likely to respond)
- Proximal small-bowel dilation
 - Consider surgical approach

Internally Fistulizing Disease without Intraabdominal Abscess

- Stricture immediately distal to fistula
 - Surgical approach
- No stricture
 - Biologic agents with or without concomitant immunomodulators

Externally Fistulizing Disease without Intraabdominal Abscess

- Biologic agents with or without concomitant immunomodulators

Fistulizing Disease with Intraabdominal Abscess

- Intravenous antibiotics as appropriate
- Percutaneous drainage if appropriate
- Surgical drainage if indicated
- Biologic agents with or without concomitant immunomodulators once infectious process has been treated

Perianal Crohn's Disease without Abscess Formation

- Antibiotics: Ciprofloxacin (Cipro),¹ metronidazole (Flagyl),¹ rifaximin (Xifaxan)¹
- Immunomodulators
- Biologic agents with or without concomitant immunomodulators
- Seton placement
- Diverting ostomy

Colonic Crohn's Disease

- Oral steroids to induce remission
- Immunomodulator therapy
- Biologic agents with or without concomitant immunomodulator therapy

¹Not FDA approved for this indication.

Abbreviations: OhsCRP = high-sensitivity C-reactive protein.

ulcerative colitis. It should be considered as one of the treatment options when patients have begun failing therapy with mesalamine products or are at risk for developing steroid dependence. After two starter doses it is a monthly self-injectable treatment.

Anti- α_4 Therapy
Natalizumab

Natalizumab (Tysabri) is a humanized monoclonal antibody against the α_4 integrin subunit, a molecule involved in cellular adhesion that is required for recruitment of key immune cells to sites affected by IBD. In several studies, it has been shown to be efficacious in inducing remission and maintaining response in CD patients. Enthusiasm has been tempered by the apparent risk for progressive multifocal leukoencephalopathy, a rare but fatal opportunistic infection. Before initiating therapy with this agent, patient will need to be enrolled in the TOUCH program (www.tysabri.com) and should be tested for evidence of prior exposure to JC virus. If the test is positive, alternative therapies should be considered. If the test is negative, JC virus antibody testing should be done at least twice a year while the patient is on natalizumab.

Vedolizumab (Entyvio) is another humanized α_4 , β_7 integrin inhibitor that mediates its anti-inflammatory activity in the gastrointestinal tract via MAdCAM pathway. It does not affect CSF T lymphocyte immunophenotype and its activity seems to be localized in the gut.

The treatment regimens for UC and CD are summarized in Box 1.

INTESTINAL PARASITES

Method of

Nathan Thielman, MD, MPH; and Elizabeth Reddy, MD

CURRENT DIAGNOSIS

Signs and Symptoms

- Watery diarrhea—Most protozoal infections: *Giardia*, *Blastocystis*, *Dientamoeba*, *Cryptosporidium*, *Cyclospora*, *Cystoisospora*, *Microsporidia*
- Dysentery—Most commonly *Entamoeba histolytica*; less commonly *Balantidium coli*, *Trichuris trichiura* (whipworm)
- Eosinophilia—Throughout chronic infection: *Strongyloides*, schistosomiasis, *Cystoisospora*; usually only in early infection: *Ascaris*, hookworm, whipworm
- Prolonged or severe diarrhea in HIV infection—Spore-forming protozoal infections: *Cryptosporidium*, *Cyclospora*, *Cystoisospora*, *Microsporidia*
- Visible worms passed in stool—*Ascaris*, *Taeniasis*, *Diphyllobothrium*

Diagnosis of Parasitic Infections

- Stool antigen assay—*Entamoeba histolytica*, *Giardia*, *Cryptosporidium*
- Serology*—*Strongyloides*, schistosomiasis
- Stool for ova and parasites—All intestinal parasites. Sensitivity increased with repeat examinations if necessary. Concentration, preservation, and staining improve diagnosis of certain pathogens.

Note: Key features of intestinal parasitic infection may overlap with other conditions, including nonparasitic infections, and extra intestinal parasites.

*Optimal method of diagnosis in returned travelers and immigrants from endemic to nonendemic areas. Does not distinguish between active and resolved infections.

Intestinal parasites are a diverse group of pathogens with local and global significance. Immigration, international adoption, travel, and the frequency of HIV/AIDS and other immune-compromising conditions (e.g., malignancy, organ transplantation) have all contributed to a need for ongoing or increased awareness of parasitic infections in the United States. Persons who reside in chronic care facilities, children in daycare, and persons whose sexual practices increase the likelihood of fecal–oral contact are also at risk for acquiring intestinal parasitic infection.

Globally, intestinal parasites are responsible for an enormous burden of disease. Although these pathogens are rarely fatal, ongoing exposure to intestinal parasites among persons in endemic areas exacerbates malnutrition, carries multiple morbidities, and causes stunting of growth and development in children, all of which have far-reaching consequences.

Patients who present with diarrheal illness (especially prolonged or travel-associated), unexplained eosinophilia, or expulsion of worms should be evaluated for intestinal parasites. In such cases, a careful history should focus on the patient's country of origin, detailed travel and recreational activities, dietary habits and new or unusual food exposures, occupation, sexual history, sick contacts, and risks for or known immunodeficiency. Some specialists advocate obtaining a complete blood count with differential to assess eosinophil count in all international adoptees and immigrants from areas where parasitic infections are common. If eosinophilia is present, antibody testing for schistosomiasis and

strongyloidiasis—two chronic parasitic infections with potentially serious consequences—should be performed, and appropriate therapy should be administered if infection is discovered. For key features of common intestinal parasitic infections, see the Current Diagnosis box.

Diagnosis of intestinal parasites has improved recently with the advent of quick, simple, and accurate stool antigen tests for some major pathogens, such as *Entamoeba*, *Giardia* and *Cryptosporidium* species. However, the fecal examination for ova and parasites is still the mainstay of diagnosis in many cases. Whenever possible, stool specimens should be sent to a laboratory with clinical expertise in parasitology, where wet preparation, concentration, or staining can identify most pathogens. Evaluation of fresh specimens and repeated examinations improve diagnostic sensitivity. Key diagnostic points are summarized in the Current Diagnosis box.

This review focuses on basic understanding, recognition, diagnosis and treatment of common intestinal parasites in the United States and throughout the world. Within each section, parasites are listed in order of relative clinical significance.

Protozoa: Amoebae, Flagellates, Ciliates

Entamoeba histolytica

Entamoeba histolytica, the cause of amoebic dysentery and amebic liver abscess, is a worldwide pathogen of major clinical significance. Approximately 10% of the world's population and up to 60% of children in highly endemic areas show serologic evidence of infection, and *E histolytica* is estimated to cause 100,000 deaths per year globally. In the United States, infection is almost exclusively found among returned travelers, immigrants from endemic areas (especially Mexico and Central and South America), men who have sex with men (MSM), and institutionalized persons. *E histolytica* exists in only two forms, the hardy cyst characterized by four nuclei, and the trophozoite, which has a single nucleus and survives poorly outside the human body. It is important to note that *Entamoeba dispar* and *Entamoeba moshkovskii*, which are morphologically identical to *E histolytica* in stool microscopy, are now thought to be largely nonpathogenic species. Other *Entamoeba*, including *Entamoeba hartmanni*, *Entamoeba coli*, *Entamoeba polecki*, and others, can be individually identified on microscopy but are of uncertain pathogenicity and generally considered benign.

E histolytica infection is acquired by ingestion of cysts in contaminated water or food or by fecal–oral contact, as can occur in chronic care facilities or with anal–oral sexual practices. Acquisition of the parasite can result in asymptomatic infection (most common), diarrheal illness, or extraintestinal infection, the latter most commonly manifest as amebic liver abscess. An appropriately robust layer of colonic mucin may be protective against symptomatic infection, whereas attachment to intestinal epithelium results in penetration of the organism into the submucosal layer, where extensive tissue destruction can take place in the form of apoptosis and lysis of cells, hence the name “histolytica.”

Symptoms of classic amebic dysentery begin insidiously 1 to 2 weeks after infection. Diarrhea is almost universal and typically consists of numerous small-volume stools that can contain mucus or frank blood, or both. Stools are almost always heme positive if not grossly bloody. Abdominal pain and tenesmus are common; fever is present in approximately 30% of cases. Some persons have a chronic course characterized by weight loss, intermittent loose stools, and abdominal pain. Rare presentations of amebic dysentery include amebomas, which can mimic malignancy, and perianal ulcerations or fistulae. Severe disease can occur in the form of fulminant colitis or toxic megacolon; the latter almost universally requires colectomy. Young age, pregnancy, and corticosteroid use predispose to severe infection. Although persons with HIV infection or AIDS can develop invasive disease, *E histolytica* does not appear to be a common opportunistic infection, and infection is curable in this population.

INTESTINAL PARASITES

Method of

Nathan Thielman, MD, MPH; and Elizabeth Reddy, MD

CURRENT DIAGNOSIS

Signs and Symptoms

- Watery diarrhea—Most protozoal infections: *Giardia*, *Blastocystis*, *Dientamoeba*, *Cryptosporidium*, *Cyclospora*, *Cystoisospora*, *Microsporidia*
- Dysentery—Most commonly *Entamoeba histolytica*; less commonly *Balantidium coli*, *Trichuris trichiura* (whipworm)
- Eosinophilia—Throughout chronic infection: *Strongyloides*, schistosomiasis, *Cystoisospora*; usually only in early infection: *Ascaris*, hookworm, whipworm
- Prolonged or severe diarrhea in HIV infection—Spore-forming protozoal infections: *Cryptosporidium*, *Cyclospora*, *Cystoisospora*, *Microsporidia*
- Visible worms passed in stool—*Ascaris*, *Taeniasis*, *Diphyllobothrium*

Diagnosis of Parasitic Infections

- Stool antigen assay—*Entamoeba histolytica*, *Giardia*, *Cryptosporidium*
- Serology*—*Strongyloides*, schistosomiasis
- Stool for ova and parasites—All intestinal parasites. Sensitivity increased with repeat examinations if necessary. Concentration, preservation, and staining improve diagnosis of certain pathogens.

Note: Key features of intestinal parasitic infection may overlap with other conditions, including nonparasitic infections, and extra intestinal parasites.

*Optimal method of diagnosis in returned travelers and immigrants from endemic to nonendemic areas. Does not distinguish between active and resolved infections.

Intestinal parasites are a diverse group of pathogens with local and global significance. Immigration, international adoption, travel, and the frequency of HIV/AIDS and other immune-compromising conditions (e.g., malignancy, organ transplantation) have all contributed to a need for ongoing or increased awareness of parasitic infections in the United States. Persons who reside in chronic care facilities, children in daycare, and persons whose sexual practices increase the likelihood of fecal–oral contact are also at risk for acquiring intestinal parasitic infection.

Globally, intestinal parasites are responsible for an enormous burden of disease. Although these pathogens are rarely fatal, ongoing exposure to intestinal parasites among persons in endemic areas exacerbates malnutrition, carries multiple morbidities, and causes stunting of growth and development in children, all of which have far-reaching consequences.

