Petros E. Carvounis, MD

CURRENT DIAGNOSIS

- The most common form of uveitis is anterior uveitis.
- Anterior uveitis is commonly idiopathic.
- Posterior uveitis is most likely infectious.
- In any form of uveitis, syphilis, tuberculosis, and Lyme disease need to be ruled out.
- In immunosuppressed individuals, the uveitis is most likely infectious: the patient's HIV status needs to be determined, because a positive status completely changes the diagnostic approach.
- The key to correct diagnosis is a good history, including a thorough review of systems and a careful ophthalmologic examination as well as dilated funduscopy; laboratory and radiographic investigations, sometimes including aqueous or vitreous polymerase chain reaction or cytologic studies, are frequently necessary.
- Involvement of an ophthalmologist with expertise in the diagnosis and treatment of uveitis is mandatory.

CURRENT THERAPY

- Uveitis resulting from a systemic infection (e.g., syphilis, Lyme disease, tuberculosis) needs to be treated as a central nervous system infection.
- Idiopathic anterior uveitis or anterior uveitis related to an autoimmune disease responds to topical corticosteroids (e.g., prednisolone acetate [Pred Forte] 1% 1 drop every 2 hours while awake³) and cycloplegia (e.g., homatropine [Isopto Homatropine]¹ 2% 1 drop three times daily).

- Periocular steroids (posterior or anterior sub-Tenon's steroid injection) is useful in the management of severe anterior uveitis and in intermediate uveitis.
- Intraocular triamcinolone acetonide injection (Kenalog)¹ or implantation of a sustained-release dexamethasone implant (Ozurdex) or fluocinolone acetonide implant (Retisert) is reserved for cases of severe uveitis.
- Oral steroids (prednisone 1–2 mg/kg PO) can be effective in cases of severe uveitis that is unresponsive to topical, periocular, and intraocular steroids.
- Systemic immunosuppressants can control uveitis unresponsive to steroids or be used as steroid-sparing agents. Some specific uveitides mandate systemic immunosuppression as first-line treatment.
- Commonly used immunosuppressants are azathioprine (Imuran),¹ methotrexate (Trexall),¹ cyclosporine (Neoral),¹ and mycophenolate mofetil (CellCept).¹
- Anti-tumor necrosis factor- α agents are increasingly being used for the treatment of severe uveitis unresponsive to steroids or requiring steroid-sparing agents.

¹Not FDA approved for this indication.

²Exceeds dosage recommended by the manufacturer.

Uveitis refers to intraocular inflammation: it comprises multiple disease entities, some of which are caused by infectious agents and some of which are immune mediated. Uveitis can be classified by the predominant anatomic location of the inflammation: if it is in the anterior chamber, it is an anterior uveitis (previously known as iritis or iridocyclitis); if it is in the vitreous, it is an intermediate uveitis; and if it is in the retina or choroid, it is a posterior uveitis. In panuveitis, inflammation involves all of these sites. Uveitis is said to be limited if it lasts less than 3 months or persistent if it lasts longer than 3 months.

Clinical Features and Diagnosis

Anterior Uveitis

Anterior uveitis is the most commonly encountered type. It typically manifests with sudden-onset severe photosensitivity, pain, blurred vision, and red eye. Clinical examination documents decreased vision, limbal injection, keratic precipitates (cells and protein on the corneal endothelium), and an anterior chamber reaction (white cells and flare-increased light scatter in the anterior chamber caused by the increased protein concentration resulting from inflammation-induced vascular permeability). The anterior uveitis associated with juvenile idiopathic arthritis in children may be asymptomatic.

Anterior uveitis is commonly idiopathic but may be associated with human leukocyte antigen (HLA) B27; other HLA-B27 conditions, such as ankylosing spondylitis, Achilles tendonitis, plantar fasciitis, and dactylitis, should be sought. Anterior uveitis may also be associated with psoriatic arthropathy, Reiter's syndrome (although conjunctivitis is its most common feature), inflammatory bowel disease (which is also associated with intermediate uveitis), or sarcoidosis. Rheumatoid arthritis does not cause uveitis, although it may cause scleritis. In a patient with prior intraocular surgery or recent trauma, postoperative infectious endophthalmitis is a possibility. Infectious causes such as tuberculosis, syphilis, and Lyme disease need to be excluded, because they are curable. Viral infections (e.g., herpes simplex virus, varicella-zoster virus) can lead to an anterior uveitis, but they more frequently cause keratitis. Other rare associations are possible.

A good history, including a very thorough systems review combined with a good clinical examination including dilated funduscopy (to rule out retina or choroid involvement) by an ophthalmologist with expertise and interest in uveitis is mandatory for appropriate diagnosis and management.

A first occurrence of anterior uveitis that readily responds to topical corticosteroids (see later discussion) does not require further investigation unless there is strong suggestion of an associated

systemic disorder based on the history and general physical examination. Investigation for anterior uveitis that is recurrent or is unresponsive to topical corticosteroids should be tailored based on the clinical examination findings but should not neglect to rule out syphilis, tuberculosis, Lyme disease, and HIV.

Intermediate Uveitis

Intermediate uveitis typically manifests in a young or middle-aged adult with pain, photosensitivity, blurred vision, and floaters. The most important finding on clinical examination is a vitritis (white cells in the vitreous and vitreous haze).

Intermediate uveitis is commonly idiopathic (pars planitis) or may be associated with tuberculosis, sarcoidosis, Lyme disease, syphilis, inflammatory bowel disease, or, rarely, multiple sclerosis. Intraocular lymphoma should be considered in patients older than 50 years of age who have vitritis. Investigation of intermediate uveitis is mandatory, because it is usually unresponsive to topical corticosteroid drops.

Posterior Uveitis

Posterior uveitis is commonly infectious. Patients complain of visual loss and floaters. Clinical signs include decreased visual acuity, vitreous cells and haze, and some of the following: retinal infiltrates, serous retinal detachment, retinal hemorrhage, chorioretinal scars, choroidal granulomas, venular sheathing, or arteriolar sheathing.

The most common cause of posterior uveitis is *Toxoplasma* retinochoroiditis. Viral infections such as varicella-zoster or herpes simplex can uncommonly cause acute retinal necrosis, and cytomegalovirus retinitis can be devastating in immunocompromised individuals. Tuberculosis, Lyme disease, and syphilis are bacterial causes of posterior uveitis. *Pneumocystis jirovecii* (formerly called *Pneumocystis carinii*) and *Cryptococcus* can cause a choroiditis in the immunocompromised individual. Sarcoidosis can also cause posterior uveitis. There is a plethora of well-defined posterior uveitides without associated systemic findings (e.g., serpiginous chorioretinitis). Intraocular lymphoma can masquerade as posterior uveitis and needs to be considered in older patients.

Unless a clinical diagnosis is possible (e.g., in *Toxoplasma* chorioretinitis), further investigations are required. If a rapid plasma reagin test is negative, a diagnostic vitrectomy should be considered in all patients and is mandatory in immunocompromised patients; otherwise, tailored laboratory and radiographic investigations need to be performed.

Panuveitis

Panuveitis combines the signs and symptoms of anterior and posterior uveitis, although early in the course one location may predominate. Bacterial or fungal endophthalmitis needs to be considered. Vogt-Koyanagi-Harada syndrome is a common cause in the Far East and in patients of Native American ancestry. Adamantiades-Behçet syndrome, sympathetic ophthalmia, tuberculosis, syphilis, and, rarely, Lyme disease need to be considered, among others.

Sequelae and Complications of Uveitis

Uncontrolled uveitis can be a blinding condition. Visual loss results commonly from cystoid macular edema or from cataracts, glaucoma, band keratopathy, hypotony maculopathy, macular scar, macular necrosis, or retinal detachment.

Current Treatment

Almost all of the medications employed in the treatment of uveitis are used off-label (FDA approved for an indication other than the treatment of uveitis).

Anterior Uveitis

If photosensitivity is a prominent complaint, topical cycloplegia affords considerable relief. Homatropine (Isopto Homatropine) 2% or 5%, scopolamine (Isopto Hyoscine) 0.25%, or tropicamide (Mydracil) 1% may be used. Cyclopentolate (Cyclogyl) should be

avoided, because it has chemoattractant properties in vitro. Topical cycloplegia is also necessary with severe anterior uveitis to prevent posterior synechiae.

Topical corticosteroid drops are the first line of treatment for anterior uveitis (e.g., prednisolone acetate [Pred Forte] 1% 1 drop every 2 hours while awake).³ Patient education to ensure compliance is of paramount importance. Difluprednate 0.05% (Durezol) is also being used with increasing frequency.

After 1 to 2 weeks, a slow taper of the drops is commenced (administer four times daily for 7–10 days, then taper by 1 drop every 7–10 days), provided that the anterior chamber cells have resolved. If there is an increase in activity during the taper, an increase in the dosing frequency to re-achieve a complete response, followed by a slower taper, is performed. Occasionally, patients have to be maintained for the long term on topical prednisolone; this is acceptable, provided that no adverse side effects occur.

If there is incomplete response to prednisolone acetate 1% given every 2 hours or if the drops cannot be tapered without recurrence and investigations are negative, the next step to be considered could be a sub-Tenon's (under the conjunctiva) injection of 0.5 to 1.0 mL triamcinolone acetonide 40 mg/mL (Kenalog),^{1,6,*} which forms a depot providing continuous steroid release for up to 6 months; alternatively, oral corticosteroids (usually prednisone) may be used in patients with especially severe bilateral uveitis, although this is uncommon. For the rare severe anterior uveitis that is unresponsive to these treatments or to decreases in the steroid dose, immunosuppressant medications such as methotrexate,¹ cyclosporine,¹ or mycophenolate mofetil¹ or an anti-tumor necrosis factor- α (anti-TNF- α) agent such as infliximab¹ may be given (see later discussion for recommended doses).

It cannot be overemphasized that a severe "anterior uveitis," especially with a hypopyon, occurring after recent intraocular surgery or trauma should alert the physician to the possibility of endophthalmitis. Emergent anterior chamber and vitreous cultures need to be obtained, and intravitreal nonpreserved vancomycin (Vancocin) 1.0 mg/0.1 mL⁶ and ceftazidime (Fortaz) 2.25 mg/0.1 mL⁶ must be injected.

The main side effects of topical steroid use are cataract formation and ocular hypertension, which can lead to glaucoma. Untreated uveitis can cause the same side effects; therefore, inflammation needs to be controlled promptly, and then the corticosteroids need to be tapered off as soon as possible without precipitating a recurrence. Topical steroid use also predisposes to cornea infection, including reactivation of herpes simplex or varicella-zoster keratitis.

Intermediate Uveitis, Posterior Uveitis, and Panuveitis

Uveitis associated with systemic infection (e.g., syphilis, Lyme disease) is treated in consultation with an infectious disease specialist, because intraocular involvement is considered central nervous system involvement. Adjuvant topical corticosteroids and mydriatics can afford relief without jeopardizing cure in most cases (as for anterior uveitis).

Ocular toxoplasmosis, the most common posterior uveitis, is self-limited. Treatment is required in cases in which the optic nerve or macula is threatened or the vitritis is particularly severe. Treatment consists of pyrimethamine (Daraprim) (loading dose 50 mg, then 25 mg twice daily), sulfadiazine (1 g four times daily), and folinic acid (Leucovorin)¹ 5 mg three times weekly. More recently, clindamycin (Cleocin)¹ 150 to 300 mg PO four times daily or trimethoprim-sulfamethoxazole¹ (Bactrim DS 800 mg sulfamethoxazole/160 mg trimethoprim twice daily) have been found to be equally efficacious and are more widely used. Prednisone 40 mg/day is added 24 to 48 hours later. Treatment duration is usually 30 to 40 days, with a prednisone taper guided by the clinical response.

For intermediate uveitis, posterior uveitis, or panuveitis not associated with systemic infection, treatment options are to be considered in the following order:

1. Periocular steroids (posterior sub-Tenon's injection of triamcinolone acetonide)¹ are commonly efficacious for intermediate uveitis.
2. Oral corticosteroids are very efficacious but have ocular as well as systemic side effects. If the uveitis cannot be controlled with less than prednisone 10 mg after 6 months of treatment, one of the other options needs to be considered.
3. In severe cases of intermediate, posterior, or panuveitis, intravitreal triamcinolone acetonide (Kenalog or Triessence 4 mg^{1,*}), an injectable dexamethasone implant (Ozurdex), or a fluocinolone implant (Retisert) can be used; intravitreal long-acting steroid treatment has similar efficacy to systemic immunosuppression; the former has ocular complications (cataract formation, glaucoma), and the latter carries the risk of systemic side effects.
4. Systemic immunosuppression with azathioprine (Imuran)¹ up to 2.5 to 4 mg/kg/day, cyclosporine (Neoral)¹ 2.5 to 5.0 mg/kg/day in 2 divided doses, tacrolimus (Prograf)¹ 0.15 to 0.30 mg/kg/day, mycophenolate mofetil (CellCept)¹ 500 to 1000 mg twice daily, methotrexate (Trexall)¹ (12.5 to 25 mg weekly, or an anti-TNF- α agent (e.g., infliximab [Remicade])¹ have all been used with success as steroid-sparing agents or to control uveitis that is poorly responsive to corticosteroids alone.

There are specific uveitis entities that mandate the use of immunosuppression as first-line treatment (together with steroids initially). These include Wegener's retinal vasculitis, Adamantiades-Behçet's syndrome, sympathetic ophthalmia, and possibly birdshot choroidopathy, uveitis related to Vogt-Koyanagi-Harada syndrome, and serpiginous chorioretinitis.

*Kenalog is commercially available as 40 mg/mL. Special compounding is needed for the concentration of 4 mg/mL.

¹Not FDA approved for this indication.

VISION CORRECTION PROCEDURES

Method of

Elizabeth Yeu, MD

CURRENT DIAGNOSIS

- Refractive errors are an extremely common cause for blurred vision.
- Refractive errors include myopia (nearsightedness), hyperopia (farsightedness), astigmatism, and presbyopia, which is the age-related loss of near vision.
- Medical management includes the use of spectacles, contact lenses, or both.
- Both corneal and intraocular surgical options exist to successfully and permanently correct refractive errors.
- Corneal refractive surgery options include excimer laser, such as laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK), and corneal relaxing incisions for the management of astigmatism.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

⁶May be compounded by pharmacists.

*Kenalog is commercially available as 40 mg/mL. Special compounding is needed for the concentration of 4 mg/mL.

- In eyes that are not candidates for corneal refractive surgery, intraocular surgery with phakic intraocular lens implants or refractive lens exchange can be considered.
- Increasing advancements now offer, and continue to expand, the various surgical options available to correct myopia, hyperopia, astigmatism, and presbyopia.

CURRENT THERAPY

- Laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK) use an excimer laser to reshape the anterior surface of the cornea and permanently correct the eye's refractive error. LASIK and PRK can correct myopia, hyperopia, and astigmatism and help reduce presbyopia.
- In LASIK, a corneal flap is created and lifted before the excimer laser is applied to correct the refractive error. In contrast, the PRK procedure requires no lamellar flap. In PRK, the laser treatment is applied directly to the anterior stromal surface after the surface epithelium is removed.
- Radial keratotomy (RK) was the first modern form of corneal refractive surgery to correct myopia. In RK, spokelike corneal incisions were created to flatten the central cornea and reduce myopia. Although RK surgery is effective, the results were often unpredictable and unstable and led to overcorrection, with progressive hyperopia.
- Astigmatic keratotomy (AK) incisions are a modification of RK surgery and are used to reduce corneal astigmatism. The two forms of corneal relaxing incisions, AK and limbal relaxing incisions (LRI)—or, more accurately, peripheral corneal relaxing incisions (PCRLs)—are differentiated by their location on the cornea.
- A refractive lens exchange (RLE) is a surgical option that can correct refractive errors by removing and replacing the crystalline lens. In essence, RLE is cataract surgery performed before a visually significant cataract forms; a visually significant cataract is the clouding or opacification of the natural lens. RLE is a viable option for high myopes and hyperopes, where laser vision correction is not an option, and to correct presbyopia.
- Presbyopia correction is a very dynamic field in refractive surgery. Surgical correction options include surgical monovision, which is popularly used with presbyopic contact lens wearers, where one eye is corrected for distance vision and the other eye for near vision. Monovision can be produced through excimer laser, RLE, or cataract surgery. Other options include various intraocular lenses (IOLs) and corneal inlays that can provide presbyopia correction.
- Surgically implanted lenses, or phakic intraocular lens implants, can be used to treat myopia only in the United States. Phakic IOLs are an alternative to laser vision correction and can successfully correct myopia in patients for whom keratorefractive surgery is not an option.
- No surgery is without its potential for complications. The more devastating complications of corneal refractive surgery include flap-related complications in LASIK, corneal weakening and ectasias, and vision-limiting haze in PRK. Endophthalmitis is a sight-threatening infection that can occur with any intraocular surgery such as RLE, phakic intraocular lenses, and cataract surgery.

The term *refractive error* describes any condition where light is poorly focused within the eye, resulting in blurred vision. This is the most common eye problem encountered in the United States and includes such conditions as nearsightedness (myopia), farsightedness (hyperopia), astigmatism, and age-related loss of near vision (presbyopia). A person who is able to see without the aid of spectacles or contact lenses has minimal to no refractive error. A wide variety of techniques are available for

correcting refractive errors and restoring visual function. The most common methods employ corrective eyewear, such as eyeglasses and contact lenses. In addition to these noninvasive modalities, several surgical procedures can also be used to treat these conditions. These surgical techniques include minimally invasive procedures, such as laser vision, and can be divided to corneal and intraocular procedures.

Whichever method is selected, the primary goal of every vision-correcting procedure should be to choose the technique that is most appropriate for each patient. The chosen method should not only correct the patient's visual deficit but also satisfy the patient's goals for visual function. This chapter focuses on the various surgical options that are available for vision correction. To set the groundwork for this discussion, we begin with some background information on ocular anatomy, refractive errors, and the clinical assessment of visual function.

Pathophysiology

Background

Although the human eye is a complex structure, from a conceptual standpoint, it can be thought to function much like a simple camera. In general, light enters the eye and needs to be focused on the center of the retina, or the fovea, to generate images. Light first enters through the cornea, a convex transparent window that performs approximately 66% to 75% of the focusing for the eye. After passing through the cornea, the light encounters the iris and pupil. The pupil is an aperture centered within the iris, a muscular diaphragm that controls the diameter of the pupil and thus the amount of light that continues into the eye.

The crystalline lens sits behind the pupil and provides the remaining 25% to 34% of the eye's focusing ability (Figure 1). The lens is suspended by a network of hundreds of supporting cables called zonular fibers. These zonules insert into the ciliary body, a muscular ring that is a peripheral extension of the iris. The refractive power of the lens is somewhat adjustable and can be increased to move the focal point of the eye from distance to close range, a process known as *accommodation* (Figure 2). Accommodation results from contraction of the ciliary muscle, which results in a decreased diameter of the ciliary ring, similar to a lens aperture of a camera. This loosens the zonules, which simultaneously reduces zonular tension on the lens, thereby causing the thickness and anterior curvature to increase, along with its amplified refractive power.

After being focused by the lens, light passes through the transparent vitreous humor until it reaches the retina, which lines the inside of the back of the eye. The retina functions like the film in a camera, converting the focused image into an electrical signal that is transmitted to the brain via the optic nerve.

Figure 1 The refraction, or bending, of light in the eye occurs through the cornea and the crystalline lens. Refractive errors result when the light is not perfectly focused onto the retina. (Illustration courtesy A.D.A.M, Inc.)

Figure 2 The lens is suspended in place by the zonular fibers. These zonules insert into the ciliary body. Accommodation, or the ability to focus at close range, occurs as the result of the contraction of the zonules and a change in shape to the crystalline lens.

Refractive Errors

Emmetropia is the condition where the eye has essentially no refractive error and requires no correction for distance vision. Refractive errors result when the cornea and lens inadequately focus incoming light, resulting in blurred images projected onto the retina. The unit of measure for refractive error is the diopter (D), which for a thin lens (in air) is defined as the reciprocal of the lens focal length. Most refractive errors refer to the patient's visual status when viewing objects in the distance. For example, a lens that focuses light over a distance of 0.5 m has a refractive power of +2.0 D.

In myopia, or nearsightedness, the focusing powers of the cornea are too strong or the axial length of the eye is too long, or both. The resulting image comes into focus anterior to the retina and is out of focus by the time it reaches the back of the eye. As a result, myopic eyes can see better at close range than at a distance. To correct a myopic eye, its refractive power must be decreased by using a lens with negative refractive power, which weakens the focusing of light and redirects it toward the retina.

Hyperopes, or farsighted persons, are the opposite of myopes. The cornea is flatter and focuses too weakly or the axial length is too short (or both) in the hyperopic eye. The images from objects viewed at a distance are not yet in focus by the time they reach the retina. To see clearly, a hyperopic eye must accommodate to increase its lenticular power to bring distant objects into sharp focus. Because this requires contraction of the ciliary muscle, the farsighted eye is never at rest and must work even harder to see near objects clearly. Because of this, hyperopic refractive corrections must add positive focusing power to the eye (Figure 3).

In astigmatism, the eye has different refractive powers along different meridians; light entering in the vertical direction gets focused differently than light in the horizontal direction. Conceptually, it is easier to think of the astigmatic cornea or lens as shaped like a football rather than a basketball, with the meridian of steeper curvature having greater refractive power. The astigmatic eye produces a blurred image because essentially two focal points of images are being produced. This requires different corrections along each of these meridians to produce a single focused image on the retina (Figure 4).

Presbyopia describes the normal age-related loss of near vision. To see near objects clearly, young distance-corrected eyes must accommodate to increase their refractive power. However, this ability progressively declines with age, usually reaching clinical significance in the 5th decade. Several factors have been implicated in this process, including loss of lens elasticity, decreased zonular

Figure 3 Emmetropia, myopia, and hyperopia. In emmetropia, the secondary focal point (F_2) is at the retina. In myopia, the secondary focal point (F_2) is in the vitreous. In hyperopia, the secondary focal point (F_2) is behind the eye. (Reprinted with permission from Mimura T, Azar DT: Part 3: Refractive Surgery. In Yanoff M, Duker JS (eds): *Ophthalmology*, 3rd ed. St. Louis, Mosby, 2008.)

Figure 4 Astigmatism occurs when the refractive power of the eye is not symmetrical. The focusing power of one axis is stronger than the other axis. This effectively leads to multiple focal points of light, which results in blurred images. (Reprinted with permission from Haw WW, Manche EE: Vision correction procedures. In Bope ET, Rakel RE, Kellerman R (eds): *Conn's Current Therapy 2010*. Philadelphia, Saunders, 2010, pp. 193–197.)

tension, and altered ciliary muscle function. Although there is currently no way to reverse this natural consequence of aging, several vision correction options are available to improve near vision in presbyopic persons.

Epidemiology

Population-based studies indicate that approximately 25% to 40% of people in their 40s have myopia, and 10% to 20% have hyperopia. Myopia is the most common refractive error and affects about 35% of whites and 13% to 30% of African Americans. Approximately three-quarters of the American population older than 40 years have refractive errors greater than 0.5 D. Astigmatism of more than 0.5 D is common in adults, and the prevalence increases to approximately 28% in persons in their forties. In general, a higher prevalence of hyperopia and less myopia is observed with increasing age from about 45 to 65 years. This levels off with older age and is eventually followed by an increase in myopia at older ages, which is thought to largely be from cataract formation. Regarding the correction of refractive errors, about 150 million Americans currently use some form of eyewear to correct refractive errors at a cost of approximately \$150 billion annually, including 36 million who use contact lenses.

Diagnosis (Assessment of Vision)

There are many aspects of vision, including visual acuity, contrast sensitivity, color perception, and peripheral vision. The most common assessment of visual function is to test the central vision through visual acuity. Visual acuity testing determines a patient's ability to read high-contrast symbols (usually black letters on a white background) of varying sizes at a standard testing distance. This reference distance approximates optical infinity and is typically 20 feet in the United States and 6 meters in Europe. A 20/20 letter on the standard eye chart devised by Snellen is approximately three-eighths of an inch tall at a distance of 20 feet (subtending a visual angle of 5 minutes of arc). Twenty-twenty vision is considered normal visual acuity.

Visual acuities less than 20/20 are represented by ratios whose denominator is greater than 20. For example, a visual acuity of 20/60 means that the smallest letter the eye can read is three times larger than a 20/20-size letter.

Refractive errors can result in *uncorrected* visual acuities that fall below 20/20. However, in the absence of other disease, the conditions of myopia, hyperopia, astigmatism, and presbyopia can be corrected with restoration of normal visual function. This can be achieved with spectacles, contact lenses, or the various surgical procedures discussed next.

Treatment (Surgical Correction of Refractive Errors)

Laser Vision Correction

Laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK) use an excimer laser to reshape the anterior surface of the cornea and permanently correct the eye's refractive error. The excimer laser was developed in the 1970s and emits ultraviolet light at a wavelength of 193 nm. This particular wavelength has been found to accurately and efficiently ablate corneal tissue without causing thermal damage to the surrounding collagen. In myopia, the excimer laser treatment flattens the central cornea to decrease its focusing power. Conversely, for hyperopia, laser pulses are applied to the periphery, indirectly steepening the central cornea and thereby increasing its refractive power. Astigmatism is corrected by combining central and peripheral treatments to differentially steepen the flattest corneal meridian and flatten the steepest meridian. Since the first excimer treatment in the late 1980s, LASIK and PRK have been used to treat refractive errors in millions of patients.

Laser in Situ Keratomileusis

In LASIK, a lamellar or partial-thickness corneal flap is first created in the cornea. The flap thickness typically varies from about 100 to 180 μm , as compared with a total corneal thickness that usually ranges from 500 to 600 μm . The LASIK flap is reflected at its hinge

Figure 5 LASIK procedure. 1, The normal cornea. 2 and 3, A microkeratome (or laser) is used to create a partial-thickness corneal flap attached at a hinge. 4, The corneal flap is lifted. 5, The excimer laser ablates the corneal stroma. 6, The corneal stroma is reshaped. 7 and 8, The corneal flap is repositioned. (Reprinted with permission from Haw WW, Manche EE: Vision correction procedures. In Bope ET, Rakel RE, Kellerman R (eds): *Conn's Current Therapy* 2010. Philadelphia, Saunders, 2010, pp. 193–197.)

and the excimer laser ablation is applied directly to the corneal stroma. Once the ablation is complete, the flap is returned to its original position (Figure 5).

The LASIK flap is created by either a microkeratome, a device containing a motorized oscillating blade connected to a suction ring, or via a femtosecond laser. The femtosecond laser uses ultra-short microscopic pulses of infrared light to define the lamellar flap. The femtosecond laser has allowed greater accuracy with the flap thickness. Also, there are significantly less flap-related complications, such as free (without flap hinge), partial, or button-hole (doughnut-shaped) flaps.

Recovery of vision usually takes a few days; some patients note gradual improvement over a few weeks. Postoperative medications usually include topical antibiotic and steroid eye drops for approximately 5 to 7 days.

Complications with laser vision correction in general are extremely low. Most intraoperative complications associated with LASIK involve the flap. If during the surgery the patient moves the eye (fixation loss), the laser can focus on the wrong part of the eye (decentration of the laser treatment), which can degrade the postoperative vision creating a chromatic aberration called coma.

LASIK carries the postoperative risks of flap displacement or induction of flap striae. Most of these cases require a lifting and repositioning of the flap. However, more severe or refractory cases can require further intervention, such as suturing.

On rare occasions, epithelial cells from the corneal surface can migrate underneath the LASIK flap and proliferate in the interface. Usually, the peripheral nests of epithelial cells are small and insignificant visually, thus requiring no intervention. Larger collections of cells can compromise vision or cause corneal necrosis and scarring, so they need to be removed. Epithelial ingrowth requires lifting the flap and manually debriding the cells. This treatment might

need to be supplemented with alcohol or suturing, or both, to prevent recurrence.

Corneal weakening and subsequent distortion are other potential sequelae of laser vision correction. Certain preoperative corneal shapes suggest a predisposition toward weakening, especially those with steeper curvature in the inferior region as compared with the superior region. Preoperative corneal thicknesses less than 500 μm or post-LASIK residual stromal bed thicknesses less than 250 μm can also be associated with corneal weakening.

As with any surgery, LASIK and PRK are also associated with a risk of infection. The incidence varies, but published rates have been about 0.03%. Staphylococcal and streptococcal species are most common, but atypical organisms such as mycobacteria and fungi have also been reported. Sterile inflammation can also occur in the flap interface and is known as *diffuse lamellar keratitis*. Diffuse lamellar keratitis has been associated with bacterial endotoxin, cleaning solutions, corneal abrasions, and excessive femtosecond laser energy levels. Treatment primarily relies on topical steroid eyedrops, but it may also include oral steroids and irrigation of the flap interface.

Photorefractive Keratectomy

PRK also uses the excimer laser to reshape the cornea, but this procedure requires no lamellar flap. In this method, the laser treatment is applied directly to the anterior stromal surface after the surface epithelium is removed. Several techniques are available to remove the corneal epithelium. Mechanical débridement with a spatula or rotating brush is very common. *Advanced surface ablation* has replaced other techniques used to manipulate the surface epithelium, including a devitalizing 20% alcohol solution, followed by gentle débridement with a blunt spatula or an epikeratome (similar to a LASIK microkeratome) to separate a flap of epithelium at the level of the basement membrane.

Laser-assisted subepithelial keratomileusis (LASEK) was another modification of PRK but has now fallen largely out of use. In LASEK, a flap consisting of only epithelium is created and replaced onto the cornea, which some surgeons believed provided greater postoperative comfort and expedited re-epithelialization of the corneal surface. Each of these methods has certain advantages and disadvantages, but all do an effective job of preparing the corneal surface for laser ablation.

Once the laser treatment is complete, a soft contact lens is placed on the cornea. The corneal epithelium typically heals in 4 to 7 days, after which the contact lens is removed. Once the contact lens is removed, recovery of vision can take a few more weeks, although some patients experience improvement in vision that continues over several months. Antibiotic eye drops are used until the contact lens is removed, and steroid eye drops may be tapered over several months.

Regarding complications, PRK has fewer intraoperative risks than LASIK because no lamellar flap is being created. Postoperatively, there is a higher risk of subepithelial haze. Fibroblastic transformation of keratinocytes can cause the deposition of disorganized collagen that decreases the smoothness and clarity of the post-PRK cornea. This development is usually associated with higher myopic corrections and may be reversed by increased application of topical steroid eyedrops. Short-duration intraoperative use of low-concentration topical mitomycin-C (Mitosol)¹ (0.02%) appears to decrease the risk of haze formation. As discussed with LASIK, postoperative infectious or sterile inflammation is a rare but potential risk with PRK as well.

Both PRK and LASIK damage corneal nerves, which appears to have a secondary effect on the ocular hydration status. Postoperative dry eye is greater in LASIK than PRK owing to its greater depth of penetration into the cornea. The increased dryness appears to be temporary, and most patients return to baseline by 6 to 9 months, but a subset of patients experience chronic dry eyes following the procedure. A careful preoperative assessment of dry eye risk factors is recommended, and those at risk may be steered toward PRK or toward no surgery at all.

Radial Keratotomy

Modern keratorefractive surgery can attribute some of its origins to a flurry of research produced by Sato of Japan in the 1940s that led to radial keratotomy (RK) and astigmatic keratotomy (AK) surgeries. Russian ophthalmologist Fyodorov is credited with advancing keratorefractive surgery in the 1970s through RK surgery. He created up to 16 spoke-like cuts radiating from the central cornea at 90% to 95% corneal depth to balloon the peripheral cornea. This would, in turn, flatten the central cornea and reduce myopia. The combination of RK and AK surgeries were very popular procedures that effectively reduced myopia and astigmatism throughout the 1970s and 1980s. Although RK surgery was effective, the results were often unpredictable and unstable and led to overcorrection, with progressive hyperopia. RK surgery was quickly replaced by laser vision correction with the introduction of PRK in the late 1980s (Figure 6).

Astigmatic Keratotomy

Astigmatic keratotomy incisions are a modification of RK surgery and are used to reduce corneal astigmatism. The two forms of corneal relaxing incisions, astigmatic keratotomy (AK) and limbal relaxing incisions (LRI), or more accurately peripheral corneal relaxing incisions (PCRI), are differentiated by their location on the cornea (Figure 7).

Several nomograms exist for AK and PCRI that consider the age of the patient and the amount and meridian of the steep axis of astigmatism in order to calculate the length of the incisions. In both procedures, incisions are made to a 90% to 95% depth in the cornea to flatten the steep meridian. The basic principles of astigmatism correction hold true for both types of keratotomy surgeries: a greater effect is achieved with longer incisions, with smaller optical zones, with deeper incisions, and in older patients. Hence, the more central AK incisions have a greater effect and can correct upward of 6 to 7 diopters of astigmatism.

PCRI have a weaker effect because of their more peripheral location and generally can correct 2 to 3 diopters of astigmatism. Because the incisions are made closer to the limbus, they heal faster, and thus the refractive effect stabilizes more quickly. Given their peripheral location, the ratio of flattening in meridian of incision-to-steepening ratio in the opposite meridian, or *coupling ratio*, is usually 1:1. Patients experience less irregular astigmatism, flare, and foreign body sensation as compared to their more central counterparts. Technically, PCRI are easier to perform and more forgiving as well.

Corneal relaxing incisions are most commonly performed intraoperatively, at the time of cataract surgery, but are also performed as a separate procedure to treat corneal astigmatism.

Figure 6 Radial keratotomy was the first modern form of refractive surgery for the correction of myopia. Up to 16 spokelike cuts radiating from the central cornea at 90% to 95% of corneal depth can be created to flatten the central cornea and balloon the peripheral cornea to correct myopia.

¹Not FDA approved for this indication.

Figure 7 Incisions can be placed on the cornea to reduce astigmatism. The more central astigmatic keratotomy (AK) incisions have a greater effect than their peripheral limbal relaxing incision (LRI) counterparts. (Reprinted with permission from Yeu E, Rubenstein JB: Management of astigmatism during lens-based surgery. In *American Academy of Ophthalmologists: Focal Points, Clinical Modules for Ophthalmologists*, February, 2008.)

The procedure is fairly quick to perform, and the patient experiences little discomfort. Postoperatively, a topical antibiotic is used for 4 to 7 days, and a topical analgesic is used as needed.

Regarding complications of corneal relaxing incisions, patients commonly experience a foreign body sensation during the first few days. Less common complications include glare, undercorrection or overcorrection, irregular astigmatism from the incisions, wound gape or perforation, decreased corneal sensation, and dry eye syndrome.

Intraocular Procedures

Refractive Lens Exchange

Unlike the corneal procedures that have been discussed, refractive lens exchange (RLE) is a surgical option that can correct refractive errors by removing and replacing the crystalline lens. In essence, RLE is cataract surgery without a visually significant cataract,

which is the clouding or opacification of the natural lens. RLE is a viable option for high myopes and hyperopes, where laser vision correction is not an option, and for correcting presbyopia.

The natural crystalline lens is removed via emulsification with ultrasound energy. This lens is then replaced by an acrylic or silicone intraocular lens (IOL) implant that can effectively and accurately correct refractive errors. Preoperative biometric measurements, including the corneal curvature and axial length, are used in different formulas to calculate the proper intraocular lens power.

Since the turn of the century, a variety of IOLs has been brought forth to address presbyopia correction. There are different designs, including multifocal designs and accommodating IOLs. Monovision, popularly used with presbyopic contact lens wearers (one eye is corrected for distance vision and the other eye for near), can also be reproduced permanently with RLE and cataract surgery.

Although currently available presbyopia-correcting IOL technology is effective in providing a greater range of vision and freedom from spectacle use, the IOLs are not without their faults. Although improved, the multifocal IOL can cause glare and halos from its inherent concentric ring design, and diminished contrast sensitivity can result from the light's being "split" for distance and near vision. The only currently FDA-approved accommodating IOL has neither of these disadvantages of the multifocal IOLs, but it does not provide UV light protection and also provides less predictable near vision (Figure 8).

Because RLE is intraocular, it is much more invasive than the previous extraocular corneal procedures. Hence, although both eyes can undergo corneal procedures simultaneously, elective intraocular procedures should always be performed as two separate staged surgeries. Being intraocular, RLE procedures likely have a similar risk of endophthalmitis (severe postoperative intraocular infection) as modern cataract surgeries do, which is between 0.05% to 0.10%. Other postoperative complications of RLE include retinal detachment in high myopes (1.85%–8%) and a likely need for a laser capsulotomy procedure to treat capsular haze that commonly occurs behind the IOL after surgery.

In addition to the postoperative risks of RLE, other common obstacles can be encountered intraoperatively, because operating on soft lenses, very long eyes (high myopes), and very short eyes (high hyperopes) has its own set of potential complications. Preoperative surgical planning and strategy are key to a successful RLE.

Figure 8 Examples of currently FDA-approved intraocular lens implants. A and B, Multifocal. C, Accommodating. (A, From Alcon Labs, Fort Worth, TX. B, From Abbott, Abbott Park, IL. C, From Bausch and Lomb, Rochester, NY.)

Phakic Intraocular Lens Implant

Surgically implanted lenses, or phakic intraocular lens implants, may be used only to treat myopia in the United States. Phakic IOLs are an alternative to laser vision correction and can successfully correct myopia in patients for whom keratorefractive surgery is not an option. As compared to laser vision correction for myopia, some studies suggest that the quality of vision with a phakic IOL is superior. Phakic IOLs function very similarly to contact lenses that are permanently implanted inside the eye. Regarding the two FDA-approved phakic IOLs available today, a phakic IOL can be implanted to sit in front of and attached to the iris (see Figure 8) or just behind the iris. As in RLE, the implantation of a phakic IOL is intraocular, and surgery should be performed on only one eye at a time to respect the risks involved in the more invasive procedure. Unlike RLE, all structures inside the eye, including the crystalline lens, are left untouched when a phakic IOL is implanted.

As do all surgical procedures, phakic IOLs are subject to various complications, of which cataract formation is a more common one (up to 9%). Other surgical complications include infection, retinal detachment, acute glaucoma, and loss of corneal endothelial cells, which are the nonregenerating cells on the back surface of the cornea that are responsible for maintaining corneal clarity.

Corneal Inlays for the Correction of Presbyopia

Presbyopia is the most ubiquitous refractive error, and the presbyopic population is undergoing rapid growth worldwide. In recent years, corneal inlays have gained popularity worldwide, and they can be an effective option for correcting presbyopia in appropriate patients. The three types include small aperture (KAMRA) (Figure 9), corneal reshaping (Raindrop) (Figure 10), and refractive (Flexivue Microlens) inlays. The KAMRA inlay received US FDA approval in 2015, followed by the Raindrop inlay in 2016. The pivotal clinical trial data from the Flexivue inlay were expected to be submitted to the FDA toward the end of 2017. Each provide

Figure 9 Kamra inlay. Uses pinhole effect to increase depth of field.

Figure 10 Raindrop inlay. Reshapes cornea to a hyperprolate state.

greater near vision while minimally sacrificing the distance vision, and each technology provides such near vision differently.

Small Incision Lenticular Extraction (SMILE)

Regarding corneal refractive surgery, there has been a lot of focus on procedures that involve removing an intracorneal lenticule of stromal corneal tissue to change the shape of the cornea in order to create refractive correction. Small incision lenticular extraction (SMILE), approved by US FDA in September 2016 for the correction of myopia, removes the lenticule through a small incision without the creation of a corneal flap. SMILE appears to cause less dry eye syndrome in a statistically significant manner. In a study by Sekundo et al., 1.1% of subjects after the SMILE procedure had superficial punctate keratitis at 1 week follow-up with none having subjective complaints of dry eye syndrome. SMILE may also lead to less complications of corneal ectasia, as flap-based procedures (like LASIK) appear to produce a 49% greater reduction in effective corneal stromal collagen stiffness than in SMILE cases.

Future Outlook

Refractive surgery technology continues to evolve, particularly in presbyopia correction. Topical drop technologies are in clinical trials, as are other surgical procedures and lasers that are targeting the sclera and ciliary body of the eye. Numerous intraocular lens technologies are on the horizon, including more advanced bifocal and trifocal IOL designs and true accommodating IOLs.

For intraocular refractive surgery options, phakic lens technology, which is currently only approved in the United States for the correction of myopia, may be available for hyperopic and astigmatism correction, as it is in Europe.

VISION REHABILITATION

Method of

August Colenbrander, MD; Donald C. Fletcher, MD;
and Kim Schoessow, OTD, OTR/L

Vision rehabilitation refers to the multidisciplinary effort of assisting those with various degrees of vision loss in coping with the *consequences* of that loss. To describe vision rehabilitation, the nature of vision itself must be understood.

Vision is the major source of information about our environment. The eyes alone contribute as much information to the brain as all other organs combined. It is not surprising therefore that many people fear loss of vision almost as much as loss of life.

Most people will state that “We see with our eyes.” On closer examination, this is not true. An isolated eyeball cannot produce any vision; our brain, however, can produce exquisite visual imagery in our dreams, without any input from the eyes.

The visual process goes through three distinct stages. Each stage comes with its own specific problems.

- First is the *optical stage*, where the refractive media of the eye deliver an image to the retina. Familiar problems in this area include refractive errors and cataracts.
- Second is the *receptor stage*, where the optical image is translated into neural impulses. Age-related macular degeneration (AMD) is a significant problem of the receptor stage, which is becoming increasingly common as the population ages.
- Third are various stages of *neural processing*, initially in the inner retina, then in the visual cortex, and finally in higher cortical centers, where the visual input gives rise to visual perception and to visually guided behaviors, actions, and interactions.

The most common visual problems vary for different ages. Today, brain-damage-related vision problems (cerebral visual impairment or CVI) are the most prevalent cause of visual impairment in *infants and young children*. Given that vision is so important for normal development, vision loss in infants constitutes a developmental emergency and should be detected and addressed as early as possible. When a child does not smile back at the mother, the mother may be inclined to leave the baby in its crib instead of holding him or her to provide extra tactile stimulation to compensate for missing visual stimulation.

At *school age* and later, visual health is critical because reading becomes important for academic development. For *adults*, vision is important for maintaining independence in activities of daily living (ADL) and development of vocational skills. For *seniors*, vision loss

may exacerbate other age-related dysfunctions. Studies of the elderly have shown correlations between visual impairment and depression, falls, and reduced longevity. In all of these instances, early detection and early intervention are essential; the primary care physician plays a crucial role in this respect.

Four Aspects of Vision Loss

Vision is a complex phenomenon.

A convenient framework for discussing the various impacts of vision loss is to consider four aspects of visual functioning (Figure 1). First to consider is how various external causes may result in *structural changes* to the eyes and the visual pathways. For this aspect, the focus is on the tissue; an ocular pathologist is needed to describe the pathologic condition. However, structural changes alone do not determine how well the eyes actually function. Clinicians need to measure *organ function*, such as visual acuity, visual field, and contrast sensitivity.

Yet even knowing how the eyes function does not tell us how the person functions. In other words, the *abilities* of the person to perform tasks, such as reading, mobility, face recognition, and ADL, must be considered. Occupational therapists (OTs) and other rehabilitation professionals work with patients to teach them how residual vision can be used most effectively. OTs also assess the person in a societal context. For example, do the visual changes have an impact on the person's *participation* in society, on his or her ability to perform necessary tasks, and on general satisfaction with one's quality of life? It is clear that to cover all aspects of vision rehabilitation, a team approach is necessary, and that the patient must be part of that team.

A single activity of daily living may cover several of the above aspects. When reading, the aspect of minimum print size falls under organ function (retinal resolution). Reading speed (words/minute) and reading endurance (hours/day) define abilities of the person; reading endurance may be poor, even if reading acuity is adequate. Reading enjoyment, finally, falls under the aspect of quality of life.

It is helpful to draw a line between the organ side of Figure 1 on the left and the person side on the right. On the left side of the diagram, we discuss *visual functions*, which describe how the eyes function. On the right side, we speak of *functional vision*, which describes how the person functions in vision-related activities. Medical specialists are well versed in dealing with the left side of the diagram. Yet, the ultimate goal of all interventions is to improve the patient's quality of life. It is the function of vision rehabilitation to make sure that “eye” doctors become “people” doctors by extending their interest to the right side of the diagram as well.

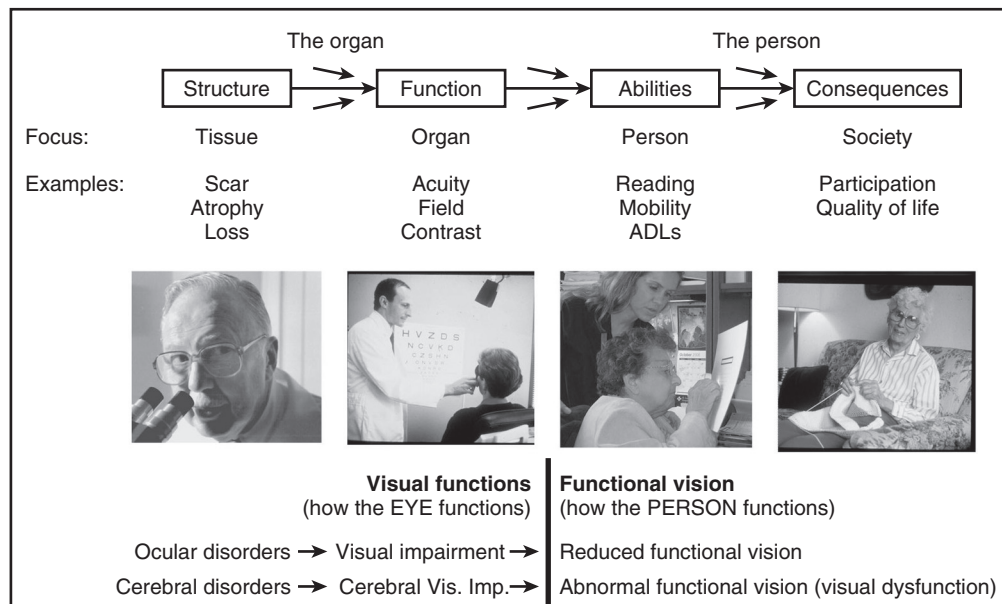

Figure 1 Aspects of vision loss.

Comprehensive Vision Rehabilitation

Considering all of these aspects, comprehensive vision rehabilitation involves much more than the patient's performance on a letter chart and requires teamwork by different professionals who specialize in different aspects of vision loss. All vision loss starts with some medical condition. So, primary care physicians are well positioned to coordinate team activities. Primary care physicians need to be aware of what other team members can contribute and should know where to locate vision rehabilitation resources and to make appropriate referrals.

Figure 2 illustrates that comprehensive vision rehabilitation involves much more than does the traditional low vision care offered in the past.

Low vision is a term used to describe individuals who suffer from a visual impairment that cannot be eliminated with refractive correction, yet are not blind. Individuals who suffer from visual impairment from low vision may benefit from vision enhancement, vision substitution, and vision assistance as well as from honing of coping skills.

Low vision is distinct from blindness (i.e., no vision). Blindness differs from low vision in that in blindness, the emphasis of rehabilitation is entirely on vision substitution. Patients with severe or profound low vision may combine the use of some blindness rehabilitation skills with some low vision rehabilitation skills.

Vision enhancement, which is the traditional focus of low vision care, is primarily oriented at improving residual visual function through visual aids, including a wide range of magnification devices. Additionally, enhancement of contrast, illumination, and filters need to be explored.

Vision substitution expands the options for rehabilitation by optimizing the use of other senses. This can range from using simple tactile markings to sense the position of a stove dial to devices such as talking books, a long cane for travel, and Braille for reading. Vision enhancement and vision substitution are not mutually exclusive. A patient may use a magnifier to read price tags and may prefer talking books for recreational reading. A patient with retinitis pigmentosa, which causes reduced night vision, may have normal mobility in the daytime and need a cane at night. Digital audio books may have Braille labels.

Vision assistance. A special form of vision substitution involves using the eyes of others. Family members, caregivers, and office personnel should be familiar with *sighted guide* techniques to effectively assist visually impaired patients with minimal embarrassment. *Guide dogs* are also a possibility. Using a guide dog requires training of the patient as well as of the dog, so that they can work as a team. Dog users must also demonstrate mastery of long cane travel skills.

Coping skills. How different patients will accept visual aids may differ greatly. It is important to recognize that vision loss often causes a reactive depression. On the one hand, a depressed patient will be less receptive to rehabilitative suggestions. On the other hand, demonstration of rehabilitative success can be a powerful tool to lift a reactive depression and to motivate the patient

for further success. It has been shown that the teaching of problem-solving skills may improve the effectiveness of vision rehabilitation.

Many professionals may be involved in vision rehabilitation. Technicians may prescribe magnifiers, rehabilitation workers may teach daily living skills, and psychologists may address depression. Acceptance of the work of these professionals will be improved if the trusted primary care physician is credited with making the referrals.

Beyond the factors that directly involve the patient, the environment must also be considered.

The *human environment* is important. As patients go through the stages of adaptation, a supportive home environment is essential. As patients are counseled, it is important to include spouses, children, or significant others to make sure that they understand the condition, know what can be expected, and know how to support the patient. Answering family and caregiver questions directly is often better than leaving this to the patient, who initially may not have absorbed everything that was said. An overprotective environment, which deprives patients of opportunities to do things for themselves, can be as detrimental as an overdemanding one that puts too much emphasis on the patient's shortcomings. The same holds true for the work or school environment or for social groups.

Initially, patients often feel isolated and believe that they are the only ones experiencing these problems. *Peer support groups* can be helpful; in these groups, patients can experience how others are dealing with similar problems.

Finally, the *physical environment* needs to be considered. An uncluttered environment, where things have a defined, fixed place, is helpful because it reduces the need for searching. Good general illumination and task lighting often help, because at higher illumination levels retinal cells that are damaged but not dead can still contribute to vision. Good contrast is important: do not serve milk in a white Styrofoam cup; mark the edges of steps and stairs. The triangles and circles on men's and women's bathrooms are designed to be visible for those with very low vision; Braille labels in elevators are useful for people who are totally blind.

How Blind Is Blind?

The most common visual function test is the letter chart, developed by Snellen in 1862. That test determines how large a letter, or other symbol, must be to be recognized by the patient. That size is then compared to the size recognized by a standard observer. If the magnification requirement is $2\times$, visual acuity is said to be $1/2$; if it is $5\times$, visual acuity is said to be $1/5$, etc. That fraction can be recorded in different ways; in the United States, it is customary to use 20 as the denominator ($1/2 = 20/40$, $1/5 = 20/100$); in the British Commonwealth, 6 is used as the denominator ($6/12$, $6/30$); in Europe, decimal fractions are common (0.5, 0.2).

Those calculations are simple; unfortunately, the terminology used to describe various ranges of vision loss is confusing. Figure 3 shows progressively degraded pictures with examples of

Figure 2 Comprehensive vision rehabilitation.

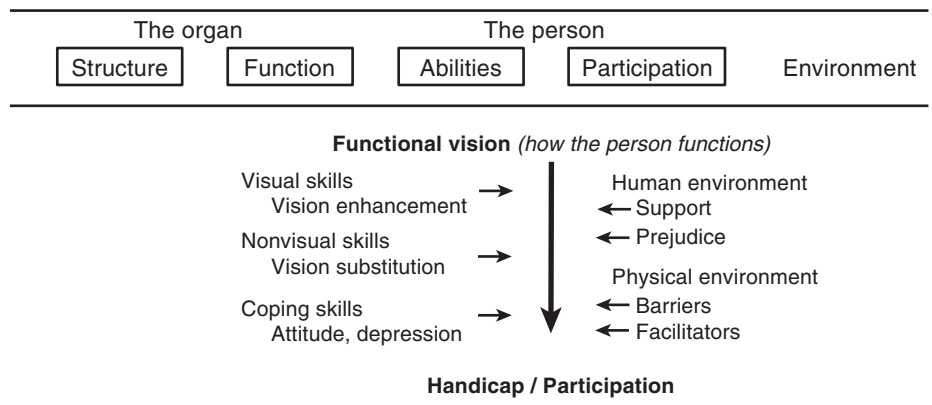

Figure 3 Ranges of vision loss.

the terminology used to describe different definitions of visual impairment. The visual acuity level represented by each picture can be determined from the number of lines that are readable on the low vision letter chart.

The first picture shows the visual acuity level that is labeled as “low vision” by the World Health Organization (WHO). Although the bottom lines of the letter chart cannot be read, the appearance of the room is near normal. The next picture shows what the U.S. Social Security Administration considers “statutory blindness” for its programs. It is clear that this is far from actual blindness. Other U.S. programs use a different definition for “legal blindness,” and the WHO does not consider a person “blind” until he or she has reached the status of the last picture. At that level, reading even the special letter chart is not possible, but one can still navigate the room. Even this level of visual impairment does not constitute actual blindness.

The widespread use of the word “blindness” is unfortunate, because it cannot be used with modifiers. One is either blind or sighted; one cannot be “a little bit blind.” This black-and-white thinking has hampered the acceptance of vision rehabilitation. Terms such as vision loss or visual impairment are preferred because they can be used with modifiers, including mild, moderate, severe, profound, and total vision loss. Although “legal blindness” and “severe vision loss” (ICD-9-CM) have the same definition, there is a big difference between telling a patient “You are legally blind” and “You have a severe visual impairment.” The first statement might be followed by “I am sorry, there is nothing more we can do for your eyes”; the second statement leads to the question “What can be done to help you cope with this problem?”

Vision Rehabilitation Techniques and Devices

Having considered the general outlines of vision rehabilitation, some details of rehabilitative interventions can be discussed. Primary care physicians should know what vision rehabilitation techniques are available.

Optical Problems

The most commonly encountered visual problems are those involving the optical system of the eye.

Refractive errors are the easiest visual problems to deal with. Refractive errors can be corrected with glasses or contact lenses, and for those who hate glasses, by refractive surgery. Even if there

are other causes of vision loss, determining the best refractive correction is still important.

Uncorrected refractive error is a major cause of visual impairment worldwide. In developed countries, the question may be why people do not avail themselves of the solutions that are available. In developing countries, availability of and accessibility to eye care and to the means for correcting refractive errors often do not exist. Providing these is a matter of infrastructure, not of individual health care.

Opacities disrupt visual image formation. Cataracts are the most familiar opacity; they can be removed by surgery. Other opacities of a temporary or permanent nature may occur in the cornea, in the anterior chamber, or in the vitreous cavity. Corneal and conjunctival infections may cause corneal scarring, as is the case in trachoma; this condition does not exist in the developed world anymore but is a major cause of blindness worldwide.

Letter chart acuity is a good way to measure optical problems. It should be understood, however, that letter chart acuity only measures the function of the retina where the letter read is projected. Even for a patient with 20/200 acuity, this area of the retina is less than 1° in diameter. For optical problems this does not matter, because foveal defocus predicts equal defocus in all other areas of the retina.

Magnification is the primary way to compensate for reduced acuity. One way to provide magnification is to bring print closer to the eye. For the elderly, this requires reading glasses with extra power. Alternatively, large print may be helpful. Larger print on medicine labels, as required in several states, can reduce medication errors by the elderly, who often take several medications. Handheld magnifiers are another option; many have built-in LED illumination that provides more light. Video-magnifiers with a table-mounted large screen are ideal for prolonged reading; they can enhance contrast and brightness, while some devices can even read the text out loud. Tablets and smartphone apps can provide similar advantages in a portable form, as can an increasing number of portable electronic magnifiers that can provide not only magnification, but also contrast enhancement.

Retinal Problems

While primitive forms of cataract surgery have existed for centuries, the study of retinal disorders has only been possible since the invention of the ophthalmoscope in 1851. The ability to effectively treat some retinal disorders is even more recent. Important retinal disorders include the following.

AMD is the most frequent diagnosis encountered in any low vision rehabilitation service. Because the condition is age related, its frequency will increase in the future as our population ages. This has caused profound changes in the nature of low vision care. Until the mid-20th century, most low vision care was provided by special education teachers serving young students in schools for the blind. Today, the majority of low vision patients are seniors. This has resulted in a significant influx of OTs into the field with skills in addressing multiple geriatric impairments. Yet, the needs of seniors to be served still outstrip the available services.

Given that macular degeneration affects central vision and the ability to read, most patients will ultimately seek rehabilitation help. However, if only one eye is affected, AMD may go unnoticed. The patient may only complain when the second eye starts to deteriorate; at that point, the damage in the first eye may be beyond repair. Therefore it is useful to ask patients to alternately cover one eye to see whether there is any vision difference between the eyes. If there is, this is a reason for referral.

Glaucoma is another age-related condition. Glaucoma often goes undetected because it causes loss of peripheral vision and affects central vision only in the late stages. Therefore glaucoma must be sought out, primarily by measuring the intraocular pressure.

Diabetic retinopathy is not limited to seniors. As the incidence of diabetes is rising worldwide, so is the incidence of diabetic retinopathy. Even if treated with photocoagulation, it will cause scattered blind spots throughout the visual field.

There are many other hereditary and nonhereditary retinal conditions that may cause vision loss, but they occur in small numbers. They all require the help of vision rehabilitation professionals to help patients cope effectively.

Scotomata. Whatever the cause, retinal conditions will generally cause localized blind spots (scotomata). Therefore when retinal damage is suspected, visual acuity alone is no longer a sufficient descriptor of visual impairment, because the retinal area where the chart letter is projected does not predict anything about other retinal areas. In addition to letter chart acuity, the condition of the visual field and the presence of blind spots (scotomata) must be considered (Figure 4).

Figure 4 shows a retinal image, where a word is projected across a ring scotoma that leaves only a small central island of vision. This patient will be able to recognize the central letter but will not be able to read the word. Clinicians must be careful when providing such patients with magnification, because too much magnification will mean that fewer letters fit into the central area. This example also makes it clear that when retinal involvement is suspected, a reading test may be more informative than a letter chart test, given that reading requires a larger retinal area.

Neural Processing Problems

As stated earlier, the most important stages of the visual process take place after the retinal receptors have translated the optical image into neural impulses.

Figure 4 Ring scotoma.

The first transformations take place in the *inner retina*. Here, the input from 100 M receptors in each eye is preprocessed and compressed for transmission through 1 M nerve fibers in each optic nerve. The optic nerve fibers do not simply transmit a pixel-by-pixel image, as does a digital camera. Different retinal ganglion cells probably transmit different aspects of the image, such as edges (contrast enhancement), movement, color, brightness, etc. These separate “movies” are transmitted in parallel. At a later stage of neural processing, the different aspects of the image are combined again into a single visual perception.

In the *visual cortex*, the visual information is further analyzed for shapes and contours. Interestingly, at the first synaptic station in the lateral geniculate nucleus, only 20% of the incoming connections come from the optic nerves; the other 80% come from other cortical centers and probably contribute to filtering based on attention and other factors.

In *higher cortical centers*, the visual information is further processed. Here, the flow of information is no longer strictly visual because it is combined with information from other senses. This results in identification and recognition of objects through comparison to stored concepts (through the ventral stream to the temporal lobe of the brain) and in spatial location of an object (through the dorsal stream to the parietal lobe of the brain), which then result in voluntary or involuntary visually guided action.

Our knowledge of these processes is still relatively new. It has been greatly helped by new modalities for neural and retinal imaging. Today, neural processing problems are increasingly recognized in all age groups.

In young children, CVI is now recognized as the most frequent cause of visual perceptual problems. CVI is often caused by perinatal ischemia, which may cause cortical as well as subcortical changes (periventricular leucomalacia). Because this ischemia is not localized, impairments are often not limited to the visual system. Schools for the blind have increasingly developed into schools for the multiply handicapped.

In contact sports, the results of repeated subclinical injuries are now recognized.

In veterans, traumatic brain injuries may cause problems that may be hard to define. Often visual interpretation and decision making are impaired; oculomotor system problems are often found. Traffic accidents may cause similar damage.

In the elderly, strokes may cause more localized problems and agnosias for specific tasks. In all of these cases, the term *visual impairment* may be used when visual acuity and/or visual field are impaired. The term *visual dysfunction* may be more appropriate when the visual input to the brain is normal but the processing of this information is not.

Patient-Centered Functional Priorities

Vision problems affect all aspects of a patient’s life. It is no longer sufficient for clinicians to determine that *nothing more can be done* about the *causes* of vision loss, because *much more can be done* about the *consequences* of vision impairment.

To determine the range of services that may be appropriate for an individual with vision impairment, the American Academy of Ophthalmology recommends consideration of the following functional priority areas:

- *Reading*—for many patients, this is their foremost concern.
- *Activities of Daily Living (ADL)*—even though reading may be the most prominent complaint, most people spend the larger part of their day performing a variety of other vision-dependent activities for self-care and home management.
- *Safety*—are people at risk for falls? How do they cross the street? Do they drive?
- *Community participation*—can the individual still participate in community events, including religious gatherings?
- *Physical, cognitive, and psychosocial well-being*—because many patients with vision loss are elderly, this is an important aspect that should not be overlooked. If cognitive problems exist, it may affect the recommendations to be made.

Based on these considerations, patient-centered priorities can be set and specific rehabilitation goals formulated that reflect the patient's needs and desires.

AMEBIASIS

Method of

Koji Watanabe, MD, PhD; and William A. Petri, Jr., MD

CURRENT DIAGNOSIS (SEE ALSO BOX 1)

- Amebiasis is transmitted by the ingestion of fecally contaminated water or food and by high-risk sexual behaviors (men who have sex with men [MSM] or oral–anal sexual contact).
- Although self-limiting mild to moderate colitis is the most common disease presentation, various severe illnesses (liver abscess, peritonitis, pleurisy, and pericarditis) can also occur.
- Diagnostic value of microscopic stool or abscess ova and parasite examination (O&P) is low. Antigen detection in stool for intestinal amebiasis and in serum for amebic liver abscess shows high sensitivity. Serology shows high sensitivity but cannot distinguish current infection from past infection, and it is ideally used in conjunction with fecal antigen detection or polymerase chain reaction (PCR).

CURRENT THERAPY (SEE ALSO BOX 2)

- Infected individuals who are symptom free should be treated with a luminal agent, because they can be a source of new infection and also can develop invasive amebiasis after long-term asymptomatic infection.
- Mild to severe colitis and extraintestinal disease require initial treatment with a tissue-active agent followed by a luminal agent.
- Reinfection can occur frequently in endemic settings. The clinician should discuss methods to prevent reexposure to *Entamoeba histolytica* with treated patients.

Epidemiology and Risk Factors for Acquisition

Amebiasis is transmitted by oral ingestion of the transmissible cyst form of *Entamoeba histolytica* in human stools. Transmission occurs by the ingestion of fecally contaminated food and water, mainly in developing countries. It also transmits directly from human to human by sexual contact or in institutions for the cognitively impaired. Food- or water-borne infection occurs in settings of poor sanitation. It is estimated to be the second most common cause of parasite infection–related mortality worldwide, accounting for 40,000 to 70,000 deaths annually. In developed countries, people who travel to or immigrate from developing countries are at higher risk for this parasitic disease. In the United States, amebiasis is the second most common cause of diarrhea in returning travelers. Over that last two decades, however, amebic infection has been increasingly reported as a sexually transmitted infection in East Asian developed countries and Australia. In one report from Taiwan, men who have sex with men (MSM) and people engaging in oral–anal sex were more likely to be seropositive for

E. histolytica. Although older studies from the United States had shown that amebiasis in MSM was due to nonpathogenic *Entamoeba dispar*, more recently MSM was shown to be an independent risk factor for amebiasis-related mortality. It is important for primary care physicians to take detailed histories of sexual behavior, as well as travel whenever amebiasis is suspected.

Pathophysiology and Susceptible Host Factors to Invasive Diseases

E. histolytica has two different forms: the tissue-invasive “trophozoite form” and the infectious “cyst form,” which is responsible for transmission. Cysts are notable for environmental stability, demonstrating considerable resistance to chlorination and desiccation, with several outbreaks resulting from contamination of drinking water. Once cysts are ingested, excystation occurs at the terminal ileum or large intestine, forming motile trophozoites. Trophozoites bind to the mucous layer and the underlying intestinal epithelial cells via a parasite Gal/GalNAc lectin. Blockade of activity of the Gal/Gal lectin prevents contact-dependent cytolysis. Moreover, it was shown that antilectin IgA in stool or breast milk has a protective effect against future acquisition of amebic infection in cohort studies. These results indicate that the Gal/GalNAc lectin plays a crucial role in amebic infection.

Host factors are also important for susceptibility to amebiasis. Amebiasis is more common in malnourished children, and the nutritional hormone leptin is protective, with a single nucleotide mutation of leptin receptor the predominant genetic factor controlling amebiasis susceptibility in Bangladeshi children. Amebic liver abscess is 10 times more common in men than in women and uncommon in children. Also, the very young or old, malnourished people, pregnant women, and patients using corticosteroids are at increased risk of severe amebiasis.

Clinical Manifestations and Complications of Amebiasis

Asymptomatic self-limiting infection is the most common disease form of amebiasis. Up to 80% to 90% of people exposed to cysts have no or mild symptoms and clear the infection spontaneously. However, asymptomatic infection persists for a long time in some individuals, who are reported as asymptomatic cyst passers or as fecal occult blood–positive incidentally diagnosed by colonoscopy. These asymptotically infected individuals can be a source of a new infection in the community. Also, some develop symptomatic invasive diseases after long-term latent infection.

Symptomatic intestinal amebiasis (amebic colitis) generally has a subacute onset. Usually it takes 1 to 3 weeks from disease onset to make a diagnosis. Abdominal symptoms range from mild diarrhea to severe dysentery with abdominal pain, diarrhea, and bloody stools. Weight loss and fever are common but not universal symptoms. Intestinal fistula or perforation of the large intestine, resulting in peritonitis, is a rare but life-threatening complication of intestinal amebiasis. Toxic megacolon can also be caused by amebiasis. Amebic colitis sometimes mimics acute appendicitis. In this situation appendectomy without amebicidal treatment may result in severe postoperative complications, such as abdominal sepsis, gastrointestinal fistula, or hemorrhage. Periodic acid–Schiff (PAS) stain, or ideally immunoperoxidase with anti-*E. histolytica* antibodies, in addition to routine hematoxylin and eosin (H&E) stain can help

BOX 1 Sensitivity of Tests for Diagnosis of Amebiasis¹

TEST	COLITIS	LIVER ABSCESS
Microscopy (stool)	25–60%	10–40%
Stool antigen detection	80%	40%
Serum antigen detection	65%	> 95%
Microscopy (abscess fluid)	N/A	< 20%
Real-time polymerase chain reaction	> 95%	> 95%
Serologic testing (indirect hemagglutination)		
Acute	70%	70–80%
Convalescent	> 90%	> 90%
Histopathology by biopsy	45%	N/A

¹Before the initiation of therapy.

BOX 2 Treatment Recommendations for Amebiasis in Adults**Asymptotically Infected Individuals**

Paromomycin (Humatin) 30 mg/kg/day PO tid × 5–10 days
or
Iodoquinol (Yodoxin) 650 mg PO tid × 20 days

Mild to Severe Intestinal and Extraintestinal Disease

Metronidazole (Flagyl) 750 mg PO tid × 10 days
or
Tinidazole (Tindamax) 2 g PO once daily × 5 days
Followed by
Paromomycin¹ 30 mg/kg/day PO tid × 5–10 days
or
Iodoquinol¹ 650 mg PO tid × 20 days

*Use of intravenous form of metronidazole is limited to patients who cannot take oral medications.

¹Not FDA approved for extraintestinal amebiasis.

Modified from Mandell G, Bennett JE, Dolin R, Blaser MJ. Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases. 7th ed. Philadelphia: Elsevier Saunders, 2009.

to identify the parasite by the histopathology. Thus intestinal amebiasis sometimes presents as severe and complicated clinical illnesses.

E. histolytica infection may also have extraintestinal dissemination. Liver abscess is the most common form of extraintestinal amebiasis. Patients usually present with 1 to 2 weeks of fever with or without right upper quadrant abdominal pain. Other common symptoms may include cough, sweating, malaise, weight loss, anorexia, and hiccough. Two thirds of patients lack intestinal symptoms. Physical examination reveals hepatomegaly and tenderness over the liver in approximately half of cases. Complications can occur by direct invasion of trophozoites or indirect effect of inflammation. Up to 10% of patients with amebic liver abscess have accompanying thoracic amebiasis (pleuritic and pleural effusion). Pericarditis is the next most common form of extraintestinal amebiasis; it may result from rupture of a liver abscess in the left lobe or through extension of pleural amebiasis. Cerebral amebic abscesses are a rare form of extraintestinal amebiasis; they usually accompany other metastatic lesions, such as liver abscesses and thoracic amebiasis.

Thus amebiasis can have various clinical presentations. The diagnosis can be very difficult to make in severe cases and in atypical clinical presentations because of secondary bacterial infection at the site of amebic invasion.

Diagnosis

Sensitivity of each diagnostic test is shown in Box 1. Although microscopic stool ova and parasite examination (O&P) is frequently used in many countries including the United States, it

has low sensitivity. Identification of trophozoites by microscope in aspirated fluid from amebic abscess is more challenging because trophozoites are present only at the edge of the abscess. Moreover, microscopic examination cannot distinguish pathogenic *E. histolytica* from nonpathogenic *E. dispar* or *E. moshkovskii* by shape.

Currently, the combination of antigen detection in stool or sera and serologic testing is the best diagnostic pathway. Antigen detection in feces by the TechLab *E. histolytica* II enzyme-linked immunosorbent assay (ELISA) or by the TechLab *E. histolytica* QUIK CHEK membrane enzyme immunoassay is rapid to perform (< 2 hours by ELISA or < 15 minutes by membrane enzyme immunoassay) and can distinguish *E. histolytica* from *E. dispar* and *E. moshkovskii*. In one report, when used on patients' sera, ELISA showed high sensitivity in amebic liver abscess (ALA) cases but only before metronidazole treatment began. Real-time polymerase chain reaction (PCR) in stool is superior in sensitivity to stool antigen detection but is still technically complex for diagnostic use in clinical settings. Serologic tests are sensitive (approximately 90% during the convalescent phase) and noninvasive diagnostic tools for amebiasis. Antibodies are detectable in 70% or more of patients within 5 to 7 days of acute infection and persist for years after treatment. Therefore a negative serologic result is helpful for exclusion of disease, whereas a positive result cannot distinguish between present and previous infection.

Histopathologic examination using biopsy or resected samples is sometimes useful for the diagnosis of intestinal amebiasis. As mentioned, PAS stain in addition to hematoxylin and eosin staining can increase sensitivity in detection of *Entamoeba*. However, identification of *Entamoeba* in biopsy specimens is often challenging. About half of cases with gross ulcerative lesions in the large intestine, in which *E. histolytica* was proven by PCR, had a negative result on histopathology.

Therapy

Recommended treatment regimens are shown in Box 2. Therapy for invasive infection differs from therapy for noninvasive infection. Noninvasive infections (treatment for asymptotically infected individuals) require treatment with luminal-active agents: paromomycin (Humatin) is currently recommended because of its high potency in asymptomatic cyst passers.

For symptomatic patients, tissue-active agents should be administered before luminal-active agents. Most patients with mild to moderate colitis and uncomplicated liver abscess respond to treatment with tissue-active agents, such as metronidazole (Flagyl) and tinidazole (Tindamax). Tinidazole has the advantage of less frequent dosing than metronidazole. Treatment with tissue-active agents should be followed by luminal-active agents because parasites persist in the intestine in up to 40% to 60% of patients who receive tissue-active agents. Broad-spectrum antibiotics and surgical treatment should be added to tissue-active agents in patients with fulminant colitis in which perforation and peritonitis or bacteremia are suspected. Therapeutic needle aspiration or catheter drainage is not routinely required for uncomplicated liver abscesses. Those interventions in addition to medical treatment are recommended if there is clinical deterioration or lack of response to initial medical treatment, or if alternative diagnoses need to be excluded. Also, some reports suggest that clinicians should consider those interventions for patients with a high risk of abscess rupture, as defined by a cavity with a diameter of more than 5 cm or by the presence of lesions in the left lobe, although these criteria were not conclusive in case-control studies.

Symptoms (diarrhea, dysentery, fever, pain, and tenderness) and laboratory markers (white blood cell counts, red blood cell counts, and C-reactive protein) rapidly improve after effective treatment even in patients with extraintestinal lesions. In contrast, radiologic findings, such as abscess size, often remain unchanged for months after completion of treatment.

Monitoring after Treatment and Disease Prevention

Although routine monitoring after treating amebiasis is not recommended, it is well known that reinfection frequently occurs in

endemic situations, including both water- or food-borne infections and sexually transmitted infections. In developed countries, to prevent reinfection, it is important for the primary physician to inform patients of behaviors that will place them at risk for acquisition of the cyst and how to avoid them, such as avoiding nonsterilized water or food in developing countries, unsafe homosexual contact, and oral–anal sexual contact. In developing countries, more than 1 billion people still have no access to safe food and water, resulting in the urgent need for an effective vaccine. Induction of acquired mucosal immunity is the current goal for vaccine development. Although there is currently no vaccine in human clinical trials, a vaccine containing the naive or recombinant Gal/GalNAc lectin of *E. histolytica* has strong immunogenicity and protective effect against amebic colitis and liver abscess in animal models. Continuous effort will be needed to develop an effective vaccine to save the lives of affected people in endemic areas.

ANTHRAX

Method of

Shingo Chihara, MD

CURRENT DIAGNOSIS

Cutaneous Anthrax

- Incubation period of 1 to 7 days from exposure to cattle
- Painless or pruritic lesion progresses to ulcer and eschar
- Significant swelling
- Gram stain and culture of lesion

Gastrointestinal

- Incubation period of 1 to 6 days after consumption of raw or undercooked meat
- Nonspecific symptoms followed by abdominal pain, ascites
- Diarrhea uncommon
- Obtain blood culture and ascitic fluid for culture and Gram stain

Inhalational

- Incubation period of 1 to 7 days (up to 43 days)
- Biphasic: fever, malaise, myalgia followed by dyspnea

- Widened mediastinum seen on chest x-ray and computed tomography (CT) of chest
- Blood cultures turn positive in most

Injection

- Injection drug use
- Significant swelling seen; eschar rare

CURRENT THERAPY

Systemic Anthrax With Possible/Confirmed Meningitis

- Ciprofloxacin (Cipro) 400 mg IV every 8 hours or levofloxacin (Levaquin) 750 mg IV every 24 hours or moxifloxacin (Avelox)¹ 400 mg IV every 24 hours
plus
- Meropenem (Merrem)¹ 2 g IV every 8 hours or imipenem/cilastatin (Primaxin)¹ 1 g IV every 6 hours or doripenem (Doribax)¹ 500 mg IV every 8 hours
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin¹ 3 g IV every 6 hours could be an alternative to carbapenems
plus
- Linezolid (Zyvox)¹ 600 mg IV every 12 hours or clindamycin (Cleocin) 900 mg IV every 8 hours or rifampin (Rifadin) 600 mg IV every 12 hours or chloramphenicol 1 g every 6 to 8 hours

Systemic Anthrax When Meningitis Has Been Excluded

- Ciprofloxacin 400 mg IV every 8 hours or levofloxacin 750 mg IV every 24 hours or moxifloxacin¹ 400 mg IV every 24 hours
or
- Meropenem¹ 2 g IV every 8 hours or imipenem/cilastatin¹ 1 g IV every 6 hours or doripenem¹ 500 mg IV every 8 hours
or
- Vancomycin (Vancocin)¹ 60 mg/kg/day IV divided every 8 hours (goal trough 15–20 µg/mL)
or
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin¹ 3 g IV every 6 hours
plus
- Clindamycin¹ 900 mg IV every 8 hours or linezolid¹ 600 mg IV every 12 hours
or
- Doxycycline 200 mg IV × 1, then 100 mg IV every 12 hours, or rifampin¹ 600 mg IV every 12 hours

Oral Treatment for Cutaneous Anthrax Without Systemic Involvement

- One of the agents below for 7 to 10 days in naturally-acquired cases and for 60 days in bioterrorism-associated cases
- Ciprofloxacin 500 mg PO every 12 hours
- Doxycycline 100 mg PO every 12 hours
- Levofloxacin 750 mg PO daily
- Moxifloxacin¹ 400 mg PO daily
- Clindamycin¹ 600 mg PO every 8 hours
- If penicillin-susceptible strain
- Amoxicillin¹ 1 g PO every 8 hours
- Penicillin VK 500 mg PO every 6 hours

¹Not FDA approved for this indication.

Anthrax has been described for centuries and the name is derived from Greek for “burnt coal” owing to eschar formation from cutaneous anthrax. Anthrax is rarely seen in developed countries, including the United States, but it is important to be aware of this condition because of its potential as a bioterrorism agent. When anthrax is suspected, the clinician needs to contact the local or state

endemic situations, including both water- or food-borne infections and sexually transmitted infections. In developed countries, to prevent reinfection, it is important for the primary physician to inform patients of behaviors that will place them at risk for acquisition of the cyst and how to avoid them, such as avoiding nonsterilized water or food in developing countries, unsafe homosexual contact, and oral–anal sexual contact. In developing countries, more than 1 billion people still have no access to safe food and water, resulting in the urgent need for an effective vaccine. Induction of acquired mucosal immunity is the current goal for vaccine development. Although there is currently no vaccine in human clinical trials, a vaccine containing the naive or recombinant Gal/GalNAc lectin of *E. histolytica* has strong immunogenicity and protective effect against amebic colitis and liver abscess in animal models. Continuous effort will be needed to develop an effective vaccine to save the lives of affected people in endemic areas.

ANTHRAX

Method of

Shingo Chihara, MD

CURRENT DIAGNOSIS

Cutaneous Anthrax

- Incubation period of 1 to 7 days from exposure to cattle
- Painless or pruritic lesion progresses to ulcer and eschar
- Significant swelling
- Gram stain and culture of lesion

Gastrointestinal

- Incubation period of 1 to 6 days after consumption of raw or undercooked meat
- Nonspecific symptoms followed by abdominal pain, ascites
- Diarrhea uncommon
- Obtain blood culture and ascitic fluid for culture and Gram stain

Inhalational

- Incubation period of 1 to 7 days (up to 43 days)
- Biphasic: fever, malaise, myalgia followed by dyspnea

- Widened mediastinum seen on chest x-ray and computed tomography (CT) of chest
- Blood cultures turn positive in most

Injection

- Injection drug use
- Significant swelling seen; eschar rare

CURRENT THERAPY

Systemic Anthrax With Possible/Confirmed Meningitis

- Ciprofloxacin (Cipro) 400 mg IV every 8 hours or levofloxacin (Levaquin) 750 mg IV every 24 hours or moxifloxacin (Avelox)¹ 400 mg IV every 24 hours
- plus
- Meropenem (Merrem)¹ 2 g IV every 8 hours or imipenem/cilastatin (Primaxin)¹ 1 g IV every 6 hours or doripenem (Doribax)¹ 500 mg IV every 8 hours
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin¹ 3 g IV every 6 hours could be an alternative to carbapenems
- plus
- Linezolid (Zyvox)¹ 600 mg IV every 12 hours or clindamycin (Cleocin) 900 mg IV every 8 hours or rifampin (Rifadin) 600 mg IV every 12 hours or chloramphenicol 1 g every 6 to 8 hours

Systemic Anthrax When Meningitis Has Been Excluded

- Ciprofloxacin 400 mg IV every 8 hours or levofloxacin 750 mg IV every 24 hours or moxifloxacin¹ 400 mg IV every 24 hours
- or
- Meropenem¹ 2 g IV every 8 hours or imipenem/cilastatin¹ 1 g IV every 6 hours or doripenem¹ 500 mg IV every 8 hours
- or
- Vancomycin (Vancocin)¹ 60 mg/kg/day IV divided every 8 hours (goal trough 15–20 µg/mL)
- or
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin¹ 3 g IV every 6 hours
- plus
- Clindamycin¹ 900 mg IV every 8 hours or linezolid¹ 600 mg IV every 12 hours
- or
- Doxycycline 200 mg IV × 1, then 100 mg IV every 12 hours, or rifampin¹ 600 mg IV every 12 hours

Oral Treatment for Cutaneous Anthrax Without Systemic Involvement

- One of the agents below for 7 to 10 days in naturally-acquired cases and for 60 days in bioterrorism-associated cases
- Ciprofloxacin 500 mg PO every 12 hours
- Doxycycline 100 mg PO every 12 hours
- Levofloxacin 750 mg PO daily
- Moxifloxacin¹ 400 mg PO daily
- Clindamycin¹ 600 mg PO every 8 hours
- If penicillin-susceptible strain
- Amoxicillin¹ 1 g PO every 8 hours
- Penicillin VK 500 mg PO every 6 hours

¹Not FDA approved for this indication.

Anthrax has been described for centuries and the name is derived from Greek for “burnt coal” owing to eschar formation from cutaneous anthrax. Anthrax is rarely seen in developed countries, including the United States, but it is important to be aware of this condition because of its potential as a bioterrorism agent. When anthrax is suspected, the clinician needs to contact the local or state

health department immediately. Anthrax has historical significance because it was the agent used in Koch's postulate during the 19th century when Koch proved that *Bacillus anthracis* is responsible for anthrax in cattle.

Background

B. anthracis is the bacterium responsible for anthrax. It forms spores that can survive in soil for years. It is hyperendemic in the Middle East and in sub-Saharan Africa. Systemic anthrax is primarily a disease of grazing animals. In naturally-acquired anthrax, humans are accidentally infected from exposure to the animal or its products.

Epidemiology

Since the mid-20th century, there has been a precipitous decline in anthrax owing to animal and human vaccines, improvement in factory hygiene, sterilization procedures for imported animal products, and increased use of alternatives to animal hides or hair. Cutaneous anthrax comprises over 95% of naturally-acquired human anthrax and there are an estimated 2000 cases annually. Between 1900 and 2001 there were 18 cases of inhalational anthrax in the United States, of which 16 were fatal. Over the last decade, there have been several cases of inhalational and cutaneous anthrax related to African drum makers. In late 2001, there were 22 cases of anthrax in the United States from spores delivered in the mail, of which five were fatal. In 1979, accidental release of dried anthrax spores from a biologic weapons facility in Sverdlovsk in the former Soviet Union resulted in 68 deaths from inhalation anthrax.

Pathophysiology

B. anthracis is a gram-positive, encapsulated, spore forming, nonhemolytic, nonmotile rod-shaped bacterium. Infection with anthrax requires three components: the edema factor, the lethal factor, and protective antigen. The edema factor combines with protective antigen and becomes edema toxin, which causes edema and impairment of the immune system. The lethal factor combines with protective antigen and becomes lethal toxin, which causes lysis of macrophages. For cutaneous anthrax, these exotoxins result in extensive edema and tissue necrosis locally. In inhalation anthrax, spores that reach the alveoli or alveolar ducts are phagocytized by the alveolar macrophage and transported to the mediastinal lymph nodes where they replicate and cause hemorrhagic mediastinitis. With gastrointestinal tract infection, *B. anthracis* is transported from the gastrointestinal tract to mesenteric lymph nodes where they multiply and cause mesenteric lymphadenitis, ascites, and sepsis.

Clinical Manifestations

There are four distinct clinical presentations: cutaneous, inhalation, gastrointestinal tract, and injection anthrax, depending on the site of entry. Meningitis is a devastating complication that could occur with any of the four infections.

Cutaneous Anthrax

Cutaneous anthrax is the most common form and seen in developing countries as a result of contact with infected animals or animal products such as wool, hair, or hides. Spores invade through either skin abrasions or hair follicles. Subsequently, they germinate and multiply. The incubation period is commonly 5 to 7 days with range of 1 to 19 days. The lesions appear in exposed areas such as head, neck, forearms, and hands and begin as a small, painless papule. They are pruritic at times and form blisters. Subsequently, they evolve into painless necrotic ulcers with a black, depressed eschar with extensive edema and lymphadenopathy.

Inhalation Anthrax

Inhalation anthrax occurs when spores are aerosolized while working with contaminated animal products or when they are released intentionally in bioterrorism. The incubation period is 1 to 7 days but could be as long as 43 days. The course of disease is usually biphasic. Initially, nonspecific symptoms such as fever, malaise, and myalgia are present, resembling influenza. These symptoms

last for several days before the bacteremic phase starts. The manifestations include rapidly, fulminant progressive respiratory symptoms such as severe dyspnea, as well as hypoxemia and shock. Once in this phase, the patient dies within a few days despite support in the intensive care unit. Therefore it is important to suspect anthrax in the prodromal phase, which is difficult owing to its rarity and lack of specific symptoms. Widening of the mediastinum on a chest x-ray may be helpful in establishing the diagnosis. This finding was seen in 7 out of 10 cases of inhalation anthrax from 2001. Hilar abnormalities, pulmonary infiltrates, or consolidation and pleural effusion may be seen.

Gastrointestinal Tract Anthrax

Gastrointestinal tract anthrax occurs after ingestion of raw or undercooked meat from an animal infected with anthrax. Gastrointestinal infection is relatively common and has been reported from mouth to ascending colon. The incubation period is 1 to 6 days. Initially, nonspecific symptoms such as asthenia, headache, low-grade fever, facial flushing and conjunctival injection occur. They are followed by abdominal pain, abdominal distention from ascites, nausea, and vomiting. Diarrhea occurs less frequently. As the disease progresses, abdominal pain becomes severe and findings of hypotension and intravascular depletion are seen. When the infection occurs in the oropharynx, necrotic ulcers with pseudomembranes cause pain and edema.

Injection Anthrax

An outbreak of injection anthrax was described in 2009. It was reported in Scotland among injection heroin users. Among the 47 confirmed cases, typical eschar formation seen in cutaneous anthrax was not seen in all but one case. Prominent edema was seen in most patients and some developed compartment syndrome.

Meningitis

Meningitis is a complication seen with all forms of anthrax. About half of patients with inhalation anthrax develop hemorrhagic meningitis. Symptoms such as altered mental status, seizures, cranial nerve palsies, and myoclonus may be seen. When anthrax is suspected, lumbar puncture should be done on presentation unless there are contraindications.

Diagnosis

When diagnosis of anthrax is suspected, the provider must notify the local department of health and the clinical microbiology laboratory. There has been reported transmission of anthrax to laboratory personnel handling *B. anthracis* and specimen handling in biosafety level 3 facilities is recommended. Because the genus *Bacillus* is part of the normal skin flora, it is crucial for the microbiology laboratory to distinguish *B. anthracis* from other non-*anthracis* species of *Bacillus*. Conventional culture and staining are used for distinction. *B. anthracis* is nonmotile and nonhemolytic and those characteristics are used to distinguish it from non-*anthracis* species of *Bacillus*. Most microbiology laboratories have the ability to make a presumptive identification of an organism, and the identification is confirmed by a reference laboratory.

Specimen Collection

When collecting clinical specimens for suspected anthrax, proper personal protective equipment such as disposable gloves, disposable aprons, and boots, should be used. When there is any potential of aerosolization of spores, then face shields and respirators are recommended. Hand washing with soap and water will reduce the endospore contamination of the skin, but alcohol handrubs are not effective against these endospores. For cutaneous anthrax, the edge of the eschar should be lifted, and two specimens of vesicular fluid should be collected by rotating a swab. One swab will be used for culture and Gram stain while the other would be used for polymerase chain reaction (PCR). Punch biopsy of the cutaneous lesion is an alternative. When inhalational anthrax is suspected, blood cultures must be obtained prior to use of antibiotics. If pleural fluid is present, then thoracentesis should be performed for

Gram stain, culture, and PCR. For alimentary tract anthrax, blood cultures must be obtained. If there are oral lesions, then specimens could be collected with swabs similar to a cutaneous lesion. If ascites is present, then paracentesis should be performed for Gram stain, culture and PCR. For meningitis, cerebrospinal fluid (CSF) should be collected for culture, Gram stain and PCR.

There are unique findings observed in routine laboratories with systemic anthrax. Marked hemoconcentration may be seen in the complete blood count, and the initial white blood cell count is frequently within normal limits. In chemistry, decreased sodium, increased blood urea nitrogen, mild transaminitis and hypoalbuminemia are seen. Inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein are elevated in most cases except in cases of injection anthrax, when C-reactive protein is low.

Treatment

Supportive Care

Hospitalization is required for all patients with systemic infections. Only uncomplicated cutaneous anthrax could be treated on an outpatient basis. Close monitoring is warranted because the patient status may deteriorate rapidly. Hemodynamic support should be given, including fluids, vasopressors, blood products, and invasive hemodynamic monitoring. Mechanical ventilation may be needed because of respiratory distress, airway protection for altered mental status, or for airway edema. Adjunctive corticosteroids may be indicated in four situations: patients with history of endocrine or corticosteroid therapy; edema of head or neck; anthrax meningitis; or vasopressor-resistant shock. Pleural fluid and ascites should be drained aggressively. Surgery is indicated in certain situations. Surgery for cutaneous anthrax has led to dissemination and poor outcome. Therefore, in cutaneous anthrax, indication for surgery is limited to tracheotomy for airway obstruction and surgery for compartment syndrome. In gastrointestinal anthrax, surgery might be considered for complications such as bowel ischemia or infarct and perforation. In injection anthrax, removal of necrotic nidus would help reduce the toxin and spore reservoir.

Antimicrobial Treatment for Systemic Disease with Possible Meningitis

At least three intravenous antibiotics with good penetration to the central nervous system are recommended. At least one drug should have bactericidal activity, and at least one drug should inhibit protein synthesis. These should be continued for at least 2 weeks or until clinically stable, whichever is longer. The fluoroquinolone class is bactericidal, has good penetration to the central nervous system, and has no reported resistance by *B. anthracis*. Intravenous ciprofloxacin (Cipro) is the primary bactericidal component in the treatment of systemic disease. Levofloxacin (Levaquin) and moxifloxacin (Avelox)¹ are considered to be alternatives. The carbapenem class has good central nervous system penetration, and meropenem (Merrem)¹ is the preferred second antibiotic in treatment of systemic disease with possible meningitis. Imipenem/cilastatin (Primaxin)¹ and doripenem (Doribax)¹ are considered alternatives. Penicillin G or ampicillin¹ could be used in place of carbapenems when the isolate is known to have a minimum inhibitory concentration (MIC) of less than 0.125 µg/mL. As for protein synthesis inhibitor, linezolid (Zyvox)¹ is preferred because it provides good central nervous system penetration. If there is contraindication to linezolid use such as drug-drug interaction or myelosuppression, then clindamycin (Cleocin)¹ is the alternative. When both linezolid and clindamycin cannot be used, rifampin (Rifadin)¹ could be used for synergistic effect in combination with the bactericidal drugs. Chloramphenicol is another antibiotic that is a protein synthesis inhibitor. It could be used if linezolid, clindamycin, and rifampin are unavailable. Doxycycline (Vibramycin) is an inhibitor of protein synthesis but does not adequately penetrate

the central nervous system. Therefore doxycycline should not be used when meningitis is not ruled out. If the patient had been exposed to aerosolized spores, then the patient should be transitioned to oral antibiotics after completion of initial intravenous combination therapy to prevent relapse from spores.

Antimicrobial Treatment for Systemic Disease when Meningitis is Ruled Out

At least two antimicrobial agents are recommended for systemic anthrax without meningitis. At least one should be bactericidal and at least one should be a protein synthesis inhibitor. This combination should be administered intravenously for at least 2 weeks or until clinically stable, whichever is longer. For penicillin-susceptible strains, penicillin G is considered equivalent to ciprofloxacin. Vancomycin (Vancocin)¹ is an acceptable alternative bactericidal agent. Clindamycin¹ and linezolid¹ are equivalent first choices for protein synthesis inhibitors. Doxycycline is an alternative agent. If the patient had been exposed to aerosolized spores, then the patient should be transitioned to oral antibiotics after completion of initial intravenous combination therapy to prevent relapse from spores.

Treatment for Cutaneous Anthrax without Systemic Involvement

A single oral antibiotic is adequate to treat cutaneous anthrax without systemic involvement. Fluoroquinolones and doxycycline are considered first-line agents. Clindamycin¹ is a second-line agent when first-line agents are unavailable or contraindicated. Penicillin or amoxicillin¹ may be used if the isolate is found to be sensitive in vitro. It is important to give an adequate dose because resistance may develop when underdosed.

Antitoxins

There are two antitoxins in the Centers for Disease Control and Prevention (CDC) Strategic National stockpile: raxibacumab and anthrax immune globulin intravenous (AIGIV). These agents are not readily available to the public. They inhibit binding of protective antigen to the anthrax toxin receptor and translocation of lethal factor and edema factor into cells. There are human and animal data from the pre-antibiotic era that suggest that there is lower mortality in those who received the antitoxin in cutaneous anthrax compared with those who did not. Whether this agent should be given for systemic anthrax is controversial owing to lack of data. Because the mortality rate with systemic anthrax is high whereas the complication of antitoxin treatment is low, the potential benefit from antitoxins outweighs the potential risk from the antitoxins in systemic anthrax. This agent should be given in addition to appropriate antibiotics when systemic anthrax is suspected.

Pregnancy

Overall management is similar to that in the nonpregnant patient. In pregnancy, ciprofloxacin is preferred over doxycycline for both treatment and prevention. Newer fluoroquinolones such as levofloxacin and moxifloxacin¹ are not preferred because embryo toxicity has been observed in animal studies. This was not seen with ciprofloxacin. Transplacental transmission of anthrax is known to occur. Ciprofloxacin, levofloxacin, meropenem,¹ ampicillin,¹ penicillin, clindamycin,¹ and rifampin¹ are known to have adequate concentration in the placenta and at least one agent should be used with treatment.

Prognosis

Uncomplicated cutaneous anthrax has a mortality rate of less than 2% with treatment. Injection anthrax has a mortality rate of 28%, and gastrointestinal anthrax has a mortality rate of 40%. Inhalational anthrax has mortality of 45% despite antibiotics and modern intensive care. Meningitis from anthrax is almost always fatal.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Prevention

Postexposure prophylaxis should be started as soon as possible after exposure. Sixty days of antibiotics for immediate protection and a three-dose series of Anthrax Vaccine Adsorbed (AVA, BioThrax) for long-term protection are recommended by the United States Advisory Committee on Immunization Practices. Ciprofloxacin and doxycycline are recommended as first-line antibiotic therapy for postexposure prophylaxis and are FDA-approved for this indication. Alternative agents include levofloxacin, moxifloxacin, amoxicillin, or penicillin VK (if sensitive); and clindamycin. AVA should be administered at diagnosis and at 2 and 4 weeks. AVA is not FDA-approved for postexposure prophylaxis.

BABESIOSIS

Method of

Cheston B. Cunha, MD; and Burke A. Cunha, MD

CURRENT DIAGNOSIS

- Suspect babesiosis in patients from Ixodes tick-endemic areas who present with a malaria-like illness (MLI) with fever, chills, headache, fatigue, and malaise.
- Clinically, babesiosis usually presents as an acute febrile illness with high fevers (>102 °F), relative bradycardia, and shaking chills accompanied by fatigue and myalgias.
- Myalgias may suggest an influenza-like illness (ILI).
- Severe headaches may suggest an alternate diagnosis, e.g., meningitis.
- Some patients with babesiosis may be short of breath and may go on to develop acute respiratory distress syndrome (ARDS).
- Consider babesiosis for unexplained fevers following blood transfusion.
- In prolonged fevers that meet the definition of fever of unknown origin (FUO), consider babesiosis in patients from endemic areas.
- With babesiosis, there are usually no localizing signs except for splenomegaly. Importantly, no rash is present. If rash is present, consider an alternate diagnosis.
- In babesiosis, nonspecific laboratory test results, considered together, are helpful in excluding or narrowing diagnostic possibilities.
- Common nonspecific laboratory findings of babesiosis include a normal/slightly decreased white blood cell count, relative lymphopenia, atypical lymphocytes, thrombocytopenia, elevated total bilirubin, and high lactate dehydrogenase levels. Sera are mildly elevated.
- The erythrocyte sedimentation rate is usually highly elevated (>90 mm/h) as are serum ferritin levels.
- Definitive babesiosis diagnosis is by peripheral blood smears (thick and thin); thick smears are best for the detection of babesia and thin smears are best to assess the degree of parasitemia.

- In normal hosts, the degree of parasitemia is usually low (1%–5%), but high in compromised hosts (>10%). Severe babesiosis may occur in asplenic individuals (Howell-Jolly bodies reflect the degree of splenic dysfunction), the immunosuppressed, the elderly, and those with coinfections, e.g., ehrlichiosis, Lyme disease.
- If present, babesiosis is diagnosed by peripheral stained blood smears demonstrating the characteristic (but uncommon) “Maltese cross” in tetrads (four merozoites).
- In nonmalarious areas, babesiosis may be diagnosed by demonstrating intraerythrocytic ring forms on the peripheral smear.
- Babesiosis, like malaria, has intracellular ring forms, but babesiosis, unlike malaria, has no intracellular pigment (hemozoin).
- Alternatively, *Babesia microti* serology in the Northeastern United States is diagnostic if IgM titers are highly elevated (>1:64).
- Polymerase chain reaction to detect Babesia is more sensitive than blood smear review. It is particularly useful in patients with a low level of parasitemia.

CURRENT THERAPY

- Preferred therapy is atovaquone (Mepron)¹ plus azithromycin (Zithromax).¹
- Alternatively, clindamycin (Cleocin)¹ plus quinine¹ may be used.
- In addition to antibabesia therapy, exchange transfusion may be lifesaving in severe cases.
- For severe cases, continue therapy until degree of parasitemia is <5%.
- Recurrent or persistent babesiosis should be treated for >2 weeks after resolution of parasitemia.
- Doxycycline is not effective in babesiosis.
- Coinfection with other tick-borne pathogens is rare, but possible.

¹Not FDA approved for this indication.

Epidemiology

Babesiosis is a tick-borne zoonosis that clinically presents as a malaria-like illness (MLI). There are many *Babesia* species, but only five are pathogenic in humans. The geographic distribution of babesiosis mimics that of hard-bodied *Ixodes dammini* (*I. scapularis*) ticks and their vertebrate hosts, e.g., dogs, cats, cattle, and rodents. The primary reservoir for babesiosis in the Northeastern United States is the white-footed mouse (*I. dammini* nymphs) and the white-tailed deer (*I. dammini* adults). Sporadic cases of babesiosis also occur in states with the tick vector/vertebrate hosts. Babesiosis may also be acquired by blood/blood product transfusions.

Clinical Features

In the Northeastern United States, babesiosis is usually *B. microti* and clinically manifests as an MLI. Babesiosis may be asymptomatic (IgG seropositive) or a mild, self-limited influenza-like illness (ILI). The incubation period for naturally acquired babesiosis is 1 to 6 weeks and 6 to 9 weeks for transfusion-acquired babesiosis. Clinical presentations in normal hosts are subacute with fever, fatigue, headache, malaise, and anorexia often mimicking Epstein-Barr virus infectious mononucleosis (with false-positive Monospot test results). Babesiosis presenting in patients with prolonged fevers of unknown origins (FUOs) and anorexia/weight loss may mimic a lymphoreticular malignancy. Presentation may be acute in those with impaired splenic function, those on immunosuppressives, or the elderly. Babesiosis may be viewed clinically as the “malaria of Long Island/Nantucket” as it presents with many malarial features, e.g., fever, chills, headache, sweats, myalgias. Excluding epidemiologic considerations, babesiosis differs in geographic distribution from malaria. Clinically, babesiosis differs

Prevention

Postexposure prophylaxis should be started as soon as possible after exposure. Sixty days of antibiotics for immediate protection and a three-dose series of Anthrax Vaccine Adsorbed (AVA, BioThrax) for long-term protection are recommended by the United States Advisory Committee on Immunization Practices. Ciprofloxacin and doxycycline are recommended as first-line antibiotic therapy for postexposure prophylaxis and are FDA-approved for this indication. Alternative agents include levofloxacin, moxifloxacin, amoxicillin, or penicillin VK (if sensitive); and clindamycin. AVA should be administered at diagnosis and at 2 and 4 weeks. AVA is not FDA-approved for postexposure prophylaxis.

- Definitive babesiosis diagnosis is by peripheral blood smears (thick and thin); thick smears are best for the detection of babesia and thin smears are best to assess the degree of parasitemia.

- In normal hosts, the degree of parasitemia is usually low (1%–5%), but high in compromised hosts (>10%). Severe babesiosis may occur in asplenic individuals (Howell-Jolly bodies reflect the degree of splenic dysfunction), the immunosuppressed, the elderly, and those with coinfections, e.g., ehrlichiosis, Lyme disease.
- If present, babesiosis is diagnosed by peripheral stained blood smears demonstrating the characteristic (but uncommon) “Maltese cross” in tetrads (four merozoites).
- In nonmalarious areas, babesiosis may be diagnosed by demonstrating intraerythrocytic ring forms on the peripheral smear.
- Babesiosis, like malaria, has intracellular ring forms, but babesiosis, unlike malaria, has no intracellular pigment (hemozoin).
- Alternatively, *Babesia microti* serology in the Northeastern United States is diagnostic if IgM titers are highly elevated (>1:64).
- Polymerase chain reaction to detect Babesia is more sensitive than blood smear review. It is particularly useful in patients with a low level of parasitemia.

CURRENT THERAPY

- Preferred therapy is atovaquone (Mepron)¹ plus azithromycin (Zithromax).¹
- Alternatively, clindamycin (Cleocin)¹ plus quinine¹ may be used.
- In addition to antibabesia therapy, exchange transfusion may be lifesaving in severe cases.
- For severe cases, continue therapy until degree of parasitemia is <5%.
- Recurrent or persistent babesiosis should be treated for >2 weeks after resolution of parasitemia.
- Doxycycline is not effective in babesiosis.
- Coinfection with other tick-borne pathogens is rare, but possible.

¹Not FDA approved for this indication.

Epidemiology

Babesiosis is a tick-borne zoonosis that clinically presents as a malaria-like illness (MLI). There are many *Babesia* species, but only five are pathogenic in humans. The geographic distribution of babesiosis mimics that of hard-bodied *Ixodes dammini* (*I. scapularis*) ticks and their vertebrate hosts, e.g., dogs, cats, cattle, and rodents. The primary reservoir for babesiosis in the Northeastern United States is the white-footed mouse (*I. dammini* nymphs) and the white-tailed deer (*I. dammini* adults). Sporadic cases of babesiosis also occur in states with the tick vector/vertebrate hosts. Babesiosis may also be acquired by blood/blood product transfusions.

Clinical Features

In the Northeastern United States, babesiosis is usually *B. microti* and clinically manifests as an MLI. Babesiosis may be asymptomatic (IgG seropositive) or a mild, self-limited influenza-like illness (ILI). The incubation period for naturally acquired babesiosis is 1 to 6 weeks and 6 to 9 weeks for transfusion-acquired babesiosis. Clinical presentations in normal hosts are subacute with fever, fatigue, headache, malaise, and anorexia often mimicking Epstein-Barr virus infectious mononucleosis (with false-positive Monospot test results). Babesiosis presenting in patients with prolonged fevers of unknown origins (FUOs) and anorexia/weight loss may mimic a lymphoreticular malignancy. Presentation may be acute in those with impaired splenic function, those on immunosuppressives, or the elderly. Babesiosis may be viewed clinically as the “malaria of Long Island/Nantucket” as it presents with many malarial features, e.g., fever, chills, headache, sweats, myalgias. Excluding epidemiologic considerations, babesiosis differs in geographic distribution from malaria. Clinically, babesiosis differs

from malaria in two important aspects. The clinical hallmarks of malaria are acute onset, intermittent fevers, and the classic “malaria paroxysm.” *Babesia* reproduce by asynchronous asexual budding, which is clinically manifest as constant/nonintermittent fever. With malaria, fevers are intermittent with fever periodicity related to the *Plasmodium* species. Only *P. falciparum* has no fever periodicity and like babesiosis has no hepatic phase. Malaria and babesiosis both have extraerythrocytic ring forms, but babesiosis has two distinct morphologic features: extracellular merozoites (tetrads), known as “Maltese crosses,” and no extraerythrocytic pigment, which malaria does have.

Unless the liver or spleen is enlarged, the physical features in babesiosis are limited to the fever. The fever curve of babesiosis is remittent without periodicity; fever is between 102 °F and 105 °F and accompanied by relative bradycardia. Rash is not a feature. When babesiosis is suspected, the presence of a rash is either indicative of coinfection, e.g., Lyme disease, or an alternative cause, e.g., viral or drug exanthem. Babesiosis should not be in the differential diagnosis of Rocky Mountain spotted fever with rash on the wrists/ankles. Babesiosis may clinically resemble ehrlichiosis. Peripheral blood smears are the best way to differentiate babesiosis from ehrlichiosis. Nonspecific laboratory abnormalities in babesiosis include normal/decreased white blood cell (WBC) count (leukopenia). Relative lymphopenia is usually present. Atypical lymphocytes are frequently present in the peripheral smear. Thrombocytopenia is a constant finding. The erythrocyte sedimentation rate (ESR) is highly elevated (usually >90 mm/h and often >100 mm/h) as is C-reactive protein (CRP). Since the pathophysiology of babesiosis is that of an acute hemolytic anemia, like malaria, intravascular hemolysis in babesiosis is manifested by increased lactate dehydrogenase (LDH)/total bilirubin. Increased LDH and total bilirubin are the most sensitive indicators of the degree of intravascular hemolysis in babesiosis. The hemoglobin/hematocrit is decreased later in more severe cases. Ferritin levels are highly elevated and prolonged (higher/longer) than would occur with acute-phase ferritin elevations. Since babesiosis impairs T cell function, as in malaria, serum protein electrophoresis often shows polyclonal gammopathy reflecting compensatory B cell hyperactivity. Serum transaminases are mildly elevated, but alkaline phosphatase is unelevated. Cold agglutinins are not a feature of babesiosis. In patients with decreased/absent splenic function, Howell-Jolly bodies are present in the peripheral smear. The number of Howell-Jolly bodies present is inversely proportional to the degree of splenic dysfunction.

Diagnosis of babesiosis is microscopic or serologic. Like malaria, babesiosis may be diagnosed on Giemsa stained blood smears. If malaria is not a diagnostic consideration (geographic distribution, blood transfusion), the presence of intraerythrocytic ring forms is diagnostic. Less common, but more specific, are pathognomonic tetrads (Maltese crosses) of babesiosis in peripheral smears. Also, unlike malaria, there is no extraerythrocytic pigment in babesiosis. Alternatively, elevated IgM *Babesia* species titers are diagnostic.

Therapy

The preferred therapy of babesiosis consists of 7 days combination therapy of azithromycin (Zithromax)¹ plus atovaquone (Meptron).¹ Alternatively, clindamycin (Cleocin)¹ plus quinine¹ for 7 days may be used (Table 1).

Treatment failure may occur in those with impaired T cell function, e.g., patients with HIV or with decreased splenic function. In such cases, exchange transfusion may be lifesaving.

BACTERIAL MENINGITIS

Method of

Gary D. Overturf, MD

CURRENT DIAGNOSIS

- Patient age and epidemiology:
 - Clinical symptoms: Fever, headache, meningeal signs
 - CSF examination: High opening pressure (>300 mm Hg)
 - Elevated white blood cell count (>10–>5000)
 - >60% polymorphonuclear cells
- Low CSF glucose (<40 mg/dL or <50% serum glucose)
- High CSF protein (>50–>1.0 g/dL)
- Bacteria present on Gram stain of CSF

Abbreviation: CSF = cerebrospinal fluid.

CURRENT THERAPY

- Neonates <2 mo
 - Group B streptococcal infection: cefotaxime (Claforan) or ampicillin
 - Gram-negative rods, other than *Pseudomonas*: cefotaxime

BACTERIAL MENINGITIS

Method of

Gary D. Overturf, MD

CURRENT DIAGNOSIS

- Patient age and epidemiology:
 - Clinical symptoms: Fever, headache, meningeal signs
 - CSF examination: High opening pressure (>300 mm Hg)
 - Elevated white blood cell count (>10–>5000)
 - >60% polymorphonuclear cells
- Low CSF glucose (<40 mg/dL or <50% serum glucose)
- High CSF protein (>50–>1.0 g/dL)
- Bacteria present on Gram stain of CSF

Abbreviation: CSF = cerebrospinal fluid.

CURRENT THERAPY

- Neonates <2 mo
 - Group B streptococcal infection: cefotaxime (Claforan) or ampicillin
 - Gram-negative rods, other than *Pseudomonas*: cefotaxime

- *Pseudomonas*: cefepime (Maxipime), ceftazidime (Fortaz), or meropenem (Merrem)
- *Listeria*: Ampicillin + gentamicin (Garamycin)
- Children >2 mo
 - Empirical for unknown etiology: cefotaxime or ceftriaxone (Rocephin)
 - *Streptococcus pneumoniae*: cefotaxime or ceftriaxone
 - *Haemophilus influenzae*: cefotaxime or ceftriaxone
 - *Neisseria meningitidis*: ampicillin or cefotaxime
- Older children and adults
 - Empirical for unknown etiology: cefotaxime or ceftriaxone
 - *S. pneumoniae*: cefotaxime or ceftriaxone
 - *N. meningitidis*: ampicillin or cefotaxime
 - Gram negative, postoperative, or *Staphylococcus aureus* (see Tables 1–4)
 - Add vancomycin if at risk for infection with resistant pneumococcus

Acute bacterial meningitis occurs in all age groups, but predominantly in children younger than 2 years and the elderly (older than 60 years). With the introduction of effective protein conjugate vaccines for *Haemophilus* and pneumococcal infection, the incidence of bacterial meningitis is rapidly declining in children, and adults are now the major population affected. Bacterial meningitis is a medical emergency requiring rapid and decisive action to prevent death or neurologic sequelae. Since the introduction of chloramphenicol (Chloromycetin) in the early 1950s, the mortality rate has remained between 5% and 40%, depending on the age of the patient and the etiology. Of the survivors, 10% to 30% suffer permanent neurologic deficits. Prognosis is affected by the timeliness of therapy, the age of the patient, and the etiology. Presumptive diagnosis and administration of therapy are critical.

Diagnosis

Acute bacterial meningitis must be considered in the differential diagnosis of persons of any age presenting with fever and headache or signs of meningeal irritation or acute central nervous system dysfunction. Presentations can be subtle at the extremes of age or in patients who have received partially effective antibiotic therapy. The diagnosis of bacterial meningitis requires the examination of the cerebrospinal fluid (CSF), which must be performed as expeditiously as possible. Studies indicate that lumbar puncture may be safely performed on patients who have normal mental status or are without focal neurologic signs or papilledema; clinical impressions are predictive of the computed tomography (CT) findings. If there are signs or symptoms suggesting the presence of an intracranial mass (e.g., tumor, cerebral hematoma, or brain abscess), blood cultures should be obtained and empirical antibiotics should be administered prior to the performance of a CT scan.

Characteristically, the CSF findings in bacterial meningitis include a cell count of greater than 500 to 5000 white blood cells (WBCs) per mm³ with a predominance of neutrophils, a protein concentration of greater than 150 mg/mL, and a low glucose (e.g., less than 35–40 mg/dL). No single value is absolute, and a single value may be normal in up to a third of the cases. The Gram-stained sediment of centrifuged CSF is the critical examination leading to a specific diagnosis. In patients who have not received antibiotics capable of reaching the CSF, the Gram stain is positive in 80% to 90% of culture-confirmed cases. In persons previously treated with antibiotics (e.g., β -lactam antibiotics, tetracycline, fluoroquinolones), the frequency of positive Gram stains is much reduced (e.g., 60% to 70%), but the cells, cell type, protein, and glucose concentrations are not significantly affected. CSF antigen tests are not reliable, and variable negative and positive predictive values direct against relying on the use of such tests. Clinical judgment is paramount, and antibiotics should be given in situations of ambiguous results of the CSF examination.

Antibiotic Selection

The outcome of bacterial meningitis is closely related to the timely use of antibiotics. Hypotension, seizures, an altered mental status, and hypoglycorrhachia at the time of initial antibiotic administration are predictive of higher case fatality and neurologic sequelae. Because prompt administration of antibiotics is critical, the choice of antibiotics must be made before results of the CSF cultures are known. If organisms are seen on Gram stain, therapy may be directed by the probable bacterial etiology (Table 1). In the event the CSF Gram stain fails to reveal a possible pathogen, empirical antibiotic therapy should be begun based on the age of the patient for those persons who have acquired their infection in the community (Table 2). For those persons who are members of special risk groups, empirical therapy should be based on the likely etiology (Table 3). Once the CSF cultures are completed, therapy can be modified according to results of the culture and sensitivity data.

Antibiotics used in bacterial meningitis should be rapidly bactericidal and achieve high concentrations in the CSF. Antibiotics should be given in maximal doses (Table 4). Because the bactericidal activity of antibiotics in CSF is dose dependent, the fractional CSF-to-serum ratio is very small. Finally, the use of combinations of antibiotics should be minimized to avoid antagonizing the bactericidal activity.

Special Considerations for Antibiotic Therapy

During the past two decades, resistance to penicillin and some third-generation cephalosporins (e.g., ceftriaxone [Rocephin], cefotaxime [Claforan]) has steadily increased among strains of *Streptococcus pneumoniae*. Currently, approximately 30% to 50% of isolates are either intermediately (inhibitory concentration, 0.1–1.0 μ g/mL) or fully (inhibitory concentration more than 2.0 μ g/

TABLE 1 Cerebrospinal Fluid Gram Stain Morphology and Antibiotic Recommendations

MORPHOLOGY	POSSIBLE OR PROBABLE PATHOGENS	TREATMENT OPTIONS	ALTERNATIVE THERAPIES
Gram-positive cocci, short chains or pairs	<i>Streptococcus pneumoniae</i> , <i>Streptococcus agalactiae</i> (group B streptococci)	Ceftriaxone (Rocephin) or cefotaxime (Claforan) plus vancomycin (Vancocin)	Chloramphenicol (Chloromycetin)
Gram-positive cocci, clusters; or gram-positive bacilli	<i>Staphylococcus aureus</i> , <i>Listeria monocytogenes</i>	Vancomycin, ampicillin plus gentamicin (Garamycin)	Nafcillin (Unipen) or Oxacillin, trimethoprim-sulfamethoxazole (Bactrim)
Gram-negative diplococci	<i>Neisseria meningitidis</i>	Ceftriaxone or cefotaxime	Ampicillin, Penicillin G, or chloramphenicol
Gram-negative coccobacilli	<i>Haemophilus influenzae</i>	Ceftriaxone or cefotaxime	Chloramphenicol
Gram-negative bacilli	<i>Escherichia coli</i> , <i>Klebsiella</i> species, <i>Pseudomonas aeruginosa</i>	Cefepime (Maxipime) or ceftazidime (Fortaz)	Imipenem (Primaxin) or meropenem (Merrem)

TABLE 2 Antibiotic Recommendations for Bacterial Meningitis Acquired in the Community, by Age Group and Probable Pathogen

AGE GROUP	PROBABLE PATHOGENS	EMPIRICAL THERAPY
Neonate <1 mo	Group B streptococcus; <i>E. coli</i> , or other gram-negative enteric rod; occasionally <i>L. monocytogenes</i>	Ampicillin plus cefotaxime (Claforan)
Infants 1–3 mo	<i>H. influenzae</i> , <i>N. meningitidis</i> , <i>S. pneumoniae</i> , Group B streptococci	Ceftriaxone (Rocephin) or cefotaxime (Claforan)
Children 3 mo–7 y and older children and adults 7–50 y	<i>H. influenzae</i> , <i>S. pneumoniae</i> , <i>N. meningitidis</i>	Ceftriaxone or cefotaxime plus vancomycin (Vancocin)
Older adults >50 y	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i>	Ceftriaxone plus ampicillin

TABLE 3 Antibiotic Recommendations for Presumed Bacterial Meningitis in Persons with Special Risks

CONDITION OR RISK FACTOR	COMMON PATHOGENS	ANTIBIOTIC RECOMMENDATIONS
Impaired immunity (e.g., HIV, early complement deficiency, agammaglobulinemia)	<i>L. monocytogenes</i> , <i>S. pneumoniae</i> , <i>H. influenzae</i>	Ampicillin plus ceftriaxone (Rocephin) or cefotaxime (Claforan)
Closed head trauma with CSF leak	<i>S. pneumoniae</i> , <i>H. influenzae</i>	Ceftriaxone or cefotaxime plus vancomycin (Vancocin)
Asplenia	<i>S. pneumoniae</i> , <i>H. influenzae</i>	Ceftriaxone or cefotaxime plus vancomycin
Terminal complement deficiency	<i>N. meningitidis</i>	Ceftriaxone or cefotaxime
Neurosurgical procedures	<i>S. aureus</i>	Vancomycin plus ceftriaxone or cefotaxime
CSF shunt infections	Coagulase-negative staphylococci, Gram-negative bacilli	
Elderly patients (>65 y)	<i>S. pneumoniae</i> , <i>L. monocytogenes</i>	Ceftriaxone or cefotaxime plus vancomycin
Recurrent bacterial meningitis (see CSF leak)	<i>S. pneumoniae</i>	Ceftriaxone or cefotaxime plus vancomycin
Alcoholic patients	<i>S. pneumoniae</i> and Gram-negative bacilli	Ceftriaxone or cefotaxime plus vancomycin

Abbreviation: CSF = cerebrospinal fluid.

TABLE 4 Antibiotic Doses for Adults and Children for Treatment of Bacterial Meningitis

ANTIBIOTIC	DAILY ADULT DOSE	DAILY PEDIATRIC DOSE	DOSE INTERVAL
Ampicillin	12 g	200–400 mg/kg	4–6 h
Cefotaxime (Claforan)	12 g	200–300 mg/kg	4–6 h
Ceftriaxone (Rocephin)	4 g	100 mg/kg	12 h
Ceftazidime (Fortaz)	6 g	150–200 mg/kg	8 h
Cefepime (Maxipime)	6 g	100–150 mg/kg	8 h
Meropenem (Merrem)	6 g	120 mg/kg	8 h
Nafcillin (Unipen)	12 g	200 mg/kg	4–6 h
Penicillin G	24 million U	250,000 units/kg	4 h
Vancomycin (Vancocin)	2 g	60 mg/kg	12 h

Adapted from Bradley JS, Nelson JD: 2002–2003 Nelson's Pocket Book of Pediatric Antimicrobial Therapy, 15th ed. Philadelphia, Lippincott Williams & Wilkins, 2002; Gilbert DN, Moellering RC, Sande MA. The Sanford Guide to Antimicrobial Therapy 2005. Hyde Park, Antimicrobial Therapy Inc., 2005.

mL) resistant to Penicillin G and ampicillin. Resistance to ceftriaxone (Rocephin) and cefotaxime (Claforan) may occur as well in 10% to 15% of strains. Vancomycin (Vancocin) is recommended in those regimens for meningitis when pneumococci are considered. However, higher maximal doses are required for vancomycin because of its relatively poor penetration into the CSF. In general, lumbar puncture with CSF culture should be repeated in 48 hours in those cases where vancomycin therapy is the primary drug because of demonstrated penicillin or cephalosporin resistance.

Meningitis caused by gram-negative bacilli such as *Pseudomonas aeruginosa*, *Escherichia coli*, or *Enterobacter cloacae* should be treated with a cephalosporin with an extended spectrum of Gram-negative activity, such as ceftazidime (Fortaz) or cefepime (Maxipime). A carbapenem, such as imipenem (Primaxin) or meropenem (Merrem), can also be used for antibiotic-resistant gram-negative enteric and pseudomonas meningitis. Meropenem is associated with less risk of drug-induced seizures and may be a better choice for bacterial meningitis.

Patients with ventriculoatrial and ventriculoperitoneal shunt-associated meningitis and ventriculitis usually require removal of the shunt for cure, as well as the administration of antibiotics to clear the infection. Certain patients with infections caused by organisms of reduced virulence, such as coagulase-negative staphylococci, or those with exquisitely antibiotic-susceptible infections, can be treated with a trial of antibiotics alone.

Because of the extreme sensitivity of *Neisseria meningitidis* to antibiotics, uncomplicated meningitis may be treated with as little as 5 to 7 days of antibiotics. Pneumococcal meningitis may be treated with 10 to 14 days of antibiotics, and haemophilus infections are treated successfully with 7 to 10 days of antibiotics. Gram-negative meningitis was treated in the past with 3 weeks of aminoglycosides, but current experience with newer extended-spectrum cephalosporins (ceftriaxone, cefotaxime, carbapenems) suggests that 2 weeks of therapy is often sufficient in neonates as well as in some elderly patients and postoperative infections.

All patients with bacterial meningitis should be monitored carefully throughout the treatment period. Infectious disease consultation is recommended for most infections of the central nervous system. Repeated lumbar punctures are not routinely recommended for patients with fully susceptible bacterial isolates or in those who show good response to therapy. Repeated sampling of the CSF with lumbar puncture or, when appropriate, shunt or ventricular reservoir puncture should be performed in those with known resistant bacterial isolates, in patients who have an inadequate response, in those patients who deteriorate on therapy, or in those for whom clinical response may correlate poorly with the microbiologic response (shunt infections, neonates, and elderly patients).

Adjunctive Therapy

Corticosteroids reduce the incidence of permanent neurologic sequelae in children with bacterial meningitis, particularly when caused by *Haemophilus influenza* type b. Data in support of steroids in either pneumococcal or meningococcal infections are less robust. Dexamethasone (Decadron¹), 0.15 mg/kg every 6 hours for the first 2 to 4 days of treatment, was evaluated in children older than 2 months with bacterial meningitis. The first dose of dexamethasone should be given before, at the start, or no later than 12 hours after beginning antibiotics.

Use of corticosteroids in adults is more controversial. Although doses of dexamethasone are recommended by some experts for adults with bacterial meningitis, its efficacy in adult meningitis has not been evaluated in a well-designed prospective trial. A recent study in adults found that corticosteroids significantly reduced the risk for unfavorable outcomes, particularly in patients with pneumococcal meningitis. There has been concern that the anti-inflammatory properties of dexamethasone may decrease the penetration of antibiotics, especially vancomycin, into the CSF. One study in children did not show this to be the case. Dexamethasone¹ should be administered in adults with proven or suspected pneumococcal meningitis, but only if it can be given prior to the first dose of antibiotics in a dose of 10 mg every 6 hours for 4 days. In patients with meningitis caused by *S. pneumoniae* highly resistant to penicillin (minimum inhibitory concentration [MIC] >2.0 µg/mL) or cephalosporins (MIC >4.0 µg/mL), vancomycin should not be used as a single agent if corticosteroids are used. The addition of rifampin (Rifadin¹) is often recommended in these situations.

Chemoprophylaxis for Bacterial Meningitis

Prophylactic antibiotics are recommended in case of meningitis caused by *Neisseria meningitidis* and *H. influenzae* type b. Prophylaxis is provided to eliminate the carriage of organisms among contacts and prevent spread to hosts susceptible to invasive disease. In cases of meningococcal meningitis, prophylaxis is indicated only for those with household or intimate contact with the index case. Administration of prophylaxis to large groups (e.g., college students, schoolchildren, or preschool classes) requires

a special assessment and a recommendation of local or regional health departments. Chemoprophylaxis is not necessary for casual contacts or medical personnel unless there is a direct exposure to respiratory secretions. The recommended dose of rifampin (Rifadin) is 10 mg/kg (600 maximal, adults) twice a day for 2 days; ciprofloxacin (Cipro¹), 500 mg as single dose, is also effective for adults. Third-generation cephalosporins used in treatment of the index case of meningitis are sufficient to eliminate carriage of the organism.

Chemoprophylaxis for *H. influenzae* type b is recommended for all household contacts of an index case if one of the contacts is an unvaccinated child younger than 4 years. If the index case is treated with ceftriaxone (Rocephin) or cefotaxime (Claforan), prophylaxis is not required, but if treated with ampicillin or chloramphenicol (Chloromycetin), prophylaxis is recommended to eliminate carriage. The recommended regimen for prophylaxis is rifampin,¹ 20 mg/kg (or 600 mg in adults) once a day for 4 days. With the near elimination of invasive infections caused by *H. influenzae* type b with the use of routine immunization of children with conjugate haemophilus vaccines, *H. influenzae* types A, F, and (rarely) other serotypes have emerged, and the use of prophylaxis is not recommended in these situations because sufficient data are not available to support its efficacy, nor has spread within contacts been documented.

Vaccines for Bacterial Meningitis

The universal recommendation for the use of protein-polysaccharide conjugate *H. influenzae* type b (HIB) vaccines in 1987 reduced the incidence of bacterial meningitis by this organism by greater than 97%. Three HIB vaccines (PedvaxHIB, ActHIB, HibTITER), licensed in the United States, are routinely given to children in dosage schedules employing three to four doses by 12 to 18 months of age (see www.cdc.gov).

A pneumococcal protein-polysaccharide conjugate vaccine (Prevnar) licensed in 2000 is routinely recommended for children and has markedly reduced the incidence of invasive infections with seven serotypes of pneumococci in children. This vaccine is also recommended for children at high risk of pneumococcal infections (e.g., HIV infection, asplenia, sickle cell disease, and others). A new Prevnar 13 with thirteen serotypes is now recommended to replace Prevnar 7 for routine use and is also recommended for persons over 50 years of age with high-risk conditions. The full recommendations for the use of this vaccine alone and in combination with the polysaccharide vaccine (Pneumovax 23) are available from the CDC. A pneumococcal polysaccharide vaccine (Pneumovax 23) is recommended for adults older than 65 years or for those over 50 years with risk factors (e.g., alcoholism, diabetes or other metabolic or renal disease, chronic pulmonary or cardiac disease). A polysaccharide conjugate vaccine (Prevnar) has been recently approved for limited adult use in high-risk patients; please see recommendations for use in adults and children at www.vaccines.gov. Although clear evidence for prevention of bacterial meningitis is lacking, evidence supports its efficacy against invasive pneumococcal diseases, many of which are the preceding infections leading to bacteremia and meningitis.

Three vaccines are available in the United States for prevention of meningococcal disease. All available vaccines provide protection against four serotypes: A, C, Y, and 1-135. Either of two protein-conjugate vaccines (Menactra and Menveo) are currently recommended for routine administration to all children at 11 to 12 years of age with a repeated dose at 5 years after the first dose. These vaccines are also recommended for persons at high risk for meningococcal disease (e.g., those with complement deficiencies, or asplenia, as well as microbiology technologists or travelers and workers in endemic areas) as early as 9 months of age, to be repeated at 12 months (Menactra) or equal to those who are 2 years of age or older (Menactra and Menveo) up to 55 years of age. It is recommended that younger patients at high risk be given a

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

two-dose primary series and that all high-risk persons be given a second dose at 3 to 5 years depending upon risk and age at first dose (see the package inserts for dosing details). In addition, a single polysaccharide vaccine (Menomune) remains available for high-risk persons over 55 years of age.

BRUCELLOSIS

Method of

Xinghong Yang, PhD

CURRENT DIAGNOSIS

- The diagnosis of brucellosis relies on the serologic reaction of antibodies to *Brucella*'s lipopolysaccharide (LPS) located on the cell surface of smooth *Brucella melitensis*, *Brucella abortus*, and *Brucella suis*.
- Although the rough species, *Brucella canis*, does not have an intact LPS layer, its detection requires the antigens specifically prepared from *B. canis*.
- Rose Bengal test is regularly used to diagnose infection with smooth *Brucella* spp.
- When patients with brucellosis symptoms test negative by Rose Bengal test, the microagglutination test and 2-mercaptoethanol rapid slide agglutination test are used to determine whether the patient is infected with rough *Brucella* spp.

CURRENT THERAPY

- Three aspects of therapy are critical when using antibiotics to treat brucellosis:
 - The antibiotics must be able to penetrate macrophages to take effect because *Brucella* spp. are intracellular pathogens and normally reside within professional and nonprofessional phagocytes.

- Multiple antibiotics are typically used to minimize relapses commonly seen when only a single antibiotic is used.
- In complicated cases, in addition to antibiotic treatment, surgical intervention may be required to remove infected tissues.

Brucellosis is an ancient disease recorded by the Romans more than 2000 years ago. Since *Brucella* was identified as the cause of brucellosis in sick soldiers in 1887 by Sir David Bruce, brucellosis has been defined as an emerging disease. *Brucella* is a zoonotic bacterial pathogen, causing approximately 500,000 new cases annually worldwide. Although rarely fatal (<5% mortality rate), it causes an undulating fever leading to a dramatic decrease in the quality of life. Its incubation time can vary between 1 and 8 weeks, and often infection is asymptomatic; however, serious complications can lead to disability or death. Because no human vaccine is available, antibiotic therapy is the only option for treatment.

A total of ten *Brucella* species have been identified to date (Table 1). Four of these—*Brucella melitensis*, *Brucella abortus*, *Brucella suis*, and *Brucella canis*—commonly cause human brucellosis, and their genomes have been sequenced.

Epidemiology

Wildlife and domesticated animals can serve as natural reservoirs for *Brucella* spp. Humans acquire brucellae by exposure to contaminated foods or aerosols or by direct contact. Often contaminated or unpasteurized animal products, such as milk, soft cheese, and butter are consumed, causing oral exposure. *Brucella* spp. can spread via contaminated aerosols or by aerosolization of contaminated animal by-products, resulting in lung infection. *Brucella* can also infect by direct contact of skin cuts or abrasions with sick animals or their products and enter into the blood or lymphatic system and, regardless of route, produce infection, causing a bacteremia. Among the three routes, food ingestion and aerosol inhalation can result in brucellosis. Aerosolized brucellae can be used as a bioweapon because the dosage required for infecting 50% of the population is as little as 1885 colony-forming units (CFUs).

Currently, brucellosis is endemic to Latin America, Africa, the Mediterranean rim, the Middle East, and Central Asia. To prevent human infection, animal immunization campaigns were adopted by many countries, including the United States and the former Soviet Union. The campaigns successfully curbed animal infection

*“Yes” and “no” mean *Brucella* spp. are able or unable to infect humans, respectively; “unknown” indicates that it is not confirmed whether *Brucella* spp. are able to infect humans.

and consequently reduced human infection in these areas. When the programs were stopped, the incidence of brucellosis rapidly increased. Thus maintenance of animal immunization programs is essential for protecting humans from infection.

Although transmission of brucellae among humans occurs rarely, several cases have been reported. It may be disseminated via sexual contact, milking, and organ transplantation. *B. melitensis* is the most commonly isolated species from brucellosis patients, followed in descending order by *B. abortus*, *B. suis*, and *B. canis*. *B. melitensis* and *B. abortus* can cause acute brucellosis and display the most severe symptoms, which can lead to complications. *B. suis* can cause extended duration of illness and results in suppurating lesions in infected tissues. Patients with *B. canis* infections display mild to moderate illness and rarely develop complications.

Risk Factors

The susceptible population includes those who live or travel in the endemic areas, particularly veterinarians, microbiologists, and those who work with or process livestock. The current animal vaccines are all infectious to human, and consequently veterinarians who administer these vaccines are at high risk for being infected. Microbiologists or laboratory workers also can acquire brucellosis through close contact, and indeed laboratory outbreaks are frequently reported. Thus *Brucella* is also considered an occupational disease or a laboratory-acquired disease.

Pathophysiology

Brucella can be phagocytized by nonprofessional and professional phagocytic cells to establish an intracellular replication niche. Once inside host cells, brucellae stay in early-formed phagosomes, where they prevent phagosomes from fusing with late-formed endosomes and lysosomes and survive intracellularly. Antibiotics must be able to penetrate the host cell membrane to kill brucellae or inhibit their growth.

Brucella uses numerous mechanisms to evade detection by the immune system. Unlike LPS from other gram-negative bacteria, *Brucella* LPS does not trigger an inflammatory response or activate the alternative complement system, so it helps brucellae avoid recognition. *Brucella*'s LPS endows brucellae with a phenotype highly resistant to cationic bactericidal peptides. The intracellular brucellae do not cause cell death in macrophages or apoptosis in respiratory epithelial cells. Thus the LPS reduces the chances of exposure to the immune system, which aids brucellae survival and meanwhile diminishes the stimulation of the host immune system. *Brucella* inhibits the macrophage response to interferon- γ (IFN- γ), a critical cytokine for stimulating innate and adaptive immunity. Additionally, to maintain vigorous intracellular survival and replication, brucellae equip their outer membranes with phosphatidylcholine and synthesize cyclic β -1,2-glucans to preclude fusion between phagosome and lysosome.

Diagnosis

Accurate diagnosis of brucellosis is always a challenge because brucellosis exhibits symptoms similar to numerous other febrile illnesses (Table 2). In many patients, the symptoms are mild and moderate; thus in a number of cases the diagnosis might not be even considered.

Isolation of brucellae from blood, bone marrow, urine, cerebrospinal fluid, or joint aspirate serves as the gold standard for diagnosing brucellosis. However, under many circumstances, brucellae cannot be cultured from patients' samples. The rate of blood culture positivity ranges from 16% to 90%. Hence, other indices are used to identify brucellosis. Testing for antibodies against *Brucella* is commonly used. *Brucella* agglutination titer of 1:160 is considered a clear diagnostic index as long as the patient presents signs and symptoms of the disease. Recommended tests are the Rose Bengal test, the serum agglutination test alone or with 2-mercaptoethanol or dithiothreitol reduction, Coombs' antiglobulin, the complement-fixation test, and the enzyme-linked immunosorbent assay (ELISA). The results of a combination of tests such as the serum agglutination test and Coombs' antiglobulin

can be used to assess the stage of evolution of the disease at the time of diagnosis. In the blood sample, infection may also be associated with low levels of red and white blood cells, low platelets, and elevated liver function. A biopsy of body tissues can also assist in making the diagnosis because patients can experience bone marrow hypoplasia or liver fibrosis and cirrhosis.

Depending on the patient's symptoms and severity of the illness, an investigation may be undertaken. Examinations may include computed tomography (CT) scan or magnetic resonance imaging (MRI) to identify signs of inflammation or abscesses in the brain or other tissues. Electrocardiogram (ECG) may be performed to investigate heart infection or damage, and x-rays can show bone and joint deformations.

Differential Diagnosis

Because human brucellosis mimics the symptoms of many other diseases, disease complications vary from patient to patient, and the latency time between exposure and the occurrence of symptoms is irregular and relatively long, making the differential diagnosis tedious and difficult. Therefore, before diagnosis, answers to three questions can help narrow the focus to brucellosis:

TABLE 3 Treatment for Brucellosis

MEDICATION	ADULT DOSAGE	DOSAGE ADJUSTMENT			ADVERSE EFFECTS
		PEDIATRIC DOSAGE	RENAL FAILURE	HEPATIC INSUFFICIENCY	
Doxycycline (Vibramycin)	100 mg PO q12h	2.2–4.4 mg/kg ³ PO div q12h (>8 y)	No change	No change	Dizziness, headache, photosensitivity, nausea, diarrhea, hemolytic anemia, hepatotoxicity
Rifampin (Rifadin) ¹	600–900 mg PO qd	20 mg/kg PO qd (do not exceed 600 mg qd)	No change	Moderate: caution Severe: avoid	Heartburn, epigastric distress, anorexia, nausea, flatulence, cramps, liver dysfunction, jaundice
Streptomycin	15 mg/kg IM q24h <i>or</i> 1 g IM qd × 2–3 wk	20–40 mg/kg IM qd (do not exceed 1 g/d)	Necessary	No change	Nausea, vomiting, vertigo, face paresthesias, rash, fever, urticaria, angioedema, eosinophilia

³Exceeds dosage recommended by the manufacturer.

- Did the patient have direct contact with large or small ruminants, their carcasses, or their products?
- Did the patient consume unpasteurized dairy products?
- Does the patient live in or travel to areas where brucellae are endemic in humans or epidemic in animals?

In spite of the difficulties in diagnosing brucellosis, some clinical features can still be used to distinguish brucellosis from other infectious diseases. If left untreated, fever of brucellosis displays an undulating pattern. In about 50% of patients, the fever of brucellosis is associated with musculoskeletal symptoms; however, these symptoms are rarely observed in typhoid and malaria fevers.