Patients who present with diarrheal illness (especially prolonged or travel-associated), unexplained eosinophilia, or expulsion of worms should be evaluated for intestinal parasites. In such cases, a careful history should focus on the patient's country of origin, detailed travel and recreational activities, dietary habits and new or unusual food exposures, occupation, sexual history, sick contacts, and risks for or known immunodeficiency. Some specialists advocate obtaining a complete blood count with differential to assess eosinophil count in all international adoptees and immigrants from areas where parasitic infections are common. If eosinophilia is present, antibody testing for schistosomiasis and

strongyloidiasis—two chronic parasitic infections with potentially serious consequences—should be performed, and appropriate therapy should be administered if infection is discovered. For key features of common intestinal parasitic infections, see the Current Diagnosis box.

Diagnosis of intestinal parasites has improved recently with the advent of quick, simple, and accurate stool antigen tests for some major pathogens, such as *Entamoeba*, *Giardia* and *Cryptosporidium* species. However, the fecal examination for ova and parasites is still the mainstay of diagnosis in many cases. Whenever possible, stool specimens should be sent to a laboratory with clinical expertise in parasitology, where wet preparation, concentration, or staining can identify most pathogens. Evaluation of fresh specimens and repeated examinations improve diagnostic sensitivity. Key diagnostic points are summarized in the Current Diagnosis box.

This review focuses on basic understanding, recognition, diagnosis and treatment of common intestinal parasites in the United States and throughout the world. Within each section, parasites are listed in order of relative clinical significance.

Protozoa: Amoebae, Flagellates, Ciliates

Entamoeba histolytica

Entamoeba histolytica, the cause of amebic dysentery and amebic liver abscess, is a worldwide pathogen of major clinical significance. Approximately 10% of the world's population and up to 60% of children in highly endemic areas show serologic evidence of infection, and *E histolytica* is estimated to cause 100,000 deaths per year globally. In the United States, infection is almost exclusively found among returned travelers, immigrants from endemic areas (especially Mexico and Central and South America), men who have sex with men (MSM), and institutionalized persons. *E histolytica* exists in only two forms, the hardy cyst characterized by four nuclei, and the trophozoite, which has a single nucleus and survives poorly outside the human body. It is important to note that *Entamoeba dispar* and *Entamoeba moshkovskii*, which are morphologically identical to *E histolytica* in stool microscopy, are now thought to be largely nonpathogenic species. Other *Entamoeba*, including *Entamoeba hartmanni*, *Entamoeba coli*, *Entamoeba polecki*, and others, can be individually identified on microscopy but are of uncertain pathogenicity and generally considered benign.

E histolytica infection is acquired by ingestion of cysts in contaminated water or food or by fecal–oral contact, as can occur in chronic care facilities or with anal–oral sexual practices. Acquisition of the parasite can result in asymptomatic infection (most common), diarrheal illness, or extraintestinal infection, the latter most commonly manifest as amebic liver abscess. An appropriately robust layer of colonic mucin may be protective against symptomatic infection, whereas attachment to intestinal epithelium results in penetration of the organism into the submucosal layer, where extensive tissue destruction can take place in the form of apoptosis and lysis of cells, hence the name “histolytica.”

Symptoms of classic amebic dysentery begin insidiously 1 to 2 weeks after infection. Diarrhea is almost universal and typically consists of numerous small-volume stools that can contain mucus or frank blood, or both. Stools are almost always heme positive if not grossly bloody. Abdominal pain and tenesmus are common; fever is present in approximately 30% of cases. Some persons have a chronic course characterized by weight loss, intermittent loose stools, and abdominal pain. Rare presentations of amebic dysentery include amebomas, which can mimic malignancy, and perianal ulcerations or fistulae. Severe disease can occur in the form of fulminant colitis or toxic megacolon; the latter almost universally requires colectomy. Young age, pregnancy, and corticosteroid use predispose to severe infection. Although persons with HIV infection or AIDS can develop invasive disease, *E histolytica* does not appear to be a common opportunistic infection, and infection is curable in this population.

Amebic liver abscess is the most common extraintestinal complication of *E. histolytica*; cerebral and ocular amebiasis have also been reported. Amebic liver abscess affects children of both sexes equally, but it is up to nine times more common in men, indicating that hormonal milieu likely plays a role. Amebic liver abscess almost always manifests within 3 to 5 months of initial infection, but it can surface years later. Illness is characterized by fever and abdominal tenderness that worsen over several days to weeks. Weight loss, jaundice, and cough from diaphragmatic irritation can also occur. Symptoms of dysentery usually are not present, and diarrhea is reported in less than one third of cases. Laboratory abnormalities include leukocytosis, transaminitis, elevated alkaline phosphatase, and elevated sedimentation rate. Chest radiograph often demonstrates elevation of the right hemidiaphragm, and pleural effusion may be present. Rupture of the abscess can occur into the abdomen or pleuropulmonary space, manifesting as acute abdomen or empyema.

Diagnosis of intraintestinal *E. histolytica* infection has classically relied on stool microscopy, and this remains the only available method in much of the world. At least three stool specimens should be examined to improve sensitivity. Cysts visualized in stool might or might not indicate active infection and cannot be distinguished from *E. dispar* and *E. moshkovskii*. Presence of trophozoites with ingested red blood cells on stool preparation is diagnostic of dysentery secondary to *E. histolytica*, as are mobile amebae if seen within freshly examined biopsy material.

Diagnosis of *E. histolytica* infection has improved greatly with the advent of antigen tests, now available as enzyme-linked immunosorbent assays (ELISAs) and immunofluorescent probes. The

Techlab ELISA antigen test is highly sensitive and specific and can be used on a freshly passed stool specimen, serum, or hepatic abscess material. It becomes positive with onset of symptomatic disease and resolves on treatment of infection. Other available antigen tests appear to function well but have not been as rigorously studied. Aspirate of liver abscess material may be necessary to distinguish from pyogenic liver abscess; a negative stool examination for *E. histolytica* does not preclude amebic liver abscess. In a patient at high risk for amebic liver abscess (e.g., young male immigrants), a trial of antimicrobial therapy can help in diagnosis because infection typically responds rapidly.

All patients who have confirmed *E. histolytica* infection and reside in nonendemic areas should be treated regardless of whether they are symptomatic, because invasive disease can develop in the future. Asymptomatic cyst passers may be treated with an intraluminal agent alone, such as paromomycin (Humatin) or iodoquinol (Yodoxin). In the United States, the most readily available effective treatment for patients with amebic colitis or liver abscess is metronidazole (Flagyl). It can be given intravenously for patients unable to tolerate oral medications. Experts recommend that a course of therapy with an intraluminal agent be given following the completed course of the systemic agent for all cases of invasive *E. histolytica*. See Table 1 for medications and doses.

Giardiasis

Giardia lamblia, also known as *Giardia intestinalis* or *Giardia duodenalis*, is the most commonly identified diarrheal parasitic infection in the United States, with an estimated 100,000 to 2.5 million cases per year. It is globally distributed and found in fresh

TABLE 1 Pharmacologic Treatment of Major Protozoan Infections

CLINICAL SITUATION	DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Amebiasis				
<i>Entamoeba histolytica</i>				
Asymptomatic	Recommended: Paromomycin ^a or Iodoquinol [†]	25–35 mg/kg/d in 3 doses × 7 d 650 mg tid × 20 d	25–35 mg/kg/d in 3 doses × 7 d 30–40 mg/kg/d (max 2 g) in 3 doses × 20 d	
	Alternative: Diloxanide furoate [‡]	500 mg tid × 10 d	20 mg/kg/d in 3 doses × 10 d	
Mild to moderate intestinal disease	Recommended: Metronidazole or Tinidazole ^{1,§}	500–750 mg tid × 7–10 d 2 g once daily × 3 d	35–50 mg/kg/d in 3 doses × 7–10 d ≥3 y: 50 mg/kg once daily (max 2 g) × 3 d	Treatment should be followed by a course of iodoquinol or paromomycin in the dosage used to treat asymptomatic amebiasis.
Severe intestinal or extraintestinal disease	Metronidazole or Tinidazole [§]	500–750 mg tid × 7–10 d 2 g once daily × 5 d	35–50 mg/kg/d in 3 doses × 7–10 d ≥3 y: 50 mg/kg once daily (max 2 g) × 5 d	Treatment should be followed by a course of iodoquinol or paromomycin in the dosage used to treat asymptomatic amebiasis.
Balantidiasis				
<i>Balantidium coli</i>				
Symptomatic and asymptomatic disease	Recommended: Tetracycline ^{1,}	500 mg qid × 10 d	40 mg/kg/d (max 2 g) in 4 doses × 10 d	
	Alternatives: Metronidazole ¹ or Iodoquinol ^{1,†}	500–750 mg PO tid × 5 d 650 mg tid × 20 d	35–50 mg/kg/d in 3 doses × 5 d 30–40 mg/kg/d (max 2 g) in 3 doses × 20 d	
<i>Blastocystis hominis</i>

TABLE 1 Pharmacologic Treatment of Major Protozoan Infections—cont'd

CLINICAL SITUATION	DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Cryptosporidiosis				
<i>Cryptosporidium</i>				
Immune competent	Nitazoxanide	500 mg bid × 3 d	1–3 y: 100 mg bid × 3 d 4–11 y: 200 mg bid × 3 d ≥12 y: adult dose	FDA approved as a pediatric oral suspension for treating <i>Cryptosporidium</i> in immunocompetent children <12 y and for <i>Giardia</i> . It might also be effective for mild to moderate amebiasis. Nitazoxanide is available in 500-mg tabs and an oral suspension; it should be taken with food.
HIV-infected	No optimal therapy available			All HIV-infected patients with cryptosporidiosis should receive HAART whenever possible. Nitazoxanide, paramomycin, or paramomycin + azithromycin may have a role in decreasing diarrhea in chronic cases of HIV-infected persons.
Cyclosporiasis				
<i>Cyclospora cayentanensis</i>	Recommended: TMP-SMX (Bactrim, Septra) ¹ Alternative: Ciprofloxacin	160 mg TMP, 800 mg SMX (1 DS tab) bid × 7–10 d 500 mg PO bid × 7 d	5 mg/kg TMP, 25 mg/kg SMX bid × 7–10 d (No recommended pediatric dose) ¹	In immunocompetent patients, usually a self-limited illness. Immunosuppressed patients might need higher doses, longer duration (TMP-SMX qid × 10 d, followed by bid × 3 wk) and long-term maintenance.
Dientamoebiasis				
<i>Dientamoeba fragilis</i> Symptomatic disease only	Iodoquinol ^{1,†} or Paromomycin ^{1,*} or Metronidazole ¹	650 mg tid × 20 d 25–35 mg/kg/d in 3 doses × 7 d 500–750 mg tid × 10 d	30–40 mg/kg/d (max 2 g) in 3 doses × 20 d 25–35 mg/kg/d in 3 doses × 7 d 35–50 mg/kg/d in 3 doses × 10 d	
Giardiasis				
<i>Giardia lamblia</i>				
All symptomatic disease and asymptomatic carriage in nonendemic areas	Recommended: Metronidazole ¹ or Nitazoxanide or Tinidazole [§] Alternatives: Quinacrine ^{1,*} or Furazolidone or Paromomycin ¹	250 mg tid × 5–7 d 500 mg bid × 3 d 2 g once 100 mg tid × 5 d 100 mg qid × 7–10 d 25–35 mg/kg/d in 3 doses × 7 d	15 mg/kg/d in 3 doses × 5 d 1–3 y: 100 mg bid × 3 d 4–11 y: 200 mg bid × 3 d 50 mg/kg (max 2 g) once 6 mg/kg/d (max 300 mg/d) tid × 5 d 6 mg/kg/d in 4 doses × 10 d 25–35 mg/kg/d in 3 doses × 7 d	Treatment should be followed by a course of iodoquinol or paromomycin in the dosage used to treat asymptomatic amebiasis. Albendazole, 400 mg daily × 5 d alone or in combination with metronidazole may also be effective. Combination treatment with standard doses of metronidazole and quinacrine × 3 wk is effective for a small number of refractory infections. In one study, nitazoxanide was used successfully in high doses to treat a case of <i>Giardia</i> resistant to metronidazole and albendazole. Nonabsorbed luminal agent; may be useful for treating giardiasis in pregnancy
Cystoisosporiasis				In immunocompetent patients, usually a self-limited illness. Immunosuppressed patients might need higher doses, longer duration (TMP-SMX qid × 10 d, followed by bid × 3 wk) and long-term maintenance. For isosporiasis in sulfonamide-sensitive patients, pyrimethamine 50–75 mg qd in divided doses (<i>plus</i> leucovorin 10–25 mg/d) is effective.