In patients with hepatosplenomegaly or lymphadenopathy, the differential diagnosis includes glandular fever-like illnesses, such as cytomegalovirus (CMV) infection, Epstein-Barr virus (EBV) infection, HIV infection, toxoplasmosis, and tuberculosis (TB). CMV patients can develop antibodies to the virus. Also, in the active infection phase, CMV can be detected from the blood, saliva, urine, or other body tissues. These indices can be used to differentiate CMV infection from the brucellosis. EBV patients have an elevated white blood cell count, an increased total number of lymphocytes, and greater than 10% atypical lymphocytes, but brucellosis patients usually show a decrease in the white blood cell count.

HIV infection can induce antibodies against HIV, and virologic tests can detect HIV antigens or RNA. HIV infection can be further confirmed by a supplemental antibody test, such as Western blot and indirect immunofluorescence assay. Brucellosis patients' sera do not display any reaction in these tests. For toxoplasmosis patients, serum immunoglobulin (Ig)G and IgM titers can be used to detect whether the patient is infected by *Toxoplasma*.

For TB patients, a skin test or a special TB blood test can be used for diagnosis, and other tests such as chest x-ray and a sample of sputum coughed up from deep in the lungs may be used for confirmation. In patients with osteomyelitis or septic arthritis, the most important alternative diagnosis is TB.

In patients with acute epididymo-orchitis, the differential diagnosis includes mumps and surgical problems, such as torsion. For mumps patients, buccal swab specimens are collected for viral detection via culturing virus in cell lines or using real-time polymerase chain reaction (RT-PCR) to detect mumps viral RNA. For testicular torsion in men, an ultrasound examination of the spermatic

cord can provide valuable information regarding whether the patient requires emergency surgery.

Treatment

To date, the only option for treating brucellosis is by means of antibiotics. However, in cases of complications, such as heart brucellosis and spinal brucellosis, antibiotic treatment in combination with surgical intervention may be needed. Antibiotics commonly used are doxycycline (Vibramycin), rifampin (Rifadin),¹ streptomycin, cotrimoxazole (TMP-SMX [Bactrim]),¹ and gentamicin (Garamycin)¹ (Table 3). Regimens of a combination of 2 or 3 antibiotics are recommended to reduce the unacceptably high relapse rates with monotherapy. Antibiotic regimens vary and depend on the patient's age, the severity of the disease, pregnancy, cost of the medicine, and availability of the medicine.

Doxycycline combined with rifampin¹ for a full 6-week course is a commonly used therapy recommended by the World Health Organization. It is considered the most effective regimen, particularly when combined with an aminoglycoside. In patients with spondylitis or sacroiliitis, doxycycline plus streptomycin is an effective combination. For pediatric patients older than 8 years, doxycycline plus gentamicin¹ is the recommended therapy. For children younger than 8 years, trimethoprim-sulfamethoxazole (TMP-SMX) therapy for 3 weeks followed by a 5-day course of gentamicin¹ is most effective. TMP-SMX¹ is also effective in treating pregnant women, either as a single agent or in combination with rifampin¹ or gentamicin¹ (see Table 3).

Once brucellosis is diagnosed, immediate therapy is critical because it can alleviate symptoms and also prevent the development of complications. Nevertheless, even when treatment is executed according to the doctor's prescription, rates of relapse can still reach up to 5% to 10%. Depending on the severity or complications of the illness and the treatment time applied, the recovery time can last from several weeks to several months.

Monitoring

After antibiotic therapy is initiated, patients are periodically monitored by doctors to evaluate whether the therapeutic regimen is

¹Not FDA approved for this indication.

effective and whether relapse occurs. Because relapse is indicated by the recurrence of a positive blood culture result during the post-therapy period or signs and symptoms of brucellosis infection, routine examination of the patient includes serum culture for *Brucella* organism and assessment for brucellosis symptoms after the treatment phase. In addition to monitoring brucellosis symptoms, both doctors and patients should monitor any adverse effects of medication. For instance, adverse reactions to TMP-SMX occur in 50% to 100% of patients with AIDS compared with about 14% of patients without AIDS. Up to 57% of AIDS patients treated with TMP-SMX¹ require a change in therapy owing to the adverse effects.

Generally, brucellosis patients should be followed up clinically for up to 2 years to detect relapse. Patients should be monitored for regaining of body weight. IgG antibody should be checked by serum agglutination test for levels that remain in the diagnostic range for more than 2 years. Complement fixation titers should fall to normal within 1 year of treatment. Relapse should respond to a prolonged course of the same therapy originally used.

Complications

Brucellae are transported into the lymphatic system and can replicate in spleen, liver, kidney, breast tissue, and joints to cause both localized and systemic infections. Infection of the reproductive system can cause fetal abortion. Owing to the low virulence, low toxicity, and multiple mechanisms to protect them from the immune system, brucellae can survive and reproduce in nearly any tissues or organs. At 1 year after infection, the disease can develop into chronic brucellosis that can further cause one or multiple complications in one organ or the whole body.

There are seven major types of complications from *Brucella* infection.

- Endocarditis: Brucellae can infect the heart's inner lining, which can destroy the heart valves and, if left untreated, will lead to death of the patient.
- Meningitis and encephalitis: Brucellae can infect the central nervous system to cause an inflammation of the brain, the membranes surrounding the brain, and the spinal cord. This is fatal if the patient is not treated in time.
- Arthritis: Osteoarthritis caused by *Brucella* infection is typically associated with pain, stiffness, and swelling of the joints, such as the knees, hips, ankles, wrists, spine, shoulder, elbow, sternoclavicular, and small joints. Spondylitis caused by brucellae is characterized by joint inflammation between the vertebrae bones of the spine or between the spine and pelvis. Spondylitis is difficult to treat and can cause lasting damage. These osteoarticular complications are the clinical forms most commonly observed.
- Epididymitis and epididymo-orchitis: Brucellae can infect the epididymis to cause swelling and pain of the testicle.
- Cutaneous complications: Brucellae can infect skin to cause lesions, rashes, nodules, erythema nodosum, papules, petechiae, and purpura.
- Respiratory complications: Inhalation of brucellae can result in lung infection, which can lead to pneumonia, bronchopneumonia, pleural effusion with a predominance of monocytic or lymphocytic infiltrates, and paroxysmal dry cough.
- Hematologic complications: Aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels can be elevated and are associated with pain in the right upper quadrant or jaundice.

Complications are common in brucellosis patients. Young patients tend to have cutaneous, hematologic, and respiratory complications. Adult patients tend toward osteoarticular and cardiac complications. Middle-aged patients tend to develop genitourinary, neurologic, and gastrointestinal complications.

Prevention

Maintaining hygienic habits is very important for avoiding *Brucella* infection. These include consuming only pasteurized milk

and cheese. Meat must be cooked thoroughly before consumption. In these regards, education is beneficial for preventing infection by this pathogen. People who handle animals or animal products should wear personal protective equipment, including glasses, rubber gloves, and clothing to protect skin and eyes from exposure or direct contact. Laboratory workers should use a Biosafety Level 3 (BSL-3) facility to handle the *Brucella* organisms and work according to the laboratory's standard operating procedures. Animal immunization programs must be maintained all over the world to cut off the transmission chain from livestock to humans. In addition, primary care physicians should be familiar with the clinical and laboratory findings of brucellosis symptoms and complications.

CAMPYLOBACTER

Method of

Gregory Juckett, MD, MPH

CURRENT DIAGNOSIS

- *Campylobacter jejuni* and *Campylobacter coli* are the leading causes of childhood and traveler's diarrhea worldwide.
- Raw or undercooked poultry (or cross-contamination with poultry juices) is the best-known source of infection.
- Infection is characterized by abrupt onset of crampy abdominal pain, nausea, and profuse diarrhea or dysentery.
- A prodrome of high fever and myalgias precedes diarrheal illness in one third of cases.
- *Campylobacter* gastroenteritis can mimic acute appendicitis and inflammatory bowel disease.
- Late complications of *Campylobacter* infection include reactive arthritis and Guillain-Barré syndrome 1 to 2 weeks after diarrhea.

CURRENT THERAPY

- Antibiotics are not essential for most healthy patients because the illness is self-limited.
- Azithromycin (Zithromax)¹ 500 mg daily × 3 days (pediatric dosage, 10 mg/kg/day) is effective if given early in the course (less than 5% resistance).

¹Not FDA approved for this indication.

effective and whether relapse occurs. Because relapse is indicated by the recurrence of a positive blood culture result during the post-therapy period or signs and symptoms of brucellosis infection, routine examination of the patient includes serum culture for *Brucella* organism and assessment for brucellosis symptoms after the treatment phase. In addition to monitoring brucellosis symptoms, both doctors and patients should monitor any adverse effects of medication. For instance, adverse reactions to TMP-SMX occur in 50% to 100% of patients with AIDS compared with about 14% of patients without AIDS. CAMPYLOBACTER

Method of

Gregory Juckett, MD, MPH

CURRENT DIAGNOSIS

- *Campylobacter jejuni* and *Campylobacter coli* are the leading causes of childhood and traveler's diarrhea worldwide.
- Raw or undercooked poultry (or cross-contamination with poultry juices) is the best-known source of infection.
- Infection is characterized by abrupt onset of crampy abdominal pain, nausea, and profuse diarrhea or dysentery.
- A prodrome of high fever and myalgias precedes diarrheal illness in one third of cases.
- *Campylobacter* gastroenteritis can mimic acute appendicitis and inflammatory bowel disease.
- Late complications of *Campylobacter* infection include reactive arthritis and Guillain-Barré syndrome 1 to 2 weeks after diarrhea.

CURRENT THERAPY

- Antibiotics are not essential for most healthy patients because the illness is self-limited.
- Azithromycin (Zithromax)¹ 500 mg daily × 3 days (pediatric dosage, 10 mg/kg/day) is effective if given early in the course (less than 5% resistance).

¹Not FDA approved for this indication.

- Quinolone antibiotics have been effective, but resistance is developing, particularly in South and Southeast Asia owing to the use of quinolones in poultry feed.
- Prevention entails reducing *Campylobacter* colonization of poultry and using proper food-handling techniques. Vaccination may be possible in the future.

¹Not FDA approved for this indication.

Epidemiology

Campylobacter enteritis is one of the most common forms of bacterial diarrhea in the world and the most common food-related illness in North America. Most cases (95%) are caused by *Campylobacter jejuni*, a commensal gram-negative bacteria found in the gut of animals, particularly poultry. The related *Campylobacter coli* causes a clinically identical but much less common (5%) infection. Children in developing countries are usually infected before age 2 years.

Foodborne outbreaks affect adults in developed countries, as well as travelers to developing nations. *Campylobacter* is a common cause of traveler's diarrhea, and 13% of US *Campylobacter* infections are acquired abroad. Most infections are due to cross-contamination of food with raw poultry (unwashed cutting boards) or from drinking unpasteurized milk or contaminated water. Infections increase in spring and peak during the summer months. The typical incubation period is 3 to 4 days (range, 1–8 days), with the illness lasting up to a week. After recovery, the bacteria are excreted in the feces for several weeks and may be transmitted by improper hand washing, although person-to-person transmission is unusual.

Risk Factors

Anyone exposed to improperly prepared food, unpasteurized milk, or unchlorinated water is at risk. Improperly cooked poultry or food contaminated by raw poultry is the most common source. Contact with infected pets is a common cause of childhood exposure. A 17-state outbreak of multidrug-resistant *Campylobacter* was linked to pet store puppies in 2017. (Reference www.cdc.gov/Campylobacter/outbreaks/puppies-9-17/index.html posted 1/30/18 (accessed 2/13/18). Elderly, immunocompromised, or very young patients are at additional risk for prolonged symptoms, invasive disease, and hospitalization. Proton-pump inhibitors, by reducing protective stomach acid, appear to increase the risk of campylobacteriosis and other bacterial enteritides.

Pathophysiology

Campylobacter infection starts in the small intestine (jejunum, ileum) and spreads to the colon. Symptoms can begin with enteritis (profuse watery stools) or with frank colitis (bloody stools). Colitis thus can mimic inflammatory bowel disease or appendicitis. Inflammatory bowel disease may be excluded by colon biopsies, which demonstrate acute but not chronic inflammatory change.

Prevention

Proper food-handling techniques are the best means of prevention. Poultry products should be cooked until an internal temperature of 165° F is reached and all juices run clear. Hands must be washed with soap after contact with raw poultry or animal feces and after using the rest room. Cross-contamination should be avoided by careful disinfection of countertops and utensils after preparing meats or, better yet, using entirely separate surfaces. Only one drop of poultry juice (<500 organisms) is sufficient to cause disease. Although not currently feasible, *Campylobacter* vaccination has been proposed for prevention.

Clinical Manifestations

Campylobacter enteritis typically manifests as sudden onset of cramping, nausea, vomiting, and diarrhea, often indistinguishable from other bacterial diarrheas. Most cases are self-limited, with recovery in 3 to 4 days. About a third of patients experience a febrile

prodrome, with myalgias occurring for about a day before onset of diarrheal illness. Dysenteric (bloody) stools are common (15%) and imply more-invasive disease. Like *Yersinia*, *Campylobacter* infection can mimic acute appendicitis (ileocecalitis), especially if this occurs in the absence of significant diarrhea. Computed tomography or ultrasound scanning in bacterial pseudoappendicitis usually documents mesenteric adenitis, and surgery can be avoided. In young children, seizures can occur before the onset of diarrhea and fever, and dysenteric illness (50%) is more common.

Diagnosis

Most cases are diagnosed by stool culture in the setting of acute diarrhea and crampy abdominal pain. On microscopic examination, *C. jejuni* is a gram-negative, spiral-shaped rod with a single polar flagellum at one or both ends. It can be isolated in culture media containing cephalothin, to which it is usually resistant. Darkfield microscopic stool examination is occasionally attempted for early diagnosis, but this is not very sensitive. Polymerase chain reaction analysis of stool samples is a very promising diagnostic approach, although it is not yet available in many laboratories. Later diagnosis, subsequent to resolution of diarrhea, requires serologic testing.

Differential Diagnosis

Campylobacter infections are clinically indistinguishable from other bacterial enteritides such as salmonellosis and shigellosis. All of these produce fever, cramps, diarrhea, and dysentery. However, *Campylobacter* colitis is more likely to mimic inflammatory bowel disease and appendicitis and later to cause Guillain-Barré syndrome.

Treatment

Most cases of *Campylobacter* infection are mild and self-limited, and antibiotics are not required. If antibiotics are to be used, they are most effective if given early to high-risk patients, because delayed treatment (e.g., after positive stool culture results) is less likely to affect outcome. First-line choices include macrolides, such as azithromycin (<5% resistance), or fluoroquinolones, such as ciprofloxacin (Cipro). Azithromycin (Zithromax)¹ is preferred for traveler's diarrhea acquired in South and Southeast Asia, where quinolone-resistant *Campylobacter* is common. Azithromycin has supplanted erythromycin (Ery-Tab)¹ because it is better tolerated and has fewer gastrointestinal side effects. Rarely, intravenous aminoglycosides or carbapenems are necessary in very ill patients unable to take oral medication.

Unfortunately, quinolone resistance is not limited to Asia. Resistance has also increased in the United States. The widespread practice of using antibiotics, especially fluoroquinolones (enrofloxacin [Baytril]),² as additives to chicken feed has resulted in increasing quinolone resistance in *Campylobacter* strains found in poultry, the major source of infection. The Foodborne Diseases Active Surveillance Network (FoodNet) of the Centers for Disease Control and Prevention (CDC) found that 40% of US poultry products were contaminated with *Campylobacter*, and 10% of these strains were ciprofloxacin resistant. Although fluoroquinolones were removed from US animal feed in 2005, they continue to be used overseas. A newer strategy involves supplementing poultry feed with bacteriocins, nontoxic antimicrobial peptides, to reduce *Campylobacter* colonization. Irradiation of poultry meat might also be effective.

Empiric self-treatment of traveler's diarrhea is intended to shorten the duration of symptoms and involves immediate ciprofloxacin (Cipro) or azithromycin (Zithromax)¹ at the onset of diarrheal illness. One or two doses of antibiotics are usually sufficient to abort symptoms, and prolonged treatment is usually unnecessary. Loperamide (Imodium) might help control diarrhea in adults, but it should be avoided in dysenteric illness and in young children.

¹Not FDA approved for this indication.

²Not available in the United States.

BOX 1 Acute and Chronic *Campylobacter* Complications**Acute Complications**

Acute colitis, dysentery
Cholecystitis
Pseudoappendicitis (mesenteric adenitis)
Peritonitis
Pericarditis (chest pain)
Postinfectious irritable bowel syndrome

Chronic Complications

Inflammatory bowel disease (possible contributor)
Guillain-Barré syndrome (1:1000 cases)
Reactive arthritis

Complications

Campylobacter complications can occur either acutely or after the illness. Acute complications include cholecystitis, pseudoappendicitis, peritonitis, sepsis, and chest pain (pericarditis) (Box 1). Rashes, such as vasculitis or erythema nodosum, can occur. Rarely, focal extraintestinal infections such as septic arthritis or osteitis develop. Childhood complications include meningitis and encephalopathy, and dysenteric illness in infants occasionally mimics intussusception. *Campylobacter* can provoke postinfectious irritable bowel syndrome and is suspected of contributing to inflammatory bowel disease by damaging the intestinal epithelium, leading to chronic inflammation.

Late-term complications include Guillain-Barré syndrome and reactive arthritis. About 1 in 1000 *Campylobacter* infections is complicated by Guillain-Barré syndrome, which occurs several weeks after infection and carries a worse prognosis when associated with *Campylobacter*. As much as 30% to 40% of all Guillain-Barré syndrome has been attributed to *Campylobacter* infection, and even subclinical cases have been associated by later serologic testing.

Reactive arthritis after *Campylobacter* infection is common and also appears unrelated to the severity of the preceding diarrhea. Swelling and arthralgia in the hands, wrists, knees, or ankles develops 1 to 2 weeks after diarrhea and can persist for weeks to months. Nonsteroidal antiinflammatory drugs are usually helpful, and complete recovery is the rule.

CAT SCRATCH DISEASE

Method of

Ronen Ben-Ami, MD

**CURRENT DIAGNOSIS**

- The combination of a compatible clinical syndrome of regional lymphadenopathy with a primary inoculation lesion and cat contact is highly suggestive of cat scratch disease.
- Results of *Bartonella henselae* serology are helpful in confirming the diagnosis; however, up to 20% of patients remain seronegative throughout their disease.
- Detection of *B. henselae* DNA by polymerase chain reaction from pus obtained by needle aspiration or lymph node biopsy is a highly sensitive diagnostic modality and may be particularly useful in seronegative patients.

**CURRENT THERAPY**

- Typical cat scratch disease is a self-limited disease; therefore systemic antimicrobials are not routinely indicated in immunocompetent patients with uncomplicated cat scratch disease.
- Indications for antimicrobial therapy include an immunocompromised host, endocarditis, retinitis, and other atypical syndromes.
- Treatment may also be considered for patients who have typical cat scratch disease and who have extensive or bulky lymphadenopathy and are highly symptomatic.
- Suppurative lymph nodes should be drained by large-bore needle aspiration.

Cat scratch disease is a worldwide zoonotic infection caused by *Bartonella henselae*, an intracellular, pleomorphic, gram-negative bacillus. Other *Bartonella* species have rarely been implicated. The disease typically manifests as benign regional lymphadenopathy, but atypical disease can involve almost any organ system and is associated with significant morbidity.

Epidemiology

B. henselae infection is widespread among domestic cats and other felids worldwide, and serologic studies indicate a higher prevalence in warm, humid climates. Transmission among cats occurs via an arthropod vector, the cat flea *Ctenocephalides felis*. *B. henselae* bacteremia is detected at higher rates in feral than in domesticated cats and in kittens as compared to adult cats, explaining the higher infectivity of these animals. Cats infected with *B. henselae* are asymptomatic. Transmission to humans occurs via a scratch, bite, or lick; contamination of cat scratches by flea feces may enhance *Bartonella* transmission.

Cat scratch disease has been estimated to occur in the United States at a rate approaching 10 per 100,000 population. There is some seasonality, with incidence peaking between September and January. Although traditionally considered a disease of childhood, epidemiologic surveys have found a similar incidence of cat scratch disease in adults, and 6% of patients are aged 60 years or older. Cat contact is the most important risk factor: Almost all patients are cat owners or were otherwise exposed to cats, and about half can recall a recent bite or scratch, most commonly by a kitten.

Clinical Manifestations

Cat scratch disease is divided into two clinical syndromes. Typical cat scratch disease is a subacute, self-limited regional lymphadenopathy and constitutes 80% to 90% of cases. Atypical cat scratch disease encompasses Parinaud's oculoglandular syndrome and other clinical entities with systemic extranodal involvement.

BOX 1 Acute and Chronic *Campylobacter* Complications**Acute Complications**

Acute colitis, dysentery
Cholecystitis
Pseudoappendicitis (mesenteric adenitis)
Peritonitis
Pericarditis (chest pain)
Postinfectious irritable bowel syndrome

Chronic Complications

Inflammatory bowel disease (possible contributor)
Guillain-Barré syndrome (1:1000 cases)
Reactive arthritis

Complications

Campylobacter complications can occur either acutely or after the illness. Acute complications include cholecystitis, pseudoappendicitis, peritonitis, sepsis, and chest pain (pericarditis) (Box 1). Rashes, such as vasculitis or erythema nodosum, can occur. Rarely, focal extraintestinal infections such as septic arthritis or osteitis develop. Childhood complications include meningitis and encephalopathy, and dysenteric illness in infants occasionally mimics intussusception. *Campylobacter* can provoke postinfectious irritable bowel syndrome and is suspected of contributing to inflammatory bowel disease by damaging the intestinal epithelium, leading to chronic inflammation.

Late-term complications include Guillain-Barré syndrome and reactive arthritis. About 1 in 1000 *Campylobacter* infections is complicated by Guillain-Barré syndrome, which occurs several weeks after infection and carries a worse prognosis when associated with *Campylobacter*. As much as 30% to 40% of all Guillain-Barré syndrome has been attributed to *Campylobacter* infection, and even subclinical cases have been associated by later serologic testing.

Reactive arthritis after *Campylobacter* infection is common and also appears unrelated to the severity of the preceding diarrhea. Swelling and arthralgia in the hands, wrists, knees, or ankles develops 1 to 2 weeks after diarrhea and can persist for weeks to months. Nonsteroidal antiinflammatory drugs are usually helpful, and complete recovery is the rule.

CAT SCRATCH DISEASE

Method of

Ronen Ben-Ami, MD

**CURRENT DIAGNOSIS**

- The combination of a compatible clinical syndrome of regional lymphadenopathy with a primary inoculation lesion and cat contact is highly suggestive of cat scratch disease.
- Results of *Bartonella henselae* serology are helpful in confirming the diagnosis; however, up to 20% of patients remain seronegative throughout their disease.
- Detection of *B. henselae* DNA by polymerase chain reaction from pus obtained by needle aspiration or lymph node biopsy is a highly sensitive diagnostic modality and may be particularly useful in seronegative patients.

**CURRENT THERAPY**

- Typical cat scratch disease is a self-limited disease; therefore systemic antimicrobials are not routinely indicated in immunocompetent patients with uncomplicated cat scratch disease.
- Indications for antimicrobial therapy include an immunocompromised host, endocarditis, retinitis, and other atypical syndromes.
- Treatment may also be considered for patients who have typical cat scratch disease and who have extensive or bulky lymphadenopathy and are highly symptomatic.
- Suppurative lymph nodes should be drained by large-bore needle aspiration.

Cat scratch disease is a worldwide zoonotic infection caused by *Bartonella henselae*, an intracellular, pleomorphic, gram-negative bacillus. Other *Bartonella* species have rarely been implicated. The disease typically manifests as benign regional lymphadenopathy, but atypical disease can involve almost any organ system and is associated with significant morbidity.

Epidemiology

B. henselae infection is widespread among domestic cats and other felids worldwide, and serologic studies indicate a higher prevalence in warm, humid climates. Transmission among cats occurs via an arthropod vector, the cat flea *Ctenocephalides felis*. *B. henselae* bacteremia is detected at higher rates in feral than in domesticated cats and in kittens as compared to adult cats, explaining the higher infectivity of these animals. Cats infected with *B. henselae* are asymptomatic. Transmission to humans occurs via a scratch, bite, or lick; contamination of cat scratches by flea feces may enhance *Bartonella* transmission.

Cat scratch disease has been estimated to occur in the United States at a rate approaching 10 per 100,000 population. There is some seasonality, with incidence peaking between September and January. Although traditionally considered a disease of childhood, epidemiologic surveys have found a similar incidence of cat scratch disease in adults, and 6% of patients are aged 60 years or older. Cat contact is the most important risk factor: Almost all patients are cat owners or were otherwise exposed to cats, and about half can recall a recent bite or scratch, most commonly by a kitten.

Clinical Manifestations

Cat scratch disease is divided into two clinical syndromes. Typical cat scratch disease is a subacute, self-limited regional lymphadenopathy and constitutes 80% to 90% of cases. Atypical cat scratch disease encompasses Parinaud's oculoglandular syndrome and other clinical entities with systemic extranodal involvement.

Bacillary angiomatosis and bacillary peliosis are manifestations of *B. henselae* infection in immunocompromised persons and are not discussed here.

Typical Cat Scratch Disease

A primary skin lesion, usually a papule or pustule, appears at the site of inoculation 3 to 10 days after cat contact and persists for 1 to 3 weeks. Regional lymphadenopathy develops within 1 to 7 weeks and resolves spontaneously after 2 to 4 months. The primary lesion is still present in about two thirds of patients when they present for evaluation of lymphadenopathy. The most commonly involved lymph nodes are, in descending order of frequency, axillary and epitrochlear nodes, head and neck nodes, and femoral and inguinal nodes. One third of patients develop lymphadenopathy at multiple sites. Lymph nodes are often painful and red; suppuration occurs in 10% of nodes. Mild constitutional symptoms, including low-grade fever and malaise, are noted in about half the cases. Rash, night sweats, anorexia, and weight loss are uncommon. Infection results in lifelong immunity.

Atypical Cat Scratch Disease

Parinaud's oculoglandular syndrome, the most common form of atypical cat scratch disease, is a specific type of regional lymphadenopathy that occurs following conjunctival inoculation of *B. henselae*. The syndrome includes granulomatous conjunctivitis and preauricular lymphadenopathy. Endocarditis and encephalitis represent severe forms of *B. henselae* infection and are more common in elderly patients. Encephalitis manifests with various degrees of altered mental status, agitation, headache, and seizures. Cerebrospinal fluid lymphocytic pleocytosis occurs in only one third of cases, and brain-imaging studies usually fail to show any abnormalities. Neuroretinitis manifests as sudden unilateral loss of visual acuity. The diagnosis is suspected on the basis of typical findings on fundoscopic examination: papilledema and macular exudates in a starlike configuration. However, these findings are not pathognomonic of cat scratch disease. Other infrequent manifestations are self-limited granulomatous hepatitis and splenitis and osteoarticular disease. Prolonged fever of unknown origin has been described in children and adolescents.

Diagnosis

A compatible clinical syndrome in a person with a positive history of cat exposure suggests cat scratch disease. The diagnosis is most commonly confirmed with specific serologic assays. Immunofluorescence and enzyme immunoassays are comparably sensitive, although cross-reactivity can occur with other organisms such as *Chlamydia* species, *Coxiella burnetii*, and non-*henselae* *Bartonella* species. A single elevated titer of immunoglobulin (Ig)M or IgG in the acute phase or a fourfold increase of IgG in convalescent serum supports the diagnosis.

Biopsy and histopathologic examination of lymph nodes are usually only performed when malignancy is suspected. Necrotizing granulomas are typically observed. The pleomorphic gram-negative bacilli are best visualized with the Warthin-Starry stain; however, the sensitivity of this method is too low to be clinically useful. Similarly, culture lacks sensitivity and requires prolonged incubation, making it impractical for routine use.

Polymerase chain reaction assays for the detection of *B. henselae* in pus aspirated from suppurative lymph nodes or primary skin lesions is highly sensitive and specific, and it can be performed with a rapid turnaround time. However, these assays are not widely available in most clinical microbiology laboratories.

Differential Diagnosis

Cat scratch disease should be differentiated from other infectious and noninfectious causes of regional lymphadenopathy. Importantly, lymphoma and solid tumors with metastases to lymph nodes may be confused with cat scratch disease. Malignancy should be suspected in patients who have marked constitutional symptoms, who are seronegative, or whose lymphadenopathy fails to resolve spontaneously after more than 6 months. Unlike cat scratch disease, pyogenic lymphadenitis manifests with rapid progression, high-grade fever, and a septic-appearing patient. Mycobacterial infection, syphilis, bubonic plague, tularemia, histoplasmosis, and sporotrichosis should be considered based on the presence of specific risk factors and endemic exposures. *Bartonella* endocarditis must be differentiated from other causes of culture-negative endocarditis, specifically Q fever and brucellosis.

Treatment

Because of the self-limiting course of typical cat scratch disease, patients usually only require observation and reassurance of its benign nature. The goals of therapy are alleviation of symptoms in patients with bulky lymphadenopathy and drainage of suppurating lymph nodes to prevent spontaneous formation of chronic sinus tracts. If drug treatment is initiated, azithromycin (Zithromax)¹ is the agent of choice based on a small randomized placebo-controlled study that showed more-rapid resolution of lymphadenopathy in the azithromycin arm as determined by ultrasound. Suppurative nodes should be drained by large-bore needle aspiration. Incisional drainage is best avoided because it can promote sinus tract formation.

Atypical cat scratch disease syndromes usually require treatment, but there are scant data to support specific regimens, and treatment duration is not well defined. For patients with endocarditis, treatment with an aminoglycoside for at least 14 days is associated with a higher likelihood of recovery and survival (Table 1).

¹Not FDA approved for this indication.

TABLE 1 Antibiotic Treatment Regimens for Cat Scratch Disease

CLINICAL SYNDROME	FIRST CHOICE	SECOND CHOICE	COMMENTS
Typical cat scratch disease	Not indicated*	Azithromycin (Zithromax) ¹ 500 mg PO on day 1, then 250 mg PO × 4 days	Drain suppurative nodes using large-bore aspiration
Endocarditis	Gentamicin (Garamycin) ¹ 1 mg/kg IV q8h × >14 days plus doxycycline (Vibramycin) 100 mg IV/PO bid × 6 wk	Doxycycline 100 mg PO bid plus rifampicin (Rifadin) ¹ 300 mg PO bid × 6 wk	Some experts recommend extending oral doxycycline treatment × 3–6 mo Surgical valve excision may be required
Neuroretinitis	Doxycycline 100 mg PO bid plus rifampicin ¹ 300 mg PO bid × 4–6 wk	NA	Spontaneous resolution is the rule; the utility of treatment remains unproven
Other atypical cat scratch disease	As for neuroretinitis	NA	Treatment duration should be individualized

¹Not FDA approved for this indication.

*Treatment may be considered for patients with bulky or extensive lymphadenopathy and for immunocompromised patients.

Abbreviation: NA = not available.

Prevention

Flea control in domestic cats can reduce the likelihood of *Bartonella* bacteremia and transmission to humans. Bites and scratches should be promptly rinsed. HIV-infected patients and other immunocompromised persons should be cautioned about the risks of cat exposure because they are susceptible to disseminated visceral *B. henselae* infection, as well as other zoonotic infections such as toxoplasmosis.

CHIKUNGUNYA

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

CURRENT DIAGNOSIS

- Clinically, chikungunya is a diagnosis of exclusion, particularly when laboratory testing is not available. Accurate diagnosis depends on the patient's clinical symptoms and the epidemiology of endemic disease.
- Acute symptoms include incapacitating relapsing bilateral symmetrical polyarthralgia accompanied by high fever, headache, backache, and fatigue. Some may have a pruritic maculopapular rash at onset.
- Chronic symptoms include episodic incapacitating symmetrical polyarthralgia. Many have long-term asthenia and depression.
- Virus isolation provides definitive diagnosis.
- Immunoglobulin M antibody levels peak 3 to 5 weeks after the onset of illness and persist for approximately 2 months.
- Paired acute-phase and convalescent-phase antibody sampling may be required for diagnosis.

CURRENT THERAPY

- Medical treatment if primarily supportive.

The word “chikungunya” is a derivation of the Kimakonde (a Mozambique dialect) word “kungunyala” meaning “to become desiccated or contorted.” In the Democratic Republic of the Congo, it is called “buka-buka,” translated as “broken-broken,” reflecting the incapacitating arthralgias that are common manifestations of Chikungunya fever.

Epidemiology

Chikungunya, first diagnosed in Tanganyika in 1952, is found in a large percentage of countries in Africa, Asia, and Southeast Asia

and is prevalent in India. Dense human populations and lack of herd immunity likely contribute to the explosive nature of chikungunya epidemics in many regions. In India during 2006, more than 1,500,000 cases of chikungunya were reported, with *Aedes aegypti* implicated as the vector. Prior to 2006, chikungunya virus disease was rarely identified in travelers returning to the United States. From 2006 to 2013, an average of 28 people per year in the United States tested positive for recent chikungunya virus infection. During 2014, there was a large uptick in chikungunya, with 2811 cases reported, with all but 12 infections acquired outside of the continental United States. These 12 cases were locally transmitted in Florida. In 2015, 895 cases were reported, with only one locally transmitted in Texas. In 2016, the case reports dropped to 249, all in returning travelers, and in 2017 there were 114 chikungunya virus disease cases reported from 26 states, all occurring in travelers returning from affected areas. No locally transmitted cases have been reported in the United States since 2015.

It is believed that chikungunya virus originated in Africa and migrated to Asia 200 years ago. Evidence derived from molecular genetics suggests it evolved around 1700; the first recorded outbreak of this disease was probably in 1779.

Interestingly, some medical historians believe that a pandemic of chikungunya occurred in the western hemisphere in the 1800s but was diagnosed as dengue fever. The 21st-century researchers who have examined the accounts of this pandemic now speculate that it was caused by chikungunya because the cases exhibited severe joint arthritis, which is more indicative of chikungunya than dengue. The virus then disappeared from the Americas until it reemerged during the last decade. Chikungunya epidemics appear suddenly and unpredictably and proceed explosively.

Risk factors

Individuals at the highest risk of contracting chikungunya and enduring more-severe symptoms are those who have chronic arthritis, underlying chronic medical conditions, those over the age of 65, and pregnant women. Travelers who spend extended periods of time in endemic areas are at greater risk. These include missionaries, humanitarian aid workers, and those who frequently work outdoors. Mother-to-child transmission of chikungunya virus is frequent in the event of intrapartum maternal viremia and can often lead to severe neonatal complications.

Pathophysiology

Chikungunya is an arthropod transmitted disease caused by a single-stranded RNA arbovirus. As with dengue fever and yellow fever, chikungunya cycles from mosquito to human to mosquito. The mosquito *Aedes aegypti* is the usual vector for transmission of chikungunya. *Aedes albopictus*, the Asian tiger mosquito, is also a vector. Both species are found in the southeastern United States and limited parts of the southwest. The *Aedes albopictus* species survives further north into the Mid-Atlantic states and into the lower Midwest. The risk of person-to-mosquito transmission is highest during the viremic first week of illness. Birds, cattle, monkeys, and other vertebrates may serve as reservoirs. Chikungunya can be transmitted during childbirth, but there are no reported cases of transmission during breastfeeding. Theoretically, chikungunya can be transferred via blood transfusion, but there have been no reported cases. Previous infection will convey permanent immunity.

Prevention

There is no current vaccine. The best preventive measures are wearing permethrin-treated, bite-proof long sleeves and trousers and using a mosquito repellent such as 30% DEET, 20% oil of lemon eucalyptus, or 30% picaridin. Screening windows and doors has only a limited effect, because most contacts between the *Aedes* mosquitoes and humans occur outside.

Standing water, a breeding ground for mosquitoes, should be drained. *Aedes aegypti* breeding sites are associated with human habitation and are seemingly innocuous (i.e., flower vases, water storage vessels and birdbaths). Customary blood handling procedures are recommended.

Prevention

Flea control in domestic cats can reduce the likelihood of *Bartonella* bacteremia and transmission to humans. Bites and scratches should be promptly rinsed. HIV-infected patients and other immunocompromised persons should be cautioned about the risks of cat exposure because they are susceptible to disseminated visceral *B. henselae* infection, as well as other zoonotic infections such as toxoplasmosis.

It is believed that chikungunya virus originated in Africa and migrated to Asia 200 years ago. Evidence derived from molecular genetics suggests it evolved around 1700; the first recorded outbreak of this disease was probably in 1779.

Interestingly, some medical historians believe that a pandemic of chikungunya occurred in the western hemisphere in the 1800s but was diagnosed as dengue fever. The 21st-century researchers who have examined the accounts of this pandemic now speculate that it was caused by chikungunya because the cases exhibited severe joint arthritis, which is more indicative of chikungunya than dengue. The virus then disappeared from the Americas until it reemerged during the last decade. Chikungunya epidemics appear suddenly and unpredictably and proceed explosively.

Risk factors

Individuals at the highest risk of contracting chikungunya and enduring more-severe symptoms are those who have chronic arthritis, underlying chronic medical conditions, those over the age of 65, and pregnant women. Travelers who spend extended periods of time in endemic areas are at greater risk. These include missionaries, humanitarian aid workers, and those who frequently work outdoors. Mother-to-child transmission of chikungunya virus is frequent in the event of intrapartum maternal viremia and can often lead to severe neonatal complications.

Pathophysiology

Chikungunya is an arthropod transmitted disease caused by a single-stranded RNA arbovirus. As with dengue fever and yellow fever, chikungunya cycles from mosquito to human to mosquito. The mosquito *Aedes aegypti* is the usual vector for transmission of chikungunya. *Aedes albopictus*, the Asian tiger mosquito, is also a vector. Both species are found in the southeastern United States and limited parts of the southwest. The *Aedes albopictus* species survives further north into the Mid-Atlantic states and into the lower Midwest. The risk of person-to-mosquito transmission is highest during the viremic first week of illness. Birds, cattle, monkeys, and other vertebrates may serve as reservoirs. Chikungunya can be transmitted during childbirth, but there are no reported cases of transmission during breastfeeding. Theoretically, chikungunya can be transferred via blood transfusion, but there have been no reported cases. Previous infection will convey permanent immunity.

Prevention

There is no current vaccine. The best preventive measures are wearing permethrin-treated, bite-proof long sleeves and trousers and using a mosquito repellent such as 30% DEET, 20% oil of lemon eucalyptus, or 30% picaridin. Screening windows and doors has only a limited effect, because most contacts between the *Aedes* mosquitoes and humans occur outside.

Standing water, a breeding ground for mosquitoes, should be drained. *Aedes aegypti* breeding sites are associated with human habitation and are seemingly innocuous (i.e., flower vases, water storage vessels and birdbaths). Customary blood handling procedures are recommended.

If a Chikungunya epidemic were to occur in the United States, the standard public health measures of avoidance and mosquito control would be major lines of defense. To prevent local spread, the patient diagnosed with chikungunya should use mosquito repellent for 1 week after onset of fever.

Clinical Manifestations

Chikungunya virus infection should be considered in patients with acute onset of fever and polyarthralgia, especially in travelers who have recently returned from areas with endemic chikungunya. The incubation period of the chikungunya virus ranges from 1 to 12 days, most typically 3 to 7 days, 72% to 97% of those infected develop symptoms. Clinical onset is abrupt. The hallmarks of chikungunya are erratic, relapsing, and incapacitating polyarthralgia accompanied by high fever, backache, headache, and fatigue. Polyarthralgia is reported in 87% to 98% of cases and represents the most characteristic symptom. The joint pain is mostly polyarticular, bilateral, and symmetrical and occurs mainly in peripheral joints (wrists, ankles, and phalanges) and some large joints (shoulders, elbows and knees). Joint swelling is less frequent, occurring in 25% to 42% of cases. Typically, the fever lasts for 2 days and then will defervesce abruptly. Headache and an extreme degree of prostration may persist for a variable period, usually about 5 to 7 days. Rare symptoms include uveitis, retinitis, myocarditis, hepatitis, nephritis, hemorrhage, and neurologic problems such as myelitis, meningoencephalitis, Guillain-Barré syndrome, and cranial nerve palsies.

In 40% to 50% of cases, skin involvement is present consisting of a pruritic maculopapular rash predominating on the thorax, facial edema, and localized petechia. Though rarely affected, children may exhibit a bullous rash with pronounced sloughing. The case fatality ratio is approximately 1 per 1000, with most deaths occurring in newborns, the elderly, and the infirm.

Diagnosis

The instructions for serum diagnostic testing are found on the Centers for Disease Control and Prevention's website (<http://www.cdc.gov/chikungunya/hc/diagnostic.html>). The virus may be cultured within the first 3 days of illness. Virus isolation provides the most definitive diagnosis but requires 1 to 2 weeks for completion and must be processed in a biosafety level 3 laboratory. Chikungunya viral RNA may be identifiable in the serum during the first 8 days of illness because chikungunya virus antibodies usually develop by the end of the first week of illness. IgM antibody levels peak 3 to 5 weeks after the onset of illness and persist for approximately 2 months. In some cases, paired acute-phase and convalescent-phase antibody sampling may be required for accurate diagnosis. False-positive results may occur due to infection from closely related viruses.

A complete blood count may show lymphopenia and thrombocytopenia. Liver enzymes may elevate, and the serum creatinine might also increase. Radiologic findings are normal, and biologic markers of inflammation are normal or modestly elevated.

In many parts of the world, chikungunya is a clinical diagnosis of exclusion, particularly when laboratory testing is not readily available. The probability of accurate clinical diagnosis depends on the epidemiology of endemic diseases and the patient's clinical symptoms.

Differential Diagnosis

The differential diagnosis for chikungunya includes influenza, malaria, rickettsia, and a multitude of viruses, especially dengue fever. Dengue and chikungunya viruses are transmitted by the same mosquitoes, may have similar clinical features, and can occasionally coinfect the same individual. Clinically differentiating chikungunya from dengue may be difficult, however; in chikungunya the onset of fever is typically more abrupt and shorter lived, with severe arthralgia, rash, and lymphopenia more prevalent, whereas infection with dengue is more likely to present with neutropenia, thrombocytopenia, hemorrhage, shock, and death. Seasonally,

chikungunya is more likely to be seen in the summer months when *Aedes* mosquitoes proliferate.

Treatment

Medical treatment is primarily supportive. The use of antiviral agents is unproven. It is generally recommended that acetaminophen and, once dengue has been excluded, nonsteroidal antiinflammatory drugs and corticosteroids are useful for the treatment of joint pain. Those infected with chikungunya, during the first week of the illness, should be protected from further mosquito exposure to reduce the risk of local transmission.

Monitoring

Suspected chikungunya cases should be reported immediately to state or local health departments to facilitate diagnosis and mitigate the risk of local transmission.

Complications

Over the 3 years after the 2006 La Reunion outbreak, 60% of patients experienced continued symptoms of arthralgia, typically polyarthralgia (70%), symmetrical (90%), highly incapacitating (77%), and episodic. Local swelling, asthenia, and depression were common long-term complaints. Age >35 years and the presence of joint pain 4 months after the disease onset were risk factors for long-term arthralgia. Chikungunya is one of the agents researched as a potential biologic weapon.

CHOLERA

Method of

Mark Pietroni, MD

Cholera affects about 3 million people per year and kills approximately 100,000. It can kill within hours of the onset of symptoms, and even today the impact of an outbreak of cholera can be catastrophic in locations in which the water and sanitation

If a Chikungunya epidemic were to occur in the United States, the standard public health measures of avoidance and mosquito control would be major lines of defense. To prevent local spread, the patient diagnosed with chikungunya should use mosquito repellent for 1 week after onset of fever.

Clinical Manifestations

Chikungunya virus infection should be considered in patients with acute onset of fever and polyarthralgia, especially in travelers who have recently returned from areas with endemic chikungunya. The incubation period of the chikungunya virus ranges from 1 to 12 days, most typically 3 to 7 days, 72% to 97% of those infected develop symptoms. Clinical onset is abrupt. The hallmarks of chikungunya are erratic, relapsing, and incapacitating polyarthralgia accompanied by high fever, backache, headache, and fatigue. Polyarthralgia is reported in 87% to 98% of cases and represents the most characteristic symptom. The joint pain is mostly polyarticular, bilateral, and symmetrical and occurs mainly in peripheral joints (wrists, ankles, and phalanges) and some large joints (shoulders, elbows and knees). Joint swelling is less frequent, occurring in 25% to 42% of cases. Typically, the fever lasts for 2 days and then will defervesce abruptly. Headache and an extreme degree of prostration may persist for a variable period, usually about 5 to 7 days. Rare symptoms include uveitis, retinitis, myocarditis, hepatitis, nephritis, hemorrhage, and neurologic problems such as myelitis, meningoencephalitis, Guillain-Barré syndrome, and cranial nerve palsies.

In 40% to 50% of cases, skin involvement is present consisting of a pruritic maculopapular rash predominating on the thorax, facial edema, and localized petechia. Though rarely affected, children may exhibit a bullous rash with pronounced sloughing. The case fatality ratio is approximately 1 per 1000, with most deaths occurring in newborns, the elderly, and the infirm.

Diagnosis

The instructions for serum diagnostic testing are found on the Centers for Disease Control and Prevention's website (<http://www.cdc.gov/chikungunya/hc/diagnostic.html>). The virus may be cultured within the first 3 days of illness. Virus isolation provides the most definitive diagnosis but requires 1 to 2 weeks for completion and must be processed in a biosafety level 3 laboratory. Chikungunya viral RNA may be identifiable in the serum during the first 8 days of illness because chikungunya virus antibodies usually develop by the end of the first week of illness. IgM antibody levels peak 3 to 5 weeks after the onset of illness and persist for approximately 2 months. In some cases, paired acute-phase and convalescent-phase antibody sampling may be required for accurate diagnosis. False-positive results may occur due to infection from closely related viruses.

A complete blood count may show lymphopenia and thrombocytopenia. Liver enzymes may elevate, and the serum creatinine might also increase. Radiologic findings are normal, and biologic markers of inflammation are normal or modestly elevated.

In many parts of the world, chikungunya is a clinical diagnosis of exclusion, particularly when laboratory testing is not readily available. The probability of accurate clinical diagnosis depends on the epidemiology of endemic diseases and the patient's clinical symptoms.

Differential Diagnosis

The differential diagnosis for chikungunya includes influenza, malaria, rickettsia, and a multitude of viruses, especially dengue fever. Dengue and chikungunya viruses are transmitted by the same mosquitoes, may have similar clinical features, and can occasionally coinfect the same individual. Clinically differentiating chikungunya from dengue may be difficult, however; in chikungunya the onset of fever is typically more abrupt and shorter lived, with severe arthralgia, rash, and lymphopenia more prevalent, whereas infection with dengue is more likely to present with neutropenia, thrombocytopenia, hemorrhage, shock, and death. Seasonally,

chikungunya is more likely to be seen in the summer months when *Aedes* mosquitoes proliferate.

Treatment

Medical treatment is primarily supportive. The use of antiviral agents is unproven. It is generally recommended that acetaminophen and, once dengue has been excluded, nonsteroidal antiinflammatory drugs and corticosteroids are useful for the treatment of joint pain. Those infected with chikungunya, during the first week of the illness, should be protected from further mosquito exposure to reduce the risk of local transmission.

Monitoring

Suspected chikungunya cases should be reported immediately to state or local health departments to facilitate diagnosis and mitigate the risk of local transmission.

Complications

Over the 3 years after the 2006 La Reunion outbreak, 60% of patients experienced continued symptoms of arthralgia, typically polyarthralgia (70%), symmetrical (90%), highly incapacitating (77%), and episodic. Local swelling, asthenia, and depression were common long-term complaints. Age >35 years and the presence of joint pain 4 months after the disease onset were risk factors for long-term arthralgia. Chikungunya is one of the agents researched as a potential biologic weapon.

CHOLERA

Method of

Mark Pietroni, MD

Cholera affects about 3 million people per year and kills approximately 100,000. It can kill within hours of the onset of symptoms, and even today the impact of an outbreak of cholera can be catastrophic in locations in which the water and sanitation

infrastructure is weak, especially in crisis or war situations. The 21st century has already seen large-scale cholera epidemics in Haiti, Zimbabwe, Pakistan and Yemen, as well as many smaller outbreaks in countries and areas in which cholera is endemic. When cholera is untreated, mortality can be as high as 60% to 70%, but even in epidemics, with appropriate management and well-run diarrhea treatment centers, mortality can be reduced to well below 1%.

Oral rehydration therapy (ORT) is now the mainstay of treatment (Table 1). Developed in the 1960s in Dhaka, Bangladesh, ORT was used to great effect during the Bangladesh Liberation War of 1971. Cholera broke out in the refugee camps outside Calcutta, and the medical services ran out of intravenous fluid. ORT was not accepted as routine therapy by the medical profession at that time. The courageous decision to treat people with ORT saved thousands of lives and convinced the world of the effectiveness of ORT in the management of cholera.

Pathophysiology

Cholera is caused by a gram-negative, comma-shaped bacterium called *Vibrio cholerae*. Clinical disease is caused by two serogroups: *V. cholerae* O1 (which has two biotypes: classical and El Tor) and *V. cholerae* O139. Humans are the only known natural host, and asymptomatic human carriage is rare. *V. cholerae* is rapidly killed by boiling water, but it can lie dormant for months in blue-green algae, crustaceans, and copepods in brackish water, especially in estuaries. The Ganges delta provides an ideal habitat and is believed to be the place cholera first emerged.

Human infection is caused by ingestion of contaminated food or drink or from poor hand hygiene in epidemic situations. Relative or absolute achlorhydria facilitates passage through the stomach. Proliferation occurs in the small intestine, where a number of toxins are released. This results in massive secretion of isotonic fluid into the gut. The fluid passes out of the anus full of vibrios to perpetuate the cycle of transmission. Killing the host does not appear to interrupt this cycle!

The cholera toxin is secreted only by the O1 and O139 serogroups. It has two subunits: A (active) and B (binding). Subunit B binds to receptors in the small intestine and subunit A activates adenylate cyclase. This causes the active secretion of a number of ions into the gut, which drags water by osmosis and also blocks the reabsorption of sodium from the gut. The net result is a massive loss of water, sodium chloride, and bicarbonate. This cannot be replaced by drinking a sodium solution because sodium reabsorption is blocked. However, the addition of glucose to a solution of sodium activates a sodium-glucose co-transporter; sodium is absorbed and water follows by osmosis. This is the basis of oral rehydration therapy for diarrhea today.

Clinical Presentation and Diagnosis

Cholera manifests as an acute watery diarrhea without blood in the stool or (usually) abdominal cramps. The majority of cases are clinically indistinguishable from other causes of watery diarrhea. About 10%-20% will develop dehydration but most require only oral rehydration fluid as treatment. However, some will progress to classic or severe cholera.

The classic picture is of the rapid onset of profuse watery diarrhea (rice-water stool) and vomiting, which is painless and can result in circulatory collapse within hours without effective treatment. The history is usually less than 24 hours, although it may be longer if the patient is taking oral rehydration solution. Abdominal cramps can occur. Fever is absent. Patients usually remain alert, but severe electrolyte abnormalities such as hypoglycemia and hyponatremia can cause a reduced level of consciousness or convulsions, especially in children. Acidosis is often severe and results in tachypnea, which is commonly misdiagnosed as pneumonia. Patients should be reassessed for the presence or absence of pneumonia 1 to 2 hours after adequate rehydration. The diagnosis of cholera can be confirmed by the presence of rapidly motile vibrios detected by dark-field microscopy or by stool or rectal swab culture. However, the classic history, appearance of the stool, and rapid presentation mean that the diagnosis is usually clinical.

Treatment

A clinical syndrome of acute watery diarrhea (three or more watery stools in the last 24 hours) of short duration (24–48 hours) with or without vomiting associated with dehydration in anyone older than 2 years in an endemic or epidemic situation should be treated as cholera. Children younger than 2 years may be managed in the same way, but other diagnoses such as rotavirus should be considered. The mainstay of management (whatever the causative organism) is appropriate early rehydration, and time should not be wasted worrying about investigations or which antibiotic to use (Figure 1).

The initial assessment should be brief but must:

- Confirm the diagnosis of acute watery diarrhea
- Assess the level of dehydration
- Assess the presence or absence of malnutrition
- Recognize any other comorbidities

Accurate assessment and rapid, appropriate treatment of dehydration is critical to the management of cholera. A simple scoring system based on five clinical signs is sufficient and can accurately predict patients with 5% to 10% (some) dehydration and greater than 10% (severe) dehydration. Common mistakes include overreliance on individual clinical signs and giving too little intravenous fluid during the initial phase and too much during the recovery phase.

TABLE 1 Composition (mEq/L) of Common Solutions Used for Rehydration

SOLUTION	NA ⁺	K ⁺	CL ⁻	HCO ₃ ⁻	CITRATE	CA ²⁺	GLUCOSE OR CARBOHYDRATE
Intravenous Solution							
Normal saline	154	—	154	—	—	—	—
Ringer's lactate	130	4	111	28	—	3	—
Ringer's lactate + D ₅	130	4	109	28	—	3	278
Cholera saline (Dhaka solution)	133	13	98	48	—	—	140
Oral Solution							
Standard ORS	90	20	80	—	10	—	75
Hypo-osmolar ORS	75	20	65	—	10	—	75
ReSoMal*	45	40	76	—	7	—	125

Abbreviations: D₅ = 5% dextrose; ORS = oral rehydration solution; ReSoMal = reduced osmolarity ORS for malnourished children.

*Also contains Mg 6 mmol/L, Zn 300 μmol/L, Cu 45 μmol/L.

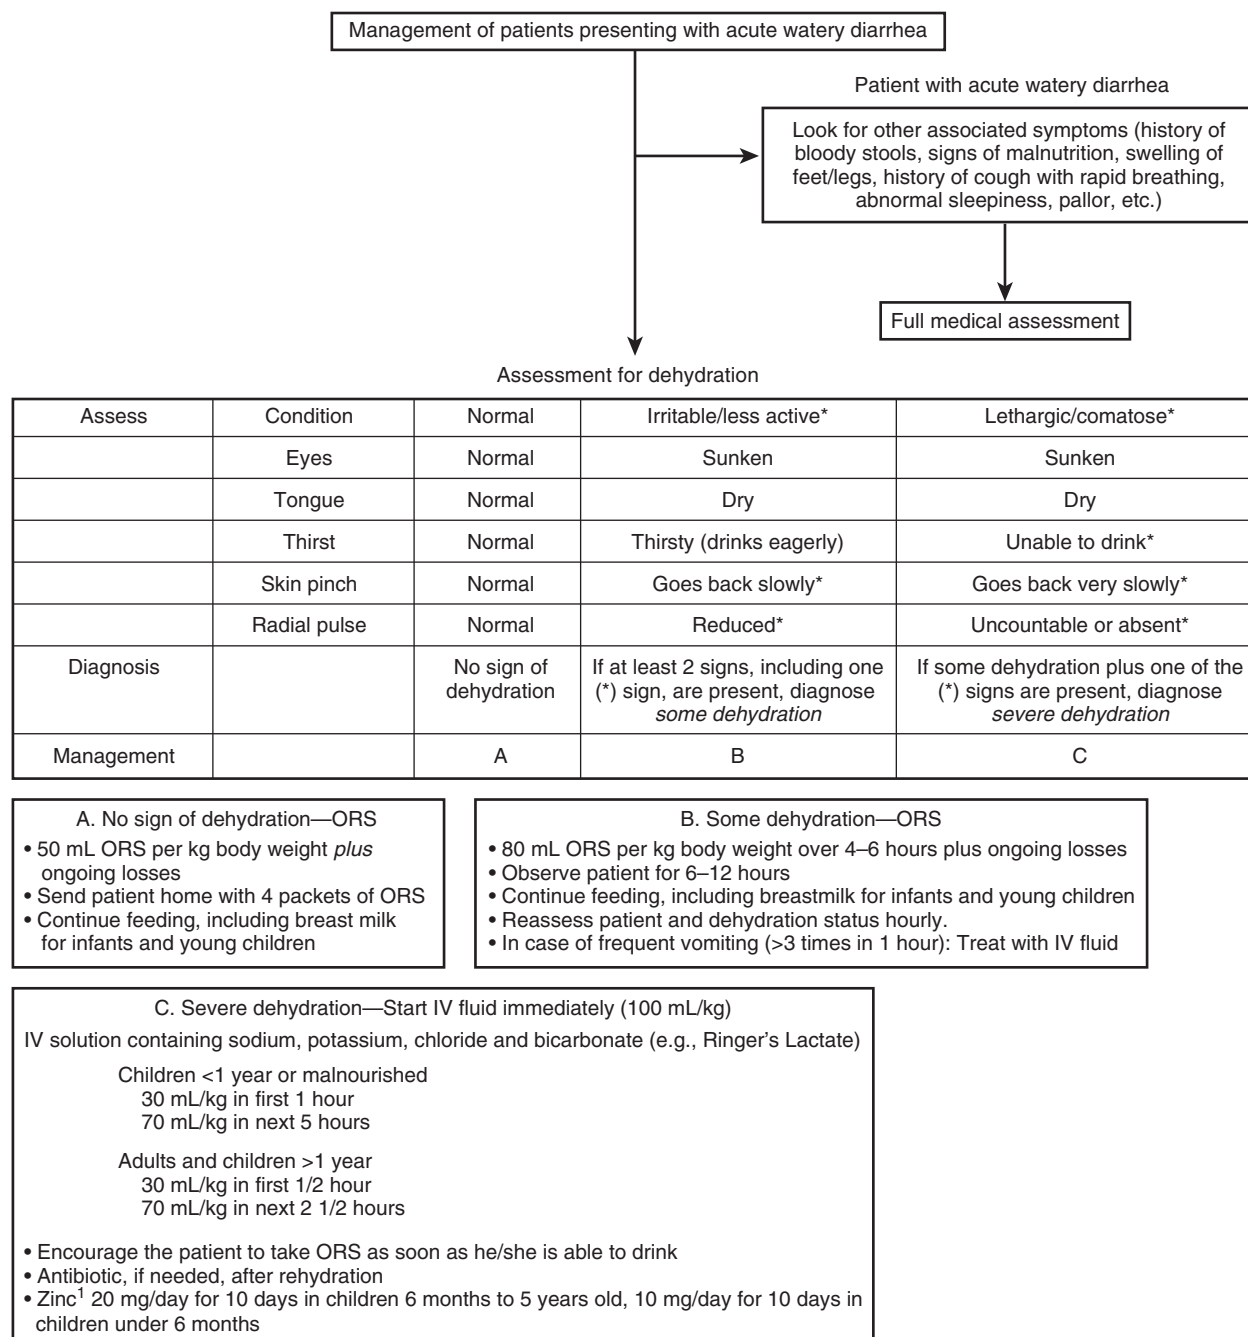

Figure 1 Quick identification of cholera cases can be made using a standard case definition. During an outbreak, cholera should be suspected in any patient who is older than 2 years, is attending a health facility, and has a history of acute watery diarrhea (passage of at least three stools in the last 24 hours) of a short duration (less than 24 hours), with or without vomiting, and with signs of dehydration. (Flow chart modified from International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B) internal treatment protocol.) *Abbreviation:* ORS = oral rehydration solution.

Patients with less than 5% (no) dehydration and 5% to 10% (some) dehydration can be managed with oral rehydration alone (Box 1) unless there is a reduced level of consciousness or inability to take fluids by mouth. Those with 5% to 10% (some) dehydration must be reassessed every 1 to 2 hours to make sure that hydration is improving.

Patients with severe dehydration require an immediate intravenous fluid bolus of 100 mL/kg given over 3 hours with one third in the first 30 minutes (double the duration in children who are younger than 1 year and have malnutrition). If possible, the intravenous fluid should contain sodium, potassium, and bicarbonate—Ringer's lactate or cholera saline—but normal saline with 5 to 10 mmol/L of potassium may also be used. Oral rehydration should start at the same time. Once the intravenous fluid bolus has finished, further intravenous fluids are usually not required.

Patients are best managed using a cholera cot, especially in an epidemic situation. The cholera cot is a bed (or sometimes a chair) covered with a nonabsorbent sheet with a hole that allows the passage of stool and urine directly to a bucket under the bed (Figure 2). The sheets and bucket should be replaced three times a day and between patients. They may be washed, sterilized, and reused. Patients do not need to use a toilet (which can be several times an hour), linen is not soiled, and body fluids are prevented from running on the floor. This system enables adequate infection control to be maintained with limited resources.

After an initial assessment has been made and fluids started, a fuller clinical assessment can take place. Patients with significant comorbidities can require individually tailored treatment plans.

Antibiotics reduce the length of stay and fluid requirement in patients with severe dehydration due to cholera (Box 2). A single

BOX 1 Fluids for Patients without Signs of Dehydration**Acceptable**

Oral rehydration solution (optimal for both repletion and maintenance)

Salted drinks (salted rice water or salted yogurt drink)

Broth or soup (salted vegetable or meat soup)

Water

Rice water

Coconut water (unsweetened)

Weak tea (unsweetened)

Fresh fruit juice (unsweetened)

Unacceptable

Carbonated beverages

Sweetened juices

Coffee

Medicinal teas or infusions

Fluids containing salt should be encouraged. Unacceptable fluids include carbonated beverages and sweetened juices; the sugar in these fluids may worsen diarrhea. Coffee and medicinal teas or infusions are also unacceptable since they can have diuretic and purgative effects.

Reprinted with permission from Harris JB, Pietroni M: Approach to the child with acute diarrhea in developing countries. UpToDate. Available at <http://www.uptodate.com/contents/approach-to-the-child-with-acute-diarrhea-in-developing-countries> (accessed August 11, 2016).

BOX 2 Antibiotics in Cholera

Antibiotics should be given to all patients with severe dehydration. Choice of antibiotic depends on local sensitivity pattern.

First-Line Drug (If Susceptibility Report Is Not Available)**Adults**

Azithromycin (Zithromax)¹ 1 g (500 mg × 2) PO as a single dose after correcting severe dehydration

Children

Azithromycin¹ 20 mg/kg PO as a single dose after correction of dehydration and cessation of vomiting (if any)

Second-Line Drug (Not Recommended for Children < 5 Years or Pregnant Women)**Adults**

Ciprofloxacin (Cipro)¹ 1 g (500 mg × 2) PO as a single dose after correction of severe dehydration

Children

Ciprofloxacin¹ 20 mg/kg PO as a single dose after correction of dehydration and cessation of vomiting (if any)

Third-Line Drugs

Doxycycline (Vibramycin) 300 mg as a single dose after food (not in children or pregnant women)

¹Not FDA approved for this indication.

Figure 2 Cholera cot.

dose is sufficient, but this should be repeated if the dose is vomited back. The choice of antibiotic should be guided by local sensitivities where these are available. If not, a single dose of azithromycin (Zithromax)¹ 1 g in adults and 20 mg/day for 10 days in children 6 months to 5 years old, 10 mg/day for 10 days in children under 6 months. All children between 6 months and 5 years of age should receive zinc¹ 20 mg/day for 10 days because this reduces subsequent mortality and further episodes of diarrhea.

Recovery from cholera is rapid, and mortality is extremely low if the dehydration is treated appropriately. The Cholera Hospital run by the International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B), in Dhaka treats around 120,000 patients a year. The average length of stay is 16 hours, and the mortality rate is zero.

Prevention

Because the transmission of cholera is feco-oral, cholera can be prevented by good hand hygiene and by providing safe drinking water and appropriate sanitation. Standard food and hygiene precautions should be followed by people travelling in endemic areas

(e.g., eat only boiled or fried foods; drink only boiled or bottled water). The FDA recently approved a single-dose live oral cholera vaccine, called Vaxchora in the United States. Vaxchora is indicated for adults 18–64 years old who are traveling to an area of active cholera. Two other oral inactivated cholera vaccines, Dukoral and ShanChol, are not available in the United States. These two cholera vaccines provide around 60% to 80% efficacy for 6 months. They are not recommended for the occasional traveler or tourist but may be given to people working in high-risk situations, such as aid workers in a cholera outbreak. The World Health Organization recommends the use of oral cholera vaccine in endemic areas as part of disease control programmes and maintains a global cholera vaccine stockpile for use in epidemic situations.

CHRONIC FATIGUE SYNDROME/SYSTEMIC EXERTION INTOLERANCE DISEASE

Method of

Stephen J. Gluckman, MD

Chronic fatigue syndrome (CFS) is an often-misunderstood syndrome that should not be confused with malingering or hypochondriasis. Patients with CFS are truly suffering from their often-disabling symptoms. It is impossible to successfully treat a patient

¹Not FDA approved for this indication.

with CFS unless the clinician believes the patient is genuinely symptomatic. CFS should also not be confused with the isolated symptom of fatigue. Fatigue is a common patient complaint, whereas CFS has a much lower prevalence.

Definition

CFS is not a new disease; the syndrome has been described since at least the mid-1700s. However, since that time it has been mistakenly ascribed to a number of incorrect pathologic and infectious causes. In the past it has been called febricula, neurasthenia, effort syndrome, DeCosta's syndrome, myalgic encephalitis, chronic brucellosis, chronic Lyme disease, chronic Epstein-Barr syndrome, total allergy syndrome, chronic candidiasis, and multiple chemical sensitivity syndrome. Most recently it has been falsely attributed to infection with xenotropic murine leukemia virus-related virus (XMRV) and related retroviruses, such as murine leukemia virus (MLV). None of these possible causes has proved to be correct.

In 1988, in an attempt to be descriptive rather than attribute an incorrect etiology to the disease, the term *chronic fatigue syndrome* was coined. Therefore the name is relatively new but the syndrome is not. The disease is chronic and fatigue is a cardinal feature, but it is more than being chronically tired. It is a syndrome that includes a number of additional symptoms as noted in [Box 1](#), the working case definition as published by the Centers for Disease Control and Prevention and then modified in 1992 by the National Institute of Allergy and Infectious Diseases. In March 2015 the Institute of Medicine (IOM) issued a 300-page review of the topic. As a result of this review they proposed a name change to Systemic Exertion Intolerance Disease (SEID). This comprehensive report has three major themes: 1. CFS has acquired a great deal of negative connotation with associated misunderstanding and prejudice. The name change to SEID is an attempt to disconnect this disease from past

BOX 1

International Consensus Definition of Chronic Fatigue Syndrome

Chronic fatigue syndrome is a clinically evaluated, unexplained, persistent or relapsing chronic fatigue (lasting more than 6 months) that is of new or definite onset (has not been lifelong); is not the result of ongoing exertion; is not substantially alleviated by rest; and results in substantial reduction in previous levels of occupational, educational, social, or personal activities.

Four or more of the following symptoms are concurrently present for more than 6 months:

- Impaired memory or concentration
- Multijoint pain
- Muscle pain
- New headaches
- Postexertional malaise
- Sore throat
- Tender cervical or axillary lymph nodes
- Unrefreshing sleep

Exclusionary Clinical Diagnoses

- Any active medical condition that could explain the chronic fatigue
- Any previously diagnosed medical condition whose resolution has not been documented beyond reasonable clinical doubt and whose continued activity can explain the chronic fatiguing illness
- Psychotic major depression, bipolar affective disorder, schizophrenia, delusional disorders, dementias, anorexia nervosa, bulimia nervosa
- Alcohol or other substance abuse within 2 years before the onset of the chronic fatigue and at any time afterward

Adapted from Fukuda K, Straus SE, Hickie I, et al. The chronic fatigue syndrome: A comprehensive approach to its definition and study. *Ann Intern Med* 1994;121:953–959.

BOX 2

New Proposed Criteria for CFS/SEID

Diagnosis requires that the patient have the following three symptoms:

- A substantial reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities that persists for more than 6 months and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest.
- Post-exertional malaise
- Unrefreshing sleep

At least one of the two following manifestations is also required:

- Cognitive impairment
- Orthostatic intolerance

misunderstandings. 2. The criteria for diagnosis were greatly simplified with emphasis on the major features. ([Box 2](#)) 3. By using the term “disease” and with the ample reference support in the document the IOM unequivocally underscores the very real nature of this malady. The IOM report is too recent to know at this time whether it will be universally adopted, but it by far the most thorough examination of the topic and it unequivocally supports the validity of this disease.

One note of caution: This case definition is an epidemiologic tool and not a strict clinical tool. It is useful for studying the disease. However, some patients do not completely fit this definition but CFS can nonetheless be diagnosed by a knowledgeable clinician.

Because some immune abnormalities are often seen in these patients, some people have called this “chronic fatigue and immune dysregulation syndrome.” The immune abnormalities seen in CFS patients are mild and differ from patient to patient. Most significantly, these patients are not immunosuppressed.

It has been noted that many of the symptoms of fibromyalgia overlap with CFS, and some clinicians consider fibromyalgia and CFS to be different aspects of the same disease because both often include pain and fatigue. These different names for the same syndrome can be confusing to patients and clinicians, and when managing patients with CFS it is important to explain this to them.

Epidemiology

Although chronic fatigue is an extremely common symptom, CFS is not. The former has been noted to have a prevalence of 10% to 25% in a number of studies. However, the point prevalence of CFS has been estimated to be in the range of 0.1%. CFS is overrepresented in young and middle-aged women, but it has been described in men and women and in all age groups.

Pathophysiology

The cause of CFS is unknown. Much effort has gone into trying to discern an infectious, endocrine, immune, or psychiatric cause, but to date none has been proved. Studies have shown a link between CFS and the presence of certain genes that mediate immune and stress responses. The findings suggest that difficulty managing stress may be linked to the development of CFS. They also suggest that there is not a single cause of CFS, but that there may be a number of stress-related triggers (physical or emotional) in those with a genetic predisposition. This is consistent with the typical course, in which a previously healthy person develops an acute illness that resolves but initiates CFS.

Clinical Features and Diagnosis

Although there is, as yet, no diagnostic test, the history, physical examination, and laboratory testing are generally very characteristic and allow a clinician to confidently make the diagnosis. The typical story is one of a previously highly functioning person who develops an acute illness or other stressor. The acute problem resolves, but, from that time on, symptoms of CFS are triggered.

Despite often-profound symptoms, physical examination is persistently normal, as is laboratory testing. Symptoms are exacerbated by physical activity. The pre-CFS medical history of the patient is not one of multiple medical problems. Affected patients are typically highly functioning persons who are struck down with this disease. Features to emphasize in addition to the case definition noted in [Box 1](#) include those noted in [Box 3](#).

In a patient with a typical story and examination, laboratory testing should be limited ([Box 4](#)). Testing for diseases with a low pretest likelihood runs the serious risk of false-positive results. This can result in further testing, diagnostic confusion, and unnecessary treatments. Specifically, the signs and symptoms of CFS are not those of systemic lupus, Lyme disease, cytomegalovirus, bartonellosis, ehrlichiosis, or babesiosis. Serologic testing for these diagnoses is not helpful and can be harmful if the presence of antibodies results in the initiation of unwarranted medications. For similar reasons, neuroimaging without objective clinical findings is not indicated. Although abnormalities can be found, they are nonspecific and of no clinical utility. Tilt-table testing seems to be abnormal in many patients with CFS; however, testing is expensive and uncomfortable, and abnormal results do not alter management. Of course, if history, physical examination, and initial laboratory

BOX 3 Frequent features of Chronic Fatigue Syndrome

- Sudden onset of fatigue after a relatively common illness or other stressor
- Previously active and healthy person
- Symptoms very sensitive to exacerbation by physical activity
- Normal physical examination and laboratory testing
- Altered sleep
- "Foggy" thought processes
- Lack of progression to organ failure or any significant objective organ abnormality
- Joint and muscle aching without physical evidence of inflammation
- Feverish feeling (sustained elevated temperatures [$>37.4^{\circ}\text{C}$] should prompt a search for an alternative diagnosis, because the CFS patient is not truly febrile)
- Diffuse aching that is not well localized to joints or muscles, but without erythema, effusion, or limitation of motion
- Muscles that are easily fatigued (however, strength is normal, and biopsies and electromyograms are also normal)
- Occasional mild cervical and/or axillary lymphadenitis (painful lymph nodes [lymphadenia] are a common complaint, but this is not a true lymphadenopathy)

BOX 4 Diagnostic Testing

Tests to Perform

- Complete blood count
- Comprehensive chemistry screen
- Thyroid-stimulating hormone
- Perhaps: cortrosyn stimulation test, sleep study
- Additional testing *only* with specific clinical indications

Do Not Routinely Do

- ANA
- Serology for CMV, EBV, *Bartonella*, *Babesia*, *Ehrlichia*, *Anaplasma*
- MRI, SPECT or PET scans
- Tilt table testing

Abbreviations: ANA = antinuclear antibody test; CMV = cytomegalovirus; EBV = Epstein-Barr virus; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single-photon-emission computed tomography.

BOX 5 Therapy of Chronic Fatigue Syndrome

- Educate the patient and his or her support system about the diagnosis of chronic fatigue syndrome. Emphasize the validity of the diagnosis and of the patient's symptoms. Make sure that there is an understanding about expectations.
- Aggressively manage specific symptoms of sleep disturbance, pain, and depression.
- Consider cognitive behavioral therapy.
- Emphasize the need for gradual, graded exercise. Give the patient a specific "prescription" for this.
- Avoid the temptation to prescribe antimicrobials, corticosteroids, or other medications with no proven benefit and the potential to do harm.
- Discuss the pros and cons of using unstudied, expensive, or potentially dangerous "alternative therapies."

testing do reveal abnormalities, further laboratory evaluation should be undertaken to elucidate the cause of the aberration(s).

Treatment

There is no established cure for CFS, but patients should be counseled that a number of things can be done to manage this often disabling illness ([Box 5](#)). These can be divided into things the clinician should do and things the patient should do.

Things the Clinician Should Do

To successfully manage CFS, a clinician must believe that the patient is truly symptomatic. Patients with CFS are not malingering. Because they often appear well and have consistently normal objective testing, they often become very defensive about their limitations. They are sensitive to the validity of their symptoms. Not only are they suffering but also they are blamed for it. Many patients with CFS are partially or totally disabled. Their outward healthy appearance belies the internal sense of ill health. It is common for relatives and colleagues to believe they are malingering. A vicious cycle of frustration, anger, and depression commonly ensues.

As part of establishing the validity of the diagnosis a clinician should review the history of CFS, emphasizing that this is not a new disease but was originally described centuries ago.

For successful management a clinician should give the patient enough time, specifically inquire about other diagnoses the patient is concerned about, and explain why they are not correct. The clinician should see the patient at regular intervals.

Make sure that the patient has reasonable expectations. Most patients with CFS have not had previous chronic illnesses or significant prolonged limitations. It is often necessary to review the information about CFS with the patient's family and to emphasize that this disabling illness is not volitional.

Although it is generally wise to avoid a discussion about whether the origin of CFS is psychiatric or organic, depression is an expected consequence of any chronic illness. Depression has specific treatments, and it should be aggressively diagnosed and treated. The patient should be told that successful management of depression will help him or her cope with CFS.

If a sleep disturbance exists that should also be aggressively managed, if necessary by a sleep specialist. Sleep deprivation makes other symptoms more difficult to deal with.

Chronic pain is very enervating. If pain is prominent, that should also be aggressively managed, often by a pain specialist.

It is important for the clinician to be cautious about ascribing all of a patient's symptoms to CFS. Such patients are, of course, not protected from getting additional illnesses. Each symptom should be considered on its own before defaulting it to CFS.

Complementary therapies must be discussed or the patient might get the impression that the clinician is not comfortable in considering them; that can partially undermine the clinician-patient relationship. Although all are of unproved benefit and often

undetermined risk, “complementary” therapies that are not dangerous, such as acupuncture, or expensive are reasonable to consider.

Things the Patient Should Do

Of the 350 studies that have looked at treatment options for CFS only cognitive behavioral therapy and graded exercise therapy have been shown to be of possible benefit. In cognitive behavioral therapy, the patient undergoes a series of 1-hour sessions designed to alter beliefs and behaviors that might delay recovery. Although exercise can exacerbate symptoms, deconditioning will also do so. Limiting activity can worsen weakness and depression. Thus increased rest is not recommended and should be discouraged. The risk of exacerbating symptoms can be reduced by cautiously setting less-ambitious activity/exercise goals. Because many patients with CFS were particularly active before the onset of their illness and are impatient to get their former lives back, they often need strict guidelines to try to prevent overdoing exercise while at the same time getting a clear prescription to exercise. The exercise prescription should be individualized based on the degree of impairment, but it is wise to initially set goals on the low side to avoid exacerbating symptoms.

As part of the management of CFS patients, their families, and, when appropriate, their employers need to reframe their expectations. CFS patients have a chronic, disabling illness. Families and others need to come to some understanding that patients cannot do all that they were able to do before the onset of CFS and that patients cannot “will” the disease away any more than they could will away a more visible disability.

Things that Should Not Be Done

There are many suggested remedies for CFS. Most are either unstudied or disproved. In particular, treatments that are expensive or potentially harmful should be avoided. There is no role for antimicrobial therapy. There is no role for antiviral therapy, including treatment for retroviruses. There is no role for intravenous immunoglobulin, corticosteroids, special diets, or vitamin treatments.

Prognosis

The likelihood for complete recovery from CFS is only fair. The disease tends to wax and wane over time, but in only a minority of patients does it completely resolve. If sustained improvement occurs it is generally over several years. Several features have been associated with a poorer prognosis, including age older than 38 years, more than eight symptoms, duration longer than 1.5 years, less than 16 years of formal education, a history of a dysthymic disorder, and a sustained belief that the disease is due to a physical cause.

Monitoring

Despite the lack of very effective treatment, many patients benefit from regular monitoring of their condition. Knowing they have scheduled visits minimizes the number of crises and emergency visits and allows the patient to reconnect with a validating physician. Follow-up on a quarterly basis is a reasonable interval.

EBOLA VIRUS DISEASE

Method of

Uma Malhotra, MD

CURRENT DIAGNOSIS

- Detection of viral RNA in the blood by reverse transcriptase-polymerase chain reaction (RT-PCR) beginning 3 days after the onset of symptoms.
- Repeat testing may be necessary for patients with illness duration shorter than 3 days.
- Details on specimen collection and handling can be found on the Centers for Disease Control and Prevention (CDC), and World Health Organization (WHO) websites.

CURRENT THERAPY

- Intensive fluid management to correct volume losses and electrolyte abnormalities.
- Aggressive use of antiemetics, antidiarrheals, and rehydration solutions.
- Respiratory and hemodynamic support.
- Blood products for management of coagulopathy.
- Evaluate and treat any concomitant infections.
- There are no approved antiviral therapies. However, a number of experimental treatments, including monoclonal antibodies, convalescent serum, small-molecule antivirals, and short interfering RNAs are available.
- Strict infection control measures, with contact and droplet precautions, must be used.
- Personnel trained in the correct use of personal protective equipment (PPE) should care for the patients.

Filoviridae, derived from the Latin word “filum,” meaning thread-like, is a family of viruses with a filamentous structure that can cause severe hemorrhagic fever and fulminant septic shock. Filoviruses have been divided into two genera: Ebola-like viruses with five species—*Zaire*, *Sudan*, *Ivory Coast*, *Bundibugyo*, and *Reston*; and Marburg-like viruses with a single species—*Marburg*, which has caused outbreaks in Central Africa. Using paleoviruses (genomic fossils) found in mammals, we can extrapolate that the viruses probably diverged several thousand years ago, and that the family itself is at least tens of millions of years old.

Epidemiology

Of the five Ebola virus species only four—*Zaire*, *Sudan*, *Ivory Coast*, and *Bundibugyo*—cause disease in humans. Since its first

undetermined risk, “complementary” therapies that are not dangerous, such as acupuncture, or expensive are reasonable to consider.

Things the Patient Should Do

Filoviridae, derived from the Latin word “filum,” meaning thread-like, is a family of viruses with a filamentous structure that can cause severe hemorrhagic fever and fulminant septic shock. Filoviruses have been divided into two genera: Ebola-like viruses with five species—*Zaire*, *Sudan*, *Ivory Coast*, *Bundibugyo*, and *Reston*; and Marburg-like viruses with a single species—*Marburg*, which has caused outbreaks in Central Africa. Using paleoviruses (genomic fossils) found in mammals, we can extrapolate that the viruses probably diverged several thousand years ago, and that the family itself is at least tens of millions of years old.

Epidemiology

Of the five Ebola virus species only four—*Zaire*, *Sudan*, *Ivory Coast*, and *Bundibugyo*—cause disease in humans. Since its first

recognition in 1976, *Zaire ebolavirus* has caused multiple outbreaks in Central Africa. It is the causative agent of the 2014 West African epidemic, with an initial estimated case fatality rate as high as 70%, although as the epidemic evolved, lower fatality rates in the range of 30% to 40% were observed. The 2014 epidemic began in Guinea, when a 2-year-old child became infected in late 2013, and *Zaire ebolavirus* subsequently spread to Liberia, Sierra Leone, Nigeria, Senegal, and Mali. The epidemic resulted in over 28,000 cases and 11,000 deaths, with more than 800 infections occurring in health care workers. *Sudan virus* has been associated with a case-fatality rate of approximately 50% in four epidemics, which occurred in Sudan and Uganda between 1970 and 2004. *Ivory Coast virus* has been identified as the cause of illness in one person following exposure during a necropsy on a chimpanzee found dead in the Tai Forest. *Bundibugyo virus*, most closely related to the Ivory Coast species, emerged in Uganda in 2007, causing an outbreak with a case fatality rate of approximately 30%. *Reston virus*, discovered after an outbreak of lethal infection in macaques imported into the United States in 1989, is maintained in animal reservoirs in the Philippines.

Risk Factors/Transmission

Outbreaks generally begin when an individual becomes infected through contact with the tissue or body fluids of an infected animal. The virus then spreads to others who come into contact with the infected individual's blood, skin, or other body fluids. Prior to the 2014 epidemic in West Africa, outbreaks occurred in remote regions with low population density and were controlled within short periods. However, the recent epidemic has shown that movement of infected individuals facilitates the extensive and rapid spread of the virus.

Transmission occurs most commonly through direct contact of broken skin or mucous membranes with virus-containing body fluids from an infected person, the most infectious being blood, feces, and vomit. During the early phase of illness, the level of virus in the blood is typically quite low, but then increases rapidly to very high levels in advanced stages of the illness, when patients become highly infectious. In fact, corpses of persons who die from Ebola are highly infectious, and ritual washing of bodies at funerals has played a significant role in the spread of infection. The virus has also been detected in urine, semen, saliva, breast milk, tears, and sweat, and can persist in some of these fluids much longer than in blood. To prevent sexual transmission the WHO recommends that men either abstain from sex, or use condoms for three months after onset of symptoms. Ebola virus may also be transmitted though contact with contaminated surfaces where the virus can remain infectious from hours to days.

Transmission to health care workers may occur when appropriate PPE is not used, especially when caring for severely ill patients in advanced stages of illness. During the 2014 outbreak in West Africa, a large number of health care workers became infected. In Sierra Leone, the incidence of confirmed cases at the peak of the epidemic was about 100-fold higher in health care workers than in the general population. Several factors have contributed to the high rates of infections among health providers, including failure to recognize infection among patients and corpses, limited availability and training in the use of appropriate PPE, and inadequate management of contaminated waste and burial of corpses. Although there is no evidence of respiratory transmission, the virus is highly infectious when released in laboratory experiments as a small-particle aerosol, and therefore health care workers may be at risk if exposed to aerosols generated during procedures.

Human infection can occur through contact with infected wild animals during hunting, butchering, and preparing meat, with several episodes having occurred following contact with infected gorillas or chimpanzees. To prevent infection, food products should be properly cooked to inactivate the virus, and basic hygiene measures should be followed. Direct transmission of virus infection from bats to wild primates or humans has not been proven, although Ebola RNA sequences and antibodies have been detected in bats in Central Africa. Bats likely form a major reservoir.

Pathophysiology

Ebolavirus is a negative-sense, single-stranded RNA virus resembling rhabdoviruses and paramyxoviruses in its genome organization and replication mechanisms. The tubular virions contain the nucleocapsid surrounded by an outer envelope, which is derived from the host cell membrane and studded with viral glycoprotein spikes. The virions attach to host cell receptors through the spikes and are then endocytosed into vesicles. Initially, productive infection occurs primarily in dendritic cells, monocytes, and macrophages, resulting in impaired interferon production and release of proinflammatory cytokines, which have secondary effects on innate and adaptive immune responses, inflammation, and vascular integrity. Neutrophils are activated, with resultant degranulation, and lymphocytes undergo apoptosis. The virus then spreads to regional lymph nodes, resulting in further rounds of replication, followed by dissemination to the liver, spleen, thymus, and other lymphoid tissues.

When the virus infects cells, it hijacks the cell and forces it to become a virus-producing factory, churning out new copies of the virus, which results in a loss of cellular function and eventual cell death by apoptosis. As the disease progresses, there is extensive tissue necrosis accompanied by a systemic inflammatory response induced by the release of various cytokines, chemokines, and proinflammatory mediators, as well as a severe coagulopathy triggered by the release of tissue factors. This systemic inflammatory response may contribute to gastrointestinal dysfunction, and ultimately there is a multisystem failure caused by the damage to vascular and coagulation systems.

Clinical Manifestations and Laboratory Findings

Patients with Ebola virus disease (EVD) typically have an abrupt onset of symptoms 5 to 10 days after exposure, with a range of 2 to 21 days. The first phase of the illness is characterized by high fever, chills, headaches, myalgia, and malaise. The second phase is marked by gastrointestinal symptoms, which develop by day 3 to 5, and includes watery diarrhea, nausea, vomiting, and abdominal pain. Patients may also develop chest pain, hiccups, shortness of breath, conjunctival injection, and rash. The rash is usually diffuse erythematous, maculopapular, involving the face, neck, trunk, and arms. Respiratory symptoms such as cough are rare. Common neurologic symptoms include delirium, manifested by confusion, slowed cognition, or agitation, and less frequently, seizures.

The final phase, beginning in the second week, is marked by either progression to shock and death or gradual recovery. Fatal disease is characterized by development of multisystem failure usually as a consequence of massive fluid losses that lead to shock, loss of consciousness, and renal failure. Major bleeding, typically hemorrhage from the gastrointestinal tract, is infrequent and seen in less than 5% during the terminal phase of illness. Patients who survive begin to improve during the second week of illness, with a prolonged convalescence marked by weakness and fatigue. About half of the survivors are plagued by chronic debilitating joint pain and a quarter experience eye problems. The virus can persist in the eye for months, leading to uveitis, cataracts, and sometimes blindness.

During acute illness patients typically develop leukopenia, lymphopenia, thrombocytopenia, serum transaminase elevations, and proteinuria. They may develop renal insufficiency and electrolyte disturbances as a result of the gastrointestinal losses. Severe cases develop coagulation abnormalities with prolonged prothrombin and partial thromboplastin times, and elevated fibrin degradation products, consistent with disseminated intravascular coagulation.

Diagnosis

The approach to evaluating patients depends on whether or not appropriate signs and symptoms are evident, and if an exposure occurred within 21 days prior to the onset of symptoms. Infection control precautions must be used for all symptomatic patients with an identifiable risk for EVD. All symptomatic patients should be isolated in a single room with a private bathroom, and implementation of contact and droplet precautions. Only essential personnel

who are well trained in the use of PPE should interact with the patient. Phlebotomy and laboratory testing should be limited to essential tests. Both the CDC and the WHO have provided detailed recommendations for approach to the evaluation of persons who may have been exposed to the virus.

Rapid diagnostic tests are the most commonly used tests for diagnosis. Viral RNA is generally detectable by RT-PCR in the blood 3 days after the onset of symptoms. Repeat testing may be necessary for patients with illness duration shorter than 3 days. A negative RT-PCR test greater than or equal to 72 hours after the onset of symptoms rules out EVD. Details on specimen collection and handling can be found on the CDC website. For clinicians outside the United States, the WHO has issued guidance for the collection and shipment of specimens from patients with suspected disease.

Differential Diagnosis

Acute onset of febrile illness in a person who lives or has recently been in West or Central Africa may be caused by a variety of local infectious diseases, which must be considered in the differential diagnosis. **Malaria** may have similar findings and might occur concurrently. Examination of blood smears and rapid antigen tests are typically used to diagnose malaria. **Typhoid** is characterized by fever and abdominal pain, and diagnosed by blood cultures.

Patients with **Lassa fever** may develop a severe clinical syndrome resembling EVD and progress to fatal shock. The illness is restricted to West Africa, where it is transmitted through exposure to the aerosolized excretions of rodents, and diagnosed by RT-PCR testing and/or serology. Clinical manifestations of **Marburg virus disease** are similar to EVD, and cases have been identified in Central Africa. The diagnosis is made by RT-PCR. Patients with **influenza** may have a similar initial presentation, but respiratory signs and symptoms are prominent.

Therapy

Good supportive care can significantly improve the chances of recovery from EVD. Mortality rates have been as low as 18% among those cared for in the US and Europe, receiving careful fluid and electrolyte management, nutritional support, and critical care. Large volumes of intravenous fluids and electrolytes are often needed to correct dehydration and electrolyte abnormalities resulting from gastrointestinal losses. Supportive care is required for complications such as shock, hypoxia, hemorrhage, and multiorgan failure. Patients may develop secondary bacterial infections, which may require concurrent management with antimicrobials. Infection prevention and control measures are critical; all bodily fluids and tissues must be considered potentially infectious. The illness is associated with high rates of pregnancy-associated hemorrhage and fetal death. The Centers for Disease Control and Prevention and the American College of Obstetrics and Gynecology have issued recommendations for the care of pregnant women with EVD. However, there are no definitive data to recommend cesarean section versus vaginal delivery or the preferred timing for delivery.

No FDA-approved antiviral drugs or therapeutic vaccines are available, although several are currently in various stages of testing. Antiviral nucleoside analog favipiravir (T-705, Avigan)⁵ has been used in patients with EVD. Favipiravir inhibits the replication of a wide range of RNA viruses, including influenza, and has been evaluated in small trials, but the studies have not demonstrated a definitive efficacy. ZMapp (a combination of humanized monoclonal antibodies)⁵ was evaluated in a small randomized controlled trial, but due to the small size of the trial, efficacy could not be conclusively demonstrated. Plasma from patients who have recovered from the disease was used to treat patients during the 2014 outbreak, but no clinical trials have been conducted to date. Clinicians may contact the CDC's Emergency Operations Center for

additional information on use of experimental therapeutics for treatment of EVD.

Long-Term Follow-up

The WHO suggests close follow-up of patients after hospital discharge for the first year. A suggested schedule is first follow-up 2 weeks after discharge, then monthly for 6 months, and then every three 3 months to complete 1 year. Survivors with ocular findings require follow-up to assess for cataracts. Semen testing should be done at follow-up visits until negative for Ebola virus RNA. If semen testing is unavailable, then WHO recommends that men practice safe sex for 12 months from onset of illness.

If patients develop fever, then they should be assessed for relapse, while also being evaluated for other causes of infection. Development of uveitis and meningitis may suggest relapse. Spinal fluid analysis should be done when meningitis is suspected, even if the blood tests are negative for Ebola virus RNA.

Prevention

There is no FDA-approved vaccine available for Ebola, although several vaccines are in various stages of development, and some have shown efficacy against virus challenge in laboratory primates. A vesicular stomatitis virus-based vaccine expressing a surface glycoprotein of *Zaire Ebolavirus* (rVSV-ZEBOV) is a promising candidate that was rapidly escalated into efficacy trials in Africa. In August 2015, the *Lancet* published an interim analysis showing that rVSV-ZEBOV appears to provide 100% protection against the virus. The trial was carried out in Guinea and used a "ring" design in which contacts of infected people are vaccinated, as are any subsequent contacts of those people.

Recommendations for travelers to an area affected by an Ebola outbreak or those residing in such an area are as follows:

- Practice careful hand hygiene and avoid contact with an infected person's blood or body fluids, including personal items that may have come in contact with blood and body fluids.
- Avoid unprotected contact with the body of a deceased person who was infected with EVD.
- Avoid contact with bats and nonhuman primates, including blood, bodily fluids, and tissues from these animals.
- Monitor health for 21 days after return from an Ebola endemic region, and seek medical care immediately if any symptoms develop.

Health care workers at risk for exposure to Ebola must wear PPE and notify appropriate health officials at their institutions if they have unprotected contact with the blood or bodily fluids of a person infected with EVD. Finally institutions must have proper infection control and sterilization measures in place for handling of biohazardous materials. Clinicians may contact the CDC for additional information on use of experimental therapeutics and vaccines for prophylaxis following a high-risk occupational exposure to Ebola virus.

Monitoring

Local authorities may have specific regulations for management of asymptomatic individuals with Ebola virus exposure. This includes self-monitoring versus direct observation by a health official, and the need for quarantine. In general, asymptomatic persons who have had an exposure should be monitored for 21 days after the last known exposure, and should immediately report the development of fever or other clinical manifestations suggestive of EVD to the health authorities.

FOODBORNE ILLNESSES

Method of

Anita Devi K. Ravindran, MD; and K.N. Viswanathan, MD

CURRENT DIAGNOSIS

- Infective foodborne illnesses are innumerable and are caused by various microorganisms. Some microorganisms are established agents, several others are emerging pathogens, and the pathogenicity of the remainder is still under speculation.
- Classification of these illnesses is best done according to their incubation periods, the symptoms they produce, or both.
- Nausea and vomiting predominate in illnesses with short incubation periods caused by preformed toxins, whereas diarrhea predominates in those with long incubation periods caused by toxins produced in the intestine.
- Undercooked charcuterie, meat, poultry, and seafood account for a majority of foodborne illness, but dairy products, salads, pastries, fruits, and vegetables can also cause illness.
- Contaminated water acts as a vehicle in almost all instances.

CURRENT THERAPY

- The majority of infective foodborne illnesses with symptoms confined to the gastrointestinal tract, although apparently alarming, are self-limiting and need only supportive measures including replacement of water and electrolytes.
- Antimicrobial agents are indicated only in certain patients, including those with systemic illnesses, extremes of age, immunocompromised and malnourished states, and severe life-threatening illness.
- Antitoxin is useful in botulism poisoning.
- Vaccines are available against *Vibrio cholerae*, *Salmonella typhi*, hepatitis A virus, and rotavirus, but their effectiveness and cost-effectiveness are debatable.

The Centers for Disease Control and Prevention (CDC) estimates that each year roughly one in six Americans (about 48 million people) gets sick from foodborne illnesses; 128,000 are hospitalized, and 3000 die. These figures are higher in developing nations, and many cases are not brought to light because they occur in remote villages. The 2011 estimates provide the most accurate picture of infective foodborne illnesses, of which bacteria, viruses, and parasites account for the majority. Processing of ready-to-eat foods increases the risk of acquiring foodborne illness because of increased food handling, leading to introduction and growth of pathogens. Increased international travel and migration have also resulted in a greater risk because travelers are at high risk for developing foodborne gastroenteritis caused by pathogens to which they have not been exposed at home.

Classification of Foodborne Illnesses

Agents causing foodborne diseases may be classified in several ways. The most common scheme is a taxonomic combined with a classification based on mode of action (Tables 1 to 3).

Bacteria

Aeromonas Species

Species of *Aeromonas* are ubiquitous and autochthonous in aquatic environments, more so after the tsunami that followed the Indonesian earthquake in December 2004. These aeromonads share many biochemical characteristics with members of the Enterobacteriaceae. The mesophilic species *Aeromonas caviae*, *Aeromonas hydrophila*, and *Aeromonas veronii* are principally associated with gastroenteritis; *A. caviae* particularly infects children younger than 3 years.

Transmission is documented as occurring from a contaminated piped water source, as seen in community-based outbreaks, especially among children. The probability of occurrence of *Aeromonas* infection increased significantly when the mean seasonal temperature exceeded 14°C (57°F), and this was exacerbated where the mean free chlorine concentration fell below 0.1 mg/L.

Aeromonas species are potential food-poisoning agents. *A. hydrophila* is psychrotrophic and has been associated with spoilage of refrigerated animal products including chicken, beef, pork, lamb, fish, oysters, crab, and milk.

The incubation period for *Aeromonas*-associated traveler's diarrhea is 1 to 2 days. It usually causes a sporadic illness. Usually a mild to moderate but self-limiting diarrhea occurs, but it can be severe enough in children to require hospitalization. *Aeromonas* gastroenteritis can occur as a nondescript enteritis, as a more-severe form accompanied by bloody stools, as the etiologic agent of a subacute or chronic intestinal syndrome, as an extremely rare cause of cholera-like disease, or in association with episodic traveler's diarrhea. By far the most common presentation of *Aeromonas* gastroenteritis is watery enteritis. The most serious complication resulting from *Aeromonas* gastroenteritis is hemolytic uremic syndrome.

Pathogenesis

Mesophilic *Aeromonas* spp. can express a range of virulence factors, including attachment mechanisms and production of a number of toxins. Toxins include aerolysin (a pore-forming cytolysin that attaches to cell membrane, leading to leakage of cytoplasmic contents) and a cytotoxic enterotoxin with activity similar to that of cholera toxin. Strains of *A. hydrophila* produce lectins and adhesins, which enable adherence to epithelial surfaces and gut mucosa.

Laboratory Diagnosis

Samples are best transported using Cary-Blair medium. *Aeromonas* forms a bull's-eye-like colony on the selective medium cefsulodin irgasan novobiocin (CIN) agar owing to fermentation of D-mannitol. Ampicillin blood agar has an advantage over CIN agar in that hemolytic colonies can readily be tested for oxidase. *Aeromonas* species produce hemolysis on sheep blood agar.

Treatment

In *Aeromonas* infections, ciprofloxacin (Cipro)¹ 500 mg PO or 400 mg IV twice daily is the antimicrobial treatment of choice. Piperacillin-tazobactam (Zosyn)¹ 4.5 g IV three times daily or cef-tazidime (Fortaz)¹ 2 g IV daily may be added in severe infections. The organism is also susceptible to aminoglycosides and carbapenems. Resistance is now becoming a problem because *Aeromonas* can produce β -lactamases and carbapenemases. Therefore it is preferable to initiate therapy with a fluoroquinolone when the organism is isolated.

Bacillus cereus

Bacillus cereus is found abundantly in the environment and vegetation. It is known to produce two forms of food poisoning, emetic and diarrheal. The emetic (short-incubation) type of illness is associated with contaminated fried rice that is not refrigerated. The organism is present in uncooked rice, and the spores survive boiling. The illness is usually self-limiting, with recovery in a day. It is

¹Not FDA approved for this indication.

TABLE 1 Classification of Foodborne Illnesses

SIGNS AND SYMPTOMS OR MECHANISM	PATHOGENS
Based on Symptoms and Duration of Onset	
Nausea and vomiting within 6 h	<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i>
Abdominal cramps and diarrhea within 8–16 h	<i>Clostridium perfringens</i> , <i>Bacillus cereus</i>
Fever, abdominal cramps, and diarrhea within 16–48 h	<i>Salmonella</i> , <i>Shigella</i> , <i>Vibrio parahaemolyticus</i> , enteroinvasive <i>Escherichia coli</i> , <i>Campylobacter jejuni</i>
Abdominal cramps and watery diarrhea within 16–72 h	Enterotoxigenic <i>E. coli</i> , <i>Vibrio cholerae</i> O1, O139 Bengal, <i>Vibrio parahaemolyticus</i> , NAG (nonagglutinable) vibrios, <i>Norovirus</i>
Fever and abdominal cramps within 16–48 h	<i>Yersinia enterocolitica</i>
Bloody diarrhea without fever within 72–120 h	Enterohemorrhagic <i>E. coli</i> O157:H7
Nausea, vomiting, diarrhea, and paralysis within 18–36 h	<i>Clostridium botulinum</i>
Based on Pathogenesis	
Food intoxications resulting from the ingestion of preformed bacterial toxins	<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i> , <i>Clostridium botulinum</i> , <i>Clostridium perfringens</i>
Food intoxications caused by noninvasive bacteria that secrete toxins while adhering to the intestinal wall	Enterotoxigenic <i>E. coli</i> , <i>Vibrio cholerae</i> , <i>Campylobacter jejuni</i>
Food intoxications that follow an intracellular invasion of intestinal epithelial cells	<i>Shigella</i> , <i>Salmonella</i>
Diseases caused by bacteria that enter the bloodstream via the intestinal tract	<i>Salmonella typhi</i> , <i>Listeria monocytogenes</i>
Based on Toxin Production	
The organisms responsible produce two major types of toxins, or they may be invasive, with no toxin production.	
Secretory toxins are enterotoxins produced by microbes that colonize the intestines in large numbers by attaching to the mucosal epithelial cells without invasion of mucosa, and, hence, there is no fever or other systemic symptoms as a result of lack of inflammatory response. Massive quantities of fluid and electrolytes are lost into the large bowel as its reabsorbing capacity is exceeded by the hypersecretion of isotonic fluid produced by the enterotoxins.	<i>Vibrio cholerae</i> , enterotoxigenic <i>E. coli</i> , <i>Shigella dysenteriae</i> , <i>Salmonella typhimurium</i>
Cytotoxins are those that destroy the epithelial cells of the mucosa.	<i>Shigella dysenteriae</i> elaborating Shiga toxin, causing destructive colitis, enterohemorrhagic <i>E. coli</i> , producing a similar toxin causing hemorrhagic colitis and hemolytic uremic syndrome (HUS), and <i>Vibrio parahaemolyticus</i> <i>Clostridium perfringens</i> , which produces a secretory enterotoxin, also has a cytotoxic action.
Secretory toxins, cytotoxins, and/or neurotoxins that are preformed are ingested directly in food.	<i>Bacillus cereus</i> , <i>Staphylococcus aureus</i> , <i>Clostridium botulinum</i>
Certain invasive microbes produce systemic symptoms such as fever, headache, and myalgia, in addition to gastrointestinal symptoms.	Salmonellosis typhoid fever, shigellosis, and brucellosis

mediated by a heat-stable, preformed enterotoxin resembling that of *Staphylococcus aureus*. The first major outbreak of *Bacillus cereus* food poisoning was in 1971 in England. The diarrheal (long-incubation) type of illness is produced by a heat-labile diarrheal enterotoxin formed in the intestine, which activates adenylate cyclase, causing intestinal fluid secretion, similar to *Escherichia coli* LT toxin and the toxin of *Clostridium perfringens*.

Pathogenesis

During the slow cooling of cooked rice, spores germinate and vegetative bacteria multiply; then they sporulate again. Sporulation is also associated with toxin production. The toxin is heat stable and can easily withstand the temperatures used to cook fried rice.

Laboratory Diagnosis

The disease is diagnosed by the isolation of *B. cereus* from the incriminated food (emetic type) or from stool and food (diarrheal type). Isolation from stools alone is not sufficient because gastrointestinal colonization with *B. cereus* occurs in many persons.

Treatment

B. cereus food poisoning may be symptomatically managed with replacement of fluids and electrolytes. Antimicrobials have no role in treatment. *B. cereus* is also known to produce a variety of ocular and systemic infections such as meningitis, osteomyelitis, pneumonia, and endocarditis. These are usually not foodborne, and it is in this situation that vancomycin (Vancocin)¹ becomes the drug of choice, with clindamycin (Cleocin)¹ and carbapenems being the alternative drugs, both being used along with aminoglycosides for synergistic action.

Campylobacter jejuni

Campylobacter jejuni are harbored in the reproductive and alimentary tracts of some animals. Other than gastrointestinal symptoms, the patient has malaise and headache. The organism may be shed in the patient's stool for up to 2 months. Bacteremia is observed in a

¹Not FDA approved for this indication.

TABLE 2 Common Organisms Implicated in Infective Foodborne Illness

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
Upper Gastrointestinal Tract Symptoms (Nausea, Vomiting) Occur First or Predominate				
<i>Staphylococcus aureus</i> (preformed toxin)	1–6 h	Sudden onset of severe nausea and vomiting Abdominal cramps, diarrhea, and fever may be present	24–48 h	Unrefrigerated or improperly refrigerated meat, potato and egg salads, cream pastries
<i>Bacillus cereus</i> (preformed toxin)	1–6 h	Sudden onset of severe nausea and vomiting Diarrhea may be present	24 h	Improperly refrigerated cooked or fried rice, meat
Lower Gastrointestinal Tract Symptoms (Abdominal Cramps, Diarrhea) Occur First or Predominate				
<i>Bacillus cereus</i> (diarrheal toxin)	10–16 h	Abdominal cramps, watery diarrhea, nausea	24–48 h	Meat, stew, gravy, vanilla sauce
<i>Clostridium perfringens</i> (toxin)	8–16 h	Watery diarrhea, nausea, abdominal cramps; fever is rare	24–48 h	Meat, poultry, gravy, dried or precooked foods, time- and/or temperature-abused food
<i>Vibrio cholerae</i>	2 h to 5 d	Rice-water purging diarrhea leading to dehydration, shock, acidosis, renal failure, abdominal pain Cholera sicca is a severe form; patient dies before diarrhea is manifest; ileus and abdominal bloating result	2–7 d	Sewage-contaminated water Seafood: fish, shellfish, crabs, oysters, clams Contaminated rice, millet gruel, vegetables
<i>Vibrio parahaemolyticus</i>	12–24 h	Watery diarrhea, abdominal cramps, nausea, vomiting Neurologic symptoms can occur, as with <i>Clostridium botulinum</i> and <i>Trichinella spiralis</i>	2–5 d	Raw or undercooked seafood
<i>Shigella</i>	1–4 d	Abdominal cramps, fever, diarrhea Stool might contain blood and mucus	4–7 d	Food or water contaminated with fecal matter Ready-to-eat food touched by infected food worker
<i>Salmonella</i> (not typhi)	1–3 d	Diarrhea, fever, abdominal cramps, vomiting	4–7 d	Contaminated eggs, unpasteurized milk or juice, cheese, contaminated raw fruits and vegetables
Enterotoxigenic <i>Escherichia coli</i>	1–3 d	Watery diarrhea, abdominal cramps, some vomiting	3–7 d (or longer)	Food or water contaminated with human feces
Shiga toxin–producing <i>E. coli</i> , including <i>E. coli</i> O157:H7	2–6 d	Severe diarrhea that is often bloody; abdominal pain and vomiting Usually little or no fever	5–10 d	Undercooked beef, especially hamburger, unpasteurized milk and juice, raw fruit and vegetables (e.g., sprouts), salami (rarely), contaminated water
<i>Campylobacter jejuni</i>	2–5 d	Diarrhea, cramps, fever, vomiting Diarrhea may be bloody	2–10 d	Raw and undercooked poultry, unpasteurized milk, contaminated milk
<i>Vibrio vulnificus</i>	1–7 d	Vomiting, diarrhea, abdominal pain Fever, bleeding within the skin, ulcers requiring surgical removal Can be fatal to people with liver disease or weakened immune systems	2–8 d	Undercooked or raw seafood, especially oysters
<i>Yersinia enterocolitica</i>	3–7 d	Appendicitis-like symptoms: diarrhea, vomiting, fever, abdominal pain	Can remit and relapse over weeks to 1 mo	Drinking water, food contaminated with human fecal matter
<i>Cyclospora</i>	7–10 d	Diarrhea (usually watery), loss of appetite, weight loss, stomach cramps, nausea, vomiting, fatigue	Can remit and relapse over weeks to 1 mo	Fresh herbs and produce (e.g., raspberries, basil, lettuce)
<i>Giardia lamblia</i> (beaver fever)	7–10 d	Diarrhea (acute or chronic), stomach cramps, flatulence, weight loss, malabsorption, developmental delay	Days to weeks	Drinking water, food contaminated with human fecal matter

TABLE 2 Common Organisms Implicated in Infective Foodborne Illness—cont'd

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Entamoeba histolytica</i>	1–4 wk	Intestinal: diarrhea, fever, abdominal pain, dysentery, colitis, bowel perforation, ameboma Extraintestinal amebiasis: liver abscess with anchovy-sauce pus, spread to viscera, lungs, and brain	Days to weeks	Drinking water Food contaminated with human fecal matter
Both Upper and Lower Gastrointestinal Tract Symptoms				
Rotavirus	18–36 h	Acute onset of fever and vomiting followed 12–24 h later by frequent watery stools	3–7 d	Contaminated drinking water, food, fomites
Norovirus and other caliciviruses	12–48 h	Nausea, vomiting, cramping, diarrhea, fever, myalgia, some headache Diarrhea is more prevalent in adults; vomiting is more prevalent in children	12–60 h	Food (including shellfish) or water contaminated with human fecal matter Ready-to-eat food touched by an infected food worker
Generalized Symptoms				
<i>Listeria monocytogenes</i>	9–48 h or GI symptoms; 2–6 wk for invasive disease	Fever, muscle aches, nausea or diarrhea Pregnant women can have mild flulike illness, and infection can lead to premature delivery or stillbirth Elderly and immunocompromised patients can have bacteremia or meningitis	Variable	Fresh soft cheese, unpasteurized milk, ready-to-eat deli meat, hot dogs
<i>Balantidium coli</i>	4–5 d	Mostly asymptomatic Chronic diarrhea, occasional dysentery, nausea, foul breath, colitis, abdominal pain, weight loss, deep intestinal ulcerations, possible perforation of the intestine, pneumonia-like illness	Variable	Water contaminated with pig feces
<i>Salmonella typhi</i>	8–14 d	Fever, anorexia, lethargy, malaise, headache, rose spots, constipation or diarrhea, hepatosplenomegaly	4–6 wk	Contaminated water; contaminated food, mainly via food handlers; shellfish from polluted water
<i>Ascaris lumbricoides</i>	4–16 d	Nausea, abdominal pain, intestinal obstruction, malnutrition, Loeffler's syndrome (cough, pneumonitis, eosinophilia), biliary colic, colangitis, pancreatitis, appendicitis	Variable (chronic)	Soil-contaminated raw food, food handlers, water
<i>Trichinella spiralis</i>	1–2 wk	Asymptomatic or chronic diarrhea, abdominal pain Allergy leading to rash, periorbital edema, vasculitis, intramural thrombi Weakness of jaw, biceps, diaphragm, intercostals Eosinophilia, subconjunctival, splinter hemorrhages Muscle penetration: myalgia, orbital pain, diplopia Chronic phase: neurologic symptoms	Variable Acute phase: 1–3 wk	Raw or undercooked meat of pig, horse, wild boar, bush pig, warthog, bear
Infective cysticerci of <i>Taenia solium</i> (pork tape worm)	2 months on average	Seizures, vasculitis, focal neurologic deficits, intracranial hypertension, hydrocephalus, mental changes, encephalitis and Brun's syndrome (intermittent obstruction of cerebral aqueduct), myositis, vasculitis	Highly variable	Undercooked charcuterie (pork), contaminated raw vegetables, salads, water
Hepatitis A	15–50 d	Diarrhea, dark urine, jaundice, flulike symptoms, fever, headache, nausea, aversion to food, vomiting, abdominal pain; distaste for cigarettes	Variable: 2 wk to 3 mo	Food (including shellfish) or water contaminated with human fecal matter Inadequately cooked clams, oysters, mussels, cockles Contaminated lettuce, slush beverages, frozen strawberries and salad items Ready-to-eat foods touched by an infected food worker

Continued

TABLE 2 Common Organisms Implicated in Infective Foodborne Illness—cont'd

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Brucella</i> species	1–8 wk	Flulike illness; undulating fever, malaise, arthralgia, anorexia, hepatosplenomegaly, pleurisy, nausea, vomiting, diarrhea, new onset of increased desire to sleep after lunch	Variable	Unpasteurized dairy products, undercooked meat, bone marrow Contact with laboratory cultures and tissue samples Accidental injection of live brucellosis vaccine
Hepatitis E	3–8 wk	Prodrome: anorexia, nausea, vomiting, arthralgia, myalgia, weight loss, dehydration, abdominal pain Icteric phase: jaundice, pruritus, light-colored stool Urticaria, diarrhea, malaise	Variable (several weeks)	Fecally contaminated drinking water and food Raw and undercooked shellfish incriminated in sporadic outbreaks Possibly zoonotic spread
Microsporidium: <i>Encephalitozoon</i> , <i>Pleistophora</i> , <i>Nosema</i> , <i>Vittaforma</i> , <i>Trachipleistophora</i> , <i>Brachiola</i> , <i>Microsporidium</i> , <i>Enterocytozoon</i>	Unknown	Watery or bloody or unspecified diarrhea, abdominal discomfort, cramps, flatulence, weight loss, loss of appetite, wasting syndrome, subfebrile temperatures Extraintestinal: pneumonitis, myositis, keratoconjunctivitis, seizures, nephritis, cholangiopathy	Variable; self-limiting (1–2 wk) in immunocompetent patients	Contaminated water, food, or inhalation

Abbreviation: GI=gastrointestinal.

small minority of cases. The disease is usually self-limiting. Guillain-Barré syndrome and Reiter's syndrome are recognized sequelae.

Pathogenesis

As few as 500 organisms can cause enteritis. The organism is invasive but generally less so than *Shigella*. *Campylobacter* produces adenylate cyclase-activating toxins resembling *E. coli* LT and cholera toxin.

Laboratory Diagnosis

The feces may be inoculated in enrichment medium or on selective media such as Campy-BAP or Skirrow's medium.

Treatment

Indications for antibiotic therapy in *C. jejuni* infections are prolonged fever, severe diarrhea, dysentery, and persistent symptoms for more than a week. Therapy of *Campylobacter* infection with ciprofloxacin (Cipro 500 mg orally twice daily for 7 days) early in the course of the illness shortens its duration. Unfortunately, this has led to the emergence of fluoroquinolone-resistant *Campylobacter* infections. Erythromycin eradicates carriage of susceptible *C. jejuni* and might shorten the duration of illness if given early in the disease. Erythromycin (Ery-Tab)¹ 250 mg PO four times daily is the drug of choice in *Campylobacter* enteritis. Azithromycin (Zithromax)¹ is also useful and has the advantage of shorter duration of therapy.

Gentamicin (Garamycin), carbapenems, amoxicillin-clavulanate (Augmentin),¹ and chloramphenicol¹ are useful in systemic infections. The usual duration of treatment is 2 weeks. The therapy is prolonged in immunocompromised persons and in patients with endovascular infections.

Clostridium botulinum

Clostridium botulinum is widely distributed in soil, in sediments of lakes and ponds, and in decaying vegetation. *C. botulinum* elaborates the most potent toxin known in humans. When the toxin is ingested, paralysis occurs, often requiring prolonged artificial ventilation. Common signs and symptoms include vomiting, thirst, dry

mouth, constipation, ocular palsies, dysphagia, dysarthria, bulbar paralysis, and death due to respiratory paralysis. Coma or delirium occurs in some. Infants present with lethargy, poor feeding, loss of head control, and sometimes sudden infant death syndrome (SIDS).

The incriminated foods are corn syrup, home-canned or bottled meat, fruits, fish, vegetables, herb-infused oils, and cheese sauce. Infant botulism is associated with consumption of honey; honey should not be given to infants younger than 1 year.

Pathogenesis

Not all strains of *C. botulinum* produce botulinum toxin. Toxicogenic types of the organism, designated A, B, C1, D, E, F, and G, produce immunologically distinct forms of botulinum toxin. Lysogenic phages encode toxin C and D serotypes.

Foodborne botulism is not an infection but an intoxication because it results from the ingestion of foods that contain the preformed clostridial toxin. If contaminated food has been insufficiently heated or canned improperly, the spores can germinate and produce botulinum toxin. The toxin is released only after cell lysis and death. The toxin resists digestion and is absorbed by the upper gastrointestinal tract and enters the blood. The toxin blocks release of acetylcholine by binding to receptors at synapses and neuromuscular junctions and causes flaccid paralysis.

Laboratory Diagnosis

Spoilage of food or swelling of cans or presence of bubbles inside the can indicate growth of *C. botulinum*. Food is homogenized in broth and inoculated in Robertson cooked meat medium and blood agar or egg-yolk agar, which is incubated anaerobically for 3 to 5 days at 37°C. The toxin can be demonstrated by injecting the extract of food or culture into mice or guinea pigs intraperitoneally.

Treatment

Hospitalization in an intensive care unit with immediate administration of botulinum antitoxin is vital in the management of botulism. The antitoxin neutralizes only toxin molecules unbound to nerve endings and does not reverse the paralysis. It should be given within 24 hours after the diagnosis is made. Penicillin is the antimicrobial of choice. Intubation and mechanical ventilation are needed

¹Not FDA approved for this indication.

TABLE 3 Rare and Emerging Infections

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Bacillus subtilis</i>	10 min to 14 h (average, 2.5 h)	Vomiting, diarrhea, abdominal cramps, nausea, headache, flushing, sweating	1.5–8 h	Sausage rolls, meat pasties, turkey stuffing, chicken stuffing, pizza, whole-grain bread, steak pie, pork sandwiches
Cyanobacteria: <i>Microcystis aeruginosa</i> , <i>Anabaena circinalis</i> , <i>Anabaena flosaquae</i> , <i>Aphanizomenon flosaquae</i> , <i>Cylindrospermopsis racibarskii</i>	3–6 h	Diarrhea, vomiting, allergic reactions, breathing difficulty, dizziness, tingling and numbness, liver and kidney toxicity	8–16 h	Drinking water from untreated surface sources, inhaling aerosols from jet-skis and boats, consuming dietary supplements contaminated by microcystin
<i>Anisakis</i>	Few hours to days	Gastric: abdominal pain, nausea, vomiting Allergic: urticaria, anaphylaxis Intestinal: ileus, perforation, peritonitis, stenosis	2 wk	Raw, lightly pickled, or salted marine fish: Mackerel, squid, horse mackerel, salmon, bonito Squid, cuttlefish Sushi, sashimi
Astrovirus	1–4 d	Watery diarrhea (especially in children), vomiting, fever, anorexia, abdominal pain	3–4 d	Sewage-polluted water and food
<i>Plesiomonas shigelloides</i>	5 d	Diarrhea with blood and mucus, abdominal pain, headache, nausea, chills, fever, vomiting	1–7 d	Contaminated water used for drinking or rinsing foods to be eaten raw Contaminated raw shellfish, salted fish, crabs, oysters
<i>Cyclospora</i>	7 d	Frequent watery diarrhea, weight loss, abdominal pain, bloating, flatulence, vomiting, nausea, low-grade fever, fatigue, malabsorption, cholecystitis	1–4 wk Relapse is common	Fecally contaminated fresh raspberries, snow peas, mesclun
<i>Iosopora belli</i>	8–11 d	Diarrhea, steatorrhea, headache, fever, malaise, abdominal pain, vomiting, dehydration, weight loss Mesenteric lymph node, liver, spleen involvement	Variable; runs a chronic course in immunocompromised patients	Contaminated food and water
<i>Edwardisella tarda</i>	Not defined	Nausea, vomiting, diarrhea, dysentery, colitis, wound infections, septicemia	Variable: 1–2 wk or longer	Fecal contamination of food, water, raw fish
<i>Citrobacter</i> species	Not defined	Diarrhea, hemolytic uremic syndrome, thrombocytopenic purpura		Meat and milk Parsley (in green butter) from organic gardens using pig manure
<i>Arizona</i>	Not defined	Diarrhea		Cream pie, chocolate eclairs, custard, eggs, chicken, turkey
<i>Achromobacter xylosoxidans</i>	Not defined	Abdominal pain, diarrhea, headache, vomiting		Raw milk, spoiled canned food, contaminated well water

for respiratory failure. If swallowing difficulty persists, intravenous fluids or alimentation should be given through a nasogastric tube.

Clostridium perfringens

C. perfringens is heat resistant and elaborates two toxins that can induce specific pathology in the human intestinal tract. It is the third leading cause of foodborne illnesses in United States, after norovirus and *B. cereus*. It is present abundantly in the environment, vegetation, sewage, and animal feces.

Human diseases caused by this organism are the more common *C. perfringens* type A food poisoning and the less common, but more serious, *C. perfringens* type C food poisoning producing

necrotic enteritis. Necrotic enteritis is characterized by vomiting, severe abdominal pain, and bloody diarrhea. The incubation period is 2 to 5 days. Progression to necrosis of the jejunum and death occur.

Pathogenesis

Spores in food can survive cooking and then germinate when the food is improperly stored. When these vegetative cells form endospores in the intestine, they release enterotoxins. Food poisoning is mainly caused by type A strains, which produce alpha and theta toxins. The toxins result in excessive fluid accumulation in the intestinal lumen.

Laboratory Diagnosis

Because the bacterium is present normally in intestines, isolation from feces might not be sufficient to implicate it as the cause of the illness. Similarly, isolation from food, except in large numbers ($>10^9$ /g), might not be significant. The homogenized food is diluted and plated on selective medium, as well as Robertson cooked meat medium, and subjected to anaerobic incubation. The isolated bacteria must be shown to produce enterotoxin.

Treatment

Food poisoning due to *Clostridium perfringens* is managed conservatively with hydration and replacement of electrolytes. *C. perfringens* is susceptible to benzylpenicillin (penicillin G), which may be useful in managing severe infections (1 mU IV every 4 hours). Vancomycin,¹ clindamycin,¹ cefoxitin (Mefoxin), and metronidazole (Flagyl) are alternatives. *C. perfringens* type C toxoid vaccine² (two doses, 4 months apart) is preventive in pigbel.

Cronobacter sakazakii

Cronobacter sakazakii causes neonatal meningitis or necrotizing enterocolitis and bacteremia, which results in an alarming mortality rate. Surviving patients sometimes develop ventriculitis and cerebral abscess. *C. sakazakii* has been isolated from infant formulas.

Enterobacter species are generally resistant to the cephalosporins, except cefepime (Maxipime),¹ but are responsive to carbenicillin (Geocillin),¹ piperacillin (Pipracil),¹ ticarcillin (Ticar),¹ amikacin (Amikin),¹ and tigecycline (Tygacil).¹

Enterohemorrhagic *Escherichia coli*

Many serogroups of *E. coli*, including O4, O26, O45, O91, O111, O145, and O157, are pathogenic, but the most common pathogenic serotype is O157:H7. Cattle are the main sources of infection; most cases are associated with the consumption of undercooked beef burgers and similar foods from restaurants and delicatessens.

Pathogenesis

Enterohemorrhagic *E. coli* (EHEC) strains can produce one or more types of cytotoxins, which are collectively referred to as Shiga-like toxins because they are antigenically and functionally similar to Shiga toxin produced by *Shigella dysenteriae*. (Shiga-like toxins were previously known as verotoxins.) The toxins provoke cell secretion and kill colonic epithelial cells, causing hemorrhagic colitis and hemolytic-uremic syndrome (HUS), leading occasionally to disseminated intravascular coagulation (DIC). A fibrin layer forms in the glomerular capillary bed, and acute renal failure occurs due to DIC. These are most likely to occur in children, elderly patients, and pregnant women. The young recover fully, but at times dialysis is warranted.

Laboratory Diagnosis

Laboratory diagnosis is performed by culturing the feces on McConkey's agar or sorbitol McConkey's agar. Strains can then be identified by serotyping using specific antisera. Shiga-like toxins can be detected by enzyme-linked immunosorbent assay (ELISA), and genes coding for them can be detected by DNA hybridization techniques.

Treatment

Hydration with electrolyte replacement is the mainstay of treatment in *E. coli* O157:H7 infection, and patients should be monitored closely and constantly for the development of HUS, which requires management in an intensive care setting with blood transfusion and dialysis. Although dysentery is self-limiting, the use of rifaximin (Xifaxan), a nonabsorbable agent, is recommended in those who are increasingly susceptible to infections. In the absence of dysentery, early institution of drugs like ciprofloxacin (Cipro) or

azithromycin (Zithromax),¹ especially in traveler's diarrhea, decreases the duration of illness.

Enterotoxigenic *Escherichia coli*

Enterotoxigenic *E. coli* (ETEC) is now ubiquitous in nature. Wild animals and cattle act as reservoirs of the organism. *E. coli* is carried normally in the intestine of humans and animals. Some specific serotypes harbor plasmids that code for toxin production. This bacterium is responsible for a majority of traveler's diarrhea. The disease is self-limiting and resolves in a few days.

Pathogenesis

The bacteria colonize the gastrointestinal tract by means of fimbriae, attaching to specific receptors on enterocytes of the proximal small intestine. Enterotoxins produced by ETEC include the LT (heat-labile) toxin and the ST (heat-stable) toxins. LTs are similar to cholera toxin in structure and mode of action, consisting of A and B subunits. The B (binding) subunit of LTs binds to specific ganglioside receptors (GM1) on the epithelial cells of the small intestine and facilitates the entry of the A (activating) subunit, which activates adenylate cyclase. Stimulation of adenylate cyclase causes an increased production of cyclic adenosine monophosphate (cAMP), which leads to hypersecretion of water and electrolytes into the lumen and inhibition of sodium reabsorption.

Laboratory Diagnosis

The sample of feces is cultured on McConkey's agar. The ETEC stains are indistinguishable from the resident *E. coli* by biochemical tests. These strains are differentiated from nontoxigenic *E. coli* present in the bowel by a variety of in vitro immunochemical, tissue culture, or DNA hybridization tests designed to detect either the toxins or the genes that encode for these toxins. With the availability of a gene probe method, foods can be analyzed directly for the presence of ETEC in about 3 days. LTs can be detected by ligated rabbit ileal loop test and by observing morphologic changes in Chinese hamster ovary cells and Y1 adrenal cells. ELISA, immunodiffusion, and coagglutination are also used in diagnosis.

Listeria monocytogenes

Listeria monocytogenes is quite hardy and resists the deleterious effects of freezing, drying, and heat remarkably well for a bacterium that does not form spores. It is capable of growing at 3°C and multiplies in refrigerated foods.

Pathogenesis

L. monocytogenes invades the gastrointestinal epithelium. Once the bacterium enters the host's monocytes, macrophages, or neutrophils, it is bloodborne and can grow. Its presence in phagocytes also permits access to the brain and transplacental migration to the fetus in pregnant women. Granulomatosis infantisepticum is a feature of listeriosis. The pathogenesis of *L. monocytogenes* centers on its ability to survive and multiply in phagocytic host cells.

Laboratory Diagnosis

The diagnosis of listeriosis is most commonly made by isolation of *L. monocytogenes* from a normally sterile site. β -Hemolytic colonies, which test negative for catalase, hydrolyze hippurate, and have a positive cAMP reaction, form on blood agar. Serologic testing is not useful in diagnosing acute invasive disease, but it can be useful in detecting asymptomatic disease and gastroenteritis in an outbreak or in other epidemiologic investigations. Stool testing is not commercially available.

Treatment

Ampicillin¹ (2 g IV every 4 hours) is the drug of choice in *Listeria monocytogenes* infections. Aminoglycosides are added for synergistic effect. Trimethoprim-sulfamethoxazole (TMP-SMX)¹ (Bactrim, 20 mg of trimethoprim/day IV every 6 hours) is an alternative for

¹Not FDA approved for this indication.

²Not available in the United States.

¹Not FDA approved for this indication.

patients allergic to penicillin. Ampicillin and TMP-SMX may be used in combination. Vancomycin (Vancocin),¹ linezolid (Zyvox),¹ carbapenems, macrolides, and tetracyclines are also effective. Cephalosporins are ineffective in the treatment of listeriosis and should not be used. The duration of therapy is highly variable depending on the clinical situation and is 14 days for bacteremia, 21 days for meningitis, 42 days for endocarditis, and 56 days for neurologic infections. Patients whose disease is promptly diagnosed and treated recover fully, but permanent neurologic sequelae are common in patients with cerebral illnesses. Consuming only pasteurized dairy products and fully cooked meats, meticulously cleaning utensils, and thoroughly washing fresh vegetables before cooking will prevent foodborne listerial infections. Pregnant women and others at risk should avoid soft cheeses and thoroughly reheated ready-to-serve and charcuterie foods.

Nontyphoidal Salmonellosis

Nontyphoidal salmonellosis consists of several causative organisms classified under the family Enterobacteriaceae; one such organism is *Salmonella enteritidis*. It does not occur normally in humans, but several animals act as reservoirs.

The diarrhea may be watery, with greenish, foul-smelling stools. This may be preceded by headache and chills. Other findings include prostration, muscle weakness, and moderate fever.

Pathogenesis

The organism penetrates and passes through the epithelial cells lining the terminal ileum. Multiplication of bacteria in lamina propria produces inflammatory mediators, recruits neutrophils, and triggers inflammation. Release of lipopolysaccharides and prostaglandins causes fever and also loss of water and electrolytes into the lumen of the intestine, resulting in diarrhea.

Laboratory Diagnosis

Culture in selenite F broth and then subculture on deoxycholate citrate agar isolates the organisms. Plates are incubated at 37°C overnight, and growth is identified by biochemical and slide agglutination tests.

Treatment

The antibiotics recommended for gastroenteritis due to nontyphoidal salmonellosis are ciprofloxacin (Cipro)¹ 500 mg PO twice daily, and ceftriaxone (Rocephin) 2 g IV daily, for 3 to 7 days. Amoxicillin (Amoxil)¹ and TMP-SMX¹ are also effective. Therapy is prolonged in bacteremia, endocarditis, or meningitis.

Shigella Species

Shigella species belong to the family Enterobacteriaceae. Bacillary dysentery is caused by *Shigella flexneri*, *Shigella boydii*, *Shigella dysenteriae*, and *Shigella sonnei*. *S. flexneri* is most common in developing countries where hygiene is poor and clean drinking water is unavailable; *S. sonnei* is most common in developed countries. The watery diarrhea that is present initially becomes bloody after a day or two owing to spread of infection from the ileum to the colon. The illness is caused by exotoxin acting in the small bowel.

Extraintestinal manifestations are recognized, including HUS, Reiter's syndrome, meningitis, Ekiri syndrome (reported in Japanese children and consisting of a triad of encephalopathy due to cerebral edema, bizarre posturing, and fatty degeneration of liver), vaginitis, lung infections, and keratoconjunctivitis. Toxic megacolon, pneumatosis coli, perforation, and rectal prolapse are recognized complications.

Tossed salads, chicken, and shellfish are the commonly incriminated foods. Person-to-person spread by anal intercourse or oral sex also occurs. Prepared food acts as a vehicle of transmission. Spread of infection is also linked to flies.

Children are at high risk during the weaning period, and increasing age is associated with decreased prevalence and severity. Children in daycare centers, persons in custodial institutions, migrant workers, and travelers to developing countries are also at high risk.

Pathogenesis

The virulence factor is a smooth lipopolysaccharide cell wall antigen, which is responsible for the invasive features, and the Shiga toxin, which is both cytotoxic and neurotoxic. Shigellae survive the gastric acidity and invade and multiply within the colonic epithelial cells, causing cell death and mucosal ulcers, and spread laterally to involve adjacent cells but rarely invade the bloodstream.

Laboratory Diagnosis

Shigellosis can be correctly diagnosed in most patients on the basis of fresh blood in stool. Neutrophils in fecal smears strongly suggest infection. Any clinical diagnosis should be confirmed by cultivation of the etiologic agent from stools. Cary-Blair medium is the transport medium of choice, and MacConkey agar or deoxycholate citrate agar (DCA) as well as a highly selective medium such as xylose-lysine deoxycholate (XLD), Hektoen enteric (HE), or *Salmonella-Shigella* (SS) agar are also used.

Treatment

Ciprofloxacin (Cipro, 500 mg PO twice daily for 3 days) is the antibiotic of choice for shigellosis. Alternative agents are pivmecillinam (Selexid),² ceftriaxone (Rocephin),¹ and azithromycin (Zithromax).¹

Staphylococcus aureus

A notable incident of staphylococcal food poisoning occurred in February 1975 when 196 of 344 passengers and one flight attendant aboard a jet from Tokyo to Copenhagen via Anchorage contacted a gastrointestinal illness characterized by nausea, vomiting, and abdominal cramps. The flight attendant and 142 passengers were hospitalized. Symptoms developed shortly after a ham and omelet breakfast had been served. *S. aureus* was incriminated as the offending agent and ham as the vehicle of the outbreak. The source was traced to a cook with pustules on his fingers.

S. aureus is ubiquitous in the environment. Only strains that produce enterotoxin cause food poisoning. Food is usually contaminated by infected food handlers.

Pathogenesis

If food is stored for some time at room temperature, the organism can multiply in the food and produce enterotoxin. Most food poisonings are caused by enterotoxin A, and the isolates commonly belong to phage type III. These are heat stable, and ingestion of as little as 23 µg of enterotoxin can induce symptoms. The toxin acts on the receptors in the gut, and sensory stimulus is carried to the vomiting center in the brain by vagus and sympathetic nerves.

Because the ingested food contains preformed toxin, the incubation period is very short. In severe illness, profound hypotension occurs. Death is known to occur at extremes of age and in the malnourished.

Laboratory Diagnosis

The presence of a large number of *S. aureus* in food can indicate poor handling or sanitation; however, it is not sufficient evidence to incriminate the food as the cause of food poisoning.

Staphylococcal food poisoning can be diagnosed if staphylococci are isolated in large numbers from the food and their toxins are demonstrated in the food or if the isolated *S. aureus* is shown to produce enterotoxins. Dilutions of food may be plated on Baird-Parker agar or mannitol salt agar. Enterotoxin may be detected and identified by gel diffusion.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

²Not available in the United States.

Treatment

Therapy is mainly supportive. Antibiotics have no role in the treatment because they are not antitoxins. Intravenous fluids and electrolyte replacement are imperative in the severely dehydrated patient.

Yersinia Species

The *Yersinia* species that cause food poisoning are commonly *Yersinia enterocolitica* and rarely *Yersinia pseudotuberculosis*. Pigs and other wild or domestic animals are the hosts, and humans are usually infected by the oral route. Serogroups that predominate in human illness are O:3, O:5, O:8, and O:9.

Yersiniosis is common in children and occurs most often in winter. *Y. enterocolitica* is associated with terminal ileitis and *Y. pseudotuberculosis* with mesenteric adenitis, but both organisms can cause mesenteric adenitis and symptoms that cause a clinical picture resembling appendicitis, resulting in surgical removal of a normal appendix. Rarer strains of *Y. enterocolitica* are likely to cause systemic infections, especially in patients with diabetes or in iron overload states. In Japan, a form of vasculitis, called Izumi fever, occurs, and in Russia a scarlet fever–like illness has been reported.

Pathogenesis

Yersinia organisms can survive and grow during refrigerated storage. Strains that cause human yersiniosis carry a plasmid that is associated with a number of virulence traits. Ingested bacteria adhere and invade M cells or epithelial cells.

Laboratory Diagnosis

Suspect food is homogenized in phosphate-buffered saline and inoculated into selenite F broth and held at 4°C for 6 weeks. The broth is subcultured at weekly intervals on deoxycholate citrate (DCA) or *Yersinia*-selective agar plates. This is termed *cold-enrichment technique*.

Treatment

Antibiotics are not recommended for gastroenteritis caused by *Yersinia enterocolitica* and the less-common *Yersinia pseudotuberculosis*, but bacteremia and extraintestinal infections require treatment with ciprofloxacin¹ (500 mg PO or 400 mg IV twice daily for 2 weeks). Third-generation cephalosporins (cefotaxime¹ [Claforan]), amoxicillin¹ (Amoxil), TMP-SMX¹ (Bactrim), amoxicillin-clavulanate¹ (Augmentin), carbapenems, and gentamicin (Garamycin) are also effective agents in therapy.

Viruses

Noroviruses

Noroviruses (formerly called Norwalk or Norwalk-like viruses and small round structured viruses [SRSV]) and sapoviruses belong to the family Caliciviridae and are the most common cause of gastroenteritis. They account for about 90% of epidemic nonbacterial outbreaks of gastroenteritis around the world. Norovirus infection often affects people during the winter months and is therefore sometimes called winter vomiting disease; however, people may be affected at any time of the year. After a norovirus infection, immunity lasts only for 14 weeks and is incomplete. Persons with blood group O are more susceptible to infection, whereas those with groups B and AB are partially protected. Norovirus infection outbreaks more commonly occur in closed or semiclosed communities, such as prisons, dormitories, cruise ships, schools, long-term care facilities, and overnight camps—places where infection can spread rapidly from human to human or through tainted food and surfaces. Infection outbreaks can also result from food handled by an infected person.

Outbreaks have often been linked to consumption of cold foods, including salads, sandwiches, and bakery products. Salad dressing, cake icing, and oysters from contaminated waters have also been implicated in gastroenteritis outbreaks. Weight loss, lethargy,

low-grade fever, headache, and (rarely) ageusia occur. Vomiting is more likely with infections caused by norovirus than sapovirus.