TABLE 1 Pharmacologic Treatment of Major Protozoan Infections—cont'd

CLINICAL SITUATION	DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
<i>Cystoisospora belli</i>	Recommended: TMP-SMX ¹	160 mg TMP, 800 mg SMX bid × 7–10 d	5 mg/kg TMP, 25 mg/kg SMX bid × 7–10 d	Ciprofloxacin is an alternative but may not be as effective.
Microsporidiosis				
<i>Enterocytozoon bieneusi</i>				
Intestinal disease	Fumagillin* Albendazole [†]	60 mg/d PO × 14 d 400 mg PO bid × 21 d	15 mg/kg/d in 2 doses (max 400 mg/dose)	Oral fumagillin (Sanofi Recherche, Gentilly, France) is effective in treating <i>E bieneusi</i> but is associated with thrombocytopenia and neutropenia. HAART can lead to microbiological and clinical response in HIV-infected patients with microsporidial diarrhea. Octreotide (Sandostatin) has provided symptomatic relief in some patients with large-volume diarrhea.
<i>Encephalitozoon intestinalis</i>				
Diarrheal or disseminated disease	Albendazole [†]	400 mg bid × 21 d	15 mg/kg/d in 2 doses (max 400 mg/dose)	

Abbreviations: DS = double strength; GI = gastrointestinal; HAART = highly active antiretroviral therapy; max = maximum; tab = tablet; TMP-SMX = trimethoprim-sulfamethoxazole.

Adapted from World Health Organization. Drugs for parasitic infections. Med Lett Drug Ther 2010; 8 (Supl.).

¹Not FDA approved for this indication.

*Should be taken with meals.

[†]Should be taken after meals.

[‡]The drug is not available commercially, but as a service it can be compounded by Panorama Compounding Pharmacy, 6744 Balboa Blvd., Van Nuys, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-6816).

[§]A nitroimidazole similar to metronidazole, tinidazole is FDA approved and appears to be as effective and better tolerated than metronidazole. It should be taken with food to minimize GI adverse effects. For children and patients unable to take tablets, a pharmacist may crush the tablets and mix them with cherry syrup. The syrup suspension is good for 7 d at room temperature and must be shaken before use. Ornidazole, a similar drug, is also used outside the United States. Dosing recommendations are only available for children ≥3 years of age.

^{||}Contraindicated in pregnant and breastfeeding women and children <8 y.

[¶]Clinical significance of these organisms is controversial; metronidazole 750 mg tid × 10 d, iodoquinol 650 mg tid × 20 d, or TMP-SMX11 double-strength tab bid × 7 d are effective. Metronidazole resistance may be common. Nitazoxanide is effective in children.

**Should be taken with liquids after a meal.

water throughout mountainous regions of the United States and Canada. The organism is a flagellated aerotolerant anaerobe that exists in a cyst and trophozoite form. Cysts can survive for several weeks in cold water. Contaminated food and water are the most common sources of infection, but the organism can also be passed by person-to-person contact. In the United States, giardiasis is primarily diagnosed among international travelers, persons with recreational water exposure, institutionalized persons and children in day care, and persons with anal–oral sexual practices.

Illness can result from ingestion of as few as 10 to 25 cysts, which transform into trophozoites in the small intestine and attach to and damage the small bowel wall. Symptomatic disease begins insidiously over approximately 2 weeks in 25% to 50% of persons who ingest *Giardia* cysts. Others become asymptomatic cyst passers (5%–15%) or have no signs of infection (35%–50%). Hallmarks of infection are watery diarrhea, bloating, gas, abdominal pain, and weight loss; less commonly, patients have nausea, vomiting, or low-grade fever. Steatorrhea and malabsorption, particularly secondary to *Giardia*-induced lactase deficiency, can be observed. Chronic *Giardia* infection should be considered in the differential diagnosis for a long-standing diarrheal illness, especially if there is history of exposure to possibly contaminated water. Patients with common variable immune deficiency, X-linked agammaglobulinemia, and IgA deficiency syndromes are at risk for fulminant and sometimes incurable disease, suggesting a significant role for humoral immunity in control of infection. Persons with HIV infection or AIDS have symptoms similar to those in patients without HIV and typically can be cured of infection with standard therapy.

Diagnosis of giardiasis is made by examination of fresh or preserved stool or by stool antigen assays. In the case of fecal

examination, trophozoites may be directly visualized in fresh liquid stool; semiformal and preserved stool should be stained before examination. Currently, there are immunochromographic, direct fluorescence antibody, and ELISA tests for diagnosis of *Giardia*, including the ImmunoCard STAT! Cryptosporidium/*Giardia* Rapid Assay (Meridian Bioscience, Cincinnati, Ohio), which tests for both pathogens simultaneously. Although it is rarely necessary, the diagnosis can sometimes be made on duodenal biopsy.

For details of treatment options, see Table 1. Metronidazole¹ is the most commonly prescribed treatment in the United States and should be given for a 10-day course. Tinidazole (Tindamax), recently approved in the United States, appears to have excellent efficacy and improved tolerability over metronidazole. Nitazoxanide (Alinia) has also been shown to eradicate infection well and can be used as an alternative or in patients who fail a first course of treatment. Patients who fail first-line therapy might have a persistent source of infection (contaminated water source, close contact with an infected person), immune deficiency predisposing to difficult eradication, or persistence of cysts. Once possible sources of reinfection have been investigated and eliminated, relapsed infections should either be re-treated with a longer course of therapy (21–28 days) or treated with a different agent. Patients who fail more than one course of therapy should undergo immunologic work-up.

Prevention of *Giardia* infection, as with other parasitic infections, involves primarily close attention to personal hygiene, hand washing, and avoidance of ingestion of fresh unfiltered water. Boiling water or use of a 0.2- to 1-μm water filter offer optimal

¹Not FDA approved for this indication.

protection against *Giardia* and other parasitic pathogens, although such filters still might not protect against *Cryptosporidium*.

Blastocystis hominis

Blastocystis hominis, formerly considered a protozoan, has been reclassified as a fungus. It has a worldwide distribution found most commonly in tropical regions; it is present in humans and several other animals. In temperate regions, *B hominis* is detected at a high rate among MSM. *B hominis* was long thought to cause only asymptomatic colonization, but there is some evidence to suggest a role in human disease, although this remains controversial. Ongoing molecular analysis might elucidate subtypes of *B hominis* with varying degrees of pathogenicity in humans.

B hominis has four forms: vacuolated, amoeba-like, granular, and cyst, the latter of which is likely to be the infectious form. It appears to be transmitted via the fecal–oral route, possibly from waterborne sources.

As suggested previously, the majority of infections appear to be entirely asymptomatic, and number of organisms does not appear to accurately predict severity of illness. Symptoms consist mainly of watery diarrhea, bloating, and abdominal cramps. There are typically no pathologic findings on colonoscopy and there are no reports of invasive disease. Infection is diagnosed by stool microscopy with use of a trichrome or hematoxylin-stained preserved specimen. The organism is susceptible in vitro to numerous antimicrobials. Bactrim¹ or metronidazole is the treatment of choice; details are listed in Table 1.

Dientamoeba fragilis

Dientamoeba fragilis was originally classified as an amoeba, but it is more closely related to the flagellates such as *Trichomonas vaginalis*. It is distributed worldwide, including in Western nations, and has only recently been recognized as a clinically significant pathogen, possibly because it is difficult to visualize without specific staining techniques. Illness has commonly been found in travelers and MSM, but it can affect anyone.

The parasite exists only in the trophozoite form. Despite its genetic relationship to the flagellates, *D fragilis* does not have a flagellum and is immotile. Trophozoites range in size from 4 to 20 μm and are binucleate. Patients in the United States who have *D fragilis* were found in some studies to harbor other intestinal parasites as well, such as *E vermicularis* and *B hominis*, and in general *D fragilis* is more prevalent in areas of the world with limited public sanitation. These features support a fecal–oral mode of transmission for *D fragilis*.

Most patients are asymptomatic; however, numerous case reports and small series describe patients with no other organisms identified to cause their symptoms who improve significantly after treatment and documented clearance of *D fragilis* from their stool. Illness is typically subacute to chronic, characterized by abdominal pain, watery diarrhea, anorexia, fatigue, and malaise. Diagnosis can be difficult, because the parasite is fastidious. If *D fragilis* is suspected, stool should be preserved with polyvinyl alcohol and quickly stained with iron–hematoxylin and trichrome. Polymerase chain reaction (PCR) has been used for diagnosis as well, but it is not readily available for use in most clinical settings.

For full treatment information, see Table 1. Iodoquinol (Yodoxin)¹ and metronidazole¹ have both been used successfully to treat *D fragilis*.

Balantidium coli

Balantidium coli is the largest protozoan that infects humans, and the only ciliate. Balantidiasis is a relatively rare cause of illness and is found primarily in rural agrarian communities in Southeast Asia, Central and South America, and Papua New Guinea. *B coli* is highly associated with animal farming, in particular, pigs; humans are incidental hosts. The parasite is transmitted by direct contact with animals or on ingestion of water or food contaminated by

animal excrement. Persons with malnutrition or immune deficiency are particularly susceptible to infection.

B coli invades the intestinal mucosa from the terminal ileum to the rectum. About one half of infections are asymptomatic; the other one half result in a subacute or chronic diarrheal illness with abdominal cramping, nausea, vomiting, weight loss, and occasional low-grade fever. Fewer than 5% of patients present with severe or even fulminant dysentery, and rare cases of colonic penetration with peritonitis, mesenteric lymphadenitis, or hepatic infection have been reported.