Pathogenesis

Norovirus strains that infect humans are found in genogroups I, II, and IV. GII.4 strains are more commonly associated with person-to-person transmission, and GI strains are identified more commonly in shellfish-associated outbreaks.

Noroviruses were shown to differentially bind to histo-blood group antigens, and the binding pattern correlates with susceptibility to infection and illness. A number of enzymes are important in the synthesis of histo-blood group antigens, including fucosyl transferase-2 (FUT-2, secretor enzyme), FUT-3 (Lewis enzyme), and the A and B enzymes. The glycan produced by FUT-2 H type 1, serves as a viral receptor for noroviruses.

Laboratory Diagnosis

The virus can be recovered from the infected person's stool and vomitus during illness for about 2 weeks. Electron microscopy and reverse-transcriptase polymerase chain reaction (RT-PCR) antigen-detection assays are performed on stool samples. Serologic assays are not available for clinical use. However, infection can be diagnosed by identifying a fourfold or greater increase in antibody titer between acute and convalescent sera using norovirus virus-like particles as antigen.

Treatment

There is no specific treatment for norovirus infection. Hydration is generally adequate for most patients. In developing countries, oral rehydration therapy is the treatment of choice. Effective hand washing, careful food processing, and education of food handlers along with chlorination of water are important preventive measures. A vaccine for norovirus is in clinical trials.

Rotavirus

Among the seven rotavirus species (A to G), rotavirus A, B, and C can cause disease in humans. Rotavirus A is the most common and is the major cause of waterborne outbreaks in humans. Infections are referred to as infantile diarrhea, winter diarrhea, or acute viral gastroenteritis. Children 6 months to 2 years of age, premature infants, the elderly, and the immunocompromised are particularly prone to more-severe symptoms caused by infection with group A rotavirus. Rotavirus can survive in water for days to weeks, depending on water quality and temperature. Waterborne outbreaks are most common, followed by spread by fomites. Rotaviruses infect intestinal enterocytes; diarrhea may be caused by malabsorption secondary to the destruction of enterocytes, villus ischemia and activation of the enteric nervous system, and intestinal secretion stimulated by the action of rotavirus nonstructural protein 4 (NSP4), a novel enterotoxin and secretory agonist with pleiotropic properties.

Outbreaks caused by group B rotavirus, also called adult diarrhea rotavirus, have also been reported in the elderly and adults. Such infections are rare and usually subclinical. Group C rotavirus has been associated with rare and sporadic cases of diarrhea in children in many countries. Subclinical infection to severe gastroenteritis leading to life-threatening dehydration can occur. The illness has an abrupt onset, with vomiting often preceding the onset of diarrhea. Up to one third of patients have fever of about 39°C. The stools are characteristically watery and only occasionally contain red or white cells. Symptoms generally resolve in a week.

Respiratory and neurologic features in children have been reported. Rotavirus infection has been associated with other clinical conditions including sudden infant death syndrome (SIDS), necrotizing enterocolitis, Kawasaki's disease, and type 1 diabetes.

Laboratory Diagnosis

Electron microscopy, direct antigen detection assays (ELISA, immunochromatography, latex agglutination), and nucleic acid detection (e.g., RT-PCR, polyacrylamide gel electrophoresis [PAGE]), are used mainly in epidemiologic studies during outbreaks.

¹Not FDA approved for this indication.

Treatment

Dehydration due to group A rotavirus infection is treated with early institution of oral and intravenous fluids. The role of probiotics,⁷ bismuth subsalicylate (Pepto Bismol),¹ inhibitors of enkephalinase, and nitazoxanide (Alinia)¹ are not clearly defined. Antimicrobials and antimotility agents should be avoided. A marked fall in deaths from childhood diarrhea following introduction of rotavirus vaccines (Rotarix, RotaTeq) has been reported from various parts of the world, and surveillance information has not revealed an association of any serious adverse reactions with the vaccine.

Other Pathogens

Cryptosporidium

Transmission of *Cryptosporidium* is usually by the fecal-oral route, often through food and water contaminated by livestock mammal feces. Persons most likely to be infected by *Cryptosporidium parvum* are infants and young children in daycare centers; those whose drinking water is unfiltered and untreated; those involved in farming practices such as lambing, calving, and muck-spreading; people engaging in anal sexual practices; patients in a hospital setting (from other infected patients or health care workers); veterinarians; and travelers.

Pathogenesis

Cryptosporidium spp. are believed to be noninvasive. Malabsorption resulting from the intestinal damage caused by prolonged protozoal infection can be fatal. Although host cells are damaged in cryptosporidiosis, the means by which the organism causes damage is not known. Mechanical destruction and the effects of toxins, enzymes, or immune-mediated mechanisms, working alone or together, may be instrumental. In the immunocompromised, the illness is much more debilitating, with cholera-like diarrhea.

Laboratory Diagnosis

Traditionally, cryptosporidiosis is diagnosed by microscopic observation of developmental stages of the organism in an intestinal biopsy specimen. Oocysts can be recovered from stool samples by formalin-concentration techniques, staining with a modified Ziehl-Neelsen acid-fast stain. Serologic tests (ELISA, immunofluorescence antibody, PCR) are of added value.

Treatment

Nitazoxanide (Alinia, 500 mg PO twice daily for 3 days) is recommended with antiretrovirals for HIV-positive patients. Fluid replacement and antidiarrheal agents are also given.

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

Trichinosis

Trichinosis is due to *Trichinella spiralis* infection, commonly as a result of consuming improperly cooked pork. The parasite lodges in the extraocular muscles, deltoid, biceps, intercostals, diaphragm, tongue, or masseter and produces severe weakness with pain, fever, and cough along with splinter hemorrhages and eosinophilia.

Moderate *T. spiralis* infection is treated with mebendazole (Vermox 200–400 mg PO three times daily for 3 days) or albendazole¹ (Albenza 400 mg PO twice daily for 7–14 days). For severe infections, prednisone is added in a dose of 1 mg/kg/day for 5 days.

Neurocysticercosis

Neurocysticercosis is caused by *Taenia saginata* infection, commonly as a result of consuming improperly cooked pork or contaminated raw vegetables and water. The parasite lodges in the central nervous system and skeletal muscle and presents as intracranial calcifications and ring-enhancing lesions on radioimaging studies. Other than leukocytosis, eosinophilia, and raised erythrocyte sedimentation rate, antibodies to species-specific antigens of *T. solium* can be detected by immunosorbent assay and complement fixation-tests. Treatment is aimed at controlling seizures and relief of hydrocephalus. Albendazole (15 mg/kg/day for 8–28 days) or praziquantel (50–100 mg/kg/day in three divided doses for a month) are given for parenchymal cysticerci with glucocorticoids to suppress the inflammatory response around the dying parasites. Surgery may be required to reduce intracranial pressure.

Dinoflagellate toxins

Dinoflagellates, a very large and diverse group of eukaryotic algae in the marine ecosystem, are the major group producing toxins that impact humans. Dinoflagellate toxins are structurally and functionally diverse, and many present unique biological activities. Five major seafood poisoning syndromes caused by toxins have been identified from the dinoflagellates (Table 4): paralytic shellfish poisoning (PSP), neurotoxic shellfish poisoning (NSP), amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP) and ciguatera fish poisoning (CFP). Symptoms include allergic manifestations, neurologic including paresthesia of the extremities, headache, ataxia, vertigo, cranial nerve palsies, and paralysis of respiratory muscles as well as gastrointestinal. Symptomatic treatment and antihistamines are the mainstay of treatment.

Tetrodotoxin poisoning

It is a neurotoxin concentrated in the skin and viscera of puffer fish, and other fishes of the order Tetraodontiformes and in some amphibian, octopus, and shellfish species. Human poisonings occur when the flesh or organs of the fish are improperly prepared and eaten. Tetrodotoxin acts by blocking the conduction of nerve

¹Not FDA approved for this indication.

BOX 1

Miscellaneous Organisms Implicated in Foodborne and Waterborne Illnesses

Adenovirus 40, 41
Bacillus anthracis
Bacillus mycoides
Burkholderia cepacia
Burkholderia pseudomallei
Clostridium bifermentans
Corynebacterium diphtheriae
Coxiella burnetii
Dientamoeba fragilis
Enterococcus faecalis, *E. faecium*
Erysipelothrix rhusiopathiae
Francisella tularensis
Klebsiella spp.
Leptospira spp.
Mycobacterium bovis
 Parvovirus B
Pediococcus
 Pestivirus
 Picobirnavirus
Proteus spp.
Pseudomonas aeruginosa
Pseudomonas cocovenenans
 Reovirus
Streptobacillus moniliformis
Taenia solium, *T. saginata*
 Torovirus
Toxoplasma gondii

impulses along nerve fibers and axons and interferes with the transmission of signals from nerves to muscles. Onset of symptoms usually is 30–40 minutes but may be as short as 10 minutes; it includes lethargy, paraesthesia, emesis, ataxia, weakness, and dysphagia; ascending paralysis occurs in severe cases with high mortality (1–2 mg is lethal). Management is symptomatic.

Group B Streptococcus (GBS)

GBS bacteria is found in 15%–30% of adult human intestines and urinary tract. Rarely implicated in infections of skin, joints, heart and brain, a recent outbreak of food-borne illness caused by the Type III GBS ST283 strain was reported in Singapore during the period of January–July 2015. It is the largest of its kind and first association to food-borne transmission of GBS to people via consumption of “yusheng-style” raw fresh water fish. The primary case presented with giddiness and suffered bouts of vomiting and diarrhea. Further studies are ongoing to establish the link between increase in cases of Group B streptococcus (GBS) infection to consumption of raw fish. Treatment is symptomatic.

Miscellaneous

Many other organisms are implicated in foodborne and waterborne illnesses (Box 1). Some are discussed elsewhere in this book. Amebiasis, brucellosis, cholera, hepatitis A and E, giardiasis, typhoid fever, and other foodborne intestinal nematodes and cestodes are covered in the infectious diseases section of this text and are not covered in this section.

GIARDIASIS

Method of

Rodney D. Adam, MD

CURRENT DIAGNOSIS

- Giardiasis is the most common intestinal protozoan infection worldwide.
- Most cases result from exposure to contaminated drinking or recreational water.
- The clinical manifestations range from asymptomatic to chronic diarrhea with malabsorption and weight loss.
- The diagnosis can be established by stool microscopy or by immunoassays of fecal specimens.
- Occasionally, the trophozoites can be found in duodenal specimens when fecal assays are negative.
- Serologic testing plays no role in the diagnosis.
- Irritable bowel symptoms are very common after successful treatment of giardiasis.

CURRENT THERAPY

- The treatment of choice is metronidazole (Flagyl)¹ or tinidazole (Tindamax); tinidazole can be given as a single dose.
- Albendazole (Albenza)¹ and nitazoxanide (Alinia) are alternative agents.
- Paromomycin,¹ a poorly absorbed aminoglycoside, is commonly recommended during early pregnancy when other agents are avoided.
- True drug resistance has not been documented, but refractory or recurrent cases can be treated by two drugs: a nitroimidazole combined with quinacrine (Atabrine)² or albendazole.¹

¹Not FDA approved for this indication.

²Not available in the United States.

Background

Giardia lamblia (syn. *Giardia intestinalis*, *Giardia duodenalis*) was initially described by Leeuwenhoek in the seventeenth century while doing a microscopic examination of his own diarrheal feces. However, *G. lamblia* was not widely accepted as a human pathogen until the 1960s, when a number of outbreaks were reported in travelers to endemic areas. The presumed source of infection in these cases was contaminated drinking water. Subsequently, *Giardia* has become the most commonly identified parasitic cause of diarrhea, and, along with *Cryptosporidium* species, is among the most commonly identified parasitic causes of water-borne diarrheal disease.

Organism

Giardia species are members of the diplomonad (two bodies) group of flagellated protozoans. The life cycle consists of the environmentally resistant cyst, which infects its host on ingestion. It is oval in shape, is about $8\ \mu\text{m} \times 12\ \mu\text{m}$ in size and contains four nuclei. It excysts into pear-shaped trophozoites in the proximal small intestine that are about $10\text{ to }12\ \mu\text{m}$ by $5 \times 7\ \mu\text{m}$ in size. Two symmetrically placed nuclei are in the body of the trophozoites and four pairs of flagella aid with motility. A ventral concave disk uses primarily mechanical means to attach to the intestinal wall of the host. While still in the small intestine, some of the trophozoites then encyst into the cyst form, which is passed in the feces to continue the cycle of infection. The *Giardia* species are all parasitic and were initially assigned to species on the basis of host of origin. However, in 1952, they were divided into three species [*Giardia agilis*, amphibians; *Giardia muris*, rodents; *G. duodenalis* (*G. lamblia*), mammals and birds] that could easily be distinguished on the basis of morphologic appearance of the trophozoites. Subsequently, the *G. lamblia* morphologic group has been divided into additional species based on differences that can be seen at the ultrastructural or molecular level. Of the organisms that remain assigned to *G. lamblia*, all are found in mammals but are divided into eight genotypes or assemblages (A through H) on the basis of molecular differences with varying host specificities. Only genotypes A and B have been found in humans. It is likely that at least some of these eight genotypes will eventually be assigned to separate species.

Epidemiology

Giardiasis is the most commonly diagnosed human protozoan infection and is one of the most commonly identified forms of gastroenteritis. Most cases occur from ingestion of contaminated water or by human-to-human transmission through the fecal-oral route. Thus the epidemiology of human infections can be understood by examining these mechanisms of transmission. In the United States, most cases are sporadic and occur more often in the summer, probably reflecting infection from recreational water exposure. Infections were more commonly reported in children from ages 1 to 9 years, especially those younger than 4 years of age. In general, the incidence is higher in the northern states, perhaps because cysts survive longer in cool, moist environments (Figure 1).

Direct human-to-human transmission by the fecal oral route also occurs, leading to the higher prevalence found in children in day-care centers. The occasional reports of food-borne transmission most likely occurred because of food being contaminated by infected food handlers.

The greater incidence in children could reflect an increased use of recreational water facilities, daycare exposure, or increased susceptibility to symptomatic disease. The epidemiology of giardiasis in the United States is similar to that found in other developed countries located in temperate regions. However, in developing regions with inadequate availability of purified water, the epidemiology is very different. For example, in a shantytown near Lima, Peru, children were almost universally infected by the age of 2 years, and when treated, they were rapidly reinfected, but there were no symptoms that could clearly be correlated with their infections. Perhaps an outbreak at a ski resort town in the United States can explain these different epidemiologic patterns. In this water-borne outbreak, tourists were disproportionately affected despite drinking from the same water source as the local residents. The conclusion was that the local residents had repeatedly been exposed to water

contaminated by *Giardia* cysts and were less susceptible to symptomatic disease.

The degree of zoonotic transmission of giardiasis remains controversial. Human acquisition of infection from dogs or cats has not been well documented, and usually the *Giardia* genotypes found in cats or dogs are distinct from those found in humans (A and B), even in regions where both are endemic. However, genotypes A and B have sometimes been identified in dogs or other animals, so the question is not totally resolved. On the other hand, beavers have been implicated as a source of contaminated water leading to human infections.

Risk Factors

People with hypogammaglobulinemia, and possibly those with IgA deficiency, are at increased risk for prolonged giardiasis. In animal models, deficiency in cell-mediated immunity (CMI) has been associated with increased risk, but in humans the increased risk has not been associated with defects in CMI.

Pathogenesis

Infection is initiated by the ingestion of as few as 10 cysts. After passage through the acidic environment of the stomach, each cyst excysts into two trophozoites in the proximal small intestine. However, gastric acidity is not required, and people with achlorhydria or who are treated with suppressors of gastric acid remain vulnerable to giardiasis. The trophozoites replicate in the proximal small intestine, where they attach to the intestinal mucosa by their ventral disks. The attachment appears to occur by mechanical means facilitated by the suction generated by the ventral disk and the four pairs of flagella as they provide motility. Although the trophozoites attach to the intestinal wall and leave imprints after separating from the wall, there is no well-documented evidence of invasion, either of the intestinal wall or at extraintestinal sites. Toxins have not been identified as causes of diarrhea. Thus the current evidence suggests that the symptoms result from the immune response to the trophozoite. The host-parasite interaction leads to enterocyte apoptosis, epithelial barrier disruption, and CD8 lymphocyte activation that leads to microvillous shortening, leading to the malabsorption that is a hallmark of the infection. The trophozoites are coated with a cysteine-rich protein encoded by one of a family of related genes, and expression can be switched from one to another, perhaps contributing to the chronicity of the infection.

Prevention

The strategies for prevention should be determined by the most prevalent risk factors in specific situations. For travelers to endemic regions, the major risk is from the ingestion of contaminated water. Therefore drinking water should be purified by boiling for 1 minute or by filtration through a pore size of $<1\ \mu\text{m}$. Halogenization with iodine or chlorine requires a prolonged contact time (hours) to inactivate cysts and is not recommended. In day-care centers and for food handlers, the best preventive measure is effective hand washing. In addition, children or workers who are infected should be treated.

Clinical Features

Most people with giardiasis are symptom free, but the percentages range from rates of diarrhea no higher than background among children in some highly endemic regions to attack rates of nearly 100% in visitors to endemic regions. Symptomatic patients typically present for evaluation only after several days or even weeks of illness because of the subacute onset. The symptoms of giardiasis typically develop after an incubation period of 1 to 2 weeks and consist of diarrhea that is characterized by loose, foul-smelling stools and abdominal discomfort described as cramping or bloating (Table 1). Fatigue is very common, but fever is unusual and, when present, is mild and occurs only within the first few days. Malabsorption and weight loss are often present. The majority of cases resolve within several weeks, but occasionally the symptoms will last for months in the absence of treatment. Relapse is relatively uncommon after effective treatment.

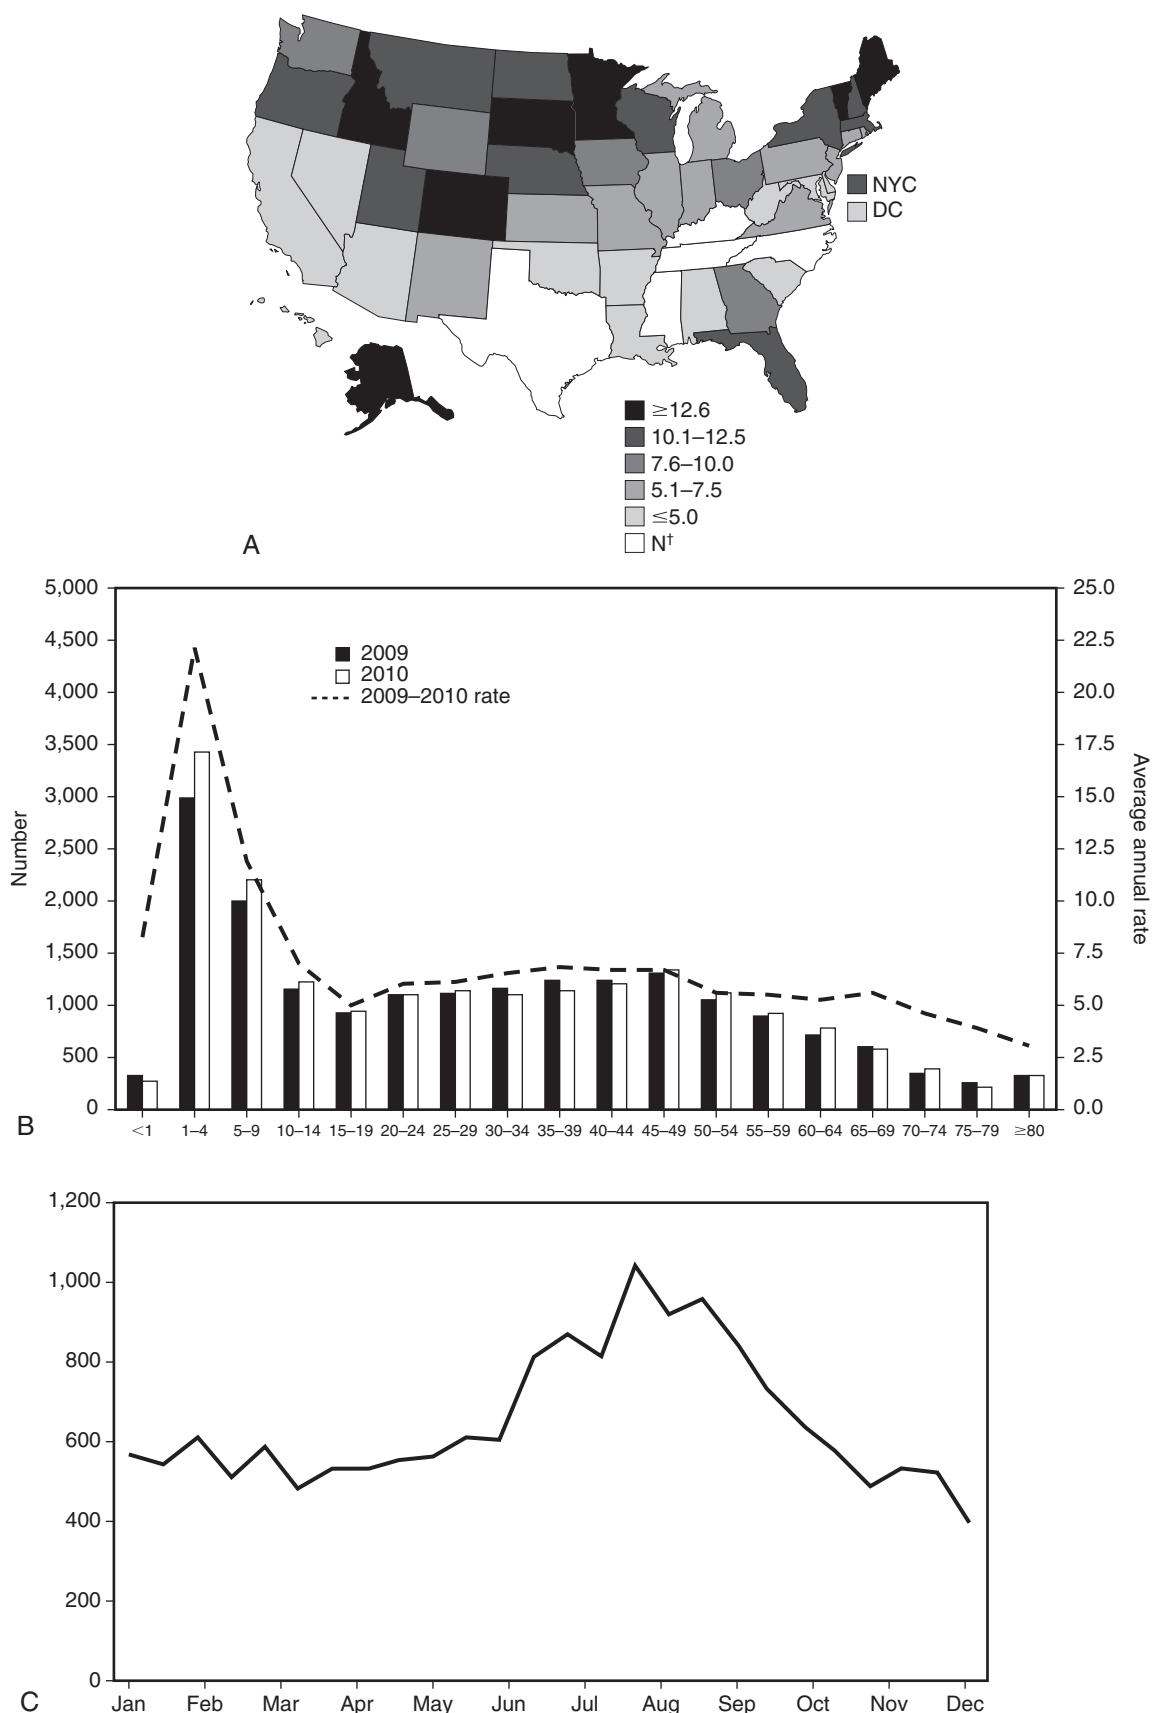

Figure 1 Incidence of giardiasis in the United States, 2011–2012. Information is collected through the National Notifiable Diseases Surveillance System (NNDSS). **A**, Incidence rate (cases per 100,000 population) of giardiasis, by reporting jurisdiction—National Notifiable Diseases Surveillance System, United States, 2012. **B**, Average annual incidence rate (cases per 100,000 population) of giardiasis, by sex and age group—National Notifiable Diseases Surveillance System, United States, 2011–2012. **C**, Number (cases per 100,000 population) of giardiasis case reports, by date of symptom onset—National Notifiable Diseases Surveillance System, United States, 2011–2012. Abdominal distention (bloating/distension)	50
Flatulence	50
Vomiting	30
Fever	20

From Hunter 2017; Giardiasis by R. Adam.

*The table includes the approximate frequency of the signs and symptoms reported in six studies of symptomatic giardiasis, but it is important to note that there is substantial variability of symptoms among studies.

Diagnosis

The gold standard of diagnosis has been the microscopic evaluation of three separate fecal samples, including concentrated specimens for cysts or, less commonly, trophozoites. The identification of trophozoites is nearly always associated with symptomatic infection, but cysts may be found in symptom-free persons. Because of the challenges in obtaining three fecal specimens and the interobserver variability in skill at identifying *Giardia* cysts, antigen detection tests have come into widespread use. The enzyme immunoassays are more commonly used and have high degrees of sensitivity and specificity. A direct fluorescent assay is slightly more sensitive than the enzyme immunoassays and can also detect *Cryptosporidium* species, but it requires the availability of fluorescent microscopy. PCR tests have also been described but are not widely available. Some patients have negative workups of stool samples, but *Giardia* trophozoites can be detected in duodenal contents with the string test. The patient swallows a capsule on a string, which is left in situ for 4 hours to overnight. The string is then removed and examined microscopically for trophozoites. Alternatively, endoscopy with sampling of duodenal contents and duodenal biopsy can be used. Endoscopy has the added advantage of being able to detect other possible diagnoses, such as celiac disease or tropical sprue.

Differential Diagnosis

The diagnosis of giardiasis should be suspected in patients presenting with prolonged (>5–7 days) diarrhea without blood in the stools and no fever. In patients presenting relatively early in the course of illness, the major considerations in the differential

diagnosis are other infectious etiologies of diarrhea, particularly *Campylobacter jejuni*, *Salmonella*, *Cryptosporidium*, and *Cyclospora cayentanensis*. Thus patients presenting with compatible symptoms should have stool samples submitted for culture and for microscopic examination for ova and parasites (O and P). Watery diarrhea is uncommon, and bloody stools are not seen with giardiasis; thus these findings should prompt the search for other etiologies.

For patients presenting with more prolonged symptoms, a number of noninfectious illnesses should be added to the differential diagnosis. Irritable bowel syndrome and lactose intolerance are among the more common etiologies and should be considered in patients presenting with diarrhea but no weight loss. Gluten enteropathy, tropical sprue, and, rarely, Whipple's disease are among the noninfectious etiologies of diarrhea accompanied by weight loss.

Treatment

Patients with symptomatic giardiasis should be treated. The criteria for treatment of patients with asymptomatic giardiasis are not well defined, but in general, patients in regions with low prevalence or linked with outbreaks should be treated. On the other hand, in settings where the prevalence is high and recurrence rates are high, there is probably no value to treating asymptomatic infection.

The most commonly used agents for treatment of giardiasis are the nitroimidazoles. Metronidazole (Flagyl)¹ and tinidazole (Tindamax) are available in the United States, and others, including secnidazole (Secnil)² and ornidazole (Tiberal)², are available in other countries (Table 2). These agents are completely absorbed from the gastrointestinal tract and are inactivated primarily by hepatic metabolism. Metronidazole has been available in the United States for decades and has generally been considered the drug of choice for treatment of giardiasis in most situations. More recently, tinidazole has become available and is the only agent available in the United States with a high degree of efficacy when given as a single dose. Metronidazole is mutagenic in bacterial assays and showed some carcinogenic activity in an animal model. However, carcinogenicity in humans has not been documented. Serious adverse reactions to the nitroimidazoles are rare, but nausea and a metallic taste are common and may decrease the compliance of patients with metronidazole. The problem with noncompliance can be addressed by the use of tinidazole or the other agents that can be given as a single dose.

Albendazole (Albenza)¹ is a tubulin inhibitor that was introduced as a broad-spectrum antihelminthic, but it also has good activity against *Giardia* trophozoites. It is generally well tolerated and in areas with endemic helminth infections has the added advantage of antihelminthic activity.

The first trimester of pregnancy poses a special problem because none of the agents have been adequately studied or approved

TABLE 2 Treatment of Giardiasis

DRUG	DOSE		FREQUENCY	DURATION	EFFICACY (%)
	ADULT	PEDIATRIC*			
Metronidazole ¹ (Flagyl)	250 mg	5 mg/kg	tid	5–7 days	90–100
Tinidazole (Tindamax)	2 gm	50 mg/kg	Single dose	Single dose	90–100
Quinacrine ^{2,6} (Atabrine)	100 mg	2 mg/kg	tid	5–7 days	80–100
Furazolidone ^{2,6} (Furoxone)	100 mg	1.5 mg/kg	qid	10 days	80–94
Paromomycin ¹ (Humatin)	500 mg	8–10 mg/kg	tid	10 days	55–90
Albendazole ¹ (Albenza)	400 mg qd	15 mg/kg	Daily	5 days	90–100
Nitazoxanide (Alinia)	500 mg bid	7.5 mg/kg	bid	3 days	70–80

*The adult dose is the maximum pediatric dose.

¹Not FDA approved for this indication.

²Not available in the United States.

⁶May be compounded by pharmacists.

for use during this time. Paromomycin¹ is a nonabsorbed aminoglycoside and is expected to be safe during pregnancy. Therefore it is usually the preferred choice in that setting; however, it is somewhat less effective than other agents. Specialty consultation should be considered for treatment of patients in their first trimester. Metronidazole is used extensively during the second and third trimesters for other indications; thus it can be considered the drug of choice for those patients. Albendazole is known to be teratogenic and should be avoided during pregnancy.

Nitazoxanide (Alinia) has been approved in the United States for treatment of giardiasis (and cryptosporidiosis) and is very well tolerated. However, the somewhat lower efficacy compared with nitroimidazoles and albendazole, along with the requirement for twice daily dosing, limits its role.

Quinacrine (Atabrine)² was one of the first effective treatments for giardiasis but has fallen into disfavor because of toxicity. Nausea and vomiting are common, and toxic psychosis is occasionally seen.

Treatment failures are not uncommon but may or may not be due to true drug resistance because in vitro cultures are not routinely performed, and in vitro testing is not standardized. When treatment failure occurs, the patient may respond to the same or an alternative drug. Treatment-refractory cases have been treated successfully with a combination of metronidazole¹ plus quinacrine² or albendazole.¹ The most common reason for persistence of symptoms after treatment is due to post-giardiasis irritable bowel syndrome, which can occur in up to 25% of patients. Thus it is important to re-evaluate stool specimens from patients with symptoms that persist after therapy.

Diet

Lactose intolerance is quite common while patients have giardiasis and potentially for months thereafter, so lactose ingestion should be moderated or eliminated as needed.

¹Not FDA approved for this indication.

²Not available in the United States.

INFECTIOUS MONONUCLEOSIS

Method of

Ben Z. Katz, MD

CURRENT DIAGNOSIS

- The classic triad of acute infectious mononucleosis consists of fever, lymphadenopathy, and pharyngitis.
- The diagnosis of infectious mononucleosis is usually based on the clinical picture, the presence of at least 10% atypical

lymphocytes in the peripheral blood, and positive heterophil serology (monospot test).

CURRENT THERAPY

- In most patients, infectious mononucleosis is self-limited and requires only symptomatic treatment.
- Steroids and antiviral therapy have no place in the therapy of uncomplicated acute infectious mononucleosis in healthy persons.

Epidemiology and Risk Factors

One must distinguish between the epidemiology of Epstein-Barr virus (EBV) infection and that of infectious mononucleosis (IM), the most common symptomatic manifestation of primary EBV infection. Almost all adults have been infected with EBV. The symptomatology of primary EBV infection varies with the infected person's age at the time, with younger children usually having inapparent or mild infections. In developing countries and in lower socioeconomic groups in industrialized nations, up to 90% of children acquire primary EBV infection by 6 years of age, and IM almost never develops. In contrast, in higher socioeconomic groups, only 40% to 50% of adolescents have previously experienced EBV infection. From 10% to 20% of susceptible adolescents and adults contract EBV every year thereafter, with IM developing in a significant fraction of these patients.

Pathophysiology

Saliva is the main vehicle for transmission of EBV, a double-stranded DNA herpesvirus. Transmission usually requires direct and prolonged contact with infected oropharyngeal secretions, with salivary exchange being the main mode of transmission. The infection begins with viral replication in oropharyngeal epithelial cells and then spreads to local B lymphocytes, which then disseminate throughout the reticuloendothelial system and induce vigorous T- and NK-cell responses and neutralizing antibodies. The atypical lymphocytes that are produced are mainly suppressor T cells directed against EBV-infected B cells.

It is thought that most of the clinical manifestations of IM are due to these T- and NK-cell responses, which might explain why young children, whose immune responses are incompletely developed, are usually asymptomatic with primary EBV infection. It is also possible that viral load determines symptomatology, and, because young adults likely spread more virus via salivary exchange than toddlers, young adults are more likely to be symptomatic. All EBV-seropositive persons shed virus intermittently throughout their lives. EBV may rarely be spread via blood transfusion or transplantation.

Clinical Manifestations

IM is usually an acute, self-limited, benign lymphoproliferative disease. EBV is responsible for nearly all heterophil-positive and most heterophil-negative cases. Other causes of heterophil-negative mononucleosis include cytomegalovirus, toxoplasmosis, hepatitis A and B, adenovirus, HIV, rubella, and human herpesvirus 6.

The classic triad of IM consists of fever, lymphadenopathy, and pharyngitis. Other typical findings include lymphocytosis with atypical lymphocytes and the presence of heterophil antibodies. After a 4- to 6-week incubation period, the illness begins with a 3- to 5-day prodrome of malaise, headache, and fatigue, typically followed in about half of the cases by onset of the triad. Additional symptoms can include anorexia, nausea, vomiting, periorbital or facial edema, and generalized lymphadenopathy, which is usually symmetrical. Splenomegaly occurs by the second or third week of illness in about half of all cases; rarely, splenic rupture can occur and may be fatal. Hepatomegaly occurs in 10% to 15%, with

for use during this time. Paromomycin¹ is a nonabsorbed aminoglycoside and is expected to be safe during pregnancy. Therefore it is usually the preferred choice in that setting; however, it is somewhat less effective than other agents. Specialty consultation should be considered for treatment of patients in their first trimester. Metronidazole is used extensively during the second and third trimesters for other indications; thus it can be considered the drug of choice for those patients. Albendazole is known to be teratogenic and should be avoided during pregnancy.

Nitazoxanide (Alinia) has been approved in the United States for treatment of giardiasis (and cryptosporidiosis) and is very well tolerated. However, the somewhat lower efficacy compared with nitroimidazoles and albendazole, along with the requirement for twice daily dosing, limits its role.

Quinacrine (Atabrine)² was one of the first effective treatments for giardiasis but has fallen into disfavor because of toxicity. Nausea and vomiting are common, and toxic psychosis is occasionally seen.

Treatment failures are not uncommon but may or may not be due to true drug resistance because in vitro cultures are not routinely performed, and in vitro testing is not standardized. When treatment failure occurs, the patient may respond to the same or an alternative drug. Treatment-refractory cases have been treated successfully with a combination of metronidazole¹ plus quinacrine² or albendazole.¹ The most common reason for persistence of symptoms after treatment is due to post-giardiasis irritable bowel syndrome, which can occur in up to 25% of patients. Thus it is important to re-evaluate stool specimens from patients with symptoms that persist after therapy.

Diet

Lactose intolerance is quite common while patients have giardiasis and potentially for months thereafter, so lactose ingestion should be moderated or eliminated as needed.

¹Not FDA approved for this indication.

²Not available in the United States.

INFECTIOUS MONONUCLEOSIS

Method of

Ben Z. Katz, MD

CURRENT DIAGNOSIS

- The classic triad of acute infectious mononucleosis consists of fever, lymphadenopathy, and pharyngitis.
- The diagnosis of infectious mononucleosis is usually based on the clinical picture, the presence of at least 10% atypical

lymphocytes in the peripheral blood, and positive heterophil serology (monospot test).

CURRENT THERAPY

- In most patients, infectious mononucleosis is self-limited and requires only symptomatic treatment.
- Steroids and antiviral therapy have no place in the therapy of uncomplicated acute infectious mononucleosis in healthy persons.

Epidemiology and Risk Factors

One must distinguish between the epidemiology of Epstein-Barr virus (EBV) infection and that of infectious mononucleosis (IM), the most common symptomatic manifestation of primary EBV infection. Almost all adults have been infected with EBV. The symptomatology of primary EBV infection varies with the infected person's age at the time, with younger children usually having inapparent or mild infections. In developing countries and in lower socioeconomic groups in industrialized nations, up to 90% of children acquire primary EBV infection by 6 years of age, and IM almost never develops. In contrast, in higher socioeconomic groups, only 40% to 50% of adolescents have previously experienced EBV infection. From 10% to 20% of susceptible adolescents and adults contract EBV every year thereafter, with IM developing in a significant fraction of these patients.

Pathophysiology

Saliva is the main vehicle for transmission of EBV, a double-stranded DNA herpesvirus. Transmission usually requires direct and prolonged contact with infected oropharyngeal secretions, with salivary exchange being the main mode of transmission. The infection begins with viral replication in oropharyngeal epithelial cells and then spreads to local B lymphocytes, which then disseminate throughout the reticuloendothelial system and induce vigorous T- and NK-cell responses and neutralizing antibodies. The atypical lymphocytes that are produced are mainly suppressor T cells directed against EBV-infected B cells.

It is thought that most of the clinical manifestations of IM are due to these T- and NK-cell responses, which might explain why young children, whose immune responses are incompletely developed, are usually asymptomatic with primary EBV infection. It is also possible that viral load determines symptomatology, and, because young adults likely spread more virus via salivary exchange than toddlers, young adults are more likely to be symptomatic. All EBV-seropositive persons shed virus intermittently throughout their lives. EBV may rarely be spread via blood transfusion or transplantation.

Clinical Manifestations

IM is usually an acute, self-limited, benign lymphoproliferative disease. EBV is responsible for nearly all heterophil-positive and most heterophil-negative cases. Other causes of heterophil-negative mononucleosis include cytomegalovirus, toxoplasmosis, hepatitis A and B, adenovirus, HIV, rubella, and human herpesvirus 6.

The classic triad of IM consists of fever, lymphadenopathy, and pharyngitis. Other typical findings include lymphocytosis with atypical lymphocytes and the presence of heterophil antibodies. After a 4- to 6-week incubation period, the illness begins with a 3- to 5-day prodrome of malaise, headache, and fatigue, typically followed in about half of the cases by onset of the triad. Additional symptoms can include anorexia, nausea, vomiting, periorbital or facial edema, and generalized lymphadenopathy, which is usually symmetrical. Splenomegaly occurs by the second or third week of illness in about half of all cases; rarely, splenic rupture can occur and may be fatal. Hepatomegaly occurs in 10% to 15%, with

hepatitis occurring in about 5% of cases. Up to 20% of patients have a rash that may be erythematous, maculopapular, morbilliform, scarlatiniform, or urticarial, especially if ampicillin or one of its derivatives has been given. Other symptoms can include arthritis and jaundice.

IM is a self-limited disease in nearly all patients. Median illness duration is 16 days.

Diagnosis

The diagnosis is usually based on the clinical picture, atypical lymphocytosis, and positive heterophil serology. Most adolescents and young adults with IM have most or all of these features, as well as an elevated white blood cell count with a relative lymphocytosis. Atypical lymphocytes generally represent more than 9% to 10% of the white blood cell count. Many infected persons also have mild thrombocytopenia and elevated hepatocellular enzymes. Heterophil antibody positivity is usually measured as a positive monospot test. If IM is suspected and heterophil antibodies are negative, specific titers for EBV, including viral capsid antigen (VCA) IgM and IgG, early antigen (EA), and Epstein-Barr nuclear antigen (EBNA), should be obtained, as well as serologic testing for cytomegalovirus (CMV) and toxoplasmosis. Acute EBV infection is characterized by the presence of IgM and IgG VCA antibodies and EA antibodies and the absence of EBNA antibodies.

Differential Diagnosis

If liver chemistry values are markedly elevated and antibodies against EBV, CMV, and toxoplasmosis are unrevealing, serology for hepatitis A, B, and C should be measured. If risk factors are present, HIV antibodies should be checked. A throat culture is indicated in patients with pharyngitis or tonsillitis because the tonsillitis of acute IM can be indistinguishable from that of group A streptococcal pharyngitis.

Treatment

In most patients, IM is self-limited and requires only symptomatic treatment, including bed rest, acetaminophen (Tylenol, 10–15 mg/kg every 4–6 hours), aspirin (10–15 mg/kg every 4–6 hours), or nonsteroidal antiinflammatory agents such as ibuprofen (Advil, 5–10 mg/kg every 6–8 hours). Saline gargles can be useful in treating a sore throat. In severe cases, meperidine (Demerol, 1–1.5 mg/kg every 3–4 hours) may be required.

Although a short, tapering course of corticosteroid therapy (e.g., a Medrol Dosepak¹) is often prescribed, there is little evidence for its clinical efficacy, and caution is warranted. Infection is ultimately self-limited in nearly all cases, and rare reports of neurologic or septicemic complications after steroid use have appeared. Long-term immune responses following steroid use appear to be normal. Corticosteroid therapy should, however, be considered for the treatment of severe cases of IM associated with hemolysis, respiratory embarrassment, or thrombocytopenic purpura. The use of corticosteroids in atypical or antibody-negative cases is inappropriate because the diagnosis of lymphoma can then be confounded.

Parenteral administration of acyclovir¹ (Zovirax, 10–20 mg/kg IV every 8 hours) to patients with acute IM secondary to EBV reduces the level of oropharyngeal viral replication; however, replication returns to the previously high levels after cessation of treatment, little or no reduction is seen in the number of EBV-infected B cells in the peripheral circulation, and the drug has little or no effect on the clinical course. Acyclovir administered in high doses orally (20 mg/kg, maximum dose of 800 mg qid for 5 days) is also ineffective. Antiviral therapy is therefore not recommended for acute IM in a normal host.

In immunosuppressed or severely ill patients, however, specific therapy has a role in many cases. For example, etoposide

(VePesid)¹, a drug that reduces macrophage activation, is often used in cases of infection-associated hemophagocytic syndrome. In posttransplant lymphoproliferative disorders, first-line therapy is often a reduction in immunosuppression; other options include rituximab¹ (Rituxan, 375 mg/m² IV weekly for 4 weeks). Oral leukoplakia in patients with AIDS responds to oral acyclovir¹ (20 mg/kg, maximum dose of 800 mg qid for 20 days), whereas a tapering course of steroids (as recommended earlier) may be used for lymphocytic interstitial pneumonitis (see below).

Monitoring

Quarantine is not indicated. Ampicillin and related drugs should be avoided when treating secondary bacterial complications because of their association with rash in persons with IM. Contact sports should be avoided as long as splenomegaly is still evident because of the rare possibility of splenic rupture, which usually occurs within 3 weeks of onset of IM but has been reported as late as 7 weeks into the illness.

Complications

Complications of acute IM can be neurologic (seizures, cranial nerve palsies, aseptic meningitis, encephalitis, optic neuritis, transverse myelitis, infectious polyneuritis [Guillain-Barré syndrome], psychosis, Alice in Wonderland syndrome, or acute cerebellar ataxia), hematologic (hemolytic or aplastic anemia, thrombocytopenic purpura, agranulocytosis, or agammaglobulinemia), cardiac (pericarditis or myocarditis), pulmonary (cough or atypical pneumonia), renal (glomerulonephritis, acute kidney failure, or acute interstitial nephritis), or ophthalmologic (conjunctivitis) in nature. In about 10% of adolescents and young adults, fatigue can persist for 6 months or longer, and many of these patients meet the criteria for chronic fatigue syndrome.

Rare patients have very high titers of EBV antibodies, and a chronic active EBV infection associated with unusual clinical manifestations such as uveitis or lymphoma can occur. EBV is also associated with lymphoproliferative disorders in persons with underlying abnormal immune systems. These include X-linked lymphoproliferative syndrome, in which affected males usually die of acute EBV infection, and the related infection-associated hemophagocytic syndrome, which is most commonly (about 75% of the time) triggered by EBV and seems to be due to an overly exuberant macrophage response to EBV-infected lymphocytes. Transplant recipients can acquire EBV-associated lymphoproliferative disease that can range from an asymptomatic infection to fatal IM or lymphoma. Finally, although not seen much anymore due to antiretroviral therapy, patients with AIDS are susceptible to several serious complications of EBV infection, including lymphocytic interstitial pneumonitis, oral leukoplakia, leiomyosarcoma, and lymphoma.

INFLUENZA

Method of

Jeffrey A. Linder, MD, MPH

CURRENT DIAGNOSIS

- Influenza should be considered in any patient with respiratory symptoms between October and May in North America.
- The single most important piece of information when considering a diagnosis of influenza is the community prevalence of influenza.
- During outbreaks, sudden onset of fever and cough has a positive predictive value of about 85%.
- Rapid testing should be used when the community prevalence of influenza among patients with influenza-like illness is between 10% and 30%.

CURRENT THERAPY

- The influenza vaccine is the best means of preventing influenza. The inactivated influenza vaccine is recommended for all persons age 6 months and older.
- The antivirals zanamivir (Relenza) and oseltamivir (Tamiflu) can be used for prophylaxis of influenza in unimmunized patients, in close contacts of infected patients, and during institutional outbreaks of influenza.
- Early antiviral treatment should be used for patients who are hospitalized; have severe, complicated, or progressive illness; or are at higher risk for complications.
- Antivirals may be prescribed within 48 hours of symptom onset for outpatients not at higher risk for influenza complications.

Influenza is a highly contagious viral infection that should be considered in any patient with respiratory symptoms between October and May in North America. Influenza infects 5% to 20% of the population of the United States in a typical year, and is responsible for up to 431,000 hospitalizations and 51,000 deaths per year. Influenza can range in severity from mild illness to life-threatening disease. Those at highest risk of hospitalization, death, or complications from influenza are children younger than 5 years, adults older than 65 years, people of any age who have underlying medical conditions, those infected with HIV, and pregnant women.

Information about influenza changes rapidly. To care optimally for patients with influenza-like illness during the influenza season, clinicians need to keep abreast of updated recommendations and the current prevalence of influenza in their community. The influenza vaccine remains the best means of reducing the incidence, severity, and complications from influenza, but antiviral medications and symptomatic treatments have an important role in the prevention and treatment of influenza (Box).

Microbiology

There are two types of influenza viruses, A and B. Influenza A is separated into subtypes based on two surface antigens: hemagglutinin (H) and neuraminidase (N). The predominant circulating strains of influenza in recent decades have been influenza A (H1N1), influenza A (H3N2), and influenza B. Influenza A (H3N2) subtypes generally cause more severe influenza and are associated with higher mortality than other types. Influenza viruses undergo slight genetic changes from year to year, termed *antigenic drift*. Major changes in surface glycoproteins are termed *antigenic shift* and can result in severe pandemic influenza in a nonimmune population, which happened with an antigenically novel influenza

A (H1N1) virus in 2009. Because of antigenic drift, and because immunity to a given type or subtype of influenza provides limited cross-immunity to other types and subtypes, the influenza vaccine needs to be reformulated and administered most years.

Patients contract influenza by being exposed to large-sized respiratory droplets from an infected person or contact with surfaces harboring influenza virus. Influenza has a latency of 1 to 4 days before the onset of symptoms. Adults are infectious from the day before symptom onset through about day 7 of illness, but immunosuppressed adults and children shed the virus for longer periods. Symptoms generally last from 7 to 14 days.

Several novel, highly pathogenic respiratory viruses—avian influenza A (H5N1), avian influenza A (H7N9), and Middle East Respiratory Syndrome Coronavirus (MERS-CoV)—have mortality rates ranging from 30% to 60%. Collectively there have been more than 4700 human cases. These pathogens, if they acquire the ability to be highly transmissible between humans, have the potential to cause pandemic respiratory disease.

Prevention

Influenza vaccination is between 20% and 90% effective in preventing influenza or complications of influenza. Influenza vaccination is highly cost-effective and can even be cost-saving in high-risk groups. Influenza vaccination is less effective in younger children, in adults >65 years, in adults with comorbid conditions, and when there is a poor match between the influenza vaccine and circulating influenza. The Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices puts out annual recommendations and supplementary updates on the prevention and treatment of influenza (www.cdc.gov/flu). Beginning in the 2010 to 2011 influenza season, the Advisory Committee on Immunization Practices recommended vaccinating all persons 6 months of age and older.

At present, there are five commonly administered, recommended types of influenza vaccine: trivalent inactivated influenza vaccine (IIV3), quadrivalent inactivated influenza vaccine (IIV4), trivalent recombinant influenza vaccine (RIV3), quadrivalent recombinant influenza vaccine (RIV4), and quadrivalent live attenuated influenza vaccine (LAIV4). The IIV4 (Afluria Quadrivalent, Fluarix Quadrivalent, Flucelvax Quadrivalent, FluLaval Quadrivalent, Fluzone Quadrivalent) and IIV3 (Afluria, Fluvirin), RIV3 (Flublok), and RIV4 (Flublok Quadrivalent) vaccines are administered as an intramuscular injection.

Different products are approved for administration in different lower age limits. A high-dose IIV3 (Fluzone High-Dose) and an adjuvanted IIV3 (Fluad) are available for patients aged ≥65 years, who are less likely to respond immunologically to standard inactivated influenza vaccine (IIV). An intradermal IIV4 (Fluzone Intradermal Quadrivalent) is available for use in patients 18 to 64 years old. The main adverse effect of the IIV is soreness at the injection site. Patients often report a mild immune response of fever, malaise, myalgia, and headache that can last for 1 to 2 days, but rates of most of these symptoms are no different from those in patients who receive placebo injection. Allergic reactions to egg proteins or other vaccine components (e.g., antibiotics and inactivating compounds) include hives, angioedema, asthma, and anaphylaxis. For patients with egg allergy who have only hives, any otherwise appropriate IIV or RIV can be administered. For patients with more severe reactions to egg or who received treatment for an allergic reaction can also receive any recommended IIV or RIV in an inpatient or outpatient medical setting and observed for at least 15 minutes by a clinician able to recognize and manage severe allergic reactions. Recombinant influenza vaccines (RIV3, RIV4; FluBlok, FluBlok Quadrivalent) are considered egg-free. Cell culture-based IIV (ccIIV4; Flucelvax Quadrivalent) could be egg-derived and contain egg protein. Patients who have had severe allergic reaction to influenza vaccine should not receive the vaccine. Vaccination should be deferred in patients with acute febrile illness, but patients with more moderate illness can be vaccinated. Guillain-Barré syndrome was associated with the 1976 swine flu vaccine, but there is no consistent evidence that modern influenza vaccines are associated with Guillain-Barré syndrome.

The LAIV4 (FluMist Quadrivalent) is administered as a nasal spray and is approved for patients ages 2 to 49 years. LAIV4 was not recommended for the 2017–2018 influenza season because of decreased effectiveness, but was recommended for the 2018–2019 influenza season after a reformulation. The LAIV4 is contraindicated in children aged 2 to 4 years with recurrent wheezing or asthma; children who are receiving aspirin or aspirin-containing products; in patients with comorbid conditions or egg allergy; in pregnant women; and in family members or close contacts of severely immunosuppressed patients, who require a protected environment (e.g., hematopoietic stem cell transplant recipients). The LAIV4 should not be administered to those with severe nasal congestion. Adverse effects of the LAIV4 include runny nose, nasal congestion, headache, sore throat, chills, and tiredness, although these are only slightly more common than in patients receiving placebo. Those receiving the LAIV4 should avoid contact with severely immunosuppressed persons for 7 days.

Patients should be vaccinated in the fall when the seasonal vaccine becomes available, even as early as August. In the event of vaccine shortages, higher-risk patients should receive priority (Box). Patients should continue to be vaccinated until February and beyond because in the majority of recent influenza seasons the peak has been February or later. Children 6 months to 8 years of age who have not been previously immunized against influenza should be given two doses separated by at least 4 weeks.

Evaluation

Community Prevalence of Influenza

In caring for a patient with suspected influenza, the single most important piece of data is the community prevalence of influenza among patients with influenza-like illness. This ranges from near 0% during summer months to about 30% during a typical influenza seasonal peak. The prevalence may be higher during a particularly severe outbreak. Clinicians can check the local prevalence of influenza among patients with influenza-like illness through the CDC (www.cdc.gov/flu) and their state department of public health.

History and Physical Examination

Beyond the local prevalence of influenza, the diagnosis of influenza rests on the patient's history. All methods of diagnosing influenza—symptom complexes, clinician judgment, and testing—generally are highly specific but have poor sensitivity. Thus it is important to consider a diagnosis of influenza in any patient with respiratory symptoms during influenza season. Influenza is classically described as the very sudden onset of fever, headache, sore throat, myalgias, cough, and nasal symptoms. Children can also have otitis media, nausea, and vomiting. In differentiating influenza from nonspecific upper respiratory tract infections, it is most useful to consider the circulating prevalence of influenza, the abruptness of onset, and the severity of symptoms.

Certain symptom complexes have been shown in trials of antiviral treatment to strongly suggest influenza. For example, in an area with circulating influenza, the acute onset of cough and fever can have a positive predictive value as high as 85%. One rule assigned 2 points for fever plus cough, 2 points for myalgias, 1 point for duration less than 48 hours, and 1 point for chills or sweats. The prevalence of influenza for patients with 0 to 2 points, 3 points, or 4 to 6 points was 8%, 30%, and 59%, respectively. Other studies have shown that clinician judgment performed as well as or better than hard-and-fast symptom complexes or rapid testing.

The physical examination in influenza primarily serves to identify the severity of influenza, complications, and worsening of underlying medical conditions. Clinicians should record vital signs and perform examinations of the ears, nose, sinuses, throat, neck, lungs, and heart for all patients suspected of having influenza.

Testing

Testing is not required to make a diagnosis of clinical influenza. Treatment for patients at high risk for influenza complications

should not wait for test results. However, testing may help inform antiviral use, antibiotic prescribing, site-of-care decisions, and infection control measures. Specimens (nasopharyngeal swab, nasal swab, nasal wash, or nasal aspirate, depending on the particular test) should ideally be collected within 3 to 4 days of symptom onset.

Molecular assays such as reverse transcriptase polymerase chain reaction (RT-PCR) testing are highly sensitive (90% to 95%) and specific. Some can produce results in 15 to 45 minutes, and some can differentiate influenza types and subtypes. RT-PCR should be considered for hospitalized patients, institutional outbreaks, or other situations when clinicians are concerned about false-negative rapid test results. Other nucleic acid amplification tests, which can differentiate influenza from other respiratory pathogens, are becoming more available. The CDC recommends that all hospitalized patients with suspected influenza be tested with a high-sensitivity, high-specificity molecular assay.

Rapid influenza diagnostic test kits, some of which can distinguish influenza A from influenza B, can provide a point-of-care result in <15 minutes. Rapid tests have sensitivities that range from 50% to 70%, but are more than 90% specific. Testing is most useful when there is an intermediate probability of influenza (e.g., a community prevalence of influenza among patients with influenza-like illness of 10%–30%) and patients have an intermediate probability of complications from influenza. If circulating prevalence of influenza is low (e.g., <10%), testing is unlikely to be positive and is not necessary. If the circulating prevalence of influenza is high (e.g., >30%), the relatively low sensitivity of rapid tests makes the risk of a false-negative test result unacceptably high. In the event of a high prevalence of influenza or a high risk of complications from influenza, empirical antiviral treatment is indicated. Testing may be particularly helpful for hospitalized patients to rule out a need for antibiotics, but, given the low sensitivities, anti-influenza treatment should not be withheld solely on the basis of a negative rapid influenza detection test result. Chest radiography, cultures, and blood tests are not routinely indicated, but they should be obtained for patients with suspected pneumonia or to identify other suspected complications.

Complications

Complications of influenza include primary complications, suppurative complications, and worsening of comorbid conditions. Primary complications of influenza include viral pneumonia, which is a feared complication and is likely a main cause of death in pandemic influenza. Other, less common primary complications of influenza include myositis and rhabdomyolysis, Reye syndrome, myocarditis, pericarditis, toxic shock syndrome, and central nervous system disease (e.g., encephalitis, transverse myelitis, and aseptic meningitis). Children can have a severe course with influenza, including signs and symptoms of sepsis along with febrile seizures. Suppurative complications of influenza include bacterial pneumonia, otitis media, and sinusitis. Influenza can cause worsening of comorbid conditions such as asthma, chronic obstructive pulmonary disease, congestive heart failure, and chronic kidney disease.

Chemoprophylaxis

Antiviral medications can be used to prevent influenza in patients who did not receive the influenza vaccine, cannot receive the influenza vaccine, received the vaccine in the prior 2 weeks (before reliable immunity develops), or in the event of poor matching between vaccine and circulating influenza strains (Table 1). Chemoprophylaxis should also be considered for close contacts of patients with confirmed influenza or for patients with immune deficiency who are unlikely to respond to the influenza vaccine but who are at high risk for having complications from influenza. (See Box 1.)

Amantadine (Symmetrel) and rimantadine (Flumadine) are not recommended for chemoprophylaxis or treatment because of a high prevalence of resistant influenza A strains. The neuraminidase inhibitors oseltamivir (Tamiflu), and zanamivir (Relenza) are about 80% effective in preventing influenza in household

TABLE 1 Antiviral Agents for the Treatment and Prophylaxis of Influenza

ANTIVIRAL AGENT	TREATMENT*		PROPHYLAXIS†		COMMENTS
	CHILDREN	ADULTS	CHILDREN	ADULTS	
Oseltamivir (Tamiflu)	Any age‡ Dose for 5 days bid: <1 yr: 3 mg/kg per dose; ≤15 kg: 30 mg; 16–23 kg: 45 mg; 24–40 kg: 60 mg; >40 kg: 75 mg	75 mg PO bid for 5 days	3 mo–1 yr: 3 mg/kg/day‡ Dose qd: ≤15 kg: 30 mg; 16–23 kg: 45 mg; 24–40 kg: 60 mg; >40 kg: 75 mg	75 mg PO qd	For patients with creatinine clearance <30 mL/min, oseltamivir adult dosing should be reduced to 30 mg qd for treatment and to 30 mg qid for prophylaxis
Zanamivir (Relenza)	Approved for children ≥ 7 yr; 10 mg (2 inhalations) bid for 5 days	10 mg (2 inhalations) bid for 5 days	Approved for children ≥ 5 yr; 10 mg (2 inhalations) qd	10 mg (2 inhalations) qd	Avoid in patients with chronic lung disease (e.g., asthma, COPD)
Peramivir (Rapivab)	2–12 yr: One 12 mg/kg dose, up to 600 mg maximum IV over minimum 15 min§	≥13 yr: One 600 mg IV dose over a minimum of 15 min	NA	NA	For patients with creatinine clearance 30–49 mL/min, the dose should be reduced to 200 mg; For patients with creatinine clearance 10–29 mL/min, the dose should be reduced to 100 mg

NA = not approved.

Adapted from Centers for Disease Control and Prevention. Influenza Antiviral Medications: Summary for Clinicians. Available at <http://www.cdc.gov/flu/professionals/antivirals/> [accessed February 4, 2015].

*Suspected or confirmed influenza among persons with severe influenza or for persons at higher risk for influenza complications up to 5 days after symptom onset. For outpatients not at higher risk for influenza complications, treatment should be started within 48 hours of symptom onset.

†Prophylaxis should be given for 7 days after last known exposure and for institutional outbreaks for at least 2 weeks or until 1 week after the end of the outbreak.

‡Oseltamivir is approved by the FDA for treatment in children 14 days and older and prophylaxis in children 1 year and older. Treatment in children < 14 days old and prophylaxis in children < 1 year old is recommended by the Centers for Disease Control and Prevention and the American Academy of Pediatrics.

BOX 1 Influenza Vaccine Recommendations

- All persons aged ≥ 6 months should be vaccinated annually
- Vaccination efforts should prioritize people at higher risk of influenza complications:
 - Age 6 months to 5 years
 - Age ≥50 years
 - Chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, neurologic, hematologic, or metabolic (including diabetes mellitus) disorders
 - Immunosuppressed
 - Pregnant during the influenza season
 - Age 6 months to 18 years old receiving long-term aspirin therapy and who therefore might be at risk for Reye syndrome
 - Residents of nursing homes and other long-term care facilities
 - American Indians/Alaska Natives
 - Morbidly obese (body mass index ≥40)
- Vaccination efforts should also prioritize those likely to transmit influenza to higher risk people:
 - Health care personnel
 - Household contacts and caregivers of children aged <5 years and adults aged ≥50 years, with particular emphasis on vaccinating contacts of children aged <6 months
 - Household contacts and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

contacts of persons with influenza, and more than 90% effective in preventing influenza in institutional settings. Chemoprophylaxis should be taken for 10 days after a household exposure, 7 days after a non-household exposure, and for a minimum of 2 weeks or until 1 week after the end of long-term care facility or hospital

outbreak. For patients allergic to or unable to respond to the vaccine, chemoprophylaxis should be used for the duration of circulating influenza. The IIV can be given to patients receiving chemoprophylaxis. The LAIV should not be given from 2 days before to 14 days after taking an antiviral medication. Patients who receive the LAIV in this window should be revaccinated at a later date.

Treatment

The influenza vaccine is the best means of reducing influenza-related morbidity and mortality, but its limitations include production problems, low vaccination rates, and variable effectiveness. Given these limitations, there is an important role in management for influenza-specific antiviral medications (see Table 1). Antiviral medications reduce the duration of influenza symptoms by about 1 day, reduce complications requiring antibiotics by 30% to 50%, might decrease hospitalizations, decreases mortality among hospitalized patients, and are cost-effective. Early antiviral treatment, which should not wait for test results, starting up to 5 days after symptom onset can reduce complications for patients who are hospitalized; have severe, complicated, or progressive illness; or are at higher risk for complications (see Box). For outpatients not at higher risk for complications, antiviral treatment must be started within 48 hours of symptom onset.

Zanamivir is taken as an oral inhaled powder and is not recommended for patients with underlying lung or heart disease. Adverse effects of zanamivir include worsening of underlying lung disease and allergic reactions. Oseltamivir is taken as a capsule or oral suspension. The dose of oseltamivir should be reduced in patients with renal disease. Adverse effects of oseltamivir include nausea, vomiting, and, perhaps behavioral changes. Amantadine and rimantadine are not recommended because of a high prevalence of resistant influenza A strains.

Peramivir (Rapivab), an intravenous neuraminidase inhibitor, was approved in the United State in December 2014 for patients within 48 hours of symptom onset. Peramivir has been associated with diarrhea, rashes including Stevens-Johnson syndrome, and neuropsychiatric changes.

Antibiotics are generally not necessary, but they should be prescribed to treat suppurative complications of influenza. Antitussives such as guaifenesin with codeine (Robitussin AC) help coughing patients sleep at night. Beta-agonists, such as albuterol (Proventil),¹ can help patients with cough, especially if there is wheezing on examination. Analgesics and antipyretics such as acetaminophen (Tylenol) and ibuprofen (Motrin) reduce fever and generally help patients feel better. Patients should be encouraged to rest and drink plenty of fluids.

Patients with suspected influenza should minimize contact with others to avoid spreading the infection. Use of face masks and hand hygiene can reduce the transmission of influenza.

¹Not FDA approved for this indication.

LEISHMANIASIS

Method of
Luigi Gradoni, PhD

CURRENT DIAGNOSIS

- Infected tissues must be sampled for microscopy demonstration of *Leishmania* organisms in Giemsa-stained impression smears or cultures. Polymerase chain reaction (PCR) detection of *Leishmania* DNA increases diagnostic sensitivity.
- Different tissue samplings are performed depending on the clinical form of leishmaniasis: For visceral leishmaniasis, aspirate or biopsy specimens are obtained from spleen, bone marrow, the liver, or enlarged lymph nodes. For cutaneous and mucocutaneous leishmaniasis, the material is obtained by skin lesion scraping or biopsy.
- Serology is useful when the diagnosis of visceral leishmaniasis proves difficult with other methods.

CURRENT THERAPY

- The therapy of leishmaniasis relies on a limited number of drugs, most of which are old and relatively toxic. Systemic drug administration requires hospitalization and monitoring of the patient.
- The pentavalent antimony (Sb) drugs sodium stibogluconate (Pentostam)¹⁰ and meglumine antimoniate (Glucantime)² are equivalent and used in all clinical forms of leishmaniasis. Dosage is Sb 20 mg/kg/day IM for 21 to 28 days. In cases of uncomplicated cutaneous leishmaniasis, use intralesional administration intermittently over 20 to 30 days.
- Liposomal amphotericin B (Ambisome) is the gold standard for treating visceral leishmaniasis. Dosage: Total dose of 18 to 21 mg/kg IV using one of the following schedules: 3 mg/kg/day on days 1 to 5 and 10; 3 mg/kg on days 1 to 5, day 14, and day 21; 10 mg/kg/day for 2 days.

- Amphotericin B desoxycholate (Fungizone) is used in visceral leishmaniasis¹ and mucocutaneous leishmaniasis. Dosage is 0.5 mg/kg IV every other day for 14 days.
- Other parenteral drugs: Pentamidine isethionate (Pentam 300)¹ is used to treat some forms of New World cutaneous leishmaniasis; dosage is 2 mg/kg IM every other day for 7 days. Paromomycin (aminosidine) sulfate² is used for Indian visceral leishmaniasis; dosage is 11 mg/kg/day IM for 21 days.
- Miltefosine (Impavido)⁵ is recommended for visceral leishmaniasis therapy in India and Ethiopia and for cutaneous leishmaniasis therapy in Colombia and Bolivia. Dosage is 2.5 mg/kg/day (not exceeding 100 mg/day) PO for 28 days.

¹Not FDA approved for this indication.

²Not available in the United States.

⁵Investigational drug in the United States.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Epidemiology

Leishmaniasis are diseases caused by members of the genus *Leishmania*, protozoan parasites infecting numerous mammal species, including humans. The flagellated forms (promastigotes) are transmitted by the bite of phlebotomine sand flies and multiply as aflagellated forms (amastigotes) within cells of the mononuclear phagocyte system. The diseases range over the intertropical zones of America and Africa and extend into temperate regions of Latin America, Southern Europe, and Asia. About 20 named *Leishmania* species and subspecies are pathogenic for humans, and 30 sand fly species are proven vectors. Each parasite species circulates in natural foci of infection where susceptible phlebotomines and mammals coexist. The epidemiology and clinical manifestations of the diseases are largely diverse, being usually grouped into two main entities: zoonotic leishmaniasis, where domestic or wild animal reservoirs are involved in the transmission cycle and humans play a role of accidental host, and anthroponotic leishmaniasis, where humans are the sole reservoir and source of the vector's infection.

Visceral leishmaniasis (VL) is caused by *Leishmania donovani* in the Indian subcontinent and East Africa (anthroponotic entity) and by *L. infantum* (*L. chagasi*) in the Mediterranean basin, parts of Central Asia, and Latin America (a zoonotic entity with domestic dogs acting as the main reservoir host). Several species of *Leishmania* cause cutaneous leishmaniasis (CL) or mucocutaneous (MCL) leishmaniasis. The most common are *L. major* (rural zoonotic entity) and *L. tropica* (urban anthroponotic entity) in the Old World and *L. mexicana*, *L. braziliensis*, *L. amazonensis*, *L. panamensis*, *L. guyanensis*, and *L. peruviana* (sylvatic zoonotic entities) in the New World.

Globally, 80 Old World and 21 New World countries are endemic for human leishmaniasis, with an estimated yearly incidence of 0.7 million to 1.2 million cases of CL forms and 0.2 million to 0.4 million cases of VL forms. Overall estimated prevalence is 12 million people with a disability-adjusted life years burden of 860,000 for men and 1.2 million for women. The disease affects the poorest people in the poorest countries: 72 are developing countries, of which 13 are among the least developed. The incidence is not uniformly distributed in endemic areas: 90% of CL cases are found in only seven countries (Afghanistan, Algeria, Brazil, Iran, Peru, Saudi Arabia, and Syria), whereas 90% of VL cases occur in rural and suburban areas of five countries (Bangladesh, India, Nepal, Sudan, and Brazil). These figures, however, must be regarded as underestimates; currently, it appears that the global incidence of human leishmaniasis is higher than before, owing to environmental and human behavioral factors contributing to the changing landscape of these diseases.

Risk Factors

Risk factors for leishmaniasis are primarily associated with geographically and temporally defined human exposure to phlebotomine vectors. In the Old World, colonization and urbanization of desert areas have been identified as the major risk factor for

Globally, 80 Old World and 21 New World countries are endemic for human leishmaniasis, with an estimated yearly incidence of 0.7 million to 1.2 million cases of CL forms and 0.2 million to 0.4 million cases of VL forms. Overall estimated prevalence is 12 million people with a disability-adjusted life years burden of 860,000 for men and 1.2 million for women. The disease affects the poorest people in the poorest countries: 72 are developing countries, of which 13 are among the least developed. The incidence is not uniformly distributed in endemic areas: 90% of CL cases are found in only seven countries (Afghanistan, Algeria, Brazil, Iran, Peru, Saudi Arabia, and Syria), whereas 90% of VL cases occur in rural and suburban areas of five countries (Bangladesh, India, Nepal, Sudan, and Brazil). These figures, however, must be regarded as underestimates; currently, it appears that the global incidence of human leishmaniasis is higher than before, owing to environmental and human behavioral factors contributing to the changing landscape of these diseases.

Risk Factors

Risk factors for leishmaniasis are primarily associated with geographically and temporally defined human exposure to phlebotomine vectors. In the Old World, colonization and urbanization of desert areas have been identified as the major risk factor for

outbreaks of zoonotic CL. Tourists and military personnel are often exposed to *L. major* or *L. tropica* infections in rural or urban endemic settings of North African and Middle Eastern countries. In the New World, the colonization of the primary forest associated with activities of deforestation, road building, mining, and tourism is responsible for the domestication of sylvatic cycles of CL and MCL agents. Increase in density and geographic range of phlebotomine vectors resulting from climate changes, together with the increased mobility of infected pet dogs, has been identified as a cause of northward spreading of zoonotic VL in Europe.

Individual risk factors play a major role in VL disease. Most of the *L. donovani* and *L. infantum* infections are asymptomatic or subclinical in well-nourished immunocompetent persons. Malnourished persons, infants younger than 2 years, and severely immunosuppressed adults are at high risk for acute VL when exposed to infection. Before the era of HAART (highly active antiretroviral therapy), the AIDS epidemics in southern Europe caused more than 2000 HIV and VL co-infection cases among men aged 39 years on average. Other conditions have been reported that influence the clinical outcome of VL, such as immunosuppressive therapies after organ transplantation, corticosteroid and anti-tumor necrosis factor α (TNF- α) treatments for immunologic disorders, hematologic neoplasia, and chronic conditions of hepatic cirrhosis. However, most acute VL episodes in adults remain unexplained. Other factors associated with impaired immune response to *Leishmania* (e.g., genetic factors) are probably involved.

Pathophysiology

Ingestion of metacyclic promastigotes inoculated by the vector in the skin is mediated by several types of receptors found in resident macrophages, monocytes, neutrophils, and dendritic cells. *Leishmania* lipophosphoglycan, the most abundant surface glycoconjugate, is the main factor of virulence. Once in the cell phagolysosome, amastigotes survive from hydrolase activity through pH acidification while selectively inhibiting production of reactive oxygen species. Multiplication of parasites, infection of new cells, and dissemination to tissues are contrasted by the host's inflammatory and specific immune responses. Even in most susceptible natural mammal hosts, most infections are efficiently controlled, giving rise to asymptomatic latent infections. Leishmaniasis have typical immunologic polarity: Cure or control are associated with robust cellular immune responses driven by production of interleukin (IL) 12, whereas acute or chronic diseases are characterized by the absence of such responses and the presence of high levels of nonprotective serum antibodies, a condition often associated with high levels of IL-10 production. In spite of this polarity, analysis of cytokine patterns in tissues reveals a less-polar situation, as both T_H1 and T_H2 cytokines were found to be secreted in specimens from tissues infected with CL, MCL, and VL.

Prevention

There are no human vaccines available for the immune protection against leishmaniasis. Promising data on safety and immunogenicity have been provided for the only *Leishmania* candidate vaccine under development, consisting of the recombinant polyprotein antigen LEISH-F1 with MPL-SE as adjuvant. Preventive measures are thus limited to the individual protection from sand fly bites or to community protection through reservoir control. Individual protection is through the use of repellents or insecticide-impregnated nets. Reservoir control measures are largely diverse, depending on the epidemiologic entity of leishmaniasis. Examples related to zoonotic entities with synanthropic reservoir hosts are the destruction of rodent populations around human dwellings (e.g., to control zoonotic CL due to *L. major*) and the fight against canine infections through the mass use of topical insecticides or drug treatments (e.g., to control zoonotic VL due to *L. infantum*). Early diagnosis and treatment of human cases is the main control measure against anthroponotic entities of VL (*L. donovani*) and CL (*L. tropica*).

Clinical Manifestations

Visceral Disease

VL, also known as kala-azar, results from the multiplication of *Leishmania* in the phagocytes of the reticuloendothelial system. In endemic settings, the ratio of incident asymptomatic infections to incident clinical cases varies from 4:1 to 50:1 depending on the epidemiologic type (anthroponotic VL is normally more virulent) and the poverty of the affected country. Classic VL manifests as pallor, fever, and hard splenomegaly; hepatomegaly is less common. Laboratory findings document pancytopenia and hypergammaglobulinemia. The clinical incubation period ranges from 3 weeks (exceptional) to more than 2 years, but 4 to 6 months is average. Patients report a history of fever resistant to antibiotics; on physical examination, the spleen is typically appreciated 5 to 15 cm below the left costal margin. Symptomatic VL is 100% fatal when left untreated.

Cutaneous Disease

CL results from multiplication of *Leishmania* in the phagocytes of the skin. In the classic course of the disease, lesions appear first as papules, advance slowly to nodules or ulcers, and then spontaneously heal with scarring over months to years. The clinical incubation period ranges from 1 week (exceptional) to several months; lesions caused by *L. major* and *L. mexicana* tend to evolve and resolve quickly, whereas those caused by *L. braziliensis*, *L. tropica*, and dermatropic strains of *L. infantum* can have longer periods of incubation and spontaneous healing.

Mucosal Disease

MCL results from parasitic metastasis in the nasal mucosal that eventually extends to the oropharynx and larynx. It can develop from CL lesions caused by *L. braziliensis* and *L. panamensis*. Typically, MCL evolves slowly (3 years on average) and does not heal spontaneously.

Diagnosis

The standard diagnosis method for all forms of leishmaniasis is still the microscopy demonstration of *Leishmania* organisms in Giemsa-stained impression smears or cultures from samples of infected tissues. In general, sensitivity increases when both staining and culture are performed. Polymerase chain reaction (PCR) detection of *Leishmania* DNA on samples further increases the diagnostic sensitivity and also might allow species identification by target DNA sequencing or restriction fragment length polymorphism analysis.

Different tissue samplings must be performed depending on the clinical form of leishmaniasis. For VL, aspirate or biopsy specimens are obtained from the spleen, bone marrow, the liver, or enlarged lymph nodes. Higher diagnostic yields are obtained with spleen aspirates (more than 98%), although bone marrow aspirates (80% to 98% of yield) are usually preferred. For CL and MCL, material is obtained by scraping tissue juice from a nodular lesion or from the edge of an ulcer or by taking punch biopsies of inflamed tissue. Diagnostic yields of about 80% are obtained with impression smears and cultures during the first half of the natural course of the lesion. After that, standard parasitologic diagnosis becomes more difficult and PCR remains the only reliable method.

Serology is useful when the diagnosis of VL proves difficult with other methods. Commercially available dipstick tests using recombinant antigen K39 can be used in decisions for or against treatment. Negative serology results are common in CL and MCL, as well as in VL when patients are severely immunosuppressed.

Differential Diagnosis

Visceral Disease

The differential diagnosis depends on the local disease pattern associated with endemic areas. In many of them it includes chronic malaria, disseminated histoplasmosis, hepatosplenic schistosomiasis, typhoid fever, brucellosis, tuberculosis, endocarditis, relapsing

fever, and African trypanosomiasis. Other cosmopolitan diseases include syphilis, lymphomas, chronic myeloid leukemia, sarcoidosis, malignant histiocytosis, and liver cirrhosis.

Cutaneous Disease

A typical history of CL—an inflammatory, slowly developing, and painless skin lesion associated with recent exposure to sand fly bites—can strongly support a clinical diagnosis of disease. However, there is an extensive differential diagnosis, which includes acute or chronic forms of CL. For the former, insect bites, furuncular myiasis, and bacterial tropical ulcers are the most common; for the latter, keloid, lupus vulgaris, discoid lupus erythematosus, and sarcoidosis.

Treatment

The therapy of leishmaniasis relies on a limited number of drugs, most of which are old and relatively toxic compounds. Systemic drug administration requires hospitalizing and monitoring the patient.

Pentavalent Antimonials

Organic salts of pentavalent antimony (Sb) are still the mainstay therapy for all clinical forms of leishmaniasis. Two preparations are available that are equal in efficacy and toxicity when used in equivalent Sb doses: sodium stibogluconate (Pentostam),¹⁰ available in English-speaking countries, and meglumine antimoniate (Glucantime),² available in Southern Europe and Latin America. The recommended dosage of Sb is 20 mg/kg/day for 21 to 28 days, given intramuscularly or intravenously. Treatment should be prolonged for 40 to 60 days in areas with documented Sb-resistant VL (e.g., in Bihar State, India). The drugs can be administered intraleitionally in cases of uncomplicated CL, intermittently over 20 to 30 days. Systemic toxicity caused by the antimonials relates to the total dose administered and includes anorexia, pancreatitis, and changes on electrocardiography (e.g., prolongation of the QT interval), which can precede dangerous arrhythmias.

Amphotericin B Drugs

Liposomal amphotericin B (Ambisome) is the current gold standard for VL treatment, being highly effective and nontoxic. However, the high cost of the drug precludes its use in developing countries where leishmaniasis is endemic. Liposomal amphotericin B is given intravenously at the total dose of 18 to 21 mg/kg, with various treatment schedules similarly effective: 3 mg/kg/day on days 1 to 5 and 10; 3 mg/kg on days 1 to 5, 14, and 21; or 10 mg/kg/day for 2 days.

Amphotericin B desoxycholate (Fungizone) is a relatively toxic compound used in Sb-resistant VL¹ and MCL, administered intravenously at the low dosage of 0.5 mg/kg every other day for 14 days. Doses in excess of 1 mg/kg/day commonly result in severe infusion-related side effects (fever, chills, and bone pain) and delayed side effects (toxic renal effects).

Other Parenteral Drugs

Other parenteral drugs include old second-line drugs whose use is limited. Pentamidine isethionate (Pentam 300)¹ is a toxic compound used to treat some forms of New World CL resistant to Sb therapy and is given intramuscularly at the low dose of 2 mg/kg every other day for 7 days. Treatment in excess of this dosage can result in common side effects such as myalgias, nausea, headache, and hypoglycemia. Paromomycin (aminosidine) sulfate injection² (manufactured by Gland Pharma, India, on behalf of Institute of One World Health) is an old aminoglycoside that is being reevaluated as a first-line drug for Indian VL. It is given intramuscularly at the dose of 11 mg base per kg per day for 21 days. Elevation

of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) liver enzymes is usually seen during therapy.

Miltefosine, the First Oral Drug for Leishmaniasis

Miltefosine (Impavido)⁵ is a hexadecylphosphocholine originally developed as an anticancer agent. It is the first recognized oral treatment for leishmaniasis and is available in Germany and India. So far, it is recommended for VL therapy in India and Ethiopia and for CL therapy in Colombia and Bolivia. The drug is administered at 2.5 mg/kg/day (not exceeding 100 mg/day) for 28 days. Miltefosine administration does not require the patient to be hospitalized for monitoring. Mild gastrointestinal toxicity may be common. The drug is contraindicated in pregnancy.

Monitoring

In VL patients, fever recedes by day 3 to 5 of treatment, and well-being returns by the first week. Hematologic indices start to improve during the second week. Hemoglobin, serum albumin, and body weight are the most useful indicators of progress. The spleen tends to normalize 1 to 2 months after the end of therapy, although it can take up to 1 year to regress completely. Parasitologic assessment of cure is not normally necessary. Relapses can occur after apparent clinical cure from 2 to 8 months after treatment has been discontinued.

In CL patients, clinical response to drugs is rapid, but complete reepithelialization of lesions is observed in only one third of patients by the end of 3- to 4-week treatment courses.

⁵Investigational drug in the United States.

LEPROSY

Method of

Gerson O. Penna, MD, PhD; and Maria Lucia Penna, MD, PhD

CURRENT DIAGNOSIS

- Contact with other leprosy cases; travel to or residence in a leprosy-endemic country.
- Skin lesion(s) with altered sensation.
- Thickened or enlarged peripheral nerve, with sensory loss and/or weakness in the muscles supplied by the nerve.
- Presence of acid-fast bacilli in a slit skin smear.
- Skin biopsy with the presence of acid-fast bacilli or typical lesions, thereby aiding disease classification.

¹Not FDA approved for this indication.

²Not available in the United States.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

fever, and African trypanosomiasis. Other cosmopolitan diseases include syphilis, lymphomas, chronic myeloid leukemia, sarcoidosis, malignant histiocytosis, and liver cirrhosis.

Cutaneous Disease

A typical history of CL—an inflammatory, slowly developing, and painless skin lesion associated with recent exposure to sand fly bites—can strongly support a clinical diagnosis of disease. However, there is an extensive differential diagnosis, which includes acute or chronic forms of CL. For the former, insect bites, furuncular myiasis, and bacterial tropical ulcers are the most common; for the latter, keloid, lupus vulgaris, discoid lupus erythematosus, and sarcoidosis.

Treatment

The therapy of leishmaniasis relies on a limited number of drugs, most of which are old and relatively toxic compounds. Systemic drug administration requires hospitalizing and monitoring the patient.

Pentavalent Antimonials

Organic salts of pentavalent antimony (Sb) are still the mainstay therapy for all clinical forms of leishmaniasis. Two preparations are available that are equal in efficacy and toxicity when used in equivalent Sb doses: sodium stibogluconate (Pentostam),¹⁰ available in English-speaking countries, and meglumine antimoniate (Glucantime),² available in Southern Europe and Latin America. The recommended dosage of Sb is 20 mg/kg/day for 21 to 28 days, given intramuscularly or intravenously. Treatment should be prolonged for 40 to 60 days in areas with documented Sb-resistant VL (e.g., in Bihar State, India). The drugs can be administered intraleitionally in cases of uncomplicated CL, intermittently over 20 to 30 days. Systemic toxicity caused by the antimonials relates to the total dose administered and includes anorexia, pancreatitis, and changes on electrocardiography (e.g., prolongation of the QT interval), which can precede dangerous arrhythmias.

Amphotericin B Drugs

Liposomal amphotericin B (Ambisome) is the current gold standard for VL treatment, being highly effective and nontoxic. However, the high cost of the drug precludes its use in developing countries where leishmaniasis is endemic. Liposomal amphotericin B is given intravenously at the total dose of 18 to 21 mg/kg, with various treatment schedules similarly effective: 3 mg/kg/day on days 1 to 5 and 10; 3 mg/kg on days 1 to 5, 14, and 21; or 10 mg/kg/day for 2 days.

Amphotericin B desoxycholate (Fungizone) is a relatively toxic compound used in Sb-resistant VL¹ and MCL, administered intravenously at the low dosage of 0.5 mg/kg every other day for 14 days. Doses in excess of 1 mg/kg/day commonly result in severe infusion-related side effects (fever, chills, and bone pain) and delayed side effects (toxic renal effects).

Other Parenteral Drugs

Other parenteral drugs include old second-line drugs whose use is limited. Pentamidine isethionate (Pentam 300)¹ is a toxic compound used to treat some forms of New World CL resistant to Sb therapy and is given intramuscularly at the low dose of 2 mg/kg every other day for 7 days. Treatment in excess of this dosage can result in common side effects such as myalgias, nausea, headache, and hypoglycemia. Paromomycin (aminosidine) sulfate injection² (manufactured by Gland Pharma, India, on behalf of Institute of One World Health) is an old aminoglycoside that is being reevaluated as a first-line drug for Indian VL. It is given intramuscularly at the dose of 11 mg base per kg per day for 21 days. Elevation

of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) liver enzymes is usually seen during therapy.

Miltefosine, the First Oral Drug for Leishmaniasis

Miltefosine (Impavido)⁵ is a hexadecylphosphocholine originally developed as an anticancer agent. It is the first recognized oral treatment for leishmaniasis and is available in Germany and India. So far, it is recommended for VL therapy in India and Ethiopia and for CL therapy in Colombia and Bolivia. The drug is administered at 2.5 mg/kg/day (not exceeding 100 mg/day) for 28 days. Miltefosine administration does not require the patient to be hospitalized for monitoring. Mild gastrointestinal toxicity may be common. The drug is contraindicated in pregnancy.

Monitoring

In VL patients, fever recedes by day 3 to 5 of treatment, and well-being returns by the first week. Hematologic indices start to improve during the second week. Hemoglobin, serum albumin, and body weight are the most useful indicators of progress. The spleen tends to normalize 1 to 2 months after the end of therapy, although it can take up to 1 year to regress completely. Parasitologic assessment of cure is not normally necessary. Relapses can occur after apparent clinical cure from 2 to 8 months after treatment has been discontinued.

In CL patients, clinical response to drugs is rapid, but complete reepithelialization of lesions is observed in only one third of patients by the end of 3- to 4-week treatment courses.

CURRENT THERAPY

Paucibacillary Leprosy (6 months)

- ADULT (50–70 kg)
 - Dapsone: 100 mg daily
 - Rifampin (Rifadin)¹: 600 mg once a month under supervision
- CHILD (under 10 years)
 - Dapsone: 1 mg/kg per day
 - Rifampin¹: 10 mg/kg once a month under supervision

Multibacillary Leprosy (12 months)

- ADULT (50–70 kg)
 - Dapsone: 100 mg daily
 - Rifampin¹: 600 mg once a month under supervision
 - Clofazimine (Lamprene)⁵: 50 mg daily and 300 mg once a month under supervision
- CHILD (under 10 years)
 - Dapsone: 1 mg/kg per day
 - Rifampin¹: 10 mg/kg once a month under supervision
 - Clofazimine: 1 mg/kg per day

¹Not FDA approved for this indication.

Epidemiology

Leprosy is a chronic disease caused by *Mycobacterium leprae* that affects skin and nerves, often resulting in physical disabilities. The disease has been found around the world, showing that transmission occurs regardless of climate. However, several studies have associated higher transmission with more humid regions.

Nevertheless, disease transmission has ceased in nearly all developed nations, most likely as a consequence of better nutrition and socioeconomic development. Currently, new autochthonous cases are found in all tropical countries, with India and Brazil having the highest number of cases annually. Some insular countries located in the Pacific and Indian Oceans have the highest rates of new case detection, indicating a high risk of transmission.

In the Gulf region of the United States, mostly in the states of Louisiana and Texas, native cases are still diagnosed. There are armadillos (*Dasypus novemcinctus*) in the area that have been infected with strains of *M leprae* found also in autochthonous human cases. This suggests that leprosy might be a regional zoonosis, even though *M leprae* was introduced into the Americas by Europeans and Africans. There are also records of *M leprae* infection in armadillos in Central and South America.

Furthermore, cases in African chimpanzees raise the possibility that these animals could be helping to maintain leprosy transmission in Africa.

The mechanisms of leprosy transmission are not well known due to the fact that there is no easy way to diagnose infection. It is presumed that in endemic areas infection is much more frequent than actual disease onset. The incubation period can vary from a few months to 20 years.

It is known that multibacillary cases excrete a large number of viable bacilli through nasal mucus, suggesting that transmission may be by respiratory route, and, in fact, this is believed to be the main source of transmission. Because *M leprae* can also remain viable in the environment for many days, especially in humid climates, the hypothesis of indirect transmission by means of small skin lesions remains. It is possible to theorize the existence of many different forms of transmission.

Leprosy cases are not uniformly distributed in a community, tending to form clusters within different geographic regions, villages, or groups of domiciles. In the majority of countries, cases are more common among men, and the 15- to 29-year-old age group tends to present the highest risk of disease. In areas where transmission is declining, the incidence tends to be higher among the elderly, affecting those who have lived during a period with a higher risk of infection.

After the treatment of all new leprosy cases with multidrug therapy (MDT), the backlog of known cases, which had been the main problem faced by leprosy control programs in the 1980s and early 1990s, largely disappeared. Currently, control efforts target new cases so as to not only interrupt transmission but also reduce the disabilities caused by the disease. In more endemic areas, the proportion of cases diagnosed with visible disabilities (grade 2) indicates access to timely diagnosis.

Risk Factors

In endemic areas, the main risk factors are a history of household contact with leprosy cases and low socioeconomic standing. Among infected women, pregnancy is a period of greater risk for developing the disease because of immunologic modulation.

Susceptibility to leprosy is genetically mediated by a group of genes. The low frequency of genetically determined susceptibility may be the cause of the wide difference between infection and disease that is believed to exist.

Even before the highly effective application of antiretroviral treatment, there was no observed association between HIV infection and leprosy. However, in areas of high endemicity, there are accounts of leprosy cases associated with the immunologic reconstitution resulting from antiretroviral treatment. In developed countries, the main risk factor is originating from or having lived in a leprosy-endemic area.

Prevention

Vaccination with bacille Calmette-Guérin (BCG)¹ reduces the risk of leprosy, with studies showing a variable efficacy of 20% to 80%. The revaccination of household contacts also provides protection, especially against the multibacillary forms of the disease.

Chemoprophylaxis of contacts or high-risk groups with a single dose of rifampin (Rifadin)¹ has been shown to be effective for a period of 2 years.

Improving socioeconomic conditions in the general population in endemic areas is also a very effective strategy for disease control. This can be seen when comparing the current epidemiologic situation in the Hawaiian Islands with Micronesia or the Marshall Islands, where leprosy continues with a high incidence rate.

Pathophysiology

M leprae is an intercellular microorganism with a particular tropism for skin and peripheral nerve cells. It cannot be cultivated in vitro, but can be inoculated in mouse foot pads and armadillos, although growth is quite slow.

Active *M. leprae* infection is characterized by a wide clinical range, varying from a disease in which few bacilli are present in the body to one in which a high bacterial load is found in skin lesions.

Upon entering the organism, *M. leprae* can be eliminated with a local inflammatory response. When this natural resistance fails, the bacilli multiply within macrophages, enter the lymph stream and bloodstream, reach the regional lymph nodes, and from there move on to the organs of the mononuclear phagocyte system. The mycobacterial antigens are then processed and presented by antigen-presenting cells that can be Langerhans cells, dendritic cells, or others from the monocyte-macrophage system that induce the hapten-protein conjugates to link the HLA-DR class II molecules to the CD4+ lymphocytes. In those individuals where there is stimulation of the T-helper 1 cell response, these lymphocytes will produce interferon (IFN)-gamma cytokines, β -tumor necrosis factor (β -TNF), interleukin-2 (IL2) and IL12 that will promote the differentiation of macrophages in epithelioid cells that will undergo a fusion process resulting in giant cells. This inflammatory response will be sufficient to reduce the *M leprae* in the tuberculoid form of leprosy.

On the other hand, in the absence of stimulation of the T_H2 subpopulation of T lymphocytes (TLs), these will produce IL4, IL5,

¹Not FDA approved for this indication.

IL6, IL8, IL10, and TNF-alpha cytokines. The IL4 and IL10 interleukins are suppressors of macrophage activation, leading to an insufficient immune cell response to combat the level of *M leprae* proliferation within the macrophages. This characterizes the more infectious forms of the disease at the lepromatous end of the spectrum.

M leprae uses adult Schwann cells as primary nonimmune cells for colonization. Nerve damage is attributed either to bacterial proliferation or to the immune response of the host to relatively few bacilli in peripheral nerves and adjacent areas of skin.

In this disease spectrum, cell-mediated immunity protects against the disease and limits bacterial dissemination at the tuberculoid pole, whereas this is suppressed at the lepromatous end. Humoral immunity is present only at the lepromatous pole where high levels of specific antibodies to *M leprae* are found. These immune responses, whether cell mediated or humoral, are dynamic and present spontaneous variations of reactivity that are responsible for leprosy reaction episodes.

Clinical Manifestations

Due to the complexity of the parasite-host relation and the variable efficacy of the host's cellular immune response, the clinical manifestations of the disease cross a wide spectrum. This can vary from an isolated nerve lesion or a single skin patch to a systemic disease that affects several organs beyond just skin and nerves, including eyes, testicles, and kidneys.

Ridley and Jopling, in 1966, proposed a case classification system that takes into consideration clinical, histopathologic, and immunologic parameters: tuberculoid, borderline-tuberculoid, borderline-borderline, borderline-lepromatous, and lepromatous.

Indeterminate leprosy can be considered to be the first clinical manifestation of the disease. It can be cured spontaneously or evolve into one of the other clinical forms.

Indeterminate Leprosy

This is characterized by one or more hypochromic macules with imprecise borders and reduced thermal sensitivity, although pain and tactile sensation may be preserved (Figure 1). These occur as areas of sensory disturbance with no alteration in skin color, sweat glands, or hair growth. Any alteration in nerve function is preliminary, and therefore there are no physical disabilities described with this classification. Bacilloscopic readings are negative.

Tuberculoid Leprosy

This type is characterized by erythematous or hypochromic skin lesions with clear, raised borders (Figure 2). These are limited in number with an asymmetrical distribution and altered thermal, pain, and tactile sensation. Reduced perspiration and restricted partial or full alopecia may also be seen. Nerves can be affected

Figure 1 Indeterminate leprosy.

Figure 2 Tuberculoid leprosy in child.

Figure 3 Borderline-tuberculoid leprosy.

intensively, but this usually only happens to a few. Slit skin smear results are negative.

Among children, tuberculoid leprosy lesions have the appearance of nodules or tubercles, generally only on the face. Although these lesions tend to regress spontaneously, treatment should continue as per standard ethical practice.

Borderline-Tuberculoid Leprosy

This form is characterized by lesions similar to those seen at the tuberculoid end of the spectrum, although they will be more numerous. In general, there are more than five lesions with a diameter of 10 cm or more, less clearly defined borders, and containing possible satellite lesions (Figure 3). These lesions tend to be more symmetrical, and several nerves may be affected. However, the majority of patients with this disease type will still have a negative bacilloscopy.

Borderline-Borderline Leprosy

This is a relatively rare variation, given that it commonly evolves quickly toward the Virchowian pole, often spurred on by reaction episodes. There are usually many foveal lesions (infiltrated plaques with expanding outer borders and well-defined inner borders with apparently normal skin in the middle) (Figure 4). Generally, nerves are intensively affected and skin smears are almost always positive.

Borderline-Lepromatous (Virchowian) Leprosy

A wide number of lesions are present with a range of possible clinical manifestations (infiltrations, papules, plaques, foveae, and nodules) that are common to the Virchowian form. However, with

Figure 4 Borderline-borderline leprosy.

Figure 5 Lepromatous (Virchowian) leprosy (LL).

this type there is a tendency to see some delimitation between the lesions and areas of healthy skin. Bacilloscopy is positive with a high bacterial load.

Lepromatous (Virchowian) Leprosy

Lepromatous leprosy (LL) has the highest bacterial burden of human bacterial infections. Extensive lesions tend to be symmetrical, erythematous or hypochromic, infiltrated, and without clear delineation from normal skin areas. Simple lesions evolve to become papules, tubercles, and nodules that can eventually ulcerate and that are especially full of bacilli (Figure 5). There is diffuse infiltration of the face, with auricular appendages affected in the vast majority of cases and bilateral madarosis also common. Hands and feet may also be infiltrated or showing signs of xerodermia.

LL is a systemic disease that can affect the liver, spleen, adrenal glands, lymph nodes, eyes, and nose. Nasal obstruction can be present with little or no response to vasoconstrictors. Often the nasal cavities will be affected, and the oropharynxes will be full of nasal

secretion highly abundant in bacilli. Subsequent nasal dryness can lead to secondary ulceration and infection with possible perforation and destruction of the nasal septum, resulting in what is commonly referred to as saddle nose. With olfactory bulb dysfunction, anosmia will often be the outcome.

Lesions to the palate, lips, gum, and uvula can further compromise the pharynx, nasopharynx, and tonsils. The eyes may show erythema, dryness, dacryocystitis, lagophthalmos, and diminished sensation in the cornea. Likewise, iritis and iridocyclitis may be present, so proper intervention is necessary to ensure prevention of early onset of blindness.

The testes may also be directly affected by bacilli, as witnessed by atrophy of the testicular parenchyma and diffuse fibrosis with eventual sterility and alteration of sexual function. When secondary amyloidosis is present, renal insufficiency may result.

Variations of LL.

Histoid Lepromatous Leprosy (or Wade's Lepromatous). Nodular lesions are present, well defined, and of varying sizes. These may be round or oval with a reddish or pink color. These lesions contain a large number of bacilli and are normally associated with sulfone resistance. Histiocytes with a spongy appearance are present under histologic analysis.

Diffuse Lepromatous Leprosy (DLL). Described by Lucio, Alvarado, and Latapi, this is a diffuse form of LL, also called "beautiful" leprosy because this form confers a pinkish and healthy appearance to the skin. It is more frequently seen in Mexico and is characterized by the diffuse infiltration of the skin, altered sensation that starts in the hands and feet, loss of eyebrows, and telangiectasias in the face and torso. Recently a mycobacterium was isolated in cases of DLL whose DNA cannot be amplified using usual *M leprae* primers. As a result, a new species has been proposed under the name *Mycobacterium lepromatosis*, but many specialists do not yet accept that this is a separate microorganism.

Pure Neural Leprosy. This type presents only nerve lesions without any cutaneous patches. The most common nerves affected are the ulnar, tibial, and fibular. The radial, median, facial, trigeminal, and auricular nerves, among others, may also be damaged.

Neuropathic pain is often present spontaneously or when the nerve is palpated, either with or without thickening of the nerve. This can evolve to sensory loss, paresthesia, or muscular atrophy in the corresponding area, in addition to autonomic dysfunction and nerve abscess.

Leprosy Diagnosis

The patient is examined to locate any possible skin lesions with diminished sensation or areas of sensory alteration that may be due to compromised peripheral nerves. Lighting must be adequate, and it is important to observe the entire body surface moving from head to toe. Where there are possible signs of disease, thermal, pain, and tactile sensation testing should be done, also looking for areas of alopecia or anhidrosis. It must be noted whether there is any type of physical disability.

Bacilloscopy consists of the collection and examination of skin smears taken from a suspected lesion, both earlobes, and both elbows, and helps to classify a patient as paucibacillary (PB) with a negative examination result or multibacillary (MB) when positive.

The bacilloscopic results will generally be negative in the indeterminate, tuberculoid, and borderline-tuberculoid forms, which are considered to be PB forms. Similarly, they tend to be positive for the lepromatous (Virchowian), borderline-lepromatous, and borderline-borderline, which are MB forms.

Ideally, the bacilloscopic reading should be expressed quantitatively as a bacteriologic index (BI) so that it is possible to monitor the patient's progress during treatment. The histologic examination of a skin biopsy also helps to provide a more precise disease classification and can help to confirm diagnosis in cases that are bacilloscopy negative.

In regions with limited access to laboratory resources, clinical diagnosis is sufficient to warrant the beginning of the standard leprosy treatment regimen, keeping in mind that this is the only

TABLE 1 Main Differential Diagnosis by Leprosy Forms

INDETERMINATE LEPROSY	TUBERCULOID LEPROSY	BORDERLINE, BORDERLINE-BORDERLINE, BORDERLINE-LEPROMATOUS, AND LEPROMATOUS LEPROSY
Seborrheic dermatitis or seborrheic eczema	Seborrheic dermatitis	Erythema nodosum
Eczema	Dermatofitosis	Diffuse (anergic) cutaneous leishmaniasis
Localized scleroderma (morphea)	Granuloma annulare	Cutaneous and mucosal leishmaniasis
Residual hypochromia and achromia	Cutaneous leishmaniasis	Systemic lupus erythematosus and other rheumatologic diseases
Pityriasis versicolor	Discoid lupus erythematosus	Neurofibromatosis (von Recklinghausen disease)
Vitiligo	Pityriasis rosea Gibert	Pityriasis rosea Gibert
	Psoriasis	Congenital syphilis, secondary syphilis, tertiary syphilis
	Sarcoidosis	
	Secondary syphilis	
	Cutaneous tuberculosis	

dermatologic disease with altered sensation in lesions. The World Health Organization (WHO) suggests the classification of cases as either PB or MB on the basis of the number of skin lesions, with MB cases having five or more such patches.

Available serologic testing does not show sufficient accuracy for disease diagnosis or infection. Real-time polymerase chain reaction is available for leprosy and can act as a means of confirmation for diagnosis of PB cases.

Differential Diagnosis

Differential diagnoses of leprosy include a variety of dermatologic conditions, given the wide range of clinical manifestations in leprosy. The sensory loss symptomatic of leprosy can also be difficult to determine in children and in other diseases that produce changes in the normal skin characteristics (Table 1).

Treatment

Leprosy treatment, like tuberculosis treatment, has to deal with bacillar resistance and persistence. Single-drug therapy selects drug-resistant bacilli and should be avoided. Therapy duration has, as a target, the reduction of the number of persistent bacilli that could lead to relapses.

Standard MDT with dapsone, rifampin (Rifadin),¹ and clofazimine⁵ for 12 months for MB cases and 6-month MDT with dapsone and rifampin for PB cases has dramatically changed the prognosis for leprosy patients. However, the evidence is rather weak on the efficacy of this drug regimen, especially regarding the necessary length of time for treatment, both in terms of the proportion of relapse cases and other outcomes, such as physical disability. The use of rifampin once a month was determined for financial reasons, and there is no study comparing this schedule with daily use. For this reason, research on new drugs and treatment regimens continues.

Shorter regimens were used but had shown high relapse rates: daily doses of rifampin and ofloxacin (Floxin)¹ for 4 weeks; single-dose course of rifampin, ofloxacin and minocycline (Minocin)¹ for single-lesion patients.

Fluoroquinolones (pefloxacin,² ofloxacin, and moxifloxacin [Avelox]¹), macrolides (clarithromycin [Biaxin]¹), and tetracycline (minocycline) are effective against *M leprae*. Only rifampin, its

derivative rifapentine (Priftin),¹ and moxifloxacin are bactericidal drugs; all others are bacteriostatic.

In cases of intolerance or resistance to dapsone, this can be removed from the drug regimen. Where similar intolerance or resistance is related to rifampin, this should be substituted with a daily dose of 400 mg of ofloxacin. This alternate course lasts 6 months for PB cases and 24 months for MB.

For those who cannot take either dapsone or rifampin, PB patients can be treated with ofloxacin (400 mg/day), minocycline (100 mg/day), and clofazimine (50 mg/day) in self-administered doses for 6 months. Similarly, MB patients can use this regimen during the first 6 months of treatment (intensive phase), followed by 18 months with daily doses of ofloxacin or combined daily doses of minocycline and clofazimine (maintenance phase).

Leprosy Reactions and Control

Over the course of this chronic disease, it is common to experience acute inflammatory episodes called leprosy reactions. These reactions can take place before diagnosis, as well as during or after MDT treatment. They are commonly grouped into (a) type 1 (reversal) reactions (T1Rs) resulting from vigorous cell-mediated immune response; and (b) type 2 reactions (T2Rs), the clinical manifestation of which is frequently erythematous nodosum leprosum (ENL) that comes about mainly from immunocomplex deposits. In patients with borderline-lepromatous leprosy, it is possible to have both reaction types simultaneously. There is also Lucio's phenomenon, which is an immune system response with important clinical manifestations. Its physiopathology is not well understood, with abundant infection of *M leprae* in endothelium, which can lead to thrombosis in the most superficial vases from immunocomplex deposits with hemorrhaging and cutaneous infarction.

In the literature, a robust positive association has been demonstrated between bacterial load and the frequency of leprosy reactions. A reaction can be set off by various factors, such as pregnancy, childbirth, vaccinations, puberty, intercurrent infections, stress (physical, psychological, or surgical), use of potassium iodate/iodide (SSKI), and immune reconstruction inflammatory syndrome (IRIS) linked to anti-retroviral or immune-based therapies.

Those patients who experience leprosy reactions during MDT treatment should continue taking their regimen without modification while also beginning a specific and concurrent treatment for the appropriate reaction type.

TABLE 2 Differences between Reaction Type 1 and Relapse

REVERSAL REACTION	RELAPSE
Generally occurs during course of MDT or within 6 months of treatment completion	Normally takes place well after the end of MDT, at least a year after treatment completion
Sudden and unexpected onset	Slow and insidious onset
Can be accompanied by fever and malaise	In general, no systemic symptoms present
Old lesions become erythematous, shiny, and infiltrated	Old lesions may present erythematous edges
In general, many new lesions	Few new lesions
There may be ulceration of the reaction lesions	Ulceration may occur on arms and legs in addition to the lesions
Regression with desquamation	No desquamation present
Can quickly affect several nerve trunks, with presence of pain, sensory alteration, and decreased motor function	May affect a single nerve and functional alterations often take place very slowly
Excellent response to corticosteroid therapy	Does not respond well to corticosteroid therapy
Bacteriologic index stable or falls	Bacteriologic index rises

Abbreviation: MDT = multidrug therapy.

Type 1 Reaction or Reversal Reaction

Clinically speaking, lesions become more erythematous and infiltrated, and those with previously diminished sensation can become more sensitive to touch. Desquamation may occur and some lesions may even ulcerate. New lesions can erupt along with edema in the hands, feet, and face, as well as general systemic symptoms. These reactions can last for years in some patients. It is important to begin an immediate intervention given that neuritis is the most common, serious, and potentially disabling clinical manifestation of T1R.

The drug of choice for T1R treatment is prednisone (or prednisolone [Millipred]) with a dosage of 1 to 2 mg/kg/day for at least 12 weeks, at which point it can be tapered off until discontinuing medication around the 24th week.

Type 2 Reaction

This occurs in multibacillary patients, and ENL is the most frequent clinical manifestation of T2Rs. Other variations of T2R are polymorphic erythema and vasculitis.

Clinically, ENL is a systemic condition with the eruption of painful and often symmetrical erythematous nodules on the arms and legs. When deeper, these nodules are more easily palpated than the more visible ones but will often ulcerate. Neuritis is frequent, although it is less aggressive than seen in T1Rs. The systemic impact can produce edema, myalgia, fever, malaise, asthenia, weight loss, cephalalgia, iritis, episcleritis, iridocyclitis, glaucoma, epistaxis, arthralgia, orchiepididymitis with testicular atrophy, glomerulonephritis, chronic renal insufficiency, hepatosplenomegaly, and amyloidosis.

The most common medication used for ENL is thalidomide (Thalomid) in variable dosage, from 100 to 400 mg/day, depending on the severity of the reaction. The distribution of thalidomide is restricted in some countries due to its teratogenic effects. For this reason, it should be given under strict supervision with proper medical, ethical, and legal measures in place.

For ENL associated with neuritis, iritis, orchitis, and/or hand-foot reactions, or in women of childbearing age, a course of corticosteroids should be given (prednisone at 1–2 mg/kg/day).

In chronic cases and those that are nonresponsive to treatment, it is possible to administer clofazimine along with steroids, at the initial dosage of 100 mg three times per day for a maximum of 12 weeks. This should be reduced to 100 mg twice daily for another 12 weeks and finally 100 mg/day for 12 to 24 weeks.

Cyclosporine (Neoral, Sandimmune)¹ may also offer some benefit to the patient with serious ENL, as can the association of azathioprine (Imuran),¹ methotrexate,¹ and corticosteroids.

¹Not FDA approved for this indication.

Lucio's Phenomenon

Lucio's phenomenon can occur in forms of lepromatous leprosy. The skin lesions can be discreet and limited in number, pinkish or cyanotic, often very painful, and potentially necrotizing and ulcerative. This condition can lead to death. Treatment is based on a course of corticosteroid therapy appropriate for each patient.

Differential Diagnosis between Relapse and Reaction

Relapse rates are very low whereas reactions are quite frequent, even after completing treatment. Table 2 shows the main differences between reaction type 1 and relapse.

Complications

Leprosy complications are the result of permanent nerve damage. Lesions to the large nerve trunks, such as the ulnar, median, and tibial, cause motor and sensory loss leading to disabilities such as claw hand and footdrop.

The absence of sensation in the hands, soles of the feet, and cornea leaves these areas predisposed to common wounds and pressure ulcers. This reality demands that patients take specific care to avoid ulcers and detect them as soon as possible to prevent secondary infection. In addition, corneal ulcers can result in blindness.

Acknowledgment

We thank Dr. Anna Maria Salles for the patient's pictures.

LYME DISEASE

Method of

Carlos R. Oliveira, MD; and Eugene D. Shapiro, MD

CURRENT DIAGNOSIS

- Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne infection in both the United States and Europe.
- Early localized Lyme disease is a clinical diagnosis that is based on the presence of a single erythema migrans rash. The rash presents as an expanding circular macule that is often uniformly erythematous but occasionally can have central clearing that gives it the appearance of a target lesion. Erythema migrans usually appears 7 to 14 days after a tick bite (although the bite often is not recognized). If untreated, it persists for about 3 to 4 weeks.
- Early disseminated Lyme disease can present as multiple erythema migrans, cranial nerve palsy, lymphocytic meningitis, radiculomyelitis (Bannwarth syndrome), or carditis.
- Arthritis is the primary manifestation of late Lyme disease. Typically it is an oligoarthritis that most often involves a single knee.
- Patients with no objective signs but only nonspecific symptoms (e.g., arthralgia, myalgia, fatigue, or perceived cognitive difficulties) are highly unlikely to have active Lyme disease as the cause regardless of the result of antibody tests.
- Antibody test results for Lyme disease are usually negative in patients with erythema migrans (single or multiple); therefore testing for antibody generally is only indicated for patients with non-cutaneous manifestations of Lyme disease.
- The IgG antibody test has good sensitivity for patients with Lyme disease that develop ≥ 4 weeks after initial infection.
- Tests for antibodies to *B burgdorferi* should use a two-tier procedure, first with a sensitive quantitative test, usually either a whole-cell or C-6 peptide enzyme-linked immunosorbent assay (ELISA); if that result is either positive or equivocal, a more specific test, the Western immunoblot, is done to confirm a positive test result. The presence of antibodies against at least either 2 (for IgM) or 5 (for IgG) proteins of *B burgdorferi* is required for the immunoblot result to be considered positive.
- Sensitivity of PCR assays of both blood and CSF are poor because concentrations of *B burgdorferi* in these fluids are low.
- Once serum antibodies to *B burgdorferi* develop, both IgG and IgM antibodies may persist for decades despite adequate treatment; therefore elevated concentrations of antibodies in serum do not necessarily indicate active infection.

CURRENT THERAPY

- An oral course of doxycycline (Vibramycin)¹ for 10 days or of amoxicillin (Amoxil)¹ or cefuroxime axetil (Ceftin) for 14 days is highly effective for treating early localized Lyme disease.
- A 14-day course of the same antimicrobials also is highly effective in treating multiple erythema migrans and other manifestations of early disseminated Lyme disease, although

patients with Lyme meningitis or complete atrioventricular block should be treated either parenterally with ceftriaxone (Rocephin)¹ or cefotaxime (Claforan)¹ or, in some instances, orally with doxycycline.¹

- A 28-day course of an oral regimen is recommended for the treatment of Lyme arthritis.
- Doxycycline (Vibramycin) is contraindicated in women who are pregnant or are breastfeeding.
- The most effective preventive measure is avoidance of tick-infested areas. If exposure is unavoidable, visual inspection and prompt removal of embedded ticks, use of tick repellents with N, N-diethyl-3-methylbenzamide (DEET), and use of protective clothing have all been found to be modestly effective.
- An infected tick generally must be attached for 36 to 72 hours or longer for there to be a substantial risk of transmission of *B burgdorferi*. If a tick that has been embedded for at least 36 hours is removed, a single dose of doxycycline (Vibramycin) 8.8 mg/kg, maximum 200 mg,¹ given within 72 hours of removing the engorged tick, can be effective in preventing Lyme disease.
- Multiple or prolonged courses of antibiotics have not been shown to be effective and are not recommended for patients with only chronic, subjective symptoms after completing appropriate antibiotic treatment for Lyme disease.

¹Not FDA approved for this indication.

Epidemiology and Ecology

Lyme arthritis was first described in 1977 when an unusual cluster of children with arthritis in Lyme, Connecticut, was reported. Soon after, Willy Burgdorfer identified the causative bacterial agent, a spirochete that was later named *Borrelia burgdorferi*, in *Ixodes scapularis*, the deer tick. Lyme disease, the most common vector-borne illness in both the United States and Europe, is transmitted by hard-bodied ticks of the *Ixodes* genus. In the United States, *Ixodes scapularis* (in the East and upper Midwest) and *Ixodes pacificus*, the Western black-legged tick (on the Pacific coast), can be vectors of Lyme disease. More than 90% of all cases in the United States occur in nine states: Connecticut, Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. In Europe and in Asia, *Ixodes ricinus* (the sheep tick) and *Ixodes persulcatus* (the tiaga tick) can transmit *B burgdorferi*. *Ixodes* ticks feed once in each of the three stages of their 2-year life cycle: larva, nymph, and adult. There are a number of genospecies of *Borrelia burgdorferi* sensu lato that cause Lyme disease. In the United States, Lyme disease is almost exclusively caused by *B burgdorferi* sensu stricto, whereas in Europe and in Asia, *Borrelia afzelii* and *Borrelia garinii*, in addition to *B burgdorferi* sensu stricto, are the major causes of Lyme disease.

Lyme disease is a zoonosis. The primary reservoir for *B burgdorferi* are small mammals, such as mice and chipmunks, although birds and other mammals, such as foxes and coyotes, can also serve as reservoirs of the organism. Deer are not a competent reservoir for *B burgdorferi*, but they are important for supporting the life cycle of the deer tick. Ticks are uninfected when they hatch. They can become infected after they feed on an infected animal. The bacteria live in the midgut of the tick, which must remain attached to a host for 36 to 48 hours or longer for the spirochete to travel to the salivary glands so it can be injected into the host. Although ticks may become infected at any stage of the life cycle, nymphs are more likely to transmit the organism. This is because their small size (<2 mm) makes them more difficult to detect than adult ticks and because the organism can be transmitted more rapidly from an infected nymph than from an infected adult tick. Consequently, nymphal ticks are less likely than are adult ticks to be removed before the organism can be transmitted. The most important risk factor for Lyme disease is exposure to a tick-infested area in which

Epidemiology and Ecology

Lyme arthritis was first described in 1977 when an unusual cluster of children with arthritis in Lyme, Connecticut, was reported. Soon after, Willy Burgdorfer identified the causative bacterial agent, a spirochete that was later named *Borrelia burgdorferi*, in *Ixodes scapularis*, the deer tick. Lyme disease, the most common vector-borne illness in both the United States and Europe, is transmitted by hard-bodied ticks of the *Ixodes* genus. In the United States, *Ixodes scapularis* (in the East and upper Midwest) and *Ixodes pacificus*, the Western black-legged tick (on the Pacific coast), can be vectors of Lyme disease. More than 90% of all cases in the United States occur in nine states: Connecticut, Maryland, Massachusetts, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. In Europe and in Asia, *Ixodes ricinus* (the sheep tick) and *Ixodes persulcatus* (the tiaga tick) can transmit *B burgdorferi*. *Ixodes* ticks feed once in each of the three stages of their 2-year life cycle: larva, nymph, and adult. There are a number of genospecies of *Borrelia burgdorferi* sensu lato that cause Lyme disease. In the United States, Lyme disease is almost exclusively caused by *B burgdorferi* sensu stricto, whereas in Europe and in Asia, *Borrelia afzelii* and *Borrelia garinii*, in addition to *B burgdorferi* sensu stricto, are the major causes of Lyme disease.

Lyme disease is a zoonosis. The primary reservoir for *B burgdorferi* are small mammals, such as mice and chipmunks, although birds and other mammals, such as foxes and coyotes, can also serve as reservoirs of the organism. Deer are not a competent reservoir for *B burgdorferi*, but they are important for supporting the life cycle of the deer tick. Ticks are uninfected when they hatch. They can become infected after they feed on an infected animal. The bacteria live in the midgut of the tick, which must remain attached to a host for 36 to 48 hours or longer for the spirochete to travel to the salivary glands so it can be injected into the host. Although ticks may become infected at any stage of the life cycle, nymphs are more likely to transmit the organism. This is because their small size (<2 mm) makes them more difficult to detect than adult ticks and because the organism can be transmitted more rapidly from an infected nymph than from an infected adult tick. Consequently, nymphal ticks are less likely than are adult ticks to be removed before the organism can be transmitted. The most important risk factor for Lyme disease is exposure to a tick-infested area in which

the disease is endemic. Most cases of Lyme disease occur in the spring and summer, which correlates with peak activity of nymphal ticks and with frequent outdoor activity of humans.

Pathophysiology

The pathogenesis of Lyme disease is predominantly driven by the host immune response to the spirochete. During the first stage of infection, after transfer of the organism to the skin, inflammation ensues that leads to an erythematous lesion at the site of inoculation. The spirochete does not produce toxins; however, it can disseminate via the bloodstream or through the lymph vessels. After dissemination, the spirochete can adhere to distal tissues, and an immune-mediated inflammatory reaction at these sites leads to the characteristic clinical manifestations of Lyme disease.

Prevention

No vaccine is currently available to prevent Lyme disease in humans. The most effective preventive measure is avoidance of tick-infested areas. Tick repellents that contain N, N-diethyl-3-methylbenzamide (DEET) and the use of protective clothing (long sleeves and pants) have been found to be modestly effective at preventing Lyme disease. If exposure is unavoidable, frequent visual inspection with prompt removal of ticks is recommended. In endemic areas, if a nymphal or adult *Ixodes* tick is removed that is partially engorged (has been attached for at least 36 hours), a single dose of doxycycline (Vibramycin)¹ administered within 72 hours of removing the tick can be effective in preventing Lyme disease.

Clinical Manifestations

The clinical manifestations of Lyme disease can be divided into three stages: early localized disease, early disseminated disease, and late disease. About two-thirds of patients with Lyme disease in the United States have early localized disease, which is characterized by a single erythema migrans (EM) rash at the site of the tick bite (although the tick bite is recognized in only a minority of cases). The rash starts as an erythematous macule or papule and then expands as an annular macule that is often uniformly erythematous (about two-thirds of cases of EM), although it can have central clearing that gives it the appearance of a classic target lesion. EM usually appears 7 to 14 days (range 3–30 days) after the tick bite and, if untreated, may expand to an average of 15 cm in diameter before resolving after 2 to 4 weeks or longer. The rash may be asymptomatic or it may be accompanied by systemic symptoms such as fever, malaise, headache, stiff neck, myalgia, or arthralgia.

The second most common manifestation of Lyme disease is multiple EM, which accounts for 15% to 23% of the reported cases in the United States. Multiple EM, a manifestation of early disseminated Lyme disease, occurs when the spirochete disseminates via the bloodstream and presents as multiple erythematous round or ovoid macules that are usually smaller than most single EM lesions and are often accompanied by fever and other systemic symptoms. Other manifestations of early disseminated Lyme disease include cranial nerve palsy (especially facial palsy), lymphocytic meningitis, radiculomyelitis, and carditis. Cranial nerve palsies, especially facial nerve palsy, occurs more commonly in children and account for approximately 3% to 5% of all cases of Lyme disease. In most cases, facial nerve palsy resolves within 4 to 8 weeks usually leaving minor, if any, obvious residua. Lyme meningitis occurs less frequently (1% to 2% of cases) and typically has a subacute presentation similar to, though often of longer duration, that of enteroviral meningitis. There is a mononuclear pleocytosis in cerebrospinal fluid. Increased intracranial pressure with papilledema is not uncommon. Neurologic involvement in Lyme disease is more common in Europe and in Asia, presumably because local strains of the bacteria are more neurotropic. Carditis, which is found in fewer than 1% of cases, typically causes various degrees of heart block, which usually is asymptomatic and may be detected only with an electrocardiogram, but may manifest as syncope, dyspnea,

or dizziness due to complete heart block. Sudden death due to Lyme carditis has been reported but is very rare.

Arthritis is the main manifestation of late Lyme disease, and in North America accounts for approximately 6% to 8% of reported cases. Lyme arthritis typically is an oligoarthritis arthritis that involves a single knee about 90% of the time. Symptoms of arthritis develop 2 to 6 months after the tick bite and present with objective signs of inflammation of the joint. Arthritis typically resolves 2 to 6 weeks after appropriate treatment, although it may persist or recur in 10% to 20% of treated patients.

In Europe and in Asia, uncommon manifestations of Lyme disease include borrelial lymphocytoma, a painless nodule commonly located on the ear, breast, or scrotum; and acrodermatitis chronica atrophicans, a chronic fibrosing skin lesion typically found on the extensor surfaces of the extremities.

Diagnosis

Early localized Lyme disease is a clinical diagnosis based on a history of potential exposure to ticks in an endemic area and the presence of the characteristic EM rash. Antibodies to the organism typically appear 3 to 4 weeks after the onset of the rash. Consequently, serologic tests are not indicated in patients with EM because most will not have detectable antibodies. Although more patients with multiple erythema migrans may be seropositive at the time of presentation, a majority will still be seronegative early on. Moreover, detectable antibodies may never develop in patients who are treated early in their courses. In patients with extracutaneous manifestations of Lyme disease, serologic testing is useful in making a diagnosis. Tests for antibodies to *B burgdorferi* should use a two-tier procedure, in which a sensitive quantitative test, usually an enzyme-linked immunosorbent assay (ELISA) against either “whole cell” or C6 peptide antigens of the bacteria, is administered. If the result of the quantitative test is either positive or equivocal, a Western immunoblot is done to confirm the specificity of the result. As with most infections, once they develop, elevated concentrations of both IgM and IgG antibodies may persist for decades in symptom-free patients who have been cured of Lyme disease. A positive test result is evidence of prior exposure to the organism and is not evidence of active infection. In addition, false-positive antibody test results are common, especially in patients with a low prior probability of Lyme disease, such as those with chronic nonspecific symptoms such as arthralgia, myalgia, or fatigue, who do not have concomitant objective findings associated with Lyme disease. False-positive IgM test results are especially common. A diagnosis of Lyme disease should rarely be based on a positive IgM test result alone, especially in patients who have had symptoms for a month or longer.

Polymerase chain reaction (PCR) assays can detect the organism in skin biopsies, CSF, blood, or synovial fluid. However, because concentrations of the organism are low in both the blood and the CSF, sensitivity of PCR assays of these fluids is poor. Because the rash is so characteristic and because virtually all patients with Lyme arthritis will have a positive result for IgG antibodies to *B burgdorferi*, such assays rarely are needed to make a diagnosis. The organism can be cultured using special media, but sensitivity generally is poor, and it takes weeks for the organism to grow.

Differential Diagnosis

The differential diagnosis of Lyme disease depends on the clinical stage of the illness. Single EM may be confused with ringworm, cellulitis, nummular eczema, granuloma annulare or insect bites. Southern tick-associated rash illness (STARI) manifests in a rash identical to EM. However, it occurs at the site of a bite from the lone star tick (*Amblyomma americanum*) and is most common in the south-central United States. The cause of STARI is unknown, but, unlike with Lyme disease, it is not associated with significant extracutaneous manifestations. Multiple EM may look very similar to erythema multiforme. Lymphocytic meningitis occurs with numerous viral infections, most commonly enterovirus. There are many other causes of carditis, including a number of viruses, as well as rheumatologic diseases such as lupus and rheumatic fever. There is substantial variation in how Lyme arthritis presents. Most often it

¹Not FDA approved for this indication.

is a subacute arthritis that may mimic rheumatoid arthritis or other more chronic arthritides, with <50,000 white blood cells/mL in the synovial fluid. However, it can present acutely and may mimic acute bacterial arthritis (like that due to *Staphylococcus aureus*), with >100,000 white blood cells/mL in synovial fluid.

Relapse Versus Reinfection

Resistance of *B burgdorferi* to recommended antimicrobials has been reported. First-line antimicrobial therapy for Lyme disease is highly efficacious, and bacteriologic treatment failures are very rare. In a study of patients with two or more episodes of EM that occurred years apart, it was shown that the episodes were caused by different strains of bacteria, indicating that reinfection, rather than persistence of the original organism, was the cause of repeated episodes of EM. Reinfection rarely occurs in patients with late Lyme disease, indicating that most such patients are immune. On the other hand, patients with early Lyme disease who are treated may become reinfected from a new tick bite, presumably because the organism was killed before a protective immune response could occur. Persistent or recurrent arthritis does occur in 10% to 20% of patients with Lyme arthritis. So-called antibiotic-refractory arthritis occurs when frank arthritis persists despite two or more courses of antimicrobial treatment. This may be due to either an autoimmune process or slow clearance of antigens of dead organisms. There is no evidence that the cause is failure of the antibiotic to kill the organisms.

Post-Treatment Lyme Disease Syndrome and "Chronic" Lyme Disease

A small minority of patients with Lyme disease who have completed appropriate treatment may continue to have nonspecific symptoms, such as fatigue, arthralgia, myalgia, or perceived cognitive difficulties, for weeks or months after completing treatment. These have been termed *post-treatment Lyme disease symptoms* and, if they persist for 6 months or longer and are disabling, they are referred to as *post-treatment Lyme disease syndrome* (PTLDS). It is not clear

whether the frequency or the nature of these symptoms in patients with PTLDS is greater than that among the general population. In addition, several placebo-controlled, randomized clinical trials of prolonged courses (6 weeks or longer) of intensive antimicrobial treatment (e.g., with ceftriaxone) in patients with PTLDS have found there was virtually no benefit and substantial risk of adverse side effects of this treatment. Consequently, the Infectious Diseases Society of America, the American Academy of Pediatrics, the American Academy of Neurology, the American College of Rheumatology, and expert professional societies from many European countries do not recommend prolonged treatment with antimicrobials in patients with PTLDS. These patients are distinguished from patients with so-called "chronic" Lyme disease, who have complaints similar to those with PTLDS but who do not have evidence of ever having had Lyme disease. Of course, prolonged antimicrobial treatment is not indicated for these patients, who might better be described as having medically unexplained symptoms.

Chemoprophylaxis

A single dose of doxycycline (Vibramycin; 8.8 mg/kg, maximum 200 mg)¹ taken within 72 hours of a deer tick bite was effective in preventing Lyme disease. However, because the risk of Lyme disease after a recognized tick bite is low, prophylaxis generally is not recommended routinely, but only for those at higher risk, such as someone in an endemic area who removes an engorged nymphal stage deer tick.

Treatment

Antimicrobial treatment of Lyme disease is highly effective and complications are rare (Table 1). The recommendations for treatment are summarized in the table. Antimicrobials that are highly effective and are considered first-line agents to treat Lyme disease orally include doxycycline (Vibramycin)¹, amoxicillin (Amoxil)¹

¹Not FDA approved for this indication.

TABLE 1 Antimicrobials Recommended to Treat Lyme Disease

MANIFESTATION	FIRST-LINE AGENTS	ALTERNATIVE AGENTS	DURATION
Single or multiple erythema migrans, cranial nerve palsy, carditis that is asymptomatic or for which the patient is not hospitalized	Doxycycline (Vibramycin) ¹ 4.4 mg/kg/day in 2 divided doses (maximum 100 mg/dose) Amoxicillin (Amoxil) ¹ 50 mg/kg per day in 3 divided doses (maximum 500 mg/dose) Cefuroxime axetil (Ceftin) 30 mg/kg PO in 2 divided doses (maximum 500 mg/dose)	Azithromycin (Zithromax) ¹ 10 mg/kg/day in 1 dose (maximum 500 mg/dose) Clarithromycin (Biaxin) ¹ 7.5 mg/kg in 2 divided doses (maximum 500 mg/dose) Erythromycin (E.E.S.) ¹ 12.5 mg/kg in 4 divided doses (maximum 500 mg/dose)	14 days; for single EM, 10-days of doxycycline or 7–10 days of azithromycin is effective
Severe carditis, meningitis,* radiculomyelitis	Ceftriaxone (Rocephin) ¹ 50–75 mg/kg IV in 1 dose (maximum 2 g/dose)	Cefotaxime (Claforan) ¹ 150–200 mg/kg/day IV in 3 divided doses (maximum 2 g/dose) Penicillin G (Pfizerpen) ¹ 200,000–400,000 U/kg/day in 6 divided doses (maximum 4 million U/dose)	14 days; for severe carditis and for meningitis, an oral agent may be used to complete a course of treatment after substantial clinical improvement
Lyme arthritis [†]	Same oral agents used for EM	Same oral agents used EM	28 days

¹Not FDA approved for this indication.

*Some experts treat Lyme meningitis with doxycycline (Vibramycin)¹, administered orally, 4.4 mg/kg/day in 2 divided doses (maximum 100 mg/dose), for 14 days.

[†]Patients with persistent or recurrent arthritis 4 weeks after completing treatment may receive either a second 4-week course of treatment orally or 2 weeks of treatment with a parenterally administered antimicrobial listed above.

and cefuroxime axetil (Ceftin). Amoxicillin (Amoxil) is the preferred agent for women who are either pregnant or breastfeeding. Because the risk of staining of teeth is low, use of doxycycline for ≤ 14 days of treatment in children < 8 years of age is now considered acceptable. Doxycycline (Vibramycin) is the preferred oral agent due to its good activity against other tick-borne illnesses such as human granulocytic anaplasmosis. Although macrolides such as azithromycin (Zithromax),¹ clarithromycin (Biaxin),¹ and erythromycin (EES)¹ are effective for treating early Lyme disease, they may not be as effective as the first-line agents. When parenteral treatment is indicated, ceftriaxone (Rocephin)¹ is the preferred agent because of once-a-day dosing. Alternative antimicrobials such as cefotaxime (Claforan)¹ and penicillin G (Pfizerpen-G)¹ also are highly effective, although penicillin G is rarely used because of frequent dosing due to its short half-life.

For patients with single EM, a 10-day course of doxycycline or a 14-day course of either amoxicillin or cefuroxime is recommended. For multiple EM, cranial nerve palsy (without apparent meningitis) or carditis that is asymptomatic and for which the patient is not hospitalized, a 14-day course of an oral antimicrobial is recommended. For complicated carditis (complete heart block) and for meningitis, a 14-day course of a parenteral agent is recommended, although there is evidence that 14 days of doxycycline orally may be adequate for treating meningitis. Some experts complete a course of initial parenteral treatment with oral therapy after the patient has improved clinically. Patients with Lyme meningitis should be carefully evaluated for increased intracranial pressure which, if present, should be managed appropriately. There is no evidence that steroids are beneficial for patients with facial palsy due to Lyme disease. For treatment of Lyme arthritis, a 28-day course of an oral antimicrobial is recommended. Nonsteroidal antiinflammatory drugs may be effective for treating the pain and inflammation associated with Lyme arthritis.

¹Not FDA approved for this indication.

MALARIA

Method of

Lawrence M. Gibbs, MD, MEd; and Dustin A. Creech, MD

CURRENT DIAGNOSIS

History

- Does the patient have a fever? Any other flulike symptoms (chills, sweats, headache, muscle aches, nausea, and/or vomiting)?

- Did the patient travel to a malaria-endemic area? And, how long did the travel precede symptom onset?
- What *Plasmodium* species are known to be present in the area(s) of travel and what corresponding drug-resistance patterns are present?
- Did the patient use appropriate prophylaxis for the region and adequate personal protective measures during travel?

Diagnosis

- Thick and thin blood smears are required for detection, *Plasmodium* speciation, and parasite density determination.
- Use of rapid diagnostic tests for quick detection must be followed by blood smears to confirm diagnosis and monitor parasite density.
- Be mindful of severe disease signs including acidosis, acute respiratory distress, altered consciousness, high parasite density ($> 5\%$), hyperbilirubinemia, hypotension, renal impairment, seizures, and severe anemia.

CURRENT THERAPY

- Develop treatment plan based on prompt laboratory confirmation of *Plasmodium* species and drug-resistance patterns of *Plasmodium* species in known area(s) of travel.
- If severe disease is a concern, parenteral artesunate¹⁰ should be used, where available, or quinidine, and the patient should be monitored in an intensive care setting providing supportive care as needed.
- For uncomplicated disease, consider hospital admission for likely *P. falciparum* infection.
 - Administer oral therapies (i.e., artemisinin-based combination therapies or chloroquine) based on resistance patterns in area of travel.
 - To prevent relapse, prescribe primaquine to all with a normal glucose-6-phosphate dehydrogenase (G6PD) status and travel to areas having known *P. vivax* and *P. ovale*.¹

¹Not FDA approved for this indication.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Malaria is a potentially fatal parasitic disease caused by intraerythrocytic protozoa of the genus *Plasmodium* and is transmitted to humans primarily via female *Anopheles* mosquito bites. Often considered by many the most important parasitic disease affecting human beings, in 2015 it accounted for over 200 million infections and an estimated 438,000 deaths worldwide, mainly in young children, and it remains a focus of international concern. Thankfully, in the past 15 years, due in part to substantial increases in donor funding (i.e., The Global Fund, World Bank, UNICEF, and United States Agency for International Development) advances in treatment and control measures, and increased enthusiasm for elimination, there has been a significant drop in the infection and mortality rates associated with this disease by 18% and 48%, respectively. Interestingly we have witnessed a very gradual increase in the number of malaria cases in the United States largely due to more tourism to malaria-endemic locations, especially Africa. In 2012, a total of 1687 malaria cases were reported in the United States, which, though somewhat lower than the year prior when reported malaria cases were at a 40-year high, represents an overall upward trend.

By far, the majority of patients developing malaria in the United States are infected during travel to other countries. Whether or not preventive measures were appropriately used, health-care workers should have a high index of suspicion for malaria in the returning traveler with fever and other flulike symptoms. Since cases are rare in North America, misdiagnosis is not uncommon. Clinicians, therefore, must consider malaria in the differential for any febrile illness in an individual who has traveled to an area of known malaria transmission in the past several months or in those with fever of unknown origin regardless of travel history. Since

¹Not FDA approved for this indication.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

Malaria is a potentially fatal parasitic disease caused by intraerythrocytic protozoa of the genus *Plasmodium* and is transmitted to humans primarily via female *Anopheles* mosquito bites. Often considered by many the most important parasitic disease affecting human beings, in 2015 it accounted for over 200 million infections and an estimated 438,000 deaths worldwide, mainly in young children, and it remains a focus of international concern. Thankfully, in the past 15 years, due in part to substantial increases in donor funding (i.e., The Global Fund, World Bank, UNICEF, and United States Agency for International Development) advances in treatment and control measures, and increased enthusiasm for elimination, there has been a significant drop in the infection and mortality rates associated with this disease by 18% and 48%, respectively. Interestingly we have witnessed a very gradual increase in the number of malaria cases in the United States largely due to more tourism to malaria-endemic locations, especially Africa. In 2012, a total of 1687 malaria cases were reported in the United States, which, though somewhat lower than the year prior when reported malaria cases were at a 40-year high, represents an overall upward trend.

By far, the majority of patients developing malaria in the United States are infected during travel to other countries. Whether or not preventive measures were appropriately used, health-care workers should have a high index of suspicion for malaria in the returning traveler with fever and other flulike symptoms. Since cases are rare in North America, misdiagnosis is not uncommon. Clinicians, therefore, must consider malaria in the differential for any febrile illness in an individual who has traveled to an area of known malaria transmission in the past several months or in those with fever of unknown origin regardless of travel history. Since

untreated malaria infections can lead to anemia, pulmonary edema, renal failure, coma, and even death, prompt diagnosis and treatment are essential.