Diagnosis is made by visualization of trophozoites in fresh stool specimens or preserved and permanently stained samples. The trophozoite is large and ciliated; cysts are difficult to distinguish. It displays a distinct spiraling motility that can be seen under low power. On stained sample, visualization of *B coli*'s characteristic macronucleus and spiral micronucleus can help confirm the diagnosis. All patients should be treated regardless of symptoms. Tetracycline¹ (Sumycin and others) is the therapy of choice; the infection also responds to metronidazole¹; see Table 1 for dosing information.

Spore-Forming Protozoa and Microsporidia

Cryptosporidiosis

Cryptosporidium is a pathogen with worldwide distribution that is endemic to the United States. Humans are most commonly infected by the recently reclassified *Cryptosporidium hominis*, but *Cryptosporidium parvum*, primarily a bovine pathogen, also causes human disease. *Cryptosporidium* has caused multiple waterborne outbreaks in the United States and can be acquired secondary to recreational water exposure (e.g., swimming pools, water parks). The best-known outbreak occurred secondary to heavy rains that brought farm runoff into the drinking water supply in Wisconsin in 1984. It resulted in 430,000 documented cases of cryptosporidiosis and contributed to the deaths of dozens of persons with advanced HIV infection or malignancy.

Cryptosporidium is a coccidian, part of a group of spore-forming protozoa with a complex life cycle and a structure that allows mechanical penetration into host cells. *Cryptosporidium* can mature and reproduce entirely within human hosts, thereby enabling infection to occur both from environmental sources and by direct person-to-person contact. Its oocysts, the source of infection on ingestion, are markedly hardy; they can withstand heavy chlorination, survive for months in cold water, and are small enough to occasionally evade even the smallest available water filtration systems.

All persons are susceptible to infection, which usually is self-limited. Fulminant or chronic infection, or both, can be seen among patients with immune compromise secondary to HIV infection (especially those with CD4 <50), in patients with malignancy, and in malnourished children. As few as 100 oocysts can cause infection, which results when the parasite penetrates small bowel epithelium and replicates just beneath its surface. Villous flattening and small bowel wall edema are seen on pathologic examination from infected persons.

Asymptomatic infections occur but are relatively rare. Symptoms begin within several days to 1 week of ingestion of oocysts. The hallmark of infection is explosive watery diarrhea, which can be so voluminous as to resemble cholera and can cause significant dehydration and electrolyte imbalance. Abdominal discomfort, nausea, vomiting, fever, malaise, and myalgia can also be present, and weight loss is common. Illness lasts 1 to 2 weeks, but a substantial percentage of patients report a relapse of symptoms after initial improvement. The biliary tract can be involved, particularly in patients with HIV infection, and infection at other distant sites, such as the lungs, has rarely been reported.

Diagnosis of *Cryptosporidium* has improved dramatically in recent years with the advent of antigen tests, which are highly sensitive and specific and can be used on a single sample of fresh stool. The ImmunoCard STAT! *Cryptosporidium*/Giardia Rapid Assay is

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

useful because it can detect both pathogens. When such tests are not available, stools submitted for examination should be fixed in formalin and stained for trophozoites or cysts; availability of multiple stool specimens improves the diagnostic sensitivity. Luminal fluid or biopsy specimens obtained during endoscopy can also reveal the organism.

Infection with *Cryptosporidium* is typically a self-limited illness in otherwise healthy persons, but symptoms can be improved and the course shortened with the antiparasitic nitazoxanide. *Cryptosporidium* remains an extremely challenging and potentially devastating infection in immunocompromised patients, especially those with HIV and a low CD4 count (counts <200 increase risk of severe illness, and counts <50 markedly increase risk). Although anticryptosporidial therapies in this population have shown very limited efficacy, restoration of immune function with HAART often effects cure. Limited data suggest a trial of nitazoxanide may be reasonable in this circumstance as well. Appropriate supportive measures are also crucial in all patients with *Cryptosporidium*, including fluid and electrolyte replacement; avoiding lactose products is likely to be beneficial during the first 2 weeks after infection as the brush border regenerates. Appropriate treatment doses for nitazoxanide are listed in Table 1.

Prevention of *Cryptosporidium* infection requires a highly developed public water purification system including flocculation, sedimentation, and filtration. Use of 0.2- to 1- μ m personal water filters for campers and hikers greatly reduces but does not eliminate risk of infection, whereas boiling water before drinking kills oocysts. Close attention to hygiene and avoidance of fecal-oral contact is the mainstay of prevention in the settings of institutional and community outbreaks.

Cyclospora Species

Cyclospora cayetanensis is a coccidian with structure similar to that of *Cryptosporidium*. Unlike *Cryptosporidium*, *C. cayetanensis* requires a period of development outside the human body, thereby eliminating the possibility of close person-to-person contact as a means of acquiring the infection. *C. cayetanensis* is distributed worldwide, most commonly in the tropics and subtropics where infection tends to exhibit seasonality. It has also been associated with food (e.g., raspberries) and waterborne outbreaks in temperate regions, including the United States, and in recent years it has become increasingly recognized as a cause of infectious diarrhea in returned travelers.

All persons are susceptible to infection, but those with HIV are at risk for more severe and prolonged disease, as seen with cryptosporidiosis and isosporiasis. Symptomatic disease appears to be most common in adults who do not have previous exposure to *Cyclospora*, such as travelers or persons who have relocated to endemic areas. Illness begins about a week after ingestion of sporulated oocysts and is characterized by watery diarrhea, abdominal cramping, bloating, anorexia, and weight loss. Low-grade fever can occur; marked fatigue is common and can last weeks or even months, and untreated infections can relapse after apparent resolution. Biliary involvement can occur in patients with HIV coinfection, as with cryptosporidiosis. Cyclosporiasis, similar to infection with other coccidians, causes damage to the small bowel epithelium, with resultant crypt flattening, edema, and inflammatory infiltrate. Lactose deficiency can remain for months after initial infection.

Diagnosis is made by stool examination. As with diagnosis of other parasitic infections, multiple stool specimens improve sensitivity. In the case of *Cyclospora*, concentration of the stool specimen also increases yield. If cyclosporiasis is suspected, specific testing should be requested, because the organism exhibits unique properties. Organisms are about two times the size of *Cryptosporidium* and can be seen with Kinyoun acid-fast stain. They also autofluoresce and can be visualized under ultraviolet microscopy. Currently there is no stool antigen assay, but PCR testing has been used in experimental and limited clinical settings to assist in diagnosis.

Cyclosporiasis is best treated with trimethoprim-sulfamethoxazole (Bactrim)¹; ciprofloxacin¹ may be effective for patients who have a sulfa allergy. Patients with HIV infection can require longer courses of treatment or chronic suppressive therapy; appropriate antiretroviral therapy is also important in the treatment of severe or relapsing infections. See Table 1 for details.

Cystoisospora Species

Cystoisospora belli, formerly *Isospora belli*, is a large coccidian native to tropical areas. Similar to *Cyclospora*, it requires a period of maturation outside the human body and therefore cannot be spread directly from person to person. It appears to cause largely asymptomatic or mild infection in tropical areas to which it is endemic; the exception is among patients coinfecting with HIV and particularly those with AIDS, in which it is a very common cause of chronic diarrhea in the Caribbean and Central America. Currently in wealthy countries it is found primarily in travelers returning from endemic areas.

Illness is typically mild and self-limited, consisting primarily of watery diarrhea. However, some immunocompetent persons can develop a chronic spruelike syndrome with malabsorption, and those with HIV infection or AIDS often have severe and prolonged diarrhea. *Cystoisospora* can invade to the lamina propria and can cause eosinophilia, which is different from other coccidian infections.

Diagnosis is made by observation of cysts in stool. As with *Cyclospora*, they can be visualized with acid-fast stains or ultraviolet microscopy. Stool may also contain Charcot-Leiden crystals. Infection in immunocompetent hosts responds well to antimicrobials; persons coinfecting with HIV can require longer courses of therapy or chronic suppression, and appropriate antiretroviral therapy may be helpful as well. Trimethoprim-sulfamethoxazole (Bactrim)¹ is the treatment of choice. Ciprofloxacin (Cipro)¹ or pyrimethamine (Daraprim)¹ may be used in cases of sulfa allergy. Doses are listed in Table 1.

Microsporidiosis

Microsporidia are eukaryotic organisms that have been recently reclassified as fungi based on molecular genotyping. They are distributed globally, and more than 100 genera have been identified, seven of which contain species known to be pathogenic in humans: *Encephalitozoon*, *Enterocytozoon*, *Trachipleistophora*, *Pleistophora*, *Nosema*, *Vittaforma*, and *Microsporidium*. These pathogens cause a wide variety of systemic and focal illness throughout the world.

Many immunocompetent patients in wealthy nations exhibit positive serology for certain types of microsporidial infections without a history of disease or travel. Microsporidia are most commonly associated with systemic infection in immunosuppressed persons, particularly those with HIV and a CD4 count of less than 100 or patients with organ transplants. Mode of transmission is not entirely clear, but the pathogen likely is spread both from water sources and possibly from close household contact.

Encephalitozoon intestinalis and *Enterocytozoon bieneusi* are responsible for intestinal microsporidial infections. *E. bieneusi* has been associated with self-limited diarrheal illness; *E. intestinalis* is commonly found in stool specimens throughout the developing world, but its pathogenicity is often not certain. Symptomatic infections, most often in patients coinfecting with HIV, typically include a gradual onset of watery diarrhea, which may be worse in the morning and after oral intake. Significant volume and electrolyte depletion can occur, as well as fatigue, anorexia, weight loss, and malabsorption. *E. intestinalis* can disseminate and cause acute abdomen with peritonitis, cholangitis, nephritis, and keratoconjunctivitis, and *E. bieneusi* infection can result in cholangitis and nephritis as well as rhinitis, bronchitis, and wheezing. Other microsporidia are implicated in a wide variety of illness both in

¹Not FDA approved for this indication.

previously healthy and immunosuppressed hosts and include several ocular pathogens.

Diagnosis of microsporidiosis is attained by visualization of spores in stool or in tissue specimens. As suggested by their name, microsporidial spores are much smaller than those produced by spore-forming protozoal infections; most are approximately 1 μm in length and can easily be confused with bacteria or debris on slides. Special staining techniques have been described, but electron microscopy is required for species identification. See [Table 1](#) for details of treatment. Albendazole (Albenza)¹ is the treatment of choice for *Encephalitozoon intestinalis*.

Treatment of *Enterocytozoon bieneusi* is more challenging. Although some response to albendazole has been reported, oral fumagillin² may have more efficacy. Unfortunately, it is not currently commercially available in the United States. Use of appropriate antiretroviral therapy is perhaps the most important treatment for patients with HIV infection or AIDS and chronic microsporidial infections.