Epidemiology

According to the 2015 World Health Organization (WHO) World Malaria Report, 3.2 billion people were considered at risk for malaria and 97 countries reported active transmission (see Figure 1). Though 80% of cases and fatalities are accounted for in 15 sub-Saharan African countries, Asia and Central and South America also have significant disease burden with Europe and the Middle East accounting for a smaller portion of cases. *P. falciparum* is the most prevalent form of malaria in Africa and is responsible for more deaths worldwide than other *Plasmodia* species, and 70% of fatalities are in patients under 5 years of age. Though *P. falciparum* is encountered outside Africa, *P. vivax* is often more prevalent across much of Asia and Central and South America and transmission rates are more frequently low and seasonal. Meanwhile, rates of transmission are much higher across sub-Saharan Africa and parts of Oceania, where *P. falciparum* predominates. *P. vivax* is responsible for most relapsing malarial disease, though *P. ovale* is also responsible but to a lesser extent.

In endemic areas of high, stable transmission, partial immunity can develop after many years of repeat exposure to infectious mosquito bites, and young children often show resistance to severe forms of the disease by the age of 5. By adolescence they also often become resistant to more uncomplicated forms of the disease. Though resistant to clinical malaria, rarely will one become completely resistant to actual infection. In areas of unstable or seasonal transmission (i.e., sub-Sahel region of Africa), transmission can be intense but is isolated to rainy periods and full protective immunity does not develop so symptomatic disease may occur across all ages.

There are also varying drug-resistance patterns that greatly affect prevention, treatment, and mortality. Resistance to antimalarial medications continues to be an important consideration when considering treatment, especially *P. falciparum* infection. By the 1970s, *P. falciparum* chloroquine resistance had been confirmed on every continent where malaria was endemic, and currently only the Caribbean, areas of Central America west of the Panama Canal,

and a few Middle Eastern countries show sensitive strains. *P. vivax* has also shown resistance to chloroquine in areas of Indonesia and Papua New Guinea. Mefloquine, too, is currently no longer recommended to treat *P. falciparum* infections originating from Southeast Asia due to increasing levels of resistance, and even artesunate and its partner drugs are showing signs of decreased effectiveness across the Mekong Region in Southeast Asia. When in doubt, clinicians should use the Centers for Disease Control and Prevention's (CDC) online interactive malaria map (<http://www.cdc.gov/malaria/map/>) or Malaria-by-Country tables (http://www.cdc.gov/malaria/travelers/country_table/a.html) to quickly view the types of *Plasmodium* present and resistance characteristics found in the patient's area of travel.

Risk Factors for Transmission

Risk factors for malaria include both individual risk and environmental conditions that increase transmission rates. Anyone traveling to or living in a malaria-endemic area is at risk for transmission. Children, elderly, pregnant women, and HIV/AIDS patients are at higher risk than the general population. HIV-related immunosuppression, especially, may lead to more severe manifestations of malaria. Because of lack of partial immunity, travelers to endemic regions also have a higher risk of transmission. Also, given the known reductions that can occur via the use of personal protective measures (i.e., insecticide-treated bed nets and insect repellents) and chemoprophylaxis, individuals without access to or noncompliant with these measures are at increased risk. Malaria can also be transferred from mother to baby across the placenta (congenital malaria) or during birth. Though rare, there are some cases of malaria transmission during blood transfusion as well as organ transplantation.

At the population level, there are many conditions that increase transmission as well, most of which relate to effects on any of the 30 or so *Anopheles* species linked to malaria transmission. The rainy season allows for eggs of *Anopheles* mosquitoes to be laid in water more readily and larvae to develop more easily. Transmission is also higher in regions with longer mosquito lifespans and in areas where humans are the choice blood meal over other animals. In addition, elevation, temperature, and humidity of a region all contribute to transmission efficiency of malaria.

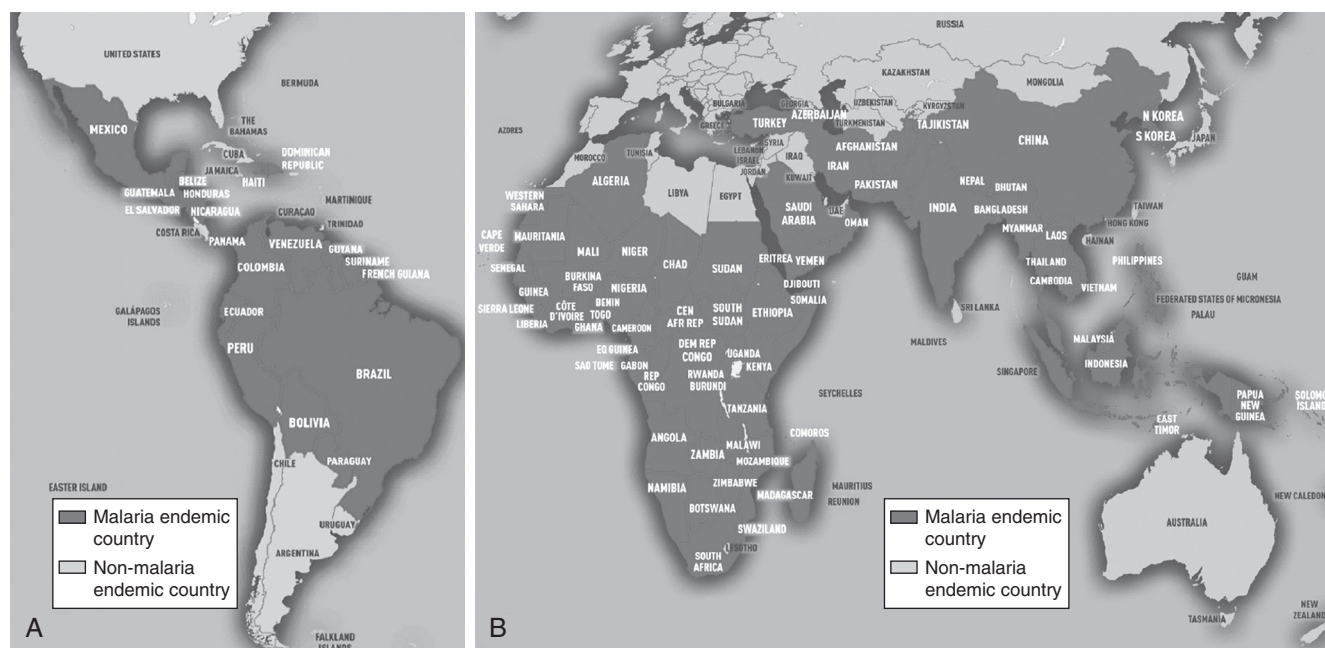

Figure 1 Malaria-endemic countries in the (A) Western and (B) Eastern Hemispheres. Transmission occurs across most of Africa, Central and South America, and Southern and Southeast Asia, as well as parts of the Caribbean, Eastern Europe, and the South Pacific. Countries are shaded completely even if the area of endemicity is only in a small area of the country. (Adapted from Centers for Disease Control and Prevention. CDC Health Information for International Travel 2016. New York: Oxford University Press; 2016. Public Domain.)

Etiology and the Parasite's Life Cycle

There are five species of *Plasmodium* indicated in human malarial disease: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. *P. knowlesi* classically was identified as a simian disease; however, it has become an appreciable cause of malaria in humans in Southeast Asia. The life cycle (Figure 2) of the malaria parasite differs slightly among *Plasmodium* species and these differences explain how species present differently. For instance, the time from initial infection to symptom presentation varies across species. *P. knowlesi* incubation is from 9 to 12 days and *P. falciparum* is often 9 to 14 days, while *P. vivax* ranges from 12 to 17 days and *P. ovale* from 16 to 18 days. *P. malariae* is the most variable with ranges from 18 to 40 or more days.

Regardless of species, the life cycle starts when an infected female *Anopheles* mosquito takes a human blood meal, injecting anywhere from 10 to 100 *Plasmodium* sporozoites into the host. The sporozoites travel to the liver, invading hepatic cells where they

then replicate and each divides forming 10,000 to more than 30,000 merozoites (haploid cells). The species determines how quickly this happens and how many merozoites are formed. In the liver, *P. vivax* and *P. ovale* produce another form, called hypnozoites, which remain in the liver for an extended time and are responsible for relapsing illness, sometimes months to even years after initial infection. The merozoites enter circulation and invade red blood cells (RBCs) (asexual replication). Once inside RBCs, the merozoites develop into schizonts, rupture, and more merozoites are released into the bloodstream to invade RBCs. Depending on the species, this cycle can repeat anywhere from 24 to 72 hours. Typically, the number of merozoites in the bloodstream is proportional to disease severity for a given species. However, this is not always the case as sometimes severe disease is seen even in small numbers of infected RBCs, especially in the case of *P. falciparum*. Some merozoites develop into male and female gametocytes entering a sexual stage. Gametocytes enter into the bloodstream where

Figure 2 The malaria parasite life cycle involves two hosts. During a blood meal, a malaria-infected female *Anopheles* mosquito inoculates sporozoites into the human host (1). Sporozoites infect liver cells (2) and mature into schizonts (3), which rupture and release merozoites (4). (In *Plasmodium vivax* and *Plasmodium ovale*, a dormant stage [hypnozoites] can persist in the liver and cause relapses by invading the bloodstream weeks to years later.) After initial replication in the liver via exoerythrocytic cycle or tissue schizogony (A), the parasites undergo asexual multiplication in erythrocytes via erythrocytic cycle or blood schizogony (B). Merozoites infect red blood cells (5). The ring stage trophozoites mature into schizonts, which rupture, releasing merozoites (6). Some parasites differentiate into sexual erythrocytic stages (gametocytes) (7). Blood stage parasites are responsible for the clinical manifestations of the disease. The gametocytes, male (microgametocytes) and female (macrogametocytes), are ingested by an *Anopheles* mosquito during a blood meal (8). The parasites' multiplication in the mosquito is known as the sporogonic cycle (C). While in the mosquito's stomach, the microgametes penetrate the macrogametes, generating zygotes (9). The zygotes in turn become motile and elongated (ookinetes) (10) and invade the midgut wall of the mosquito, where they develop into oocysts (11). The oocysts grow, rupture, and release sporozoites (12), which make their way to the mosquito's salivary glands. Inoculation of the sporozoites (1) into a new human host perpetuates the malaria life cycle.

an *Anopheles* mosquito partakes of a blood meal, ingesting the gametocytes, and then these gametocytes develop into gametes in the mosquito midgut. Male and female gametocytes sexually reproduce to form oocysts, which then grow and release sporozoites. The sporozoites travel to the salivary gland and with a subsequent human bite, complete the transmission cycle.

It is worth noting that all *Plasmodium* species may cause recrudescence, which happens when treatment is suboptimal and parasite clearance incomplete. In these cases, patients may show symptoms of infection months to years after initial infection. Patient immunosuppression also furthers this risk. In endemic areas, recurrent *P. falciparum* and *P. vivax* malaria can have pronounced negative effects in children affecting growth, development and schooling.

Clinical Manifestations

The most common presentation of malaria is fever after travel to an endemic area. Fever and chills are the chief complaint in 96% of patients, followed by headaches and muscle aches in 79% and 60%, respectively. The classic “paroxysm” of symptoms includes chills for minutes to hours, followed by high fevers when RBCs rupture and merozoites are released, and then sweating and fever breaking. However, the paroxysm is often not present. Also, *P. falciparum* tends to cause a continual fever with spikes as opposed to the cyclical nature of the other species; therefore, absence of paroxysm should not be used to rule out malaria. General malaise, weakness, fatigue, and muscle aches are common. Less common, are palpable liver and/or spleen, nausea and vomiting, abdominal pain, and diarrhea. More severe cases can present with jaundice, confusion, orthostatic hypotension, or seizures depending on the type of malaria and severity.

Most patients will develop anemia and splenomegaly as the spleen acts to remove both infected and noninfected RBCs from the bloodstream. Thrombocytopenia will occur in most patients as well, along with elevations in aspartate aminotransferase and alanine transaminase. Acute kidney injury is common, especially in more severe malaria. *P. falciparum* and *P. knowlesi* typically cause higher parasitemia than *P. vivax*, *P. ovale*, and *P. malariae* because the former two are less selective in their invasion of RBCs. Infection can quickly lead to severe disease and death if not treated promptly, and so rapid, correct diagnosis can greatly improve survival probability.

P. falciparum causes more severe disease and death than the other species. The parasite causes RBCs to develop “knobs,” which express PfEMP1, proteins regulating adhesion to endothelium of capillaries and postcapillary venules. The RBCs are also more rigid. The combination of adhesion to endothelium and rigid RBCs obstructs the vessels, also known as sequestration. Sequestration is implicated in severe disease and leads to metabolism of glucose locally, local tissue factor recruitment, edema, and ultimately end organ damage.

Sequestration in brain tissues is better described, but it is thought to occur in lung tissue as well. Sequestration is thought to increase intracranial blood pressure. Interestingly cerebral edema is frequently seen in children, but not in adults radiographically. Cerebral edema, seizures, coma, and death can be immediate sequelae of *P. falciparum*. While adult survivors typically do not have lasting neurologic effects, 3% to 15% of children survivors have lasting neurological deficits from *P. falciparum* infection. Cerebral palsy, learning disability, language deficits, and epilepsy are some of the lasting effects in children survivors of *P. falciparum*.

Cerebral malaria, severe anemia, pulmonary edema, and renal failure are examples of end organ failure that can result and quickly lead to severe morbidity and death if not treated correctly and rapidly. Although *P. falciparum* is the prominent cause of severe malaria and death, other species of *Plasmodium* can also develop complications and lead to death if not adequately diagnosed and treated.

Outside of Africa, *P. vivax* accounts for roughly half of all malaria cases and, though often having a much lower case-fatality rate than *P. falciparum*, it still may cause a debilitating febrile illness with progressive anemia and, sometimes causes severe disease including

symptoms of thrombocytopenia and acute pulmonary edema. Less common symptoms can include cerebral malaria, pancytopenia, jaundice, splenic rupture, acute renal failure, and shock. Prompt management of these severe cases and treatment in a manner similar to *P. falciparum* infection are recommended.

Chronic malaria infection, characterized by low-level parasitemia, may lead to a variety of complications. For instance, recurrent *P. vivax* infections or relapses may lead to hyperactive malarial splenomegaly that leads to significant anemia, hypersplenism, and hypergammaglobulinemia. Meanwhile, persistent *P. malariae* infection has been linked to risk for nephrotic syndrome in parts of Africa.

Diagnosis

Correctly diagnosing malaria and identifying *Plasmodium* species quickly is paramount to appropriate timely treatment, and testing should be done whether or not an appropriate chemoprophylaxis regimen was followed. Unfortunately, malaria may mimic many diseases due to its common symptom profile, especially high fevers. Other causes of fever including more common bacterial and viral illnesses (i.e., bacterial meningitis, influenza, and acute hepatitis) and tropical diseases such as dengue fever, chikungunya, rickettsial infections, typhoid, and trypanosomiasis, must be considered.

Together, thick and thin smear microscopy are still considered the gold standard for malaria diagnosis, and they are best performed by experienced personnel without delay on any patient presenting with fever and travel to endemic areas. These tests help to answer three questions: Is there malaria present? What species is present? And, what percentage of RBCs are infected?

The general process of microscopy is described here, but strict protocols should be followed to give reliable and reproducible results. Blood is sampled through finger stick or venipuncture, and the thick smear is air dried and not fixed; therefore, hemolysis occurs. Thick smears are more sensitive at identifying infection, as they concentrate parasites, and may also help estimate parasite concentration. However, hemolysis during preparation makes it difficult to identify species-level characteristics using thick smear microscopy. The thin smear is fixed with air drying and methanol and, since RBCs remain intact, can reveal the species of *Plasmodium* present and the percentage of RBCs infected, which serves as a marker for parasitemia and eventually treatment effectiveness. Both slides are stained, typically with Giemsa (pH of 7.2) and slides should be examined under 1000× oil immersion for at least 20 minutes and 200 high-powered fields before reporting as negative. Negative smears should be repeated every 8 to 12 hours until malaria can be ruled out confidently as symptoms may precede parasitemia. The CDC recommends confirming the diagnosis before treating for malaria; however, with symptoms of suspected severe malaria, it may be appropriate to treat before diagnosis to start treatment rapidly. For further information including slide preparation and diagnostic assistance, clinicians may refer to the CDC's Laboratory Identification of Parasitic Diseases website: <http://www.cdc.gov/dpdx/malaria/dx.html>.

In addition to direct microscopy, other diagnostic tests are available, such as rapid diagnostic tests (RDTs), polymerase chain reaction (PCR), and serology. Where available, RDTs are immunochromatographic tests that use a dipstick or cassette format and detect specific *Plasmodium* antigens using a single drop of blood. Current RDTs can target the histidine-rich protein 2 of *P. falciparum* (PfHRP2), a panmalarial *Plasmodium* aldolase (PMA), and parasite specific lactate dehydrogenase (pLDH). Often they specifically are designed to target *P. falciparum*, *P. vivax*, or nonspecific *Plasmodium*, and they offer a rapid way (5 to 20 minutes) to test for the presence of *Plasmodium* without the need for a laboratory, electricity, special equipment, or even highly experienced personnel. Though not as sensitive in instances of low parasitemia (<100 to 200 parasites/μL), RDTs have documented sensitivities and specificities reaching up to 95% and 99%, respectively. As they do not give information on parasitemia levels and false-negative results are possible, thick and thin smears should still be performed to confirm or rule out diagnosis and determine level of parasitemia.

PCR, a molecular method based on DNA amplification, may also be used for diagnosis and offers the most accurate method of parasite detection. PCR is less prone to observer error than is microscopy and more sensitive at low levels of parasitemia. As PCR becomes more widespread, it may offer a promising alternative for diagnosis and speciation, but currently it is not widely available due to logistical constraints and the need for well-equipped laboratories and specially trained technicians. It remains an important research tool detecting drug resistance mutations and offering a secondary means of species confirmation. Likewise, a variety of serologic tests can be performed by some laboratories (i.e., CDC reference laboratories) to assess past malaria experience, but not current malaria infection.

Antimalarial Medications

A variety of malaria chemotherapy treatment and prophylaxis options are available, each with their risks, benefits, and availability issues. Treatment options will be dictated not only by drug availability but also location of disease acquisition, infecting species, resistance patterns, and symptom severity (Table 1).

Current antimalarial medications attack the *Plasmodium* organism at various stages in its life cycle. Those that kill malaria parasites when they have been released into the bloodstream during the asexual, erythrocytic cycle are referred to as blood schizonticides. Meanwhile, tissue schizonticides kill parasites during the exoerythrocytic cycle of infection in the liver and also may prevent relapse in certain species. Some medications also have activity against gametocytes. Though not affecting the patient's clinical response, these gametocidal medications do decrease the probability of disease transmission to another person.

Chloroquine phosphate (Aralen) is one of the older drugs still used, and along with its sister medication, hydroxychloroquine sulfate (Plaquenil), is used in the prevention and treatment of malaria. These blood schizonticides are active against all *Plasmodium* species and have gametocidal activity against *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. These medications are no longer recommended for prophylaxis against *P. falciparum* (except in some parts of Central America), but can be used to prevent *P. vivax* infections. Chloroquine remains the treatment of choice for all susceptible *Plasmodium* strains; however, growing resistance limits its worldwide use, especially in malaria-endemic areas. It is safe to use in children as well as pregnant women. Response to treatment in pregnant women should be monitored closely, especially during second and third trimesters where serum drug concentrations may be lower. Major side effects include gastrointestinal (GI) upset, headache, dizziness, insomnia, vision changes, and pruritus. Long-term use can lead to ototoxicity, retinopathy, and peripheral neuropathy.

Atovaquone/proguanil (Malarone) is a combination drug effective against both blood and tissue schizonts. The combination is indicated for malaria prophylaxis in all areas and may be used for treatment of uncomplicated chloroquine-resistant malarial infections in travelers outside endemic areas or for combination treatment with artesunate¹⁰ or primaquine.¹ It is seldom used in endemic areas due to emergence of resistance to the atovaquone component. The medication is considered safe in children weighing more than 5 kg per WHO (U.S. Food & Drug Administration [FDA] sets 11 kg as the weight minimum). WHO does regard the drug as safe during pregnancy due to no evidence of adverse effects associated with its use in pregnant women. The combination medication is generally well tolerated. Headache, cough, and GI upset are the most frequent side effects in both adults and children. Rarely, dizziness, oral ulcerations, and elevated liver function study results can occur. It is contraindicated in those with severe renal impairment due to increased pancytopenia risk.

Artemisinin derivatives are plant-based compounds derived from the Chinese quinghaosu plant (*Artemisia annua*) whose

TABLE 1 Drug Recommendations for Treatment by Malaria Type

DIAGNOSIS	DRUG
Uncomplicated, chloroquine-sensitive <i>P. falciparum</i>	Chloroquine phosphate or hydroxychloroquine
Uncomplicated, chloroquine-resistant <i>P. falciparum</i> or species/resistance unknown	Artemisinin-combination therapy ¹ or atovaquone/proguanil or quinine sulfate ⁷ + one of the following: doxycycline, ^{2,3} tetracycline, ^{2,3} clindamycin, ² or mefloquine ⁴
Uncomplicated, chloroquine-sensitive <i>P. malariae</i> or <i>P. knowlesi</i>	Chloroquine phosphate or hydroxychloroquine
Uncomplicated, chloroquine-sensitive <i>P. vivax</i> or <i>P. ovale</i>	Chloroquine phosphate + primaquine phosphate ⁵ or hydroxychloroquine + primaquine phosphate ⁵
Uncomplicated, chloroquine-resistant <i>P. vivax</i>	Atovaquone/proguanil plus primaquine phosphate ⁵ or artemisinin-combination therapy ¹ + primaquine phosphate ⁵ or quinine sulfate ⁷ + one of the following: doxycycline, ^{2,3} tetracycline, ^{2,3} or clindamycin ² + primaquine phosphate ⁵ or mefloquine ⁴ + primaquine phosphate ⁵
Chloroquine-sensitive malaria during pregnancy	Chloroquine phosphate or hydroxychloroquine or mefloquine ⁴
Chloroquine-resistant malaria during pregnancy	Quinine sulfate ⁷ + clindamycin ² or mefloquine ⁴
Severe malaria	Quinidine gluconate ⁷ + one of the following: doxycycline, ^{2,3} tetracycline, ^{2,3} or clindamycin ² or artesunate ⁶ followed by one of the following: artemisinin-combination therapy, ¹ atovaquone/proguanil, doxycycline ^{2,3} (or clindamycin ² in pregnant women), or mefloquine ⁴

¹Artemisinin-combination therapy; see Table 2.

²Not FDA approved for this indication.

³Avoid in patients under 8 years old.

⁴Not recommended for infections acquired in Southeast Asia.

⁵Normal glucose-6-phosphate dehydrogenase levels should be confirmed before starting Primaquine.

⁶Contact CDC for information and to obtain.

⁷For infections acquired in Southeast Asia, quinine treatment should continue for 7 days. For infections acquired elsewhere, quinine treatment should continue for 3 days.

components are active against blood schizonts and gametocytes. They also lead to much shorter parasite clearance times than other treatments. Artemisinin and its derivatives (artesunate,¹⁰ artemether,² and dihydroartemisinin²) are highly effective at treating uncomplicated and severe *P. falciparum* infections and preparations are available in oral, rectal, and intravenous formulations. Artemisinin-based combination therapies (ACTs) are increasingly considered standard of care for treatment of uncomplicated falciparum malaria in malaria-endemic areas.

ACT involves administering a combination drug over at least 3 days (7 days for Southeast Asia *P. falciparum*), which allows

¹Not FDA approved for this indication.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

²Not available in the United States.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

for more effective blood schizonticidal activity since the individual components have different actions and targets, as well as reducing potential selection for drug-resistant parasites. Currently five ACT options are approved by stringent regulatory authorities or the WHO: artemether+lumefantrine (Coartem; the only FDA-approved treatment), artesunate+amodiaquine (Coarsucam,² European Medicines Agency-approved), artesunate+mefloquine (Artequin,² WHO prequalified), artesunate+sulfadoxine-pyrimethamine (Arsuamoon²+Fansidar,² WHO prequalified), and dihydroartemisinin+piperazine (Eurartesim,² European Medicines Agency-approved). Cure rates for all of these preparations exceed 95% based on clinical trial data.

Serious side effects from ACTs have not been reported in humans, but they are still not recommended during the first trimester of pregnancy due to lack of definitive safety data. Generally well-tolerated, common side effects include GI upset, dizziness, headache, neutropenia, and elevated liver enzymes. Although there are minor differences in the oral absorption, bioavailability, and tolerability of the different artemisinin derivatives, there is no evidence that these differences are clinically significant in currently available formulations.

For severe malaria, though artemisinin derivatives may be used alone to initiate therapy (i.e., IV artesunate¹⁰), another antimalarial medication with a different mode of action should be added as soon as possible. Parenteral artesunate has been available in the United States since 2007 under an investigational protocol. The CDC will provide it to hospitals upon request and on an emergency basis when a patient has severe malaria, a high parasite burden, inability to take oral medicines, lack of access to or failure of IV quinidine, or a contraindication to using quinidine. To enroll a patient in the protocol, clinicians should not hesitate to contact the CDC's Malaria Hotline (770-488-7788 or toll-free at 855-856-4713) from 9 am to 5 pm Eastern Time, or outside of regular hours, physicians should call 770-488-7100 and request the CDC Malaria Branch's on-call physician.

Quinine sulfate (Qualaquin) and quinidine gluconate (parenteral form) are blood schizonticides effective at killing erythrocytic stages of all *Plasmodium* species, and show gametocidal activity against *P. vivax*, *P. ovale*, and *P. malariae*. Currently, IV quinidine is the only FDA-approved treatment for severe malaria in the United States. Quinine may be used in the treatment of uncomplicated malaria, particularly during the first trimester of pregnancy, or in cases when an effective ACT is not available. Quinine has a narrow therapeutic index and many potential side effects. Potential cardiotoxic effects include conduction disturbances like QT prolongation, angina, and hypotension leading to cardiac arrest. It is, therefore, recommended that IV quinidine be administered under close telemetry monitoring. More common side effects include symptoms of tinnitus, hearing impairment, nausea, headache, dizziness, dysphoria, and sometimes disturbed vision. More severe issues at higher required doses or increased treatment duration include vertigo, vomiting, diarrhea, and marked auditory and visual loss. An important side effect of quinine seen mostly in children, pregnant women, and the elderly is hyperinsulinemic hypoglycemia. Treatment for major side effects is mostly supportive, with particular attention to maintenance of blood pressure, glucose and renal function and to treating any arrhythmias. For infection acquired outside of Southeast Asia, treatment course with quinidine may be shortened from 7 to 3 days when combining treatment with doxycycline,¹ tetracycline,¹ or clindamycin.¹

Tetracyclines (i.e., doxycycline and tetracycline) are blood schizonticides effective against the erythrocytic stages of all *Plasmodium*. Doxycycline (Vibramycin) is effective in the prophylaxis against *P. falciparum*, including chloroquine- and mefloquine-resistant strains. Tetracyclines may be combined with quinine or quinidine to treat chloroquine-resistant *P. falciparum* and *P. vivax*

infections. They should never be used as monotherapy and both are contraindicated in pregnancy and in children less than 8 years old due to possible interference with bone growth. Common side effects for these medications are GI upset, which can be lessened by ensuring it is taken with food, dry mouth, stomatitis, sun hypersensitivity, candida vaginitis, dysphagia, and esophageal irritation. To reduce esophageal problems, doxycycline should always be administered with a full glass of water.

Clindamycin (Cleocin)¹ is another blood schizonticide of all *Plasmodium* species. It may be used in combination therapy with artesunate or quinine for severe or uncomplicated malaria, but never as monotherapy. Clindamycin is often used when tetracyclines are contraindicated. It is generally well tolerated in its oral form. Major side effects include GI upset (especially diarrhea) and skin rashes. Close monitoring is recommended in the elderly, neonates, and individuals with liver disease.

Mefloquine (Lariam) is a long-acting blood schizonticide effective at killing the erythrocytic stages of all *Plasmodium* species. Structurally related to quinine, it is used as prophylaxis against malaria caused by all *Plasmodium* species, and also combined with artesunate to treat *P. falciparum* infections. It is generally thought to be safe during pregnancy, and is well tolerated when given in combination with artesunate for the treatment of uncomplicated *P. falciparum* malaria. It is also effective as a once-weekly prophylactic medication. Though generally well-tolerated, common side effects include GI disturbances, anxiety, irritability, dizziness, paranoia, depression, hallucinations, and sometimes violence in patients who were treated for malaria or taking mefloquine for long-term prophylaxis. Side effects frequently abate once the medication is discontinued. Use of mefloquine for malaria prophylaxis is not recommended for those for whom sudden dizziness or confusion could be hazardous, especially pilots and drivers. Travelers taking mefloquine are advised to stop taking the medication should any neurologic symptoms develop. Mefloquine is contraindicated to use as follow-up therapy for patients after cerebral malaria and should also not be used for prophylaxis in patients with known cardiac conduction disorders, epilepsy, depression or anxiety, psychosis, schizophrenia, or other major psychiatric disorder. It should also never be used in combination with quinine or quinidine. Due to the neuropsychiatric side effects of mefloquine, it is often not considered as first-line for prophylaxis or treatment.

Primaquine sulfate is effective at eradicating both the exoerythrocytic forms (hypnozoites) and the sexual stages of malaria parasites (gametocytes). It is used for radical cure of *P. vivax* and *P. ovale*¹ malaria, primary prophylaxis for destinations where *P. vivax* is the main species, as well as for terminal prophylaxis (presumptive antirelapse therapy) targeting parasites that may remain dormant in the liver, in *P. vivax* and *P. ovale* infections. Both antirelapse therapy and radical cure treatment should be for 14 days—started the first day the patient has left the malarious area—and used in conjunction with a malaria schizonticide. Often it is well tolerated but may cause GI upset that improves when taking the medication with food. Most importantly, primaquine can cause hemolytic anemia in individuals who are deficient in glucose-6-phosphate dehydrogenase (G6PD), so normal G6PD levels must be ensured before starting primaquine. Patients should discontinue primaquine if they pass red or black urine, or have symptomatic anemia. Primaquine is also contraindicated during pregnancy and during breastfeeding unless the infant's G6PD status is known.

In addition to the medications mentioned above, several other antimalarials may be encountered in malaria-endemic areas that are not approved for use by the FDA due to poor efficacy or unwelcome side-effect profiles (e.g., individual components of ACTs like amodiaquine [Camoquin]² and sulfadoxine-pyrimethamine,² or halofantrine [Halfan]²). Therefore, travelers and physicians counseling patients should be aware of those medications approved by the regulatory authorities in their respective countries.

¹Not FDA approved for this indication.

²Not available in the United States.

¹⁰Available in the United States from the Centers for Disease Control and Prevention.

¹Not FDA approved for this indication.

²Not available in the United States.

For travelers, authenticity of medications must also be ensured. Unfortunately, the quality of medications commercially available in malaria-endemic countries can vary greatly. While appearing to be genuine, counterfeit medications may have little to no active ingredient or may contain ingredients not indicated on their label. If travelers have to purchase medications outside of their home country, they need to scrutinize medication packaging for printing errors and signs of tampering. The color, consistency, odor, and taste of the medication may also alert one to counterfeit medication. The Medicines Quality Database (MQDB) through the U.S. Pharmacopeial Convention is one resource available to investigate medicine quality in countries throughout the world (see <http://www.usp.org/global-health-programs/promoting-quality-medicines-pqmusaid/medicines-quality-database-mqdb>).

Treatment

Unless there is clinical concern for severe disease or prompt laboratory diagnosis is unobtainable, malaria treatment should be initiated once the diagnosis is established by laboratory testing. Upon confirmation of the diagnosis, treatment management should be based on the identity of infecting *Plasmodium* species, the patient's clinical status and level of parasitemia, prior use of antimalarials, and the geographic area where the infection was likely acquired.

If identification reveals the presence of *P. falciparum* malaria or *Plasmodium* species remains uncertain, patients should be hospitalized and monitored closely for possible development of severe malaria symptoms and complications. When clinical and laboratory data support low severity, it is safe to treat patients in the outpatient setting with oral therapy. Should symptoms become more severe, though, as described below, the patient should be started on parenteral therapy and admitted to intensive care. As a default, clinicians should always treat those with malaria where the infecting species is unknown as if they had a chloroquine-resistant *P. falciparum* infection until proven otherwise. Routine serial blood monitoring for parasite density using blood smears will also help modify therapy as needed. Clinicians must be mindful, though, that increases in parasite density within the first 24 hours of treatment may represent normal release of parasite from RBCs and not worsening infection, especially when the patient's symptoms are improving with current therapy. Monitoring should continue until blood smears are negative and alternative treatments need to be considered if the patient's symptoms are not improving and parasite density is not decreasing.

Detailed treatment information regarding dosing and frequency may be found in [Tables 1–3](#).

Chloroquine-Sensitive *Plasmodium* (*P. falciparum*, *P. knowlesi*, *P. malariae*, *P. ovale*, and *P. vivax*)

Oral chloroquine phosphate is the recommended treatment for all sensitive malaria strains. Confirmed infections with *P. ovale*, *P. malariae*, and *P. knowlesi* are generally sensitive to chloroquine and treatment should not be delayed, especially for *P. knowlesi*, which has the capacity to increase parasitemia rapidly and become very severe. For *P. falciparum* and *vivax* infections, chloroquine may be indicated if the confirmed geographic area of exposure has no known chloroquine resistance. In addition, for all *P. ovale* and *vivax* infections, patients with normal G6PD activity require primaquine therapy for 14 days to reduce potential relapse.

Chloroquine-Resistant *P. falciparum*

In the case of *P. falciparum* infection from areas with known chloroquine resistance, several options are available. Where available, artemisinin-based combination therapies (ACTs) are considered the standard of care, but other agents may also be used (see [Table 3](#)). In the United States four different treatment options are available: atovaquone-proguanil, artemether-lumefantrine, quinine sulfate combined with doxycycline,¹ tetracycline,¹ or clindamycin,¹ or mefloquine. Due to neuropsychiatric side effects,

mefloquine should be considered only when other options are not available or contraindicated. It should also not be used when the *P. falciparum* strain was acquired in Southeast Asia due to increased resistance to mefloquine in that region.

Chloroquine-Resistant *P. vivax*

Though mostly sensitive to chloroquine, *P. vivax* infections acquired in Indonesia and Papua New Guinea often show resistance. Common treatment regimens for chloroquine-resistant strains include atovaquone-proguanil, quinine sulfate¹ combined with doxycycline¹ or tetracycline,¹ or mefloquine. There is also very good evidence to support using ACTs, where available, for treatment of both chloroquine-resistant and chloroquine-sensitive strains. As mentioned before, all *P. vivax*-infected patients should also receive primaquine therapy for 14 days to eradicate any hypnozoite forms.

Severe Malaria

Severe disease is likely in those patients with a positive blood smear or a concerning exposure history who also exhibit at least one of the following: impaired consciousness or coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, seizures, and parasitemia of over 5%. Mortality risk increases with increasing numbers of the signs/symptoms especially when signs of acidosis, vital organ dysfunction, or high parasite count are present. Immediate point of care testing, where available, should always include measures of hematocrit, parasite count, and blood glucose. The mortality rate for patients with untreated severe malaria (particularly cerebral malaria) is almost 100%. Fortunately, with prompt effective treatment and supportive care, mortality may fall to 10%.

Any patient considered to be at increased risk should receive the highest level of care available (e.g., intensive care unit) and parenteral antimalarial drug treatment (artesunate or quinidine) should be started without delay. Adults and children with severe malaria (including infants, pregnant women in all trimesters, and lactating women) should be treated with IV or IM artesunate for at least 24 hours where available. As soon as oral therapy can be tolerated after the initial 24 hours of parenteral therapy, treatment with 3 days of an ACT should continue (7 days if likely acquired from Southeast Asia). When IM and IV forms are not available, rectal administration of artesunate (10 mg/kg body weight) in young children (<6 years) in prereferral settings has also proven to be a life-saving adjuvant before arrival at a facility for further care. When quinidine is used, as it most frequently would be in the United States, parenteral therapy (to include IV doxycycline¹ or clindamycin¹) should be given for a minimum of 24 hours and then switched to oral treatment once tolerated after that. When an ACT is not available for follow-on treatment, artesunate + clindamycin,¹ artesunate + doxycycline,¹ quinine + clindamycin, quinine + doxycycline, or atovaquone-proguanil can be used.

Regarding general monitoring and supportive care, fluid requirements should be assessed individually and signs of shock quickly addressed. Adults with severe malaria are very vulnerable to fluid overload and pulmonary edema, while children are more likely to be dehydrated. Severe malaria can be associated with rapid development of anemia, as erythrocytes are hemolyzed and/or removed from the circulation by the spleen. Ideally, fresh, cross-matched blood should be available for transfusion when hematocrit levels fall to below 15% in children or 20% in adults. Cardiac monitoring is also essential, especially when using quinidine, which is known to cause conduction abnormalities at the loading dosages required for initial treatment. Of note, after artesunate treatment in hyperparasitemic nonimmune travelers, it is common for delayed hemolysis to occur after a week, and so such patients need to be followed for these changes. Given the potential clinical overlap between malaria and sepsis, especially in children, blood

¹Not FDA approved for this indication.

TABLE 2 Medications and Dosing

MEDICATION	ADULT DOSING	PEDIATRIC DOSING
Artesunate*	2.4 mg/kg IV push at 0, 12, 24, and 48 hours	<20 kg: 3.0 mg/kg IV push at 0, 12, 24, and 48 hours >20 kg: same as adult dosing
Artemether-lumefantrine†	1 tablet=20 mg artemether and 120 mg lumefantrine. A 3-day treatment schedule with a total of 6 oral doses is recommended for both adult and pediatric patients based on weight. Initial dose at 0 hour, second dose 8 hours later, then 1 dose PO bid for the next 2 days. 5 to <15 kg: 1 tablet/dose 15 to <25 kg: 2 tablets/dose 25 to <35 kg: 3 tablets/dose ≥35 kg: 4 tablets/dose	
Atovaquone/proguanil‡	Adult tab=250 mg/100 mg. 4 tabs PO daily as a single dose for 3 consecutive days	Pediatric tablets=62.5 mg/25 mg. 5 to 8 kg: 2 peds tabs PO qd × 3 days 9 to 10 kg: 3 peds tabs PO qd × 3 days 11 to 20 kg: 1 adult tab PO qd × 3 days 21 to 30 kg: 2 adult tabs PO qd × 3 days 31 to 40 kg: 3 adult tabs PO qd × 3 days >40 kg: 4 adult tabs PO qd × 3 days
Chloroquine phosphate	600 mg base (=1000 mg salt). PO immediately, followed by 300 mg base (=500 mg salt) PO at 6, 24, and 48 hours	10 mg base/kg PO immediately, followed by 5 mg base/kg PO at 6, 24, and 48 hours
Clindamycin	7-day treatment course recommended for adult and pediatric patients both based on weight. Switch to PO clindamycin as soon as patient can take oral medication. IV dosing: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 hours (avoid rapid administration) PO dosing: 20 mg base/kg/day tid	
Doxycycline ²	100 mg PO/IV every 12 hours for 7 days	≥8 years of age: 2.2 mg/kg PO/IV every 12 hours up to adult dose of 100 mg/dose for 7 days
Hydroxychloroquine	620 mg base (=800 mg salt). PO immediately, followed by 310 mg base (=400 mg salt) PO at 6, 24, and 48 hours	10 mg base/kg PO immediately, followed by 5 mg base/kg PO at 6, 24, and 48 hours
Mefloquine ^{3,4}	684 mg base (=750 mg salt). PO as initial dose, followed by 456 mg base (=500 mg salt). PO given 6–12 hours after initial dose.	13.7 mg base/kg (=15 mg salt/kg). PO as initial dose, followed by 9.1 mg base/kg (=10 mg salt/kg). PO given 6–12 hours after initial dose.
Primaquine phosphate ⁵	30 mg base (52.6 mg salt) ⁸ PO, daily for 14 days after departure from the malarious area	0.5 mg/kg base (0.8 mg/kg salt, off-label dosing for children) up to adult dose PO, daily for 14 days after departure from the malarious area
Quinidine gluconate ⁶	6.25 mg base/kg (=10 mg salt/kg) loading dose IV over 1–2 hours, then 0.0125 mg base/kg/min (=0.02 mg salt/kg/min) continuous infusion for at least 24 hours. Or 15 mg base/kg (=24 mg salt/kg) loading dose IV infused over 4 hours, followed by 7.5 mg base/kg (=12 mg salt/kg) infused over 4 hours every 8 hours, starting 8 hours after the loading dose. Once parasite density is <1% and patient can take PO medication, complete treatment with PO quinine.	
Quinine sulfate	542 mg base (=650 mg salt). PO every 8 hours × 3 or 7 days	8.3 mg base/kg (=10 mg salt/kg). PO every 8 hours × 3 or 7 days
Tetracycline ^{2,7}	250 mg PO every 6 hours × 7 days	≥8 years of age: 25 mg/kg/day PO divided every 6 hours × 7 days

*Available in United States through Centers for Disease Control and Prevention.

†Only FDA-approved artemisinin-combination therapy.

‡Contraindicated if severe renal impairment (creatinine clearance <30 mL/min). Not recommended for children <5 kg and pregnant women.

²Contraindicated in children <8 years of age and pregnant women.

³Contraindicated in people allergic to mefloquine or related compounds (quinine, quinidine) and in people with depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Not recommended for persons with cardiac conduction abnormalities.

⁴Currently category B in pregnancy (FDA), recommended as option for treatment and prophylaxis in all trimesters.

⁵Contraindicated in G6PD deficiency. Also contraindicated during pregnancy and lactation, unless infant has normal G6PD level.

⁶Do not give loading dose if patients have received >40 mg/kg quinine in previous 48 hours or received mefloquine within prior 12 hours; loading dose should not be given. Requires continuous cardiac monitoring.

⁷Not FDA approved for this indication.

⁸Exceeds dosage recommended by the manufacturer.

cultures should always be taken and empiric antibiotic treatment should be started along with antimalarial therapy until bacterial infection can be ruled out. Additionally, though incorporated into some older recommendations, both the CDC and WHO no longer recommend using exchange transfusions or prophylactic anticonvulsants as adjunct treatment in severe malaria as the data do not support any mortality benefit.

Clinicians with questions about effective treatment (or diagnosis) should consult with an infectious disease specialist or a physician with specialized training in travel or tropical medicine. If no

such local avenues are available, clinicians should not hesitate to contact the CDC's Malaria Hotline (referenced previously).

Treatment in Pregnancy

Pregnancy complicates the treatment strategy as it affects both the mother and her fetus. Infections, especially with *P. falciparum*, can increase susceptibility to severe disease and risk of developing anemia, while increasing fetal risk for low birth weight and prematurity in addition to miscarriage. Symptoms of pregnant patients may also be more muted in high-transmission areas than for those in

TABLE 3 Artemisinin Combination Therapies (ACTs)*¹

MEDICATION	ADULT AND PEDIATRIC DOSING (BY BODY WEIGHT)
Artemether + lumefantrine ^{2,3}	Artemether + lumefantrine (mg) bid for 3 days: 5 to <15 kg: 20 + 120 15 to <25 kg: 40 + 240 25 to <35 kg: 60 + 360 >35 kg: 80 + 480
Artesunate + amodiaquine ^{4,†}	Artesunate + amodiaquine (mg) daily for 3 days: 4.5 to <9 kg: 25 + 67.5 9 to <18 kg: 50 + 135 18 to <36 kg: 100 + 270 >36 kg: 200 + 540
Artesunate + mefloquine ^{5,†}	Artesunate + mefloquine (mg) daily for 3 days: 5 to <9 kg: 25 + 55 9 to <18 kg: 50 + 110 18 to <30 kg: 100 + 220 >30 kg: 200 + 440

*Recommended therapies per WHO.

[†]Not available in the United States.¹Artemisinins and their partner medicines above should not be used alone for treatment, only in a combination.²Only ACT that is approved for use by U.S. FDA.³Absorption of lumefantrine is enhanced by coadministration with fat.⁴In patients with HIV, concomitant use of zidovudine, efavirenz, or cotrimoxazole should be avoided.⁵Contraindicated in people allergic to mefloquine or related compounds (quinine, quinidine) and in people with depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Not recommended for persons with cardiac conduction abnormalities.⁶Only ACT that it is not available as a fixed-dose combination.⁷High-fat meals should be avoided as they significantly accelerate the absorption of piperaquine.

Lack of resolution of malaria symptoms or recurrence within 4 weeks of treatment are considered treatment failures and a different ACT should be tried.

low-transmission areas despite the adverse effects on fetal growth. Congenital malaria must be considered when infants born to mothers with acute malaria infection show signs of fever, anemia, or failure to thrive during the first few months of birth. In most cases, treatment of newborns or infants should proceed if symptoms are present and infection status is confirmed. While remaining vigilant, providers must also educate mothers about symptoms and the importance of quick follow-up should they develop. Of note, congenitally acquired malaria in infants does not involve a liver stage so primaquine is not needed.

As pregnant women are largely excluded from many clinical trials, safety and efficacy data are lacking for them, especially during the first trimester. Nevertheless, a number of recommendations have been made from available data regarding treatment of pregnant women. During the first trimester, current guidelines list

chloroquine, quinine, clindamycin, and proguanil² as safe. Additionally, review of available data has moved the FDA to list mefloquine as a pregnancy Category B medication showing no increase in birth defects or fetal loss throughout pregnancy. Though some prospective data do support its use early in pregnancy, WHO only recommends ACTs in the first trimester if it is the only treatment available, in cases of severe malaria where IV artesunate is indicated, if treatment with quinine plus clindamycin¹ fails, or if uncertainty of compliance with a 7-day treatment exists (quinine is only needed for 3 days if infection was acquired outside Southeast Asia).

After the first trimester, several artemisinin derivatives, alone or in combination with other antimalarials, have been evaluated as safe and efficacious in second and third trimester pregnancy. Therefore, the WHO recommends that ACTs be used during the second and third trimester of pregnancy where the choice of ACT is governed by local efficacy (most recommended are artemether-lumefantrine, artesunate-amodiaquine,² artesunate-mefloquine,² and artesunate-sulfadoxine-pyrimethamine²). For those with *P. malariae*, *P. vivax*, *P. ovale*, or chloroquine-sensitive *P. falciparum* malaria, chloroquine treatment, the same as for non-pregnant patients, should be instituted.

Primaquine phosphate for treatment of *P. vivax* or *P. ovale*¹ hypnozoites should not be given during pregnancy. If *P. vivax* or *P. ovale* infections are confirmed, pregnant patients should be maintained on weekly chloroquine prophylaxis for the duration of their pregnancy, 300 mg base (=500 mg salt) orally once per week. Primaquine therapy can be initiated after delivery in those patients with known normal G6PD levels. Due to possible breast milk excretion of primaquine, it should not be used by nursing women unless infants have known normal G6PD levels.

For severe malaria cases, parenteral antimalarial drugs should be given to pregnant women in full doses without delay regardless of trimester. IM artemether may be used if artesunate is unavailable; otherwise parenteral quinine should be started immediately until artesunate is obtained. Pulmonary edema and hypoglycemia are commonly seen, the latter especially when quinine is used, so patients should be monitored carefully.

Treatment of the Pediatric Patient

Delay in treating *P. falciparum* malaria in infants and young children can have fatal consequences, particularly for more severe infections. The vast majority of malaria cases and deaths in the world, especially Africa, occur in young children. Fortunately, many anti-malarial drugs have included children in clinical trials. Therefore, treatment recommendations are not just based on extrapolated data. Recommendations are consistent with those for adult patients but require appropriate dosage changes based on patient weight, and the dosage should never exceed the adult dose.

Chloroquine may be used for any chloroquine-sensitive malaria strains and, where available, artemisinin derivatives (artemether-lumefantrine being the most studied) are considered safe and very well tolerated and represent first-line treatment for chloroquine-resistant *P. falciparum*. Alternatively, quinine sulfate and quinidine may be given in combination with clindamycin¹ in those areas with poorer access to artemisinin derivatives. Atovaquone-proguanil may also be considered in this group as well as mefloquine, but only if no other options are available for the latter. Of note, for small infants weighing less than 5 kg, the WHO does recommend treatment with ACT at the same target dose as for children weighing 5 kg or more. No modifications are currently warranted in those suffering malnutrition; however, their response to treatment should be monitored closely. Regarding treatment combinations with tetracycline¹ or doxycycline,¹ these drugs should only be used with extreme prejudice in those under 8 years of age and only when other treatments are not available or not tolerated and the benefits are judged to outweigh the risks. Also, primaquine should only be given to those children with known normal levels of G6PD.

¹Not FDA approved for this indication.²Not available in the United States.

Prevention

Preventive measures are important to ensure protection against malaria. Limiting exposure to the mosquito disease vector, *Anopheles* species, as well as taking appropriate drug prophylaxis measures are key components in preventing malaria in both travelers and those living in malaria-endemic locations.

The *Anopheles* mosquito is primarily a nocturnal feeder so protecting oneself during the periods from dusk to dawn is essential to avoid possible infection. In this effort, remaining indoors or within well-screened areas, wearing clothing of a tight mesh that covers most of the body, using bed nets, ideally treated with insecticide, and using insecticide sprays on clothing and/or the body especially during evening and nighttime hours are all key. Spraying indoor areas with insecticides also adds protection. Certainly some of the malaria mortality reductions seen worldwide directly relate to the efforts in malaria-endemic areas to increase access to insecticide-treated bed nets and improved efforts in indoor residual spraying.

Several commercial insecticides and insect repellents are available. For clothing and bed nets, pyrethroids (i.e., permethrin) are typically used and fairly effective at protecting against mosquitoes, though some reports warn of developing resistance. Using insect

repellents, too, greatly minimizes *Anopheles* exposure. Currently, DEET (diethylmethyl-toluamide) is most frequently used and is known to be safe for all age groups including infants down to 2 months old. Concentrations above 25% are often recommended and individuals should remember to reapply repellent at a minimum of every 8 hours. In addition to DEET, picaradin (e.g., Natrapel 8 Hour Insect Repellent and Sawyer Premium 20% Picaradin Spray) products and IR3535 or ethyl butylacetylaminopropionate (e.g., Avon Skin-So-Soft Bug Guard Plus and Sawyer Insect and Sun Spray) are also recommended by both the CDC and WHO. Meanwhile, oil of lemon eucalyptus (e.g., Repel and Off!) is only recommended by the CDC for those repellents receiving U.S. Environmental Protection Agency approval. Travelers should always remember that when using topical skin repellents, they should be applied after any sunscreen is applied to exposed skin surfaces.

Chemoprophylaxis measures are also an important preventive medicine concern. For travelers and at-risk groups living in endemic areas, there are a number of recommended chemoprophylaxis regimens currently available (see Table 4). Key to all of these is taking an agent before, during, and after travel to a malaria-endemic area. One must ensure that the prophylactic agent is

TABLE 4 Recommendations for Malaria Chemoprophylaxis

MEDICATION	USE	ADULT DOSING	PEDIATRIC DOSING	COMMENTS
Atovaquone/proguanil ¹	Prophylaxis, all areas	Adult tab = 250 mg/ 100 mg. 1 tab daily	Pediatric tablets = 62.5 mg/ 25 mg. 5–8 kg: 1/2 pediatric tab daily >8–10 kg: 3/4 pediatric tab daily >10–20 kg: 1 pediatric tab daily >20–30 kg: 2 pediatric tabs daily >30–40 kg: 3 pediatric tabs daily >40 kg: 1 adult tab daily	Begin 1–2 days before travel to malarious areas. Take at same time every day while in malarious area and for 7 days after leaving such areas. Take with food or milk. Pharmacist may be needed to prepare some partial tablet dosing.
Chloroquine phosphate	Prophylaxis, areas with chloroquine-sensitive malaria	300 mg base (500 mg salt) PO, once/week	5 mg/kg base (8.3 mg/kg salt) PO, once/week, up to maximum adult dose of 300 mg base	Begin 1–2 weeks before travel to malarious areas. Take weekly on same day of the week while in malarious area and for 4 weeks after leaving. Can exacerbate psoriasis.
Doxycycline ²	Prophylaxis, all areas	100 mg PO, daily	≥8 years of age: 2.2 mg/kg up to adult dose of 100 mg/day	Begin 1–2 days before travel to malarious areas. Take at same time every day while in malarious area and for 4 weeks after leaving.
Hydroxychloroquine	An alternative to chloroquine. Prophylaxis, areas with chloroquine-sensitive malaria	310 mg base (400 mg salt) PO, once/week	5 mg/kg base (6.5 mg/kg salt) PO, once/week, up to a maximum adult dose of 310 mg base	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving.
Mefloquine ^{3,4}	Prophylaxis, areas with mefloquine-sensitive malaria	228 mg base (250 mg salt) PO, once/week	≤9 kg: 4.6 mg/kg base (5 mg/kg salt) PO, once/week >9–19 kg: 1/4 tablet once/week >19–30 kg: 1/2 tablet once/week >30–45 kg: 3/4 tablet once/week >45 kg: 1 tablet once/week	Begin 2 weeks before travel to malarious areas. Take weekly on the same day of the week while in malarious area and for 4 weeks after leaving. Use with caution in persons with psychiatric disturbances or a history of depression.
Primaquine phosphate ^{5,7}	Prophylaxis, areas with <i>P. vivax</i> only for short duration	30 mg base (52.6 mg salt) ⁸ PO, daily	0.5 mg/kg base (0.8 mg/kg salt) ⁷ up to adult dose PO, daily	Begin 1–2 days before travel to malarious areas. Take daily at same time each day while in malarious area and for 7 days after leaving such areas.
Primaquine phosphate ⁵	Used for presumptive antirelapse therapy (terminal prophylaxis) to decrease relapse risk of <i>P. vivax</i> and <i>P. ovale</i>	30 mg base (52.6 mg salt) ⁸ PO, daily for 14 days after departure from the malarious area	0.5 mg/kg base (0.8 mg/kg salt) ⁷ up to adult dose PO, daily for 14 days after departure from the malarious area	Indicated for people who have had prolonged exposure to <i>P. vivax</i> , <i>P. ovale</i> , or both. Take daily for 14 days starting first day of departure from malarious area.

TABLE 4 Recommendations for Malaria Chemoprophylaxis—cont'd

MEDICATION	USE	ADULT DOSING	PEDIATRIC DOSING	COMMENTS
Sulfadoxine/pyrimethamine ^{6,9}	Intermittent preventive treatment in pregnant women (first or second pregnancy) and in infants (<12 months) in African locations with moderate-high malaria transmission	Give weight-based dose to pregnant women and infants of at least 25/1.25 (25–70/1.25–3.5) mg/kg body weight. 5 to <10 kg: 250/12.5 mg 10 to <25 kg: 500/25 mg 25 to <50 kg: 1000/50 mg >50 kg: 1500/75 mg		Provide to pregnant women as part of antenatal care starting in the second trimester and dosed at least 1 month apart (ensuring at least 3 doses are received). Give to infants (<12 months of age) at the time of the second and third rounds of vaccination against diphtheria, tetanus and pertussis and vaccination against measles.

¹Contraindicated in severe renal impairment (creatinine clearance <30 mL/min). Not recommended for children <5 kg and pregnant women.

²Contraindicated in children <8 years of age and pregnant women.

³Contraindicated in people allergic to mefloquine or related compounds (quinine, quinidine) and in people with depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Not recommended for persons with cardiac conduction abnormalities.

⁴Currently Category B in pregnancy (FDA), recommended as option for treatment and prophylaxis in all trimesters.

⁵Contraindicated in G6PD deficiency. Also contraindicated during pregnancy and lactation, unless infant has normal G6PD level.

⁶Dosing based on fixed-dose combination tablets of 500 mg sulfadoxine/25 mg pyrimethamine.

⁷Not FDA approved for this indication.

⁸Exceeds dosage recommended by the manufacturer.

⁹Not available in the United States.

present in the bloodstream before any potential exposure. When in doubt, clinicians may use the CDC's online interactive malaria map or Malaria-by-Country tables (both referenced previously) to quickly view the types of *Plasmodium* present and resistance characteristics found in the patient's area of travel. In combination with the patient's individual medical history, age, medications, and travel duration, this information can be used by the clinician to treat the patient appropriately. Additionally, pregnant women who choose to travel to a malaria-endemic area must be aware that malaria severity is often increased during pregnancy. Personal protective measures and steadfast use of chemoprophylaxis (e.g., mefloquine or hydroxychloroquine) are key.

The WHO does encourage intermittent preventive treatment with sulfadoxine-pyrimethamine (SP-IPT)² for pregnant women living in endemic areas and for infants. For pregnant women during their first or second pregnancy living in endemic areas in Africa with moderate to high *P. falciparum* transmission, intermittent pregnancy treatment of malaria with SP-IPTp is recommended. Dosing should start in the second trimester and doses should be given at each antenatal visit at least 1 month apart. In addition, as a prophylactic in pediatric patients living in areas of higher malaria transmission in Africa, the WHO recommends providing intermittent preventive treatment with SP-IPTi to infants (<12 months of age) at the time of the second and third rounds of vaccination against diphtheria, tetanus, and pertussis (DTP) and vaccination against measles. Similarly, in areas with seasonal malaria transmission in the sub-Saharan region of Africa, seasonal malaria chemoprevention with monthly amodiaquine²+SP is recommended for all children less than 6 years old during each transmission season.

There is no malaria vaccine currently on the market, but RTS, S/AS01 is a candidate vaccine with somewhat promising Phase III trial data in pediatric patients. Consisting of three initial monthly doses and a booster 18 months after the third dose, over a 48-month period it showed efficacy against clinical malaria of up to 39% and against severe malaria of 31.5%. This represented an estimated number of averted clinical malaria cases in pediatric patients on the order of 1774 per 1000 children in those receiving the booster dose. Although certainly representing another worthwhile tool in combating malaria, the extent to which the protection demonstrated can be replicated in the context of a routine health-care system remains uncertain. Similarly, in an effort to combat *P. vivax* infection, Phase III data on tafenoquine, a long-acting primaquine derivative, have shown good activity against all stages of the *P. vivax* life cycle and may be developed for the radical cure of

acute *P. vivax* malaria in combination with chloroquine. It may also potentially treat *P. vivax* hypnozoites with a single dose instead of the current 14-day protocol for primaquine.

MEASLES (RUBEOLA)

Method of

Jane A. Weida, MD

CURRENT DIAGNOSIS

- Highly contagious viral illness with a prodrome of high fever, cough, conjunctivitis, and coryza.
- Red maculopapular rash beginning on face and becoming generalized

²Not available in the United States.

- Pathognomonic enanthem (Koplik's spots—small white lesions) may appear on buccal mucosa
- History of exposure, particularly history of travel to endemic areas, in non-immunized individuals
- Incubation period of about 10 days to the onset of fever and about 14 days to the onset of rash

CURRENT THERAPY

- No specific antiviral therapy is available
- Adequate hydration
- Bedrest
- Antipyretics
- Antibiotics if needed for bacterial complications

Epidemiology

Measles caused millions of deaths worldwide each year before the measles vaccines were introduced. The first measles vaccine in the United States was introduced in 1963. In the decade before 1963, there were approximately 530,000 reported measles cases per year in the United States, but it is estimated that the actual incidence was much higher, possibly up to 4 million.

Measles was declared eliminated from the United States in 2000, but sporadic outbreaks have occurred since then. There were 667 cases reported in 2014, the largest number since 2000. One US outbreak occurred in 2014–2015, linked to a travel history to two Disney theme parks in California. During that outbreak, a number of the affected patients were unvaccinated.

Measles continues to be a major problem in many regions of the world. From 2000 to 2016, because of increased worldwide measles vaccination, the annual reported measles cases decreased by 87%, and the annual estimated measles deaths decreased by 84%. In spite of this decrease, measles continues to cause 100,000 deaths worldwide each year.

Risk Factors

Being unvaccinated is the largest risk factor for measles in the United States. Infants who have lost maternal immunity but who are too young to be immunized are at higher risk for measles, as are individuals with vitamin A deficiency. Travel to international areas where measles is more common, or where there is an outbreak, also increases the risk of contracting measles. If measles is suspected in a patient, a careful travel history should be obtained.

Pathophysiology

Measles is caused by an RNA respiratory virus, of the family *Paramyxoviridae* and genus *Morbillivirus*. It is one of the most highly contagious of the communicable diseases. The virus spreads from person to person via respiratory droplets from coughing or sneezing or via direct contact. Patients are usually contagious from about 4 days before to about 4 days after the rash appears. The fact that the disease is contagious before the onset of symptoms makes quarantining difficult. The incubation period is generally 10 days before the prodrome and 14 days before the onset of the rash, but it may vary from 6 to 21 days.

The virus triggers an aggressive immune response. This leads to a suppression of the immune response to other pathogens, which makes the individual susceptible to secondary infections. This immune suppression can last for a few weeks to a few months, but in some cases it may last for 2 to 3 years.

Once a measles infection is successfully cleared, the person gains lifelong immunity as long as they remain immunocompetent. Infants are protected by maternal antibodies, for about 1 month in the case of an immunized mother and for about 4 months in the case of a mother who had a prior measles infection.

Prevention

The best way to prevent measles is with measles vaccination. The Centers for Disease Control and Prevention (CDC) recommends a measles-mumps-rubella (MMR) vaccination at ages 12 to 15 months, and a second dose at 4 to 6 years of age. Two doses are more than 99% effective in prevention of the disease. Students at post-high school institutions who are not immune to measles should have two doses of MMR vaccine at least 28 days apart. Adults born after 1957 who do not have immunity should receive at least one dose of MMR vaccine. MMR vaccine should not be given to pregnant women or to immunocompromised individuals because it is a live vaccine.

In spite of the importance of measles prevention, some parents refuse to vaccinate their children. A study published in the United Kingdom in 1998 claimed to find a link between autism and the MMR vaccine. The study was later proven to be erroneous and fraudulent, and subsequent studies have consistently shown that there is no link between vaccines and autism. It is vital for clinicians to continue to educate parents about the importance of MMR vaccination.

Clinical Signs and Symptoms

Measles generally presents with a prodrome that includes high fever, malaise, anorexia, conjunctivitis, coryza, and non-productive cough. Fever may reach over 40°C. Conjunctivitis may include redness, swelling, photophobia, and discharge. Koplik spots, which are small white spots the size of a sand grain on the buccal mucosa (Figure 1), are pathognomonic, but they are not always present. The Koplik spot may be circumscribed by a red ring.

The measles rash is erythematous and maculopapular (Figure 2). It usually appears first on the face and behind the ears and then spreads to the trunk and extremities. The rash lasts for 3 to 7 days. Recovery from generalized symptoms begins soon after the rash appears.

Diagnosis

Measles is usually diagnosed clinically, based on the presenting signs and symptoms, vaccination history, and travel/exposure history. Clinical diagnosis can be difficult when the incidence of measles is low. The World Health Organization clinical case definition for measles is a person with fever and maculopapular rash and at least one of the following symptoms: cough, coryza, or conjunctivitis.

Laboratory findings include leukopenia, unless there is a secondary bacterial infection, thrombocytopenia, and proteinuria. The most commonly-used serologic test is virus-specific immunoglobulin M (IgM) in serum or oral fluid. IgM antibodies may not be detectable until 4 or more days after the rash appears. Viral

Figure 1 Koplik spots on the buccal mucosa during the third day of rash. (From Centers for Disease Control and Prevention: Public Health Image Library, Image 4500, available at <http://phil.cdc.gov/phil/details.asp>.)

Figure 2 Typical rash on day 2 or 3 of measles. (From Maldonado YA, Shetty AK. Rubeola Virus. In: Long SS, Prober CG, Fischer M [eds]. *Principles and practice of pediatric infectious diseases*, 5th ed. 2018, Elsevier, Inc. Courtesy of J. H. Briené.)

cultures may also be obtained, as may nasopharyngeal swabs for detection by PCR.

In the United States, measles is a reportable illness. Suspected cases should be reported to the local health department immediately. The CDC recommends that serologic and viral specimens be collected in suspected cases of measles; clinicians can contact their local laboratories to find out which specimens to collect.

Differential Diagnosis

Measles may easily be mistaken for other upper viral respiratory illnesses during the prodromal stage. Although Koplik's spots are pathognomonic, they are easy to overlook. Once the rash appears, it may be mistaken for other illnesses, including erythema infectiosum, infectious mononucleosis, enterovirus, Kawasaki disease, chikungunya, Rocky Mountain spotted fever, rubella, and scarlet fever.

Treatment

No specific antiviral treatment is available for measles. Treatment is supportive, including rest, adequate fluids, and antipyretics. Patients should be kept at bedrest until they are fever free. Prompt recognition and treatment of secondary bacterial infections is essential. The World Health Organization recommends administration of vitamin A¹ to all those with measles. The CDC recommends vitamin A¹ treatment in children with severe cases of measles, such as those who are hospitalized. It is given immediately when the disease is diagnosed and then repeated the following day.

Monitoring

Most measles patients do not need hospitalization. Those with meningitis, encephalitis, myelitis, severe pneumonia, and severe dehydration should be admitted. Both standard precautions and respiratory precautions should be initiated. Respiratory precautions should continue for 4 days after the onset of rash for healthy children and for the duration of the illness in immunocompromised patients.

For those who have been exposed to measles and are not immune, MMR should be administered within 72 hours of exposure. Immunoglobulin (Gammagard) can be administered within 6 days of exposure.

Complications

Complications of measles can occur in up to 40% of patients. Complications are highest in the very young, the very old, and those who are malnourished. Often the complications affect the respiratory tract, with pneumonia being the leading cause of death associated with measles. Pneumonia may be caused by a secondary bacterial or viral infection or by the measles virus itself. Otitis media is another common complication. Gastrointestinal complications include diarrhea and stomatitis. Measles keratoconjunctivitis is a common complication, especially in children with vitamin A deficiency.

Rarely, measles can cause severe CNS complications. About 1 in 1000 cases of measles results in post-measles encephalomyelitis, leading to fever, seizures, and neurologic abnormalities. Measles causes about one to two deaths per 1000 due to respiratory or neurologic complications. Subacute sclerosing panencephalitis is a rare delayed neurologic complication of measles, occurring in about 1 in 10,000-100,000 patients. This fatal complication causes seizures and progressive intellectual and behavioral deterioration about 7-10 years after a measles infection.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA)

Method of

Elissa Rennert-May, MD; and John M. Conly, MD

CURRENT DIAGNOSIS

- Health care–associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA) is endemic in many hospital settings. The strains are polyclonal, resistant to many non- β -lactam antimicrobials, and typically cause pneumonia, line-related infection, surgical site infection, bacteremia, and infrequently skin and soft tissue infections.
- Community-associated strains of MRSA (CA-MRSA) have risen exponentially over the past decade and a half. The strains are clonal, sensitive to many non- β -lactam antimicrobials, harbor multiple virulence factors, and typically cause pyogenic skin and soft tissue infections and occasionally severe necrotizing pneumonia, fasciitis, and multifocal osteomyelitis.
- Health care–associated (HA)-MRSA infections typically affect patients with multiple comorbidities in the health care setting, but CA-MRSA typically affects previously healthy persons.
- It can be difficult to differentiate infectious syndromes due to β -hemolytic streptococci versus CA-MRSA.

¹Not FDA approved for this indication.

Figure 2 Typical rash on day 2 or 3 of measles. (From Maldonado YA, Shetty AK. Rubeola Virus. In: Long SS, Prober CG, Fischer M [eds]. *Principles and practice of pediatric infectious diseases*, 5th ed. 2018, Elsevier, Inc. Courtesy of J. H. Briené.)

cultures may also be obtained, as may nasopharyngeal swabs for detection by PCR.

In the United States, measles is a reportable illness. Suspected cases should be reported to the local health department immediately. The CDC recommends that serologic and viral specimens be collected in suspected cases of measles; clinicians can contact their local laboratories to find out which specimens to collect.

Differential Diagnosis

Measles may easily be mistaken for other upper viral respiratory illnesses during the prodromal stage. Although Koplik's spots are pathognomonic, they are easy to overlook. Once the rash appears, it may be mistaken for other illnesses, including erythema infectiosum, infectious mononucleosis, enterovirus, Kawasaki disease, chikungunya, Rocky Mountain spotted fever, rubella, and scarlet fever.