Helminths

Nematodes

Nematodes (roundworms) are cylindrical nonsegmented organisms that are found throughout the world both as free-living species and as human and animal pathogens. Nematodes are the most common type of human parasitic infestation, found in approximately one quarter of the world's population; often, susceptible hosts carry multiple different pathogenic nematodes. There are at least 60 species that have been shown to infect humans and 10 times that many that cause disease in other animals, but a few pathogens account for the bulk of human infections, in particular *Ascaris*, hookworm, and whipworm. These three organisms all require a period of maturation outside the human body—typically in warm, moist soil—underscoring the fact that repeated contact with fecally contaminated soil or food and water is necessary to sustain the cycle of infestation. *Strongyloides* and *Enterobius* are unique in that they can both complete their life cycle on or within human hosts and therefore can cause chronic infection and be transmitted directly by close person-to-person contact where there is the possibility of fecal–oral contamination.

Ascaris

Ascaris lumbricoides, the most common human helminthic infection, is estimated to affect 20% to 25% of the world's population. Up to 80% of community members are infected in heavily endemic areas, namely in Africa, Asia, and Central and South America. Cases of *Ascaris* infestation are also seen in rural areas in the southeastern United States. *A. lumbricoides* are white to pinkish worms that range from 10 to 40 cm in length; the infectious eggs are oval white bodies with an adherent mucopolysaccharide capsule that clings to multiple surfaces and aids in transmissibility of the parasite. Eggs are also remarkably durable, capable of surviving up to 6 years in moist soil and able to weather brief droughts and periods of freezing.

Fecal contamination of water, food, and environmental surfaces such as doorknobs and countertops provide the means of transmission for *Ascaris*, and recurrent infection occurs as long as living conditions that predispose people to infection remain unchanged. Lack of adequate public sanitation, use of human feces as fertilizer (night soil), and frequent contact with soil or shared contaminated surfaces among close household members are risk factors for infection. Persons who move to environments with improved sanitation typically lose their infection within 2 years as all the adult worms die. Eggs excreted by an infected person must mature outside the human body for approximately 2 weeks. On ingestion by a susceptible host, mature eggs hatch in the small intestine and release larvae, which penetrate the intestinal wall and travel through the venous circulation to the lungs, where they are coughed up and

swallowed. They then undergo maturation into adult worms in the intestine and produce eggs by 2 to 3 months after initial infection. The eggs are excreted in the feces and mature outside the body to continue the cycle.

Most persons with *Ascaris* infection are asymptomatic. Approximately 15% of infected people have morbidity, which is associated with young age, large burden of worms, coinfection with other intestinal parasites, and genetic predisposition. In children, infection contributes to malabsorption of protein, fat, and vitamins A and C, and treatment of heavily infected children can improve their nutritional status. *Ascaris* infection can also cause intestinal, pancreatic, or biliary obstruction as a result of worm mass or worm migration. Despite the low incidence of obstructive complications per infected person, the *Ascaris*-related acute abdomen is a significant problem on a global level given the enormous number of people infected. Some patients with intestinal *Ascaris* infection report vague abdominal complaints, such as abdominal discomfort, nausea, vomiting or diarrhea, but these are relatively rare. Pulmonary migration of a large quantity of worms can produce Loeffler's syndrome, or eosinophilic pneumonitis.

Diagnosis is easily attained with standard saline stool preparation, and large numbers of eggs are typically seen. Larvae or worms can also sometimes be seen in sputum or stool samples. In cases of intestinal obstruction, worms may be visualized on upper gastrointestinal series, computed tomography, and even ultrasound. Eosinophilia with *Ascaris* infection is found only during the larval migratory phase, but not at all times. Chronic eosinophilia in an at-risk person suggests another parasitic infection, often *Strongyloides*.

All persons documented to carry *Ascaris* who have migrated to nonendemic areas should be treated to prevent complications in the future; in endemic areas, adults need only be treated if they are symptomatic. Children have been shown to benefit from intermittent anthelmintic therapy in heavily affected areas of the world.

For patients with intestinal obstruction, bowel rest and intravenous hydration are usually sufficient to relieve the obstruction, at which time anthelmintic therapy can be administered. In such cases, gastroenterology consultation should be obtained. In rare cases, surgical intervention is required. Treatment of pulmonary infection is controversial; however, most experts recommend steroid therapy for severe infections followed 2 to 3 weeks later (at the time full-grown worms will have migrated to the intestine) by administration of anthelmintic therapy.

The benzimidazoles (mebendazole [Vermox], albendazole [Albenza],¹ levamisole [Stromectol], and pyrantel pamoate [Pin-X]) all exhibit excellent activity against *Ascaris*. Doses and other options are listed in [Table 2](#). Although albendazole and mebendazole carry a pregnancy class B label, they have been used in pregnant women, adolescent girls, and women of reproductive age without demonstrable effects on fetuses; most experts recommend holding treatment until the second trimester whenever possible.

Sanitary conditions that allow for proper management of human feces are crucial in control and prevention of *Ascaris* infection; boiling water kills the eggs.

Whipworm (*Trichuriasis*)

Trichuris trichiura has become recognized in recent years as a worldwide pathogen with a scope similar to that of *Ascaris*. Sanitary conditions that predispose to ingestion of food and water contaminated with human feces place people at risk for infection; in many communities infection is hyperendemic, with almost universal carriage of the pathogen.

The adult organism is a small worm about 4 cm in length with a unique whip like structure that allows its thin tail to become embedded in colonic crypts. Whipworm eggs have a characteristic barrel shape with mucous plugs at either end. Infection is acquired by ingesting *Trichuris* eggs that have undergone embryonation in the soil for 2 to 4 weeks after excretion from a previous host.

TABLE 2 Pharmacologic Treatment of Nematode, Trematode, and Cestode Infections

CLINICAL SITUATION	DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Anisakiasis				
<i>Anisaka</i> spp. or <i>Pseudoterranova decipiens</i>	No recommended medical therapy Surgical or endoscopic removal of worm	—	—	Successful treatment of a patient with <i>Anisakiasis</i> with albendazole has been reported.
Ascariasis				
<i>Ascaris lumbricoides</i>	Albendazole (Albenza) ^{1,*} or	400 mg once	400 mg PO once	In heavy infection, therapy may be given for 3 d.
	Mebendazole [†] (Vermox) or	100 mg bid × 3 d or 500 mg once	100 mg bid × 3 d or 500 mg once	
	Ivermectin ^{1,†} (Stromectol)	150–200 µg/kg once	150–200 µg/kg once	
Enterobiasis (Pinworm)				
<i>Enterobius vermicularis</i>	Mebendazole [†] or	100 mg once, repeat in 2 wk	100 mg once, repeat in 2 wk	Because all family members are usually infected, treatment of the entire household is recommended.
	Albendazole ^{1,*} or	400 mg once, repeat in 2 wk	400 mg once, repeat in 2 wk	
	Pyrantel pamoate [‡]	11 mg/kg base (max 1 g) once; repeat in 2 wk	11 mg/kg base (max 1 g) once; repeat in 2 wk	
Hookworm				
<i>Ancylostoma duodenale</i> , <i>Necator americanus</i>	Albendazole ^{1,*} or	400 mg once	400 mg once	
	Mebendazole or	100 mg bid × 3 d or 500 mg once	100 mg bid × 3 d or 500 mg once	
	Pyrantel pamoate [‡]	11 mg/kg (max 1 g) × 3 d	11 mg/kg (max 1 g) × 3 d	
Schistosomiasis				
<i>Schistosoma haematobium</i> , <i>Schistosoma mansoni</i>	Praziquantel [§] or	40 mg/kg/d in 2 doses × 1 d	40 mg/kg/d in 2 doses × 1 d	Praziquantel is first line, but oxamniquine may be effective in some patients in whom praziquantel is less effective. Contraindicated in pregnancy
<i>S. mansoni</i> only	Oxamniquine	15 mg/kg once	20 mg/kg/d in 2 doses × 1 d	
<i>Schistosoma japonicum</i> , <i>Schistosoma mekongi</i>	Praziquantel [§]	60 mg/kg/d in 2 or 3 doses × 1 d	60 mg/kg/d in 3 doses × 1 d	
Strongyloidiasis				
<i>Strongyloides stercoralis</i>	Recommended: Ivermectin [†]	200 µg/kg/d × 2 d	200 µg/kg/d × 2 d	In immunocompromised patients or in patients with disseminated disease, it may be necessary to prolong or repeat therapy or use other agents. Veterinary parenteral and enema formulations of ivermectin are used in severely ill patients unable to take oral medications.
	Alternative: Albendazole ^{1,*}	400 mg bid × 7 d	400 mg bid × 7 d	
Tapeworm				
<i>Taenia solium</i> (intestinal disease), <i>Taenia saginata</i> , <i>Diphyllobothrium latum</i>	Praziquantel ¹ or Niclosamide [¶]	2 g once	50 mg/kg once	Available in the United States only from the manufacturer
Trichuriasis (Whipworm)				
<i>Trichuris trichiura</i>	Recommended: Mebendazole	100 mg bid × 3 d or 500 mg once	100 mg bid × 3 d or 500 mg once	
	Alternatives: Albendazole ^{1,*} or	400 mg daily × 3 d	400 mg daily × 3 d	
	Ivermectin [†]	200 µg/kg daily × 3 d	200 µg/kg daily × 3 d	

Adapted from World Health Organization. Drugs for parasitic infections. Med Lett Drug Ther 2010; 8 (Suppl.).

¹Not FDA approved for this indication.

*Should be taken with a fatty meal.

[†]Safety of Ivermectin in young children (<15 kg) and pregnant women not yet established. Ivermectin should be taken on an empty stomach with water.[‡]Limited availability; can be mixed with juice or water to improve palatability.[§]Should be taken with liquids during a meal.^{||}Limited or no availability in the United States.[¶]Available in the United States only from the manufacturer. Must be chewed or crushed thoroughly and swallowed with a small amount of water. Limited or no availability in the United States.

Larvae emerge from eggs in the intestine and migrate into crypts, where they begin to mature. Egg production begins approximately 3 months later.

Most persons with whipworm carry few worms (approximately 20) and are asymptomatic. As with many other intestinal parasites, children are at greater risk for symptomatic infection, which can cause failure to thrive, anemia, clubbing, inflammatory colitis, and rectal prolapse. Adults with a high worm burden can also experience inflammatory colitis characterized by frequent—often bloody—diarrhea and tenesmus. Infection has been shown to result in production of tumor necrosis factor (TNF)- α by lamina propria cells in the colon, which can contribute to poor appetite and wasting that can be seen with significant infection.

Diagnosis is made by standard stool microscopy without a need to concentrate stool, because large numbers of eggs are excreted. Worms can also be seen on colonoscopy, or they can be visualized grossly in cases of rectal prolapse. Eosinophilia may be seen.

Treatment of symptomatic infections can be accomplished with mebendazole, albendazole,¹ or ivermectin (Stromectal)¹; see Table 2 for details.

Hookworm (*Necator americanus* and *Ancylostoma duodenale*)

Like other helminthic infections, hookworm affects a substantial portion of the world's population, particularly in rural subtropical and tropical communities where human feces is used as a component of fertilizer. Infection results primarily from parasite penetration into the skin; therefore persons with an agrarian lifestyle and significant soil contact are at greatest risk.

Two species are responsible for the majority of human hookworm: *Necator americanus* and *Ancylostoma duodenale*. *Ancylostoma braziliense*, a canine intestinal pathogen, causes cutaneous larval migrans in humans because the pathogen cannot penetrate the human dermis. Of the two common forms of human hookworm, *N. americanus* is smaller and a less aggressive pathogen with a longer life span than *A. duodenale*. Both parasites are found in warm climates throughout the world; *A. duodenale* exists in smaller pockets, whereas *N. americanus* is widely distributed throughout impoverished rural areas of the tropics in the Americas, Asia, and Africa.

Hookworms are small helminths, between 0.5 and 1 cm in length. Infection results from larval penetration of the skin on contact with contaminated soil. An intensely pruritic, erythematous, papulovesicular rash called *ground itch* can develop at the site of entry. Parasites then enter the venous or lymphatic circulation and travel to the lungs, at which point an urticarial rash with cough can develop. The larvae are swallowed and migrate to the small intestine, where they attach to the bowel wall with teeth or biting plates and take a continuous blood meal by sucking with strong esophageal muscles. As the hookworms lodge in the small intestine, peripheral eosinophilia peaks, and gastrointestinal discomfort with or without diarrhea can result. Large oral ingestion of *A. duodenale* can cause Wakana syndrome, characterized by cough, shortness of breath, nausea, vomiting, and eosinophilia. The most important clinical manifestation of hookworm infection is iron-deficiency anemia, which can be mild or severe and may be accompanied by malabsorption of protein in hosts with heavy burden of disease. Infants and pregnant women can become extremely ill or even die as a result of the anemia.

Hookworm may be difficult to diagnose because light infections often do not produce enough eggs to be readily seen on stool examination; stool should therefore be concentrated if infection is suspected. Eggs do not appear in stool until approximately 2 months after infection, so patients with pulmonary complaints will not yet have a positive stool examination.

Hookworm infection can be eradicated with benzimidazole anti-helminthics; see Table 2 for details. Prevention of hookworm infection, as with other parasites, lies in improved sanitary conditions;

wearing shoes is especially important because the majority of infections are acquired through the skin. Mass anthelmintic treatment campaigns have shown some efficacy in reducing disease in children; however, reinfection and concern for development of resistance continue to present significant challenges. Candidate vaccines are currently under investigation.

Strongyloides

Strongyloides stercoralis is a global pathogen that is estimated to affect as many as 100 million people, mostly in tropical regions of the world. In recent years, it has become more commonly recognized in the United States among immigrants as a cause of chronic eosinophilia, as well as symptomatic infection.

Strongyloides infection results when filariform larvae dwelling in fecally contaminated soil penetrate the skin or mucous membranes of a susceptible host. Larvae move to the lungs and subsequently to the trachea, where they are coughed up and swallowed. Females, about 2 cm in length, lodge in the lamina propria of the duodenum and proximal jejunum where they begin to oviposit. Rhabditiform larvae emerge from these eggs and either repenetrates the intestinal wall or are passed into the feces, at which point they can begin a free-living cycle and reproduce sexually, or can molt directly into an infectious form ready to enter a subsequent susceptible host.

Persons infected with *Strongyloides* are typically asymptomatic. Those who have symptoms might report abdominal discomfort, diarrhea alternating with constipation, or, rarely, blood-tinged stool. Severe intestinal infections can occur and are manifest by chronic watery or mucousy diarrhea. In such cases, colonoscopy reveals excessive bowel wall thickening and copious secretions, or edema (catarrhal enteritis or edematous enteritis). Parasite migration through the dermis can manifest as serpiginous, erythematous, and pruritic patches along the buttocks, perineum, and thighs, known as *larvae currens*.

Strongyloides appear to attain a balanced state in their host, with similar numbers of adult worms throughout the many years of infection. During periods of host immunocompromise, in particular in patients taking corticosteroids, *Strongyloides* can enter into a state of rapid autoinfection and rampant reproduction called *hyperinfection syndrome*, which results in devastating illness. Persons with HIV infection do not seem to be at particular risk for symptomatic disease or hyperinfection, but hyperinfection has been linked to HTLV-1 infection. *Strongyloides* has also caused hyperinfection in organ transplant patients whose donor had been infected asymptotically with the parasite. Although it has long been thought that steroid-induced immune compromise was the major trigger for hyperinfection, growing evidence suggests that steroids themselves may be the culprit by directly inducing the accelerated life cycle in the parasite.

The hyperinfection syndrome is characterized by systemic illness with fever, cough, hypoxia, patchy or diffuse pulmonary infiltrates with alveolar microhemorrhages, and dermatitis; it can include myocarditis, hepatitis, splenic abscess, meningitis and cerebral abscess, and endocrine organ involvement. Larvae migrating out of the intestines can drag bacteria with them, resulting in gram-negative or polymicrobial sepsis. The prognosis of *Strongyloides* hyperinfection syndrome is grave even with highly effective anthelmintic treatment given the diffuse nature of this disease. However, earlier recognition and intensive supportive care result in cure.

Diagnosis of uncomplicated *Strongyloides* infection in endemic areas can be challenging because few larvae are passed in stool, and numerous examinations may be necessary to detect them. ELISA is available and is highly sensitive, but it does not distinguish between active and past infections. It is, however, the test of choice for persons who have migrated to nonendemic areas, and all persons in this setting should be treated. Ivermectin is the treatment of choice; see Table 2 for dosing. During the first days of treatment, patients can experience intense dermal pruritis as parasites die. Eosinophilia and positive ELISA can persist for months even after effective therapy.

¹Not FDA approved for this indication.

Enterobius vermicularis

Human pinworm infection, caused by the thread like nematode *Enterobius vermicularis*, is found throughout the world and continues to be diagnosed commonly in the United States, especially in children. Its persistence is likely related to the fact that pinworm does not require a period of maturation outside the human body, and autoinfection or transmission by very close contact sustains the parasite within communities. *E. vermicularis* is at maximum 1 cm long with a tapered tail, and dwells in the cecum, appendix, and adjacent colon. At night, female worms travel to the anus and lay small (25–50 µm), double-walled oval eggs in the perianal skin. Within 6 hours, the eggs embryonate within their capsule and are infectious. In scratching the perianal area and subsequently bringing his or her hand to the mouth, the host ingests the embryos, which then hatch in the bowel about 2 months later and continue the cycle of infection. Embryonated eggs can also attach to bedclothes, thereby placing other household members with close contact at risk for infection. In family groups, infection is associated with close living quarters, poor hand washing, and infrequent washing of clothes and sheets. It can also be prevalent in among institutionalized persons.

Infection is often asymptomatic, but it can cause perianal itching, which helps to facilitate persistent infection by encouraging frequent touching of the perianal area. Rarely, worms migrate into ectopic foci and produce painful genitourinary tract disease with granulomatous inflammation; pinworm infection rarely results in pain that mimics acute appendicitis.

Pinworm infestation is best diagnosed by the classic Scotch tape test, which involves placing and immediately removing a piece of sticky tape firmly across the perianal area early in the morning when the eggs have been deposited. The tape can then be brought into a physician's office or laboratory, where it is placed sticky-side down for microscopic examination to detect the eggs. Three specimens should be examined if necessary to improve the sensitivity. It is also sometimes possible to see the worms directly on the perianal region, although they are so small that they may easily be mistaken for residual bits of toilet paper. *E. vermicularis* is susceptible to standard anthelmintic therapies as listed in Table 2. All household contacts should be empirically treated with the same regimen to avoid reintroducing infection from family members who may be asymptotically carrying the parasite. Careful laundering of all bedclothes is recommended as well.

Anisakiasis

Anisakiasis is a descriptive term for human infection with parasites of two distinct genera: *Anisakis* and *Pseudoterranova*. Humans are incidental hosts for these roundworms that inhabit multiple species of fish and other marine animals (tuna, mackerel, hake, cod, sardines, and cephalopods) as intermediate hosts, and marine mammals such as whales, seals, sea lions, and walruses as final hosts. Humans acquire the parasite in its larval stage by eating raw fish (e.g., sushi, ceviche), and therefore the condition predominates in cultures where uncooked fish is consumed. Cases are most commonly reported from Japan but are seen throughout the world in other coastal nations and among restaurateurs.

On consumption of fish with anisakid larvae embedded in its musculature, humans can experience immediate symptoms in the form of itching or burning in the throat, which can provoke coughing that expels the parasite. If the parasite is swallowed, the larva attempts to embed in the gastric musculature at the pylorus. This can produce acute, short-lived epigastric abdominal pain and possibly immediate vomiting, at which point the parasite might again be ejected. If the larva does manage to penetrate gastric tissue, it dies because it is incapable of further tissue invasion in humans. An intense inflammatory response to the dead pathogen can then result, with gastric pain, nausea, and occasionally diarrhea with blood or mucus if a gastric ulcerative lesion has resulted.

Rare cases have been reported in which the larva penetrates the peritoneum, causing focal peritonitis and abscess formation. *Pseudoterranova* appears to cause milder symptoms and less tissue invasion, and the worm might simply be vomited several days after

initial ingestion and presented to a physician, often by an alarmed patient. Because the vast majority of infections are caused by a single organism, vomiting of the parasite results in a definitive cure and patients can be reassured. Diagnosis in patients with ongoing symptoms related to an embedded parasite is ultimately endoscopic. Effective cure results on endoscopic or surgical removal of the worm.

Trematodes

Schistosomiasis

Schistosomes are freshwater pathogens with areas of endemicity in Africa, South America, Southeast Asia, and parts of the Middle East. These small trematodes cause varied, often chronic infections that can carry significant morbidity, although some species cannot invade beyond the dermis in humans and result strictly in cercarial dermatitis or swimmer's itch. There are five species of schistosomes known to cause disease in humans: *Schistosoma haematobium*, found through much of Africa and parts of the Middle East; *Schistosoma mansoni*, also native to Africa and the Middle East as well as Latin America; *Schistosoma japonicum*, present in China, Southeast Asia, and the Philippines; *Schistosoma mekongi*, found only in the Mekong River basin in Southeast Asia; and *Schistosoma intercalatum*, endemic only in West Africa.

All persons who come in contact with schistosomes are at risk for infection, even after only very brief exposure to fecally contaminated freshwater in which the intermediate hosts of the pathogen (snails) reside. Frequency and degree of infection tend to be highest in children in endemic areas and then level off in the early teenage years, likely secondary to level of environmental exposure and possibly to host immunity. *S. haematobium* causes disease in the genitourinary system; the others cause intestinal, hepatic, and sometimes pulmonary diseases.

Infection is acquired rapidly on contact with freshwater (including brief swims or by repeated splashing, as can occur during river rafting), when free-living fork-tailed schistosomal larvae penetrate human skin and lose their tail. These schistomorphs can cause intense itching and a papulovesicular, pruritic rash at the site of penetration, swimmer's itch. Invasive schistomorphs then enter the venous bloodstream and ultimately lodge in gut mesenteric and portal venules, where maturation occurs, and male and female forms join and mate for life. Females begin to oviposit, and the resultant inflammatory response to the eggs can cause either acute illness or chronic fibrosis and granulomatous inflammation of the tissues in which they reside.

Acute illness, called *Katayama fever*, is more common among hosts who have not been previously exposed to the organism and can be quite severe, even fatal. Katayama fever begins 4 to 8 weeks after exposure to the schistosomes, with fever, cough, abdominal pain, hepatomegaly, and lymphadenopathy. Eggs might not yet be present in the stool at the time of diagnosis. Chronic schistosomiasis is a slowly progressive illness. *S. haematobium* infection is manifest by gross or microscopic hematuria, urinary symptoms, and chronic bacterial urinary tract infections; ultimately ureteral fibrosis, hydronephrosis, and granulomatous genital lesions also can ensue. In infection with other invasive schistosomes, chronic illness can manifest as abdominal pain and diarrhea, which is often bloody, with associated iron-deficiency anemia. Hepatomegaly is often the first clinical finding in chronic intestinal schistosomiasis. Over many years, hepatic congestion and fibrosis can result in liver failure, and the pulmonary vasculature can be involved as well, which causes pulmonary hypertension and cor pulmonale.

Diagnosis of schistosomiasis is by observation of eggs in stool (intestinal disease), urine (urinary tract disease), or biopsy specimens, or by serum antibody testing. Concentration of stool may be necessary to detect the pathogen. The eggs of the three most common species of schistosomes can be readily identified microscopically: *S. haematobium* has an inferior spine, *S. mansoni* an inferolateral spine, and *S. japonicum* lacks a spine. Eosinophilia is a hallmark of chronic infection and is a common cause of

asymptomatic eosinophilia among immigrants from schistosome-endemic regions of the world. Serology is highly sensitive and specific but cannot distinguish acute, chronic, or cleared infection; it is very useful when attempting to diagnose infection in returned travelers.

All patients with schistosomiasis should be treated, and those with chronic manifestations might experience significant regression of even late-stage organ-specific disease. Treatment of choice is with praziquantel; see Table 2 for details.

Prevention of schistosomiasis involves improving access to treated water and exploration of avenues to eliminate the intermediate snail hosts. Host immunity does appear to occur, and efforts are underway to better understand and induce such immunity in the form of a vaccine.

Cestodes

Taeniasis

Human tapeworm infection has long been implicated in North American oral folklore as a cause of insatiable appetite and excessive weight loss. In reality, despite their impressive size of up to 12 meters, tapeworm infection tends to be minimally symptomatic.

Taenia solium, pork tapeworm, and *Taenia saginata*, beef tapeworm, are the two most common flatworm infections of humans worldwide and occur in any setting in which raw or undercooked meat is served and cattle and pigs have access to feed contaminated with human feces. *T. saginata* is still found in areas of North America and Europe, as well as in Central and South America and Africa; *T. solium* is common throughout Mexico, Central and South America, Africa, China, and the Indian subcontinent. Although humans are the definitive hosts for both parasites, *T. solium* is best known for its pathogenicity in the form of cysticercosis. Cysticercosis is not an intestinal parasitic infection.

Domesticated animals acquire infection on ingestion of eggs excreted by humans; the eggs mature in their musculature and develop a scolex. When humans consume infected meat, the scolex attaches in the small intestine, and the adult tapeworm develops over approximately 2 months. Adult tapeworms are made up of hundreds to thousands of gravid proglottids and can live for up to 25 years. Symptoms tend to be mild or absent but can include nausea, abdominal pain, loose stools, anal pruritus, and occasionally weakness or increased appetite, especially in children. Serious illness rarely results when a tapeworm becomes lodged in the biliary or pancreatic ducts or is coughed up and aspirated. Some patients come to medical attention when the worm is noted emerging from the anus or on extrusion of proglottids in the stool.

Diagnosis of taeniasis can be made on visualizing the round eggs in stool; however, the species cannot be determined unless a segment of the worm is examined. Serum antibody and antigen tests, as well as stool PCR, have been developed for diagnosis but are not widely used in clinical practice. Eosinophilia and elevated IgE levels may be present. Single-dose praziquantel¹ (see Table 2) is curative in almost all cases, but infectious eggs can still be released in the feces for a time; ingestion of these could result in the subsequent development of cysticercosis, so patients should be counseled to avoid fecal-oral contact.

Proper cooking of meat is the mainstay of prevention; disposal of human waste away from animals would also be effective in interrupting the life cycle.

Diphyllobothriasis

Diphyllobothrium latum is the longest parasite known to infect humans (10–12 m). It is found in freshwater lakes in areas of the Americas, Northern Europe, Africa, China, and Japan and has a complex life cycle involving two intermediate hosts: crustaceans and small fish. Humans and other fish-eating mammals are the definitive hosts and acquire the infection on ingestion of raw fish or roe.

The organism attaches within the small intestine, and hosts are usually asymptomatic. Infected persons might complain of

increased appetite, nausea, or abdominal discomfort. Many present after passage of portions of the tapeworm in stool, as with taeniasis; in others, diagnosis is on stool examination done for other purposes or during screening colonoscopy. As with other worms, the parasite occasionally migrates into biliary ducts or causes intestinal obstruction. Attachment of the parasite higher in the intestine can result in decreased levels of vitamin B₁₂. Rarely, pernicious anemia develops as a result (tapeworm anemia).

Diagnosis is made either by seeing eggs in unconcentrated stool or by encountering the adult worm. Eosinophilia is present in a minority of cases. Treatment with praziquantel¹ is curative; see Table 2. Vitamin B₁₂ supplementation is necessary in cases of severe or symptomatic deficiency, but it will not recur once the tapeworm is eliminated. Prevention involves not ingesting undercooked fish.

¹Not FDA approved for this indication.

IRRITABLE BOWEL SYNDROME

Method of

Arnold Wald, MD

CURRENT DIAGNOSIS

- Fulfilling diagnostic criteria for irritable bowel syndrome (IBS) using Manning or Rome criteria is mandatory but not sufficient, as some organic diseases may also meet these criteria.
- Against the diagnosis of IBS is new onset in old age, a steady progressive course, frequent awakening by abdominal pain or urge to defecate, and weight loss not caused by depression.
- The diagnostic approach to patients with IBS symptoms with no “alarm signs” includes a complete blood count, stool testing for occult blood or calprotectin, C-reactive protein and colonoscopy if patient is age >50 years, has positive stool or blood test result as above, or if there is a poor response to treatment.
- After a diagnosis of IBS is established with confidence, repeated testing is counterproductive unless there is a distinct change in clinical symptoms or new alarm signs develop.

¹Not FDA approved for this indication.

- After a diagnosis of IBS is established with confidence, repeated testing is counterproductive unless there is a distinct change in clinical symptoms or new alarm signs develop.

¹Not FDA approved for this indication.

CURRENT THERAPY

- A robust patient–health care provider relationship is perhaps the most important determinant of outcome and reduced health care use in patients with IBS.
- There is significant support for the use of a low-FODMAP (fermentable oligo-, di-, and monosaccharides and polyols) diet in patients with IBS. Gluten restriction is part of this diet and will cover those patients who believe that they are gluten intolerant in the absence of celiac disease.
- Pharmacologic agents can be divided into those for IBS-C or IBS-D or in any patient with IBS to ameliorate abdominal pain. The evidence to support these agents varies in quality and strength, and none are effective in the majority of patients who have been tested.
- Cognitive behavioral therapy (CBT) can be very effective in IBS with unrelenting symptoms but may also be effective for any patient with IBS who exhibits poor stress management.

Introduction and Definitions

Irritable bowel syndrome (IBS) is a chronic functional disorder of the gastrointestinal tract characterized by chronic abdominal pain and altered bowel habits in the absence of an organic disease. In the absence of a biologic disease marker, the diagnosis has traditionally been based on a cluster of symptoms. The earliest was the so-called “Manning criteria,” which was based on the presence of three or more characteristic symptoms (Table 1).

Subsequently, there have been various iterations of IBS criteria created by the Rome study groups, which are currently used for research purposes (see Table 1). When evaluating the relevant literature for IBS, it is important to note that various studies have used different criteria, which may result in variable data concerning prevalence and economic costs considerations.

From a clinical standpoint, subtypes of IBS have been defined as follows:

- **IBS with constipation (IBS-C):** Patient reports that abnormal bowel movements are usually constipation (types 1 and 2 in the Bristol Stool Form Scale; BSFS)
- **IBS with diarrhea (IBS-D):** Patient reports that abnormal bowel movements are usually diarrhea (types 6 and 7 in the BSFS)
- **Mixed IBS (IBS-M):** Patient reports that abnormal bowel movements are usually both constipation and diarrhea (more than one-fourth of all the abnormal bowel movements are constipation and more than one-fourth are diarrhea) over at least 3 months
- **Unclassified IBS (IBS-U):** Patients who meet diagnostic criteria for IBS but cannot be accurately categorized into one of the other three subtypes

TABLE 1 Criteria for IBS

Manning Criteria	Rome III Criteria*
Looser stools with onset of pain	Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with two or more of the following:
More frequent bowel movements at onset of pain	Improvement with defecation
Visible distension	Onset associated with change in stool frequency
Feeling of distension	Onset associated with change in form of stool
Mucus per rectum	
Feeling of incomplete emptying (often)	
Strict criteria > 3 of above	
Less strict criteria > 2 of above	

*Criterion fulfilled for the last 3 months with onset of symptoms at least 6 months prior to diagnosis.

Epidemiology of IBS

Prevalence

There have been numerous surveys concerning the prevalence of IBS in the community. Most of these studies have used accepted diagnostic criteria, and some have used more than one definition within the same population. In one meta-analysis, 23 studies used the Manning criteria, 24 used Rome I criteria, 36 used Rome II criteria, and 5 used Rome III criteria. The prevalence ranged from 5% to 10% (USA, China) to 15% to 20% (Canada, Brazil, Russia). There was little or no data from Africa, Central America, and large parts of South America.

Most studies did not report the predominant stool pattern in IBS. Of the nine that included IBS-U subtypes as well, there was an even distribution, ranging from 22% to 24% mean prevalence for each of the four subgroups. In general, the pooled prevalence was higher in women than in men (14%; range 11%–16% vs. 9%; range 7.3%–10.5%), with significant heterogeneity between studies. There appeared to be no relationship between socioeconomic status in the four studies that reported it and no strong influence of age as well.

It is important to note that the meta-analysis was restricted to studies based on the general population and excluded those based on convenience samples. This makes the data more generalizable to community individuals with IBS.

Causality—a biopsychosocial conceptual model for IBS

The ability to study causality in a disorder with no biologic disease markers is fraught with difficulties. This is certainly the case with IBS as a representative of functional gastrointestinal disorders. Many hypotheses have been advanced and found wanting. The current (and in my opinion most relevant) conceptual model is the biopsychosocial construct, as shown in Figure 1.

Impact on Population Health

Although there is no mortality associated with IBS, symptoms are long lasting, and there are no curative therapies available. As a chronic illness, the economic impact of this disorder is considerable.

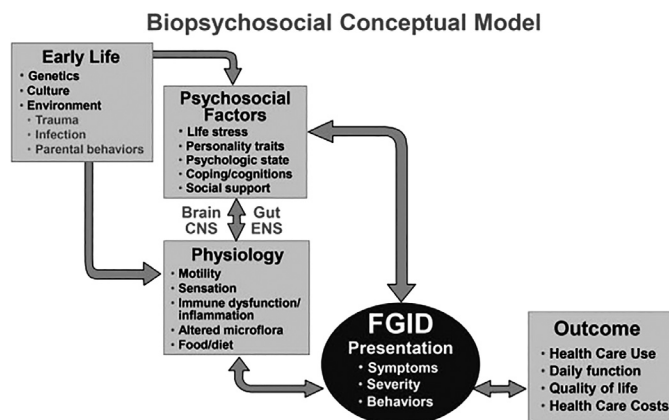

Figure 1 Predeterminants such as early life experiences, together with psychosocial factors, may interact with altered gut physiology via the brain-gut axis. This concept infers that these factors are bidirectional and mutually interactive and therefore influence both the clinical presentation of the disorder and the clinical outcomes. Among the physiological processes that may lead to GI symptoms are abnormal gut motility, visceral hypersensitivity, immune dysregulation, inflammation and barrier dysfunction, the intestinal microbiome, diet, and the brain-gut axis. No one factor alone accounts for the symptoms of IBS, and all must be considered in the management of affected patients. This becomes apparent when considering treatment approaches (Reprinted with permission from Drossman DA. Functional gastrointestinal disorders: History, pathophysiology, clinical features and Rome IV. *Gastroenterology* 2016; 150:1262-79.). FGID = functional gastrointestinal disorders.

In a 2015 survey conducted by the American Gastroenterological Association, IBS patients reported that their symptoms interfered with work productivity on an average of 9 days per month and missed work on average of 2 days per month. Indirect costs (i.e., loss of work and reduced productivity) have been estimated to be up to \$20 billion annually in the United States, with an estimated annual cost per patient of \$9933 (in 2012 US dollars).

In a study of indirect costs, impairment experienced at work (presenteeism) accounted for approximately 75% of the total annual indirect costs for respondents with IBS, far in excess of absenteeism from work. Compared with control subjects, IBS respondents missed significantly more work (5.1% vs. 2.9%), experienced higher levels of presenteeism (17.9% vs. 11.3%), and had greater overall work productivity loss (20.7% vs. 13.2%) and higher daily activity impairment.

Direct Health Care Costs

It has been estimated that up to 25% of all visits to gastroenterologists in the United States were for IBS with additional others for other functional GI disorders. This accounted for 3.5 million visits to health care practitioners in 1991 and undoubtedly is much higher today. IBS patients made twice as many health care visits per year as did age-matched control subjects, and 78% of the excess visits were for nongastrointestinal complaints. A subsequent analysis of this phenomenon suggests that comorbidity in IBS may be a consequence of the psychological trait for somatization, defined as the tendency to amplify the intensity and overinterpret the significance of any somatic sensation. This excess comorbidity is the primary determinant of excess health care costs associated with IBS, although it does not apply to all patients with IBS.

Recent attempts to identify factors of high users with IBS have been made, using a conceptual framework for accessing health care services, which holds that a decision to use health care is related to (1) predisposition to use services, (2) ability to use services, and (3) need for services. The important conclusion was that decisions to use health care are influenced not only by symptom-specific factors but by a variety of lifestyle and (most importantly) economic factors such as health insurance coverage.

Evaluation of Patients with Suspected IBS

The diagnosis of IBS should be made based on the clinical history, physical examination, minimal laboratory testing, and colonoscopy or other appropriate tests when clinically indicated. Fulfilling diagnostic criteria is, of course, mandatory but insufficient, because some organic diseases may also meet these criteria. The prevalence of organic disease is lowest in IBS-C and highest in IBS-D, followed by IBS-M; one of the most common considerations would be Crohn's disease. Against the diagnosis of IBS, include the new onset in old age, a steady progressive course, frequent awakening by pain or need to defecate, and weight loss not attributed to depression. Additional features that would increase concern about organic disease would include a positive family history of colorectal cancer or inflammatory bowel disease, rectal bleeding, and anemia associated with iron or vitamin B₁₂ deficiency.

In the absence of "alarm signs," a consensus diagnostic approach to patients with IBS symptoms is listed in [Table 2](#). This may vary according to clinical circumstances.

Tests of Unproven Value

It is not uncommon to screen patients with IBS for celiac disease based on reports of non-US populations. However, a large US study found no increased prevalence of abnormal serum tests for celiac disease in patients with IBS (n = 492) versus healthy control subjects (n = 458).

A high prevalence of small intestinal bacterial overgrowth (SIBO) has been claimed by some centers leading to the frequent utilization of either lactulose or glucose breath tests. This hypothesis is based on poor methodology and erroneous conclusions. The original studies have not been reproduced by other centers using either similar or better techniques. This has led to the frequent

TABLE 2 Diagnostic Approach to Patient With IBS Symptoms (No "Alarm Signs")

Complete blood count
Stool for occult blood
Routine colon cancer screening at ages > 50 yrs.

C-Reactive protein (inflammatory marker)
Fecal calprotectin (indicator of inflammation)
Stool for C/S (if CRP/calprotectin positive)
Diagnostic colonoscopy (if poor response to Rx)

Rome IV (2016)

use of expensive antibiotics, which can be effective in some patients with bloating and IBS but not because these patients have SIBO.

Lastly, after a diagnosis of IBS has been established with confidence, repeated testing is counterproductive unless there is a distinct change in clinical symptoms or new alarm signs develop. This is especially so if endoscopy procedures have already been performed.

Treatment of IBS

A validated standardized algorithm for the treatment of IBS does not exist. Treatment therefore depends on the type and severity of symptoms and the nature of associated psychosocial issues in an individual patient. A strong guiding principle is that a robust patient–health care provider relationship is an important determinant of outcome and reduction of health care use. Treatments may generally be divided into dietary and lifestyle modifications, pharmacologic agents, and behavioral therapies, all of which have been validated by randomized and controlled studies.

Dietary Modifications

Fiber supplements are widely recommended for IBS, but a meta-analysis of seven high-quality studies failed to find significant benefit, although some benefits might occur with soluble (psyllium) versus insoluble (bran) fiber in IBS-C. Unfortunately, fiber supplements may exacerbate symptoms such as abdominal bloating and discomfort.

Other dietary interventions such as gluten-free and low-FODMAP (fermentable oligo-, di-, and monosaccharides and polyols) diets have become increasingly popular. Several studies support the benefit of gluten-free diets in a subset of IBS patients in the absence of celiac disease. It remains uncertain whether the clinical benefits are a consequence of gluten withdrawal, elimination of other wheat proteins and highly fermentable short-chain fatty acids, or a placebo effect. Adding a gluten-free diet to patients who are already on a low-FODMAP diet offers no additional benefits.

There is accumulating evidence from prospective controlled studies that dietary FODMAP restriction is associated with significant symptom improvement in many patients with IBS ([Table 3](#)). It appears that restriction of both fructose and fructans is most beneficial. Significant symptom improvement was noted in IBS patients compared to several standard diets in Australia and the United States.

Response to a low-FODMAP diet is usually assessed after about 2 weeks. Responders are then asked to engage in a structured reintroduction of restricted foods to allow the individual to tailor his or her diet. It is optimal to involve a properly trained dietician or nutritionist oversee the care of these patients.

Pharmacologic Agents for IBS

Pharmacologic approaches to IBS may be divided into medications for IBS-C, patients with IBS-D, and for any patient with IBS in order to ameliorate abdominal pain ([Table 4](#)).

Most drugs work through different pathophysiological mechanisms. For example, for patients with IBS-C, linaclotide (Linzess), plecanatide (Trulance), and lubiprostone (Amitiza) increase

TABLE 3 Low-FODMAP Diet

AVOID OR REDUCE THESE FOODS			
FRUCTOSE	LACTOSE	OLIGOS	POLYOLS
Fruits: Apple, mango, pear, watermelon, juice, dried fruit	Milk: milk from cows/goats/sheep, custard, ice cream, yogurt, eggnog	Vegetables: Beets, broccoli, brussels sprouts, cabbage, fennel, garlic, onion, chicory root	Fruits: Apricot, avocado, blackberry, cherry, nectarine, peach, plum, prune, fig
Other: Asparagus, honey, high fructose corn syrup, molasses	Cheese: Soft, unripened cheese	Other: Barley, beans, chickpeas, couscous, inulin, lentils, pistachios, rye, soy milk, wheat (pasta, bread), veggie burgers	Vegetables: Cauliflower, corn, mushroom, sweet potato Sweeteners: Ending in "ol" (for example: xylitol, sorbitol), isomalt and sucralose (Splenda)

TABLE 4 Pharmacologic Agents for IBS

INDICATION	DRUG	DOSE
IBS-C	Linacotide (Linzess)	72-290 µg/d ³
	Plecanatide (Trulance)	3 mg/d
	Lubiprostone (Amitiza)	8 µg bid ³
	PEG-3350 (Miralax) ¹	8.5-17 g/d
IBS-D	Rifaximin (Xifaxan)	550 mg tid × 2 weeks
	Alosetron (Lotronex) [#]	1 mg qd- bid
	Eluxadoline (Viberzi)	75-100 mg/bid
	Loperamide (Imodium) ¹	2-16 mg/d
IBS-All	Dicyclomine (Bentyl)	mg QID
	Desipramine (Norpramin) ^{1*}	mg/d

*Alternative TCAs: amitriptyline (Elavil)¹, imipramine (Tofranil)¹, nortriptyline (Pamelor)¹.

[#]Available only to physicians enrolled in the REMS Program for alosetron.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

intestinal chloride and water secretion to combat constipation, whereas PEG (polyethylene glycol 3350, Miralax)¹ does so through a hyperosmolar effect. For IBS-D, rifaximin (Xifaxan) is an antibiotic, loperamide (Imodium)¹ is a µ-opioid agonist, alosetron (Lotronex) works through the serotonin 3 receptor, and eluxadoline (Viberzi) has effects on all 3 opioid receptors in the gut (mu, kappa, and delta). Tricyclic agents (TCAs) presumably work via central neurochemical changes, and antispasmodics (dicyclomine [Bentyl], encapsulated oil of peppermint⁷) work largely through peripheral anticholinergic pathways. The large and diverse number of drugs are indicative of the lack of fundamental understanding of IBS. Moreover, few drugs are effective in the majority of IBS patients, and there is no more than a 10% to 15% improvement over placebo in most published studies.

The AGA guidelines for use of pharmacologic agents in IBS incorporated the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology and best practices as outlined by the Institute of Medicine. **Recommendations** are either strong or conditional (weak). The **evidence** that provides the basis for recommendation is rated high, moderate, or low quality. Because of the relatively recent release of plecanatide and eluxadoline, these drugs were not incorporated into present guidelines, although they have been approved for use in IBS by the Food and Drug Administration (FDA).

Of the pharmacologic agents for IBS-C, linacotide received a strong recommendation with high-quality evidence, lubiprostone received a conditional recommendation on moderate-quality evidence, and PEG was given a conditional recommendation based on weak evidence. The first two agents showed modest benefit over