Treatment

No specific antiviral treatment is available for measles. Treatment is supportive, including rest, adequate fluids, and antipyretics. Patients should be kept at bedrest until they are fever free. Prompt recognition and treatment of secondary bacterial infections is essential. The World Health Organization recommends administration of vitamin A¹ to all those with measles. The CDC recommends vitamin A¹ treatment in children with severe cases of measles, such as those who are hospitalized. It is given immediately when the disease is diagnosed and then repeated the following day.

Monitoring

Most measles patients do not need hospitalization. Those with meningitis, encephalitis, myelitis, severe pneumonia, and severe dehydration should be admitted. Both standard precautions and respiratory precautions should be initiated. Respiratory precautions should continue for 4 days after the onset of rash for healthy children and for the duration of the illness in immunocompromised patients.

For those who have been exposed to measles and are not immune, MMR should be administered within 72 hours of exposure. Immunoglobulin (Gammagard) can be administered within 6 days of exposure.

Complications

Complications of measles can occur in up to 40% of patients. Complications are highest in the very young, the very old, and those who are malnourished. Often the complications affect the respiratory tract, with pneumonia being the leading cause of death associated with measles. Pneumonia may be caused by a secondary bacterial or viral infection or by the measles virus itself. Otitis media is another common complication. Gastrointestinal complications include diarrhea and stomatitis. Measles keratoconjunctivitis is a common complication, especially in children with vitamin A deficiency.

Rarely, measles can cause severe CNS complications. About 1 in 1000 cases of measles results in post-measles encephalomyelitis, leading to fever, seizures, and neurologic abnormalities. Measles causes about one to two deaths per 1000 due to respiratory or neurologic complications. Subacute sclerosing panencephalitis is a rare delayed neurologic complication of measles, occurring in about 1 in 10,000-100,000 patients. This fatal complication causes seizures and progressive intellectual and behavioral deterioration about 7-10 years after a measles infection.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA)

Method of

Elissa Rennert-May, MD; and John M. Conly, MD

CURRENT DIAGNOSIS

- Health care–associated methicillin-resistant *Staphylococcus aureus* (HA-MRSA) is endemic in many hospital settings. The strains are polyclonal, resistant to many non- β -lactam antimicrobials, and typically cause pneumonia, line-related infection, surgical site infection, bacteremia, and infrequently skin and soft tissue infections.
- Community-associated strains of MRSA (CA-MRSA) have risen exponentially over the past decade and a half. The strains are clonal, sensitive to many non- β -lactam antimicrobials, harbor multiple virulence factors, and typically cause pyogenic skin and soft tissue infections and occasionally severe necrotizing pneumonia, fasciitis, and multifocal osteomyelitis.
- Health care–associated (HA)-MRSA infections typically affect patients with multiple comorbidities in the health care setting, but CA-MRSA typically affects previously healthy persons.
- It can be difficult to differentiate infectious syndromes due to β -hemolytic streptococci versus CA-MRSA.

¹Not FDA approved for this indication.

CURRENT THERAPY

- MRSA strains harbor resistance to the β -lactam antimicrobials, including oxacillin, dicloxacillin, cloxacillin², nafcillin, methicillin,¹ and first-, second-, and third-generation cephalosporins.
- HA-MRSA strains are typically resistant to macrolides, clindamycin (Cleocin), aminoglycosides, and quinolones and are variably resistant to tetracycline and trimethoprim-sulfamethoxazole (Bactrim). They are sensitive to vancomycin (Vancocin) and the lipoglycopeptides, fusidic acid², rifampin (Rifadin)¹, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin) and ceftaroline (Teflaro).
- CA-MRSA strains are resistant to macrolides and quinolones but usually sensitive to aminoglycosides such as gentamicin (Garamycin), clindamycin, and trimethoprim-sulfamethoxazole (Bactrim)¹ in addition to vancomycin (Vancocin), the lipoglycopeptides, fusidic acid², rifampin (Rifadin)¹, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin) and ceftaroline (Teflaro).
- Empiric antimicrobial therapy should be guided by the clinical presentation, and when full sensitivities are available, the antimicrobials may be tailored accordingly.

¹Not FDA approved for this indication.

²Not available in the United States.

Epidemiology

Staphylococcus aureus (*S. aureus*) is one of the most frequently encountered bacteria causing human infections and may be considered as either methicillin-sensitive *S. aureus* (MSSA) or methicillin-resistant *S. aureus* (MRSA). MRSA was first described in 1961 and is resistant not only to the traditional antistaphylococcal β -lactam antibiotics (methicillin², nafcillin, oxacillin, cloxacillin², dicloxacillin) but also other important β -lactam antibiotics, including the first- to fourth-generation cephalosporins and the carbapenem family, thus eliminating an important class of antibiotics from the clinician's armamentarium. The only β -lactam that has activity

against MRSA is the recently approved advanced-generation cephalosporin agent ceftaroline (Teflaro).

MRSA strains acquired in the hospital or other health care settings have traditionally been referred to as health care-associated MRSA (HA-MRSA) whereas community-associated MRSA (CA-MRSA) has referred to isolates acquired in the community setting and in the absence of traditional hospital or health care exposures for at least 1 year (overnight stays in an acute care or long-term care facility, surgery, dialysis, or presence of a central venous catheter). Recently the term *community-onset* HA-MRSA has been used to describe the occurrence of MRSA infection in the setting of the presence of a health care exposure within the past year. MRSA has been recognized as a health care-associated pathogen since the 1970s, and became endemic in hospitals in many countries, including the United States, United Kingdom, and many European countries over the next two decades with exceptions being Denmark, the Netherlands, Scandinavia, and Canada. For several decades, MRSA was typically considered a hospital pathogen. Novel and virulent MRSA strains arising in the community and not associated with any traditional health care exposure risks were first encountered in the late 1990s in the United States, Australia, and some European countries and have since risen explosively on a global basis to become the predominant clone of *S. aureus* associated with community infections. Methicillin resistance among community isolates of *S. aureus* has been reported as high as 75% in some U.S. communities. More recently livestock-associated MRSA (LA-MRSA) has been reported on a global basis and transmission of these strains from swine, cattle and horses has been implicated as a source of human infections, particularly in farmers, abattoir workers and veterinarians.

Specific genetic and molecular distinctions initially distinguished the HA- and CA-MRSA strains (Table 1) and have been used to characterize MRSA strains as likely of community or health-care origin. The HA-MRSA strains were found to harbor large staphylococcal cassette chromosome (SCCmec) types known as SCCmec types I, II, or III; to have multidrug resistance to non- β -lactam antimicrobials; to have the absence of specific virulence characteristics such as carriage of the Panton-Valentine Leukocidin (PVL) gene; and to have varying multilocus sequence types (ST5, ST239, ST 247, ST250). On the other hand, the CA-MRSA strains have been found to harbor SCCmec types IV, V, and more recently VI to XII have been described; to have paucidrug resistance to non- β -lactam antimicrobials; to have the presence of specific virulence characteristics such as carriage of the Panton-Valentine Leukocidin gene, and to

²Not available in the United States.

TABLE 1 General Features Differentiating HA- and CA-MRSA*

CHARACTERISTIC	HA-MRSA	CA-MRSA
SCCmec types	I, II, III	IV, V (VI–XII)
Drug resistance to non- β -lactams	Multiresistance	Pauciresistance
Presence of PVL	—	+
Pathogenicity islands	Few	Multiple
MLST	5, 45, 239, 247, 250	1, 8, 80, 398 [†]
Pulsotype	USA100, 200, 600, 800	USA 300, 400
Age predilection	Older	Younger
Comorbidities	Multiple	None
Traditional risk factors	Health care contact, prolonged hospital stay, poor hand hygiene, contaminated equipment, invasive procedures, medical devices, recent antibiotic use	Crowded community environment, lack of cleanliness, loss of skin integrity, intravenous drug user, homelessness, incarceration, aboriginal, HIV +, contact sports, athletes, military, chronic skin disorder, veterinary worker

*Features are generalizations only given the appearance of community strains replacing traditional hospital strains in the health care setting and the appearance of typical HA strains in the community setting.

[†]ST 398 = untypable “swine-associated” strains.

Abbreviations: SCCmec = staphylococcal cassette chromosome; MLST = multilocus sequence type; pulsotype = pulsed field electrophoretic type; PVL = Panton-Valentine Leukocidin.

have multilocus sequence types ST1, ST8, and ST80. LA-MRSA strains often are non-typeable or harbor SCCmec V, have high rates of tetracycline resistance, carry multiple virulence factors and are most often multilocus sequence types ST398 or ST9. However, over the last few years, health care–associated strains have moved into the community and likewise community strains have spread rapidly within hospitals, and the original distinctions between CA-MRSA and HA-MRSA from an epidemiologic perspective have become

increasingly blurred. The point of transmission of MRSA is not always possible to identify with certainty, making the classification of CA and HA strains increasingly imprecise.

Risk Factors

The risk factors for HA-MRSA may be viewed from the perspective of the health care environment and patient-specific risk factors. A major risk factor for acquiring HA-MRSA is exposure to a health care setting and particularly in hospital or other institutional settings where the prevalence of carriage of MRSA among patients is high. Additional risk factors in the health care environment include poor hand hygiene practices among hospital employees, contaminated bedside equipment and surfaces, overcrowding, and reduced health care worker-to-patient ratios. Patient risk factors (see Table 1) include aging, multiple comorbidities, receipt of antibiotics within the preceding 3 months, prolonged duration of hospital stay, admission to a long-term care facility or hospital in the previous year, invasive procedures, and the presence of indwelling catheters or other devices. Initial risk groups for CA-MRSA were injection drug users, homeless populations, incarcerated persons, and indigenous peoples. The Centers for Disease Control and Prevention have suggested the five Cs (Figure 1, Table 2) as contributing factors implicated in the transmission among these groups. The initial risk groups have now expanded (Table 3) to include men who have sex with men (MSM), athletes

The “5 Cs” for Transmission of CA-MRSA

- Crowding
- Contact with skin
- Compromised skin
- Contaminated personal care items
- Cleanliness lack

Figure 1 The five Cs implicated in transmission of CA-MRSA. (Adapted from the US Centers for Disease Control and Prevention.)

TABLE 2 Risk Factor Associations Reported for CA-MRSA Infections

RISK CATEGORIES	FACTOR	DETAILS FROM REPORTS
High-risk populations	Younger and older age	Age distribution in CA-MRSA younger than HA-MRSA High rate of CA-MRSA in children under 2 years CA-MRSA more common in children compared to adults Outbreaks in hospital nurseries Outbreaks in nursing homes with elderly residents
	Indigenous populations: Native or Aboriginal or African American	Aboriginal communities in midwestern United States, Canada, and Australia Alaskan natives More common in African Americans
	Athletes (predominantly contact sports)	Outbreaks on football teams Outbreaks on wrestling team Other competitive sports
	Injection (intravenous) drug users (IVDUs)	San Francisco IVDUs Canadian report of USA300 strain outbreak
	Men who have sex with men (MSM)	CA-MRSA described in HIV + population of MSM
	HIV + individuals	Risk associated with overlapping social networks, intravenous drug use, hemodialysis, and CD4 counts < 200 reported as independent risks
	Military personnel	3% of US Army soldiers colonized
	Inmates of correctional facilities	Reports of outbreaks in U.S. prisons Two outbreaks (total 10 inmates) in Canada
Previous positive MRSA cultures	Students in elementary schools and college dormitories	Reports of outbreaks in schools and college dormitories
	MRSA carriage Past MRSA infection	Colonized soldiers more likely to get CA-MRSA disease Prior abscess risk factor for CA-MRSA
Medical history	Chronic skin disorder	Dermatologic condition most common underlying medical disorder for CA-MRSA infection
	Recurrent or recent antibiotic use	Classroom contact of index CA-MRSA case had chronic dermatitis Antibiotic use associated with CA-MRSA infection in rural Alaska
Environmental	Homelessness and living in shelters	Medically underserved populations at higher risk of CA-MRSA
	Overcrowding	Reports of USA300 strain outbreak involving individuals living in shelters or homeless
	Contact with colonized pet	Close contact implicated in jail outbreaks
	Veterinary workers and family members	Neonatal intensive care unit transmission Family dog source of recurrent infection
		Veterinarians working with horses and livestock
		Family members of animal care workers
		Small animal veterinarians Swine farmers

Adapted from Barton-Forbes et al. (2006).

TABLE 3

Principles of Empiric Treatment of Minor Skin and Soft Tissue Infections (Folliculitis, Furuncles, Small Abscesses Without Cellulitis, Impetigo, Secondarily Infected Lesions Such as Eczema, Ulcers, or Wounds) Where the Etiology Is Unknown but May Include MRSA as a Possibility

Recommendations

- One or more of the following measures may be employed:
 - Local therapy using hot soaks, elevation, and dressings as appropriate
 - Incision and drainage of furuncles or small abscesses without antimicrobial therapy
 - Topical 2% mupirocin ointment (Bactroban) or fusidic acid² for impetigo and secondarily infected lesions if local strains are likely sensitive
 - Topical antiseptics may be considered
- Antimicrobial therapy is recommended in addition to local measures if one or more of the following is present: multiple sites of infection, evidence of progression, clinical evidence of systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage.
- In follow-up, routine screening for colonization of the nares or other body sites is not recommended.

²Not available in the United States.

(especially those involved in team and contact sports), military personnel, those with a prior history of abscesses, individuals with chronic skin disorders, individuals with recent antibiotic receipt, underserved urban populations, individuals who have contact with colonized pets or livestock, and veterinary workers. In the drug-using and underserved urban populations, prevalence and social networking studies have identified hospices, shooting galleries, and crack houses as key sites in which CA-MRSA transmission may occur. Recent outbreaks have been reported in hospital nurseries, daycare settings, nursing home workers, schools, and college dormitories. Sexual transmission has been reported, but it may reflect close skin-to-skin genital contact rather than a true sexually transmitted pathogen. CA-MRSA has now become endemic in the general population in many communities, and the elderly and the very young seem to have a predilection for infection, especially if other risk factors are present. Risk groups for LA-MRSA include farmers, their family members and farm hands who are engaged in livestock production (especially swine and cattle), abattoir workers, veterinarians, and veterinary assistants. Recent transmission of strains of LA-MRSA has been reported in the hospital setting as well.

Pathophysiology

The resistance to the antistaphylococcal β -lactam antibiotics in MRSA strains is imparted by the presence of an altered configuration for a specific penicillin-binding protein (PBP) known as PBP2a in the cell wall of staphylococci. Normally the PBPs would act as a site for the attachment of the active moieties of the β -lactam agent, which then would inhibit further cell wall assembly. The alteration in the configuration of PBP2a occurs as the result of the presence of the *SCCmec* gene in *S. aureus*, which confers resistance to the β -lactam antibiotics. The origins of the *mec* gene and its insertion into the *SCCmec* element are not known with certainty. Once the MRSA strains acquired resistance to the antistaphylococcal β -lactam antibiotics in the health care setting, it is not difficult to appreciate how it emerged as a predominant pathogen in the hospital setting over the years, with increasing acuity of illness in the patient populations and increased use of broad-spectrum antimicrobials.

The appearance and rapid spread of CA-MRSA with the clinical impression of more virulent and lethal infections than what had been seen with traditional HA-MRSA strains may be explained by several factors. The *SCCmec* IV genetic element is very widely distributed among *S. aureus* isolates, which may explain its

appearance in multiple settings globally, and these strains appear to have more rapid growth rates than typical HA-MRSA strains, larger numbers of virulence factors, pathogenicity islands, and higher levels of expression of the virulence factors produced. Recently α -type phenol-soluble modulins were described in strains of CA-MRSA, which are produced at very high levels and are potent lysins of neutrophils. High levels of α -toxin production by these strains, which act as pore-forming toxins for multiple cell types, may also contribute to their virulence. The vast majority of CA-MRSA strains also produce the genes for PVL and it functions as a dermonecrotic factor in skin lesions, a potent cell lysis in high concentrations, and a potent inflammatory mediator in lower concentrations. However, there is controversy about the role of PVL as a single predominant virulence factor, because strains of CA-MRSA that have this gene knocked out have demonstrated no difference in pathogenicity in both vertebrate and invertebrate animal models and in human settings when the PVL is not present.

Prevention

Controlling the spread of either HA-, CA- or LA-MRSA, from an infected or colonized person to others in the hospital, family, or community is a key goal of prevention. In the hospital setting, strict adherence to hand hygiene, application of barrier precautions (gloves, gowns, and private rooms) for patients colonized or infected with MRSA, environmental and equipment cleaning, and antimicrobial stewardship are the key preventive strategies. Active surveillance cultures to identify colonized patients and decolonization may be effective in selected settings, but its general application is controversial. In the community setting, practicing hygienic measures including good personal hygiene, consistent hand hygiene, ensuring all draining skin and soft tissue lesions have adequate dressings, not sharing potentially contaminated personal articles, and keeping the household environment hygienic are important. Public health organizations may also contribute to the prevention of CA-MRSA by instituting education programs targeting health care providers and individuals in high-risk groups in the community, and by promoting appropriate antimicrobial use. In sports settings, in addition to the basic hygienic measures mentioned previously, avoidance of sharing of towels and other personal items, showering after every practice or tournament, cleaning of communal showering and bathing areas, and cleaning or laundering of equipment after each use are also important.

Clinical Manifestations

The specific clinical infections associated with MRSA parallel those associated with methicillin-sensitive *S. aureus*. Almost any body site, organ, or appendage may be affected by infections due to *S. aureus*, but there are specific predilections associated with HA- and CA-MRSA. In the hospital or other health care setting, the most commonly encountered sites of infection include pneumonia, line-related infection, surgical site infection, bacteremia, and less often skin and soft tissue infections. In the community setting, the most common sites (> 80%) are skin and soft tissue infections (furuncles, cellulitis, and soft tissue abscesses) and less commonly severely invasive infections such as necrotizing pneumonia, necrotizing fasciitis, multifocal osteomyelitis/septic arthritis, epidural abscess, pelvic septic thrombophlebitis, and bacteremia with toxic shock syndrome. The skin and soft tissue infections often affect young previously healthy patients and are characteristically very painful and pyogenic with an initial black eschar that patients presume was a "spider bite" as the initiating process.

Diagnosis

The diagnosis of MRSA infections is based on the clinical presentation and the isolation of the causative organism from purulent discharge, sputum, or urine or from specimens obtained from normally sterile body fluids (joint fluid, abscess or tissue aspirates, blood). The organism appears on Gram stain as a Gram-positive organism in clusters and is usually seen in association with neutrophils and may be either intracellular or extracellular. The organism is very hardy and grows readily on typical media in the microbiology laboratory within 24 to 48 hours. Some laboratories are using

rapid agglutination tests to detect the PBP2a protein or polymerase chain reaction (PCR)–based techniques to provide same-day or next-day identification. In settings where no cultures have been obtained or in the setting of toxic shock syndrome where cultures are often negative, the diagnosis may be difficult and only suspected based on a typical clinical presentation.

Treatment

MRSA strains harbor resistance to the β -lactam antimicrobials, including oxacillin, dicloxacillin, cloxacillin², nafcillin, methicillin², and first-, second-, and third-generation cephalosporins. The new advanced-generation cephalosporin antimicrobial ceftaroline (Teflaro) has activity against MRSA strains. The majority of HA-MRSA strains are resistant to macrolides, clindamycin (Cleocin), aminoglycosides, and quinolones (with the exception of delafloxacin [Baxdela]) and are variably resistant to tetracycline and trimethoprim-sulfamethoxazole (Bactrim)¹, depending on local epidemiologic patterns. They are sensitive to vancomycin (Vancocin) and the lipoglycopeptides such as dalbavancin (Dalvance), telavancin (Vibativ) and oritavancin (Orbactiv), and usually sensitive to fusidic acid², rifampin (Rifadin)¹, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro) and daptomycin (Cubicin). For hospitalized patients where *S. aureus* is considered a possible etiology of any major infectious syndrome, it should be considered as methicillin-resistant until proven otherwise and empiric choices of vancomycin or

lipoglycopeptides such as dalbavancin (Dalvance), telavancin (Vibativ) or oritavancin (Orbactiv), linezolid (Zyvox) or tedizolid (Sivextro), daptomycin (Cubicin) or ceftaroline (Teflaro) considered as appropriate to the presenting syndrome. CA-MRSA strains are resistant to macrolides and often quinolones (with the exception of delafloxacin [Baxdela]) but usually are sensitive to aminoglycosides such as gentamicin (Garamycin), clindamycin, and trimethoprim-sulfamethoxazole (Bactrim)¹, but the resistance patterns vary depending on local resistance patterns. In addition, these strains are sensitive to vancomycin (Vancocin) and the lipoglycopeptides, fusidic acid², rifampin (Rifadin)¹, linezolid (Zyvox), daptomycin (Cubicin) and ceftaroline (Teflaro). LA-MRSA strains are almost always resistant to tetracyclines, often resistant to quinolones, macrolides, clindamycin and variably resistant to aminoglycosides and trimethoprim-sulfamethoxazole. In addition, these strains are sensitive to vancomycin (Vancocin) and the lipoglycopeptides, fusidic acid², rifampin (Rifadin)¹, the oxazolidinones linezolid (Zyvox) and tedizolid (Sivextro), daptomycin (Cubicin) and ceftaroline (Teflaro). Treatment guidelines for MRSA with a focus on the ambulatory setting have been published in Canada, the United Kingdom, and the United States and provide both empiric choices for common infectious presentations of unknown etiology and definitive treatment once an etiology of MRSA is known. The treatment options for both empiric and definitive use where MRSA is considered or proven are presented in [Tables 3 through 6](#) and represent a constellation of the various guidelines that have been published.²

TABLE 4 Principles of Empiric Treatment of Non–Life-Threatening Skin and Soft Tissue Infections Other Than Minor Skin Infections Where the Etiology Is Unknown but May Include MRSA as a Possibility

Recommendations

- Antibiotic choice should be based on the severity of illness at presentation, clinical judgment, and regional susceptibility patterns of strains
- Empiric therapy for CA-MRSA and β -hemolytic streptococci is recommended*

*The IDSA guideline suggests to differentiate purulent and nonpurulent cellulitis and reserve empiric therapy for β -hemolytic streptococci only in nonpurulent cellulitis but acknowledges it is an area of controversy. The UK and Canadian guidelines explicitly recommend coverage for β -hemolytic streptococci and do not differentiate cellulitis into different types.

Abbreviation: IDSA = Infectious Diseases Society of America.

TABLE 5 Principles of Empiric Treatment of Life-Threatening Infections Where the Etiology Is Unknown but May Include MRSA as a Possibility

Recommendations

- Include MRSA coverage, regardless of prevalence rates of CA-MRSA in the community
- Include an agent effective against MSSA until susceptibility results become available

TABLE 6 Guidelines for the Management of MRSA Infections

CLINICAL DISEASE	KEY FEATURES	MANAGEMENT PRINCIPLES	ANTIMICROBIAL CHOICES AND COMMENTS [§]
Skin and Soft Tissue Infection (SSTI)			
Localized lesion	Infected scratches and minor wounds Insect bites Furuncles Small abscesses Absence of systemic illness	Culture selectively* No antibiotic therapy recommended <i>Exceptions: multiple sites of infection, evidence of progression, systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage: antimicrobial therapy is recommended in addition to local measures</i> Cover draining lesions Emphasize personal hygiene Close follow-up Return if worsening	Generally not indicated, though some evidence exists for treatment with clindamycin PO or trimethoprim-sulfamethoxazole (Bactrim) ¹ PO, in conjunction with incision and drainage for small simple abscesses Topical antibacterial (e.g., mupirocin [Bactroban] or fusidic ointment ²) therapy may be considered Systemic antimicrobial therapy indicated if one or more of the following: multiple sites of infection, evidence of progression, systemic symptoms and signs, presence of comorbidities, extremes of age, immunosuppression, septic phlebitis, or difficult site for incision and drainage

¹Not FDA approved for this indication. Dosing has varied in published reports and specific dosing guidelines are not available.

²Not available in the United States.

³Exceeds dosage recommended by the manufacturer.

*Patients with risk factors, as a part of an outbreak investigation, patients with slowly responding or recurrent lesions.

[†]The IDSA guideline suggests to differentiate purulent and nonpurulent cellulitis and reserve empiric therapy for β -hemolytic streptococci only in nonpurulent cellulitis but acknowledges it is an area of controversy. The UK and Canadian guidelines explicitly recommend empiric coverage for β -hemolytic streptococci and do not differentiate cellulitis into different types. A recent randomized controlled trial in the United States found no significant difference in efficacy between clindamycin and trimethoprim-sulfamethoxazole when used for treatment of uncomplicated skin and soft tissue infections, which were thought to be secondary to either β -hemolytic streptococci or *S. aureus*. Another recent placebo controlled trial in the United States found that clindamycin or trimethoprim-sulfamethoxazole in conjunction with incision and drainage improved outcomes in patients with simple small abscesses (less than 5 cm) compared to incision and drainage alone.

[§]Choice of antimicrobial therapy depends on local susceptibility patterns.

[‡]Not recommended for pediatric patients under 8 years of age or in pregnancy.

Abbreviations: ICU = intensive care unit; IVIG = intravenous immunoglobulin; MRSA = methicillin-resistant *Staphylococcus aureus*; TMP-SMX = trimethoprim-sulfamethoxazole.

MUMPS

Method of

Kristen Rundell, MS, MD

CURRENT DIAGNOSIS

- Parotitis (swelling of the parotid salivary glands): unilateral or bilateral
- Fever
- Headache
- Malaise
- Myalgias
- Anorexia
- Increased serum amylase

CURRENT THERAPY

- Supportive care
- Warm or cold packs on the parotid
- Analgesics and/or antipyretics (such as acetaminophen [Tylenol] or ibuprofen [Motrin])
- IV fluids or hospitalization for cases of pancreatitis, meningitis, or severe orchitis

Epidemiology

Mumps is an extremely contagious, self-limiting virus that had disease rates of 99% until the vaccine was introduced in 1967. Since that time, the yearly disease rate is less than 1 percent. For the United States and Finland, mumps is almost eradicated. For the rest of the world, mumps is still endemic as a result of a vaccination rate of only 61%.

Pathophysiology

Mumps is a single-stranded RNA virus and a member of the *Paramyxovirus* genus. It is transmitted through respiratory secretions, saliva, and contact with contaminated fomites.

Prevention

With the high rate of transmission and no antiviral therapy, prevention for mumps relies on community immunity as a result of high vaccine rates. There are two formulations of the mumps vaccine currently available in the United States: the measles-mumps-rubella vaccine (MMR) and the measles-mumps-rubella-varicella vaccine (MMRV, ProQuad). The dosing schedule for children calls for the first dose at age greater than 12 months to 15 months, and the second dose for children greater than 4 years to 6 years of age. For infants aged 6 through 11 months who are traveling internationally, a single MMR vaccine is recommended. These children should be revaccinated with 2 doses of MMR vaccine with the first dose at ages 12 months to 15 months and the second dose at ages 4 years to 6 years. During an epidemic, a single dose for adults born before 1957 is recommended and may be required by some health care professionals. The first dose gives approximately 80% immunity. Persons receiving both doses may still get the mumps virus if there is outbreak or if they travel to an endemic area. To avoid exposure or contraction of the disease during travel, it is suggested that travelers wash hands frequently and use alcohol-based sanitizers to decrease the contraction or spread of disease.

The vaccine is contraindicated for patients who are pregnant or planning to conceive in the 28 days after vaccination. Vaccine administration is also contraindicated for those who have a severe anaphylactic reaction to the vaccine or one of

the components, and those individuals who are severely immunocompromised.

Clinical Manifestations

The incubation period for the mumps virus is 16 to 18 days. At the onset of the illness, patients may develop acute viral infection symptoms of fever, headache, and malaise. The parotitis, swelling of the parotid gland, is the diagnostic hallmark of the mumps virus. This is caused by the infection and inflammation of the parotid ductal epithelium. The swelling may last up to 10 days. Close to 30% of persons may not have this symptom and may be only mildly symptomatic.

Diagnosis

Diagnosis is made by the history and the constellation of symptoms and physical findings. It is difficult to use IgM to determine active infection, because the response may be short in duration, delayed, or even absent. PCR testing is available and requires early sampling.

Differential Diagnosis

Viral infections such as parainfluenza (also in the paramyxovirus genus) coxsackievirus, influenza A, Epstein-Barr, adenovirus, HIV, and cytomegalovirus may present with similar symptoms as mumps. There are also noninfectious etiologies of parotitis, which include salivary stones or tumors, sarcoid, Sjögren's syndrome, and thiazide diuretics.

Therapy (or Treatment)

Treatment for mumps virus is largely supportive. For complicated cases of pancreatitis, meningitis, encephalitis, and orchitis, patient may need to be hospitalized for additional care. The additional care usually includes fever reduction, analgesia, fluid resuscitation, and treatment of secondary bacterial infections.

Monitoring

For persons with active mumps, it is suggested that they be isolated from school or work for 5 days after the onset of symptoms. Shedding of virus usually occurs 4 days prior to the onset of symptoms. For this reason, it is difficult to slow down outbreaks of the disease. The last outbreak in the United States was in 2010.

Complications

Complications from mumps are rare. In children, pancreatitis and hearing loss are the sensorineural complications most often diagnosed. For adolescents and adults the complications are more common and usually more severe. These include aseptic meningitis; orchitis in males, which rarely leads to sterility; oophoritis in females; pancreatitis; and arthritis. Even more uncommon are Guillain-Barré/ascending polyradiculitis, transverse myelitis, facial palsy, interstitial nephritis, and myocardial involvement.

Mumps in pregnancy has been associated with increased fetal loss. There are no known teratogenic effects.

NECROTIZING SKIN AND SOFT-TISSUE INFECTIONS

Method of

Kalyanakrishnan Ramakrishnan, MD

CURRENT DIAGNOSIS

- Physical examination of the affected area may detect:
 - Exquisite pain and tenderness out of proportion to local signs of infection.
 - Cutaneous anesthesia, firm woody subcutaneous tissue, edema, and tenderness extending outside involved skin margins, hemorrhage or bullae of the overlying skin, and soft tissue crepitus.
- Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is useful in diagnosing necrotizing fasciitis. Imaging (computed tomography [CT] or magnetic resonance imaging [MRI] in adults; ultrasonography [US] in children) is usually confirmatory. Imaging should not delay surgery if indicated based on suspicion.

CURRENT TREATMENT

- Empiric high-dose intravenous polymicrobial antibiotics and surgical debridement remain the cornerstones of initial management of necrotizing skin and soft-tissue infections. Organism-specific antibiotics continued until resolution of infection and debridement complete (usually 7–14 days).

Epidemiology

Necrotizing skin and soft tissue infections are rare with an estimated annual incidence of 1000 cases in the United States. These infections may be polymicrobial or monomicrobial. Polymicrobial infections are more common (70%–80%) and generally caused by synergistic activity of aerobes and anaerobes originating from the bowel or genitourinary tracts. They are more prevalent among older and immunocompromised patients, individuals with significant comorbidities, and those with underlying abdominal pathology. These infections typically involve the trunk and perineal regions, and follow penetrating abdominal injuries or surgery, genital or perianal sepsis, or decubitus ulcers. They have a more indolent course and thus are easier to diagnose. Monomicrobial infections (20%–30%) frequently follow minor trauma and are usually caused by group A streptococcus (GAS), occasionally with methicillin-resistant *Staphylococcus aureus* (MRSA), or by clostridia. They are more aggressive, involve the extremities and occur more often in younger healthy individuals. Type 3 infections follow exposure to contaminated fresh or warm seawater or ingestion of raw seafood; organisms responsible include *Aeromonas hydrophila*, *Vibria vulnificus*, *Mycobacterium marinum*, *Pasteurella multocida*, *Haemophilus* and *Klebsiella* species. Type 4 (fungal) infections generally follow burns or major trauma. Both types 3 and 4 infections are rare, progress rapidly, and have a high mortality rate, especially in immune-suppressed patients.

Risk Factors

Cardiopulmonary disease, debility, diabetes mellitus, hepatorenal disease, immunocompromised states, obesity, arteriovenous/lymphatic insufficiency, and senescence all increase risk of skin and soft tissue infections by reducing tissue vascularity and oxygenation, increasing fluid stasis and risk of trauma, and decreasing ability to counter infections. Diabetes mellitus and hepatic cirrhosis favor polymicrobial infections due to staphylococcus and streptococcus

species, anaerobes, and gram-negative bacilli. Neutropenia, intravenous drug use, and hot tub exposure promote pseudomonas infection. Human and animal bites cause infections with oral flora, staphylococci, *Pasteurella multocida*, and anaerobes. Poor sanitation and soil contamination propagate clostridial infections. Post-operative infections typically follow wound contamination with microorganisms from the patient during surgery.

Pathophysiology

Necrotizing skin and soft tissue infections advance rapidly, breaking down and traversing anatomic barriers, initiating extensive destruction of the subcutaneous tissue, fascia, and muscle and damaging the neurovascular bundle, thrombosing the subcutaneous vessels, and causing overlying skin necrosis. Most infections follow a rift in the protective cutaneous barrier due to trauma or increased tissue tension. Necrotizing fasciitis may also result from blunt injuries (bruise, muscle strain) and, occasionally vascular or lymphatic spread from a distant focus of infection. Various toxins expressed by the organisms (GAS and clostridia) display local and systemic effects (platelet aggregation and thrombosis, decreasing phagocytosis, neutrophil function and vascular tone, myocardial inhibition) triggering the systemic inflammatory response syndrome (SIRS) and multiple organ failure.

Prevention

Preserving cutaneous integrity prevents infection. Abrasions and lacerations should be washed with antibacterial solutions, foreign bodies should be removed, and dead/devitalized tissue excised to minimize infection risk. Preoperative skin cleansing with chlorhexidine/alcohol (Hibiclens) or povidone iodine diminishes rates of superficial and deep incisional infections. Intranasal 2% mupirocin ointment (Bactroban) twice daily with chlorhexidine total body wash daily for 5 days in nasal carriers of staphylococcus reduces hospital-acquired deep surgical-site infections, as does administering antibiotics (aminopenicillins, a second- or third-generation cephalosporin) 60 minutes before incision, sterile surgical technique, minimal tissue handling, and minimally invasive surgery.

Clinical Manifestations

Features of inflammation (redness, warmth, swelling, pain) and loss of function characterize necrotizing skin and soft tissue infections. Altered mental status, anorexia, diaphoresis, fatigue, fever, hypotension, nausea, and tachycardia suggest systemic spread. The extremities, trunk, or anogenital regions are usually involved. Induration denotes cutaneous involvement. Patients with necrotizing fasciitis have severe pain disproportionate to the physical findings and rapid progression of infection. Examination reveals cutaneous anesthesia, firm and woody subcutaneous tissue, edema and tenderness extending beyond involved skin, hemorrhage or bullae of the overlying skin, and crepitus (indicates soft tissue gas; seen especially with gas-forming organisms such as clostridia). Tense edema and bullae have high specificity and positive predictive value for necrotizing fasciitis. Fournier gangrene is a form of polymicrobial necrotizing soft-tissue infection involving the loose groin and genital skin, where subcutaneous vessel thrombosis causes extensive tissue loss.

Diagnosis

Diagnosis is based on a strong clinical suspicion followed by confirmatory laboratory and imaging studies (if time permits), and surgery. Leukocytosis with a marked left shift, elevated C-reactive protein, elevated serum creatinine and creatine phosphokinase (denotes muscle injury), and low serum bicarbonate (suggests acidosis) signify severe infection. The LRINEC score uses six different laboratory parameters (hemoglobin, white blood cell count, C-reactive protein, glucose, creatinine, sodium) to predict risk of necrotizing fasciitis (score ≥ 6 suggestive, ≥ 8 strongly predictive). White blood cell count ($< 15,000 \text{ mm}^3$) and serum sodium ($> 135 \text{ mmol/L}$) levels alone are useful in ruling out necrotizing fasciitis (99% negative predictive value). Gram stains and cultures of aspirates

or tissue biopsies, and blood cultures are valuable for detecting the infecting organisms and systemic spread; contamination may yield false-positive results. Biopsy or debridement typically demonstrates swollen gray soft tissue with undermining of the overlying skin, a brownish and odorous exudate and non-contractile muscle. Imaging (plain x-rays, ultrasonography [US], computed tomography [CT], magnetic resonance imaging [MRI]) may show edema or thickening, fluid collections or free air in the soft tissues. US, CT and MRI are highly sensitive (MRI highest) in detecting deep soft tissue involvement characteristic of necrotizing fasciitis; specificity is lower. US is sufficient in children, whose tissues are thin enough to allow adequate evaluation on imaging. Imaging should not delay debridement, if considered necessary.

Therapy

Patients with necrotizing skin and soft-tissue infections typically require in-hospital management, because many have underlying unstable comorbid illnesses, systemic sepsis, severe dehydration and acidosis, muscle breakdown, and organ dysfunction. Initial resuscitation may require airway and oxygen support, large-volume rehydration, and invasive monitoring. High-dose intravenous (IV) broad-spectrum antibiotics effective against the usually infecting polymicrobial spectrum of pathogens are commenced, followed by early and aggressive debridement of all necrotic tissue. IV antibiotics are maintained until the patient is afebrile for 48 to 72 hours and tolerates oral intake, debridement is completed and culture results are available. For polymicrobial necrotizing fasciitis acceptable antimicrobial choices include vancomycin plus piperacillin/tazobactam (Zosyn), a carbapenem (meropenem [Merrem], ertapenem [Invanz] or imipenem-cilastatin [Primaxin]), or cefotaxime (Claforan) with metronidazole (Flagyl) or clindamycin (Cleocin). Streptococcal and clostridial infections are treated with penicillin G and clindamycin. Antibiotic options in methicillin-susceptible *S. aureus* infections include nafcillin oxacillin or cefazolin. Options for methicillin-resistant *S. aureus* (MRSA) infections and in penicillin-allergic patients include vancomycin, daptomycin (Cubicin), or linezolid (Zyvox). Antibiotic doses are modified in children. Recommended duration is 7 to 14 days; longer as needed. Doxycycline combined with ciprofloxacin (Cipro) treats *Vibria vulnificus* infection. Ceftriaxone (Rocephin) or cefotaxime combined with doxycycline is useful in aeromonas infections. Doxycycline is contraindicated in children (<8 years), as is ciprofloxacin (<17 years), unless the infection is considered life-threatening. Fungal infections respond well to fluconazole (Diflucan), voriconazole (Vfend) or amphotericin B; the antifungals usually continued for 2 weeks after resolution of symptoms. Debridement/drainage is repeated until all diseased tissue or collections are eliminated and healing begins. Wound vacuum dressings help remove drainage and encourage formation of healing granulation tissue. The tissue defect heals by secondary intention or may require skin grafting or flap closure. Hyperbaric oxygen (3–4 daily treatments at 2–3 atmosphere pressure for 30–90 minutes each) is useful, especially in clostridium-related synergistic infections. Adding intravenous immunoglobulin¹ 0.5–2 g/kg daily for 3 days has shown some success, and is an option in critically ill hemodynamically unstable patients not responding to conventional measures, especially in those with streptococcal toxic shock syndrome. Fournier gangrene is managed along the same principles as above.

Monitoring

Patients in shock or with acute respiratory distress syndrome, SIRS, or multi-organ failure are best managed in an intensive care unit and often require invasive monitoring, cardiorespiratory and renal support, and occasionally, endotracheal intubation.

Complications

Significant disfigurement, limb loss, respiratory and renal failure, and mortality (14%–50%) may eventuate despite timely and

appropriate treatment; the mortality influenced by age, extent of infection, degree of biochemical/acid-base imbalance, presence of comorbidities, and treatment delay.

OSTEOMYELITIS

Method of

George D. Harris, MD, MS

CURRENT DIAGNOSIS (FIGURE 1)

- A bone biopsy remains the gold standard when diagnosing osteomyelitis.
- All patients should have blood cultures performed.
- No one imaging modality is routinely recommended to diagnose osteomyelitis.
- Plain film radiography should always be the initial study and can be diagnostic if positive.
- Magnetic resonance imaging (MRI) can detect acute osteomyelitis as early as 3 days.

CURRENT THERAPY

- The most important factor in any treatment is identification of the organism.
- The optimal duration of antibiotic therapy remains undefined, with most authorities recommending treatment for about 6 weeks.
- Hematogenous osteomyelitis is usually monomicrobial, whereas contiguous infections are usually polymicrobial.

Osteomyelitis is an inflammation of the bone as a result of a bacterial infection, resulting in acute or chronic inflammation caused mainly by a bacterial infection. It can primarily occur by hematogenous spread, contiguous spread to the bone from adjacent tissues, or direct inoculation usually from trauma or surgery. Patients usually complain of pain, swelling, and tenderness over the affected area of bone.

Osteomyelitis has changed over the years from a primarily hematogenous disease with high mortality to one of high morbidity as a result of infection from contiguous or direct inoculation, especially in those with diabetes mellitus and/or peripheral vascular disease.

Contiguous or local extension may occur from spread from adjacent structures or direct implantation of organisms as seen in cases of trauma, placement of internal fixation devices for fracture repair, or other surgical procedures. Direct inoculation osteomyelitis tends to involve multiple organisms and results in more clinical localized manifestations than infections from

¹Not FDA approved for this indication.

or tissue biopsies, and blood cultures are valuable for detecting the infecting organisms and systemic spread; contamination may yield false-positive results. Biopsy or debridement typically demonstrates swollen gray soft tissue with undermining of the overlying skin, a brownish and odorous exudate and non-contractile muscle. Imaging (plain x-rays, ultrasonography [US], computed tomography [CT], magnetic resonance imaging [MRI]) may show edema or thickening, fluid collections or free air in the soft tissues. US, CT and MRI are highly sensitive (MRI highest) in detecting deep soft tissue involvement characteristic of necrotizing fasciitis; specificity is lower. US is sufficient in children, whose tissues are thin enough to allow adequate evaluation on imaging. Imaging should not delay debridement, if considered necessary.

Therapy

Patients with necrotizing skin and soft-tissue infections typically require in-hospital management, because many have underlying unstable comorbid illnesses, systemic sepsis, severe dehydration and acidosis, muscle breakdown, and organ dysfunction. Initial resuscitation may require airway and oxygen support, large-volume rehydration, and invasive monitoring. High-dose intravenous (IV) broad-spectrum antibiotics effective against the usually infecting polymicrobial spectrum of pathogens are commenced, followed by early and aggressive debridement of all necrotic tissue. IV antibiotics are maintained until the patient is afebrile for 48 to 72 hours and tolerates oral intake, debridement is completed and culture results are available. For polymicrobial necrotizing fasciitis acceptable antimicrobial choices include vancomycin plus piperacillin/tazobactam (Zosyn), a carbapenem (meropenem [Merrem], ertapenem [Invanz] or imipenem-cilastatin [Primaxin]), or cefotaxime (Claforan) with metronidazole (Flagyl) or clindamycin (Cleocin). Streptococcal and clostridial infections are treated with penicillin G and clindamycin. Antibiotic options in methicillin-susceptible *S. aureus* infections include nafcillin oxacillin or cefazolin. Options for methicillin-resistant *S. aureus* (MRSA) infections and in penicillin-allergic patients include vancomycin, daptomycin (Cubicin), or linezolid (Zyvox). Antibiotic doses are modified in children. Recommended duration is 7 to 14 days; longer as needed. Doxycycline combined with ciprofloxacin (Cipro) treats *Vibria vulnificus* infection. Ceftriaxone (Rocephin) or cefotaxime combined with doxycycline is useful in aeromonas infections. Doxycycline is contraindicated in children (<8 years), as is ciprofloxacin (<17 years), unless the infection is considered life-threatening. Fungal infections respond well to fluconazole (Diflucan), voriconazole (Vfend) or amphotericin B; the antifungals usually continued for 2 weeks after resolution of symptoms. Debridement/drainage is repeated until all diseased tissue or collections are eliminated and healing begins. Wound vacuum dressings help remove drainage and encourage formation of healing granulation tissue. The tissue defect heals by secondary intention or may require skin grafting or flap closure. Hyperbaric oxygen (3–4 daily treatments at 2–3 atmosphere pressure for 30–90 minutes each) is useful, especially in clostridium-related synergistic infections. Adding intravenous immunoglobulin¹ 0.5–2 g/kg daily for 3 days has shown some success, and is an option in critically ill hemodynamically unstable patients not responding to conventional measures, especially in those with streptococcal toxic shock syndrome. Fournier gangrene is managed along the same principles as above.

Monitoring

Patients in shock or with acute respiratory distress syndrome, SIRS, or multi-organ failure are best managed in an intensive care unit and often require invasive monitoring, cardiorespiratory and renal support, and occasionally, endotracheal intubation.

Complications

Significant disfigurement, limb loss, respiratory and renal failure, and mortality (14%–50%) may eventuate despite timely and

appropriate treatment; the mortality influenced by age, extent of infection, degree of biochemical/acid-base imbalance, presence of comorbidities, and treatment delay.

OSTEOMYELITIS

Method of

George D. Harris, MD, MS

CURRENT DIAGNOSIS (FIGURE 1)

- A bone biopsy remains the gold standard when diagnosing osteomyelitis.
- All patients should have blood cultures performed.
- No one imaging modality is routinely recommended to diagnose osteomyelitis.
- Plain film radiography should always be the initial study and can be diagnostic if positive.
- Magnetic resonance imaging (MRI) can detect acute osteomyelitis as early as 3 days.

CURRENT THERAPY

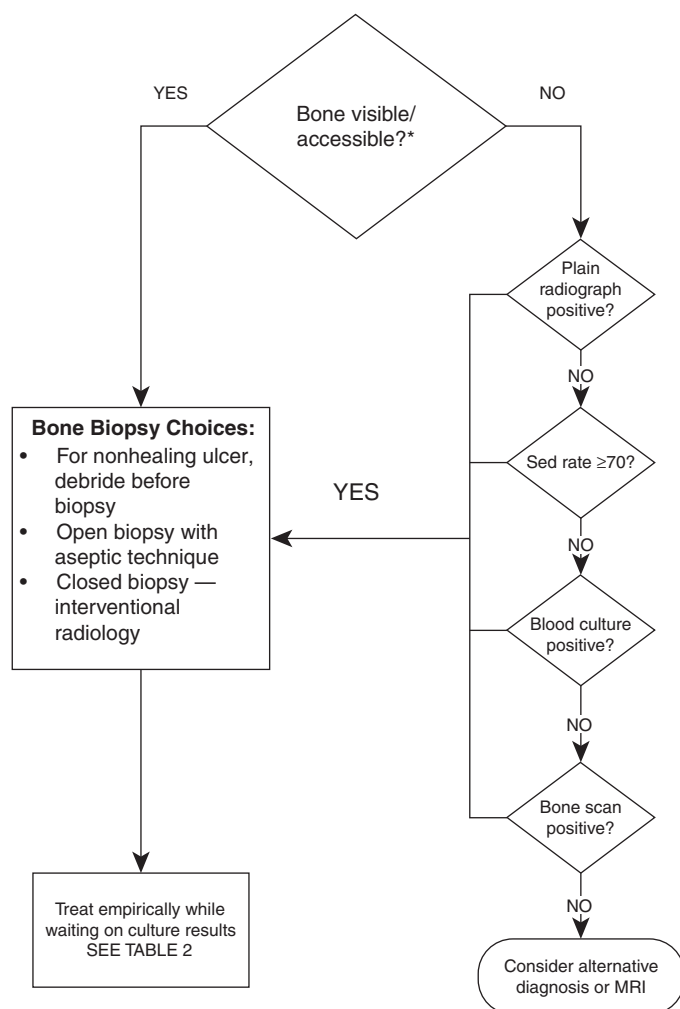

- The most important factor in any treatment is identification of the organism.
- The optimal duration of antibiotic therapy remains undefined, with most authorities recommending treatment for about 6 weeks.
- Hematogenous osteomyelitis is usually monomicrobial, whereas contiguous infections are usually polymicrobial.

Osteomyelitis is an inflammation of the bone as a result of a bacterial infection, resulting in acute or chronic inflammation caused mainly by a bacterial infection. It can primarily occur by hematogenous spread, contiguous spread to the bone from adjacent tissues, or direct inoculation usually from trauma or surgery. Patients usually complain of pain, swelling, and tenderness over the affected area of bone.

Osteomyelitis has changed over the years from a primarily hematogenous disease with high mortality to one of high morbidity as a result of infection from contiguous or direct inoculation, especially in those with diabetes mellitus and/or peripheral vascular disease.

Contiguous or local extension may occur from spread from adjacent structures or direct implantation of organisms as seen in cases of trauma, placement of internal fixation devices for fracture repair, or other surgical procedures. Direct inoculation osteomyelitis tends to involve multiple organisms and results in more clinical localized manifestations than infections from

¹Not FDA approved for this indication.

* Some advocate doing plain radiograph, CBC, sed rate, and blood cultures as part of the initial evaluation of osteomyelitis

Figure 1 Algorithm for treatment of suspected osteomyelitis. (Courtesy Edward T. Bope.)

hematogenous spread, where the osteomyelitis is usually monomicrobial. Hematogenous osteomyelitis most commonly involves the vertebrae, with the lumbar spine most commonly affected, and is also more common in infants and children, involving metaphysis of their long bones.

There are several methods used to classify osteomyelitis, separating the illness into acute or chronic types; into hematogenous or contiguous types; and according to the mode of transmission—local extension from adjacent structures or direct implantation of organisms as seen in cases of trauma or surgical procedures.

The Cierny-Mader system assigns the patient to one of several groups based on the anatomy of the infection and health of the host, risk factors such as patients with peripheral arterial obstructive disease or diabetes mellitus and tobacco use. Patients are further stratified according to systemic and local factors that may influence disease progression or healing, such as diabetes and the extremes of age. In patients with diabetes, osteomyelitis is most commonly caused by overlying lower limb cellulitis. In the nondiabetic adult patient, vertebral osteomyelitis is most common.

The Cierny-Mader classification allows the clinician to use tested treatment protocols, including chemotherapy, surgery, and adjunctive therapies, that are most effective for a specific class of disease and for the host status. The Cierny-Mader system divides the

TABLE 1 Cierny-Mader Classification System

FEATURE	EXAMPLES
Anatomic type	Stage 1: Medullary osteomyelitis Stage 2: Superficial osteomyelitis Stage 3: Localized osteomyelitis Stage 4: Diffuse osteomyelitis

Factors affecting host status	
Systemic	Malnutrition Renal and hepatic failure Diabetes mellitus Chronic hypoxia Immune disease Malignancy Extremes of age Immunosuppression
Local	Chronic lymphedema Venous stasis Major vessel compromise Arteritis Extensive scarring Radiation fibrosis Small-vessel disease Neuropathy Tobacco use

patients into four anatomic groups. Stage 1, or medullary osteomyelitis, is confined to the endosteum of the bone and is often hematogenous. Stage 2, or superficial osteomyelitis, is localized to the surface of the bone. This is a true contiguous lesion. Stage 3, or localized osteomyelitis, involves cortical sequestration or cavitation, or both, and is a full-thickness lesion that extends into the medullary region. Stage 4, or diffuse osteomyelitis, involves the hard and soft tissues (“through and through”), and it requires surgical debridement of the affected bone to remove all the infected tissue.

For treatment to be successful, the patient must be physiologically able to heal any wounds, defend against contamination or infection, and tolerate the stress of treatment. The hosts are classified as A, B, or C, depending on the ability to resist infections. Those with good immunity are classified as an A host, whereas a B host is compromised locally (B_L) or systemically (B_S); Table 1 shows the physiologic classifications. The final class assigns a C rating to patients whose treatment is more detrimental than the disability from the disease. These patients may require suppressive or no treatment. The clinical stages are adjusted during the course of therapy as conditions change, allowing adjustment of the treatment protocol to optimize therapy.

A much simpler system described by Waldvogel classifies the patient by duration (i.e., acute or chronic) and the mechanism of inoculation (i.e., hematogenous or contiguous). Contiguous infections are further classified as those with or without vascular insufficiency. However, this classification does not provide guidance for specific surgical or antibiotic therapy.

Epidemiology

Acute hematogenous osteomyelitis is usually seen in male children of lower socioeconomic class before the age of 2 years or between 8 and 12 years. There may be some genetic influences. Aboriginal children in Western Australia are known to suffer from acute hematogenous osteomyelitis at a rate nearly four times that of Western European children living in the same neighborhood. An acute infection will progress to chronic osteomyelitis if it is not treated.

Chronic osteomyelitis is usually the result of direct inoculation (e.g., trauma, surgery). Its epidemiology is less clearly described, except in diabetic foot infections.

Kremers et al., in a population-based study, described trends in the incidence of osteomyelitis over a four-decade period from 1969 to 2009. The study demonstrated that the incidence of osteomyelitis has increased over time and is generally higher in males than in females, and that the incidence rates remained relatively stable among children and young adults (< 50 years old). However, the incidence has almost tripled among the elderly, driven significantly by an increase in diabetes-related cases.

Because chronic infection can persist for life, it is important to have early identification and treatment to ensure the best possible outcome.

Pathogenesis

The presence of bacteria in an open wound is not sufficient to cause infection. It is the compromised blood supply of traumatized tissue leading to necrosis and subsequent bacterial adherence that promotes the infection. Trauma can delay the inflammatory response to bacteria, depress cell-mediated immunity, and impair chemotaxis, superoxide production, and the microbial killing capacity of polymorphonuclear neutrophils (PMNs). Osteomyelitis usually involves the metaphysis, which is well vascularized and has significant bone growth.

In acute osteomyelitis, signs or symptoms are usually abrupt. Local infection is characterized by edema, vascular congestion, and small-vessel thrombosis. This leads to increased pressure within the intramedullary canal, allowing extravasation through the Havers and Volkmann canals to the periosteum. In children, the periosteum is usually more flexible and easier to detect radiographically; in adults, the bone matrix is more firmly attached to the periosteum. Untreated, the suppurative infection can reach adjacent soft tissue, leading to a cellulitis. The presence of a Brodie or intraosseous abscess without extravasation into surrounding tissue is classified as subacute pyogenic osteomyelitis. The resulting infection can lead to sequestration involving large areas of bone destruction and dead bone, with reactive bone formation leading ultimately to chronic osteomyelitis.

Chronic osteomyelitis is usually polymicrobial and is characterized by the presence of necrotic bone, new bone growth, and exudation of polymorphonuclear leukocytes, plasma cells, and other infection-fighting cells. The involucrum (i.e., layer of reactive competent bone that covers dead bone) is often dotted with tracts that allow pus to pass into surrounding tissue or to form a sinus tract to the skin surface. These sinus tracts are often contaminated with numerous organisms that do not reflect those found with direct sampling. This repetitive process of bone loss and growth and the involucrum explains why chronic osteomyelitis is difficult to eradicate with antibiotics alone. The antibiotics cannot penetrate avascular areas.

Etiology

Children

In children of all ages, the most common bacterial pathogen is *Staphylococcus aureus*, followed by *Streptococcus pneumoniae* and *Kingella kingae*. However, age and chronic illness allow other organisms to flourish; *Salmonella* and pneumococcal disease (*S. pneumoniae*) are common in patients with sickle cell disease. *Pasteurella multocida*, *Streptococcus* species, and anaerobes often are identified after animal or human bites. In children, most cases arise hematogenously and are characteristically seen in the metaphysis of long bones (i.e., femur, tibia, and humerus), accounting for 68% of childhood infections.

The exact mechanism is unclear, but it is thought that the extensive branching of the nutrient-rich arteries at the metaphyses of the long bones leads to sluggish blood flow and ultimate bacterial seeding. Possible routes include the formation of small hematomas in the metaphysis, allowing microbial seeding after transient bacteremia; penetrating injuries or surgical manipulation, causing direct

inoculation of bacteria into bone; and local invasion from a contiguous focus of infection.

Adults

Most infections in adults arise by direct inoculation from sources such as trauma, prosthetic joints, open fractures, and diabetic foot infections. The most common organisms remain *Staphylococcus aureus*, coagulase-negative staphylococci, and aerobic gram-negative bacilli.

Other organisms to consider include streptococci, enterococci, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Serratia marcescens*. Most contiguous, related infections are polymicrobial.

Clinical Manifestations

The severity of the signs and symptoms depends on the location of the infection, the patient's age, and any comorbidities. Patients may experience many, few, or no symptoms. Classically, acute osteomyelitis presents with marked pain, erythema, tenderness, and swelling. Fever and leukocytosis are also common.

The probe-to-bone test with a sterile blunt metal tool should be included in the initial assessment of all patients with diabetes with infected pedal ulcers. The probe-to-bone test may be used in the emergency department, the inpatient hospital setting, or the outpatient primary care clinic as a screening test to assess for diabetic foot osteomyelitis. A positive result consists of detection of a hard, gritty surface through the ulcerated skin surface.

The probe-to-bone test along with other diagnostic tests (such as radiographic imaging or bone biopsy) can assist in the therapeutic decision-making process.

Vertebral osteomyelitis can occur either by hematogenous spread, direct inoculation from trauma or spinal surgery, or contiguous spread from adjacent soft tissue infection. Over 50% of cases are due to *S. aureus*. The most common presentation is back or neck pain, with or without fever, with noted local tenderness to percussion over the involved posterior spinous processes.

Vertebral osteomyelitis often causes severe pain, fever, and disability, whereas osteomyelitis of the foot rarely causes pain. An epidural abscess causes pain and neurologic deficits, whereas vertebral osteomyelitis without abscess formation has no neurologic deficits.

Children often present with systemic symptoms (e.g., fever, weight loss, pain). Pseudoparalysis may be the only sign in a newborn, but toddlers often exhibit pain, fever, erythema, edema, or warmth, or they may suddenly stop walking. In contrast, patients with chronic osteomyelitis may exhibit localized signs and symptoms, including nonhealing ulcers, purulence from sinus tracts, soft tissue edema and pain, abscesses, erythema, pain, and fatigue. Generalized signs and symptoms may be seen early in the disease, but they are unlikely in the later or chronic stages.

Leukocytosis is less common with chronic osteomyelitis, but there is usually an elevated erythrocyte sedimentation rate and C-reactive protein.

Blood cultures are most likely positive with hematogenous infection and with vertebral osteomyelitis.

Magnetic resonance imaging (MRI) is the most sensitive radiographic technique, but the infection is confirmed by biopsy of the infected intervertebral disc space or vertebral bone. The antimicrobial therapy should be withheld until a microbiologic diagnosis is confirmed unless there is neurologic compromise and/or sepsis present; in patients with negative culture results, empiric treatment is warranted based on the most likely organisms to cause infection. Treatment is usually for a minimum duration of 6 weeks, but the duration should be based on the individual patient's circumstances. In 2015, the Infectious Diseases Society of America (IDSA) issued new guidelines on vertebral osteomyelitis, and these should be used for treatment and management.

Diagnosis

Laboratory Tests

A bone biopsy remains the gold standard when diagnosing osteomyelitis. However, there is a high false-negative rate, and the

negative predictive value is close to 65%, mainly owing to the organism's patchy distribution. No specific laboratory test can be recommended. However, if osteomyelitis is suspected based on clinical history and physical findings, plain radiographs of the involved site should be ordered along with laboratory testing (acute-phase reactants, e.g., erythrocyte sedimentation rate [ESR], C-reactive protein [CRP], leukocyte count with a differential count). These labs can strongly suggest (positive predictive value of 100%) osteomyelitis if the ESR value is greater than 70 mm/h in the absence of an inflamed ulcer. However, these tests lack specificity, and it may take several days to demonstrate significantly elevated levels. Bone biopsy (open being preferred over a percutaneous approach) should be performed for pathogen identification and in cases when the diagnosis of osteomyelitis is uncertain but suspected. All patients should have blood cultures performed. A positive blood culture with a suspicious physical finding can suggest a bone infection, but only one half of the cases have a positive test result. Blood cultures, like bone biopsies, can be affected by recent antibiotic exposure. However, patients receiving antibiotics prior to the bone biopsy still may have a reasonable microbiologic yield, because areas of infection also have associated bony infarction or ischemia.

Radiology

There is no one imaging modality routinely recommended to diagnose osteomyelitis, so diagnosis often requires more than one technique. Plain film radiography should always be the initial study, and the result can be diagnostic if positive. However, changes (usually along the metaphysis) typically require at least 1 to 2 weeks to be seen radiographically.

Positron emission tomography (PET) is the most specific and sensitive of imaging techniques, but its high cost and lack of availability make it impractical for most clinicians. The best choice for imaging depends on the age of the patient, duration of symptoms, suspected location of infection (if known), and concurrent or previous medical conditions.

Plain radiographs are the most available, least expensive, and easiest to obtain, but they lack sensitivity (43%–75%), and a negative result does not exclude the diagnosis. However, they have reasonable specificity (75%–83%), and a positive finding can confirm the diagnosis or provide clues to alternative pathology, such as a tumor. Bony changes can take between 10 and 21 days to become visible on plain films; however, soft tissue changes can be seen in as little as 3 days. The soft tissue changes are especially important in neonates and children because focal soft tissue swelling around the bony metaphysis may be the first sign of bone involvement.

Radionuclide imaging (i.e., triple-phase bone scan, leukocyte scintigraphy, and PET) is a preferred method of advanced imaging, and it has several advantages compared with other techniques. Young children often complete the examination without sedation, and prosthetic joints do not produce the artifact commonly seen on MRI and computed tomography (CT) scans. Positive results can be seen 24 to 48 hours after onset of symptoms, and a negative examination result effectively rules out osteomyelitis.

The triple-phase bone scan (technetium 99 m diphosphonate) is often the examination of choice (sensitivity of 73%–100%), and it can distinguish between cellulitis and osteomyelitis when complications are absent. However, the sensitivity decreases dramatically when other conditions are present (i.e., trauma, diabetes, or recent surgery), and it has been reported to be as low as 38%. Bone scans usually lack the specificity (25%–90%) of other modalities, fail to provide detailed pictures of complex anatomy, and can be influenced by poor circulation. The examination may take up to 24 hours to complete and often requires the patient to make many trips to the facility. In the early phase, uptake is greatest in areas of acute inflammation. In the next phase, uptake occurs in areas of soft tissue inflammation, and in the late (delayed) phase, uptake remains in the presence of osteomyelitis.

Leukocyte scintigraphy using gallium 67 has a higher specificity (80%–90%) than triple-phase scanning (67%) in the

peripheral skeleton, but it decreases to 25% when looking at the axial skeleton. Leukocyte scintigraphy is the preferred method when evaluating patients with previous joint replacements, diabetes, or trauma.

MRI can detect acute osteomyelitis as early as 3 days. It is nearly as sensitive (82%–100%) and specific (75%–96%) as radionuclide studies. MRI allows tracking of disease progress and response to treatment. MRI can be used to date osteomyelitis. Some patients with osteomyelitis are treated and later develop another episode. The MRI can distinguish whether the second episode is a new infection or a recurrence of the previous infection. It also provides detailed visualization of complex anatomy and critical structures, allowing surgeons to map any planned surgical intervention.

CT is rarely used for osteomyelitis, except when sequestered bone is suspected or for interventional procedures. Sinography can be used to map sinus tracts with fluoroscopy or combined with CT. Ultrasound is sometimes used in children and can be helpful in differentiating acute from chronic infections. It provides guidance during drainage, aspirations, or biopsies of the affected bone, and it is a noninvasive method to monitor soft tissue involvement in chronic illness.

Treatment

The Cierny-Mader classification system provides a straightforward algorithm for treatment. However, surgical debridement of necrotic tissue and proper antimicrobial therapy according to the identification of the causative organism and its susceptibilities remain the most important factors in any treatment.

Antibiotic Therapy

Unlike chronic infections, acute infections require hospitalization for initiation of therapy and supportive care. Serial examinations should be undertaken to assess the success of treatment and monitor for systemic signs or symptoms. Cultures of blood and bone should be obtained to guide therapy. Laboratory studies can be followed, but other than CRP levels, they fail to provide significant data. The CRP value can be expected to decrease 24 to 48 hours after initiation of appropriate antibiotic therapy. A lack of response may indicate inappropriate therapy or an occult abscess, and the physician should reconsider surgery if previously delayed.

The medical literature remains inconclusive about the antibiotic treatment of osteomyelitis, especially when trying to determine the best agents, route, or duration of antibiotic therapy.

Initial treatment should cover for methicillin-resistant (MRSA) and methicillin-sensitive *S. aureus* (MSSA) until cultures are completed with susceptibilities.

Although the optimal duration of antibiotic therapy remains undefined, most authorities recommend treatment for usually at least 6 weeks (Table 2). After the infection is under control, the physician may switch the patient to an oral antibiotic for 3 to 12 months (i.e., a fluoroquinolone with or without rifampin [Rifadin]¹). However, treatment can be as short as 3 weeks for uncomplicated, acute, hematogenous osteomyelitis. Management can include oral preparations after a short parenteral course, provided the drug has high bioavailability and the organism is susceptible. A microbiologic diagnosis (preferably by bone biopsy) is essential so that the choice of antibiotic accounts for the specific organism, the host status, and the least toxic medication for the individual. Hematogenous osteomyelitis is usually monomicrobial, whereas contiguous infections are usually polymicrobial and may include *Pseudomonas* in certain populations. For this population, fluoroquinolones are an excellent choice.

For MSSA, nafcillin (Unipen) or a first- or second-generation cephalosporin, cefazolin, can be implemented. For MRSA, vancomycin (Vancocin) is recommended. For an anaerobic infection, clindamycin (Cleocin) is a good choice.

¹Not FDA approved for this indication.

TABLE 2 Antibiotics for Osteomyelitis

ORGANISM	PREFERRED DRUG	ALTERNATIVE DRUGS
Methicillin-sensitive <i>Staphylococcus aureus</i>	Nafcillin (Unipen) 2 g IV or IM q4h	Cefazolin, oxacillin, vancomycin, clindamycin, Trimethoprim-sulfamethoxazole (Bactrim)* 4 mg/kg of the trimethoprim component twice daily) with rifampin (Rifadin) 600 mg once daily. *
Methicillin-resistant <i>S. aureus</i>	Vancomycin (Vancocin) 30 to 40 mg/kg IV every 24 hours in two or three divided doses; not to exceed 2 g/dose	Trimethoprim-sulfamethoxazole (Bactrim)* 4 mg/kg of the trimethoprim component twice daily) with rifampin (Rifadin) 600 mg once daily.*
<i>Streptococcus pneumoniae</i> , group A β-hemolytic streptococci	Penicillin G (Pfizerpen)* 2 million units IV q4h	Cefazolin, vancomycin, clindamycin
Enterococci, <i>Haemophilus influenzae</i> β-lactamase negative	Cefotaxime (Claforan) 2 g q6h	Trimethoprim-sulfamethoxazole, ceftriaxone
<i>H. influenzae</i> β-lactamase positive, <i>Klebsiella pneumoniae</i>	Ceftriaxone (Rocephin) 2 g q24h	Trimethoprim-sulfamethoxazole, ciprofloxacin, piperacillin (Pipracil), imipenem (Primaxin)
<i>Escherichia coli</i>	Cefazolin (Ancef) 2 g q8h	Ciprofloxacin, ceftriaxone, imipenem
<i>Pseudomonas aeruginosa</i>	Ciprofloxacin (Cipro) 400 mg q8h ³	Piperacillin plus aminoglycoside, aztreonam (Azactam)*
<i>Salmonella</i>	Choose ampicillin, ceftriaxone, imipenem (Primaxin), or ciprofloxacin, depending on sensitivities	
<i>Bacteroides</i> spp.	Clindamycin (Cleocin) 600 mg q6h	Imipenem, metronidazole (Flagyl)
<i>Serratia marcescens</i>	Ceftriaxone (Rocephin) 2 g q24h	Imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin

(Modified from Cohen J, Powderly WG, editors. *Infectious Diseases*. 2nd ed. St. Louis: Mosby; 2003.)

*Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Surgery

Bones can heal in the presence of active infection. However, in the presence of obvious signs of infection, such as an abscess or Cierny-Mader stage 3 or 4 disease, acute surgical debridement and irrigation are warranted. The goals of surgery include drainage, debridement, and stabilization. After successful debridement and stabilization, antibiotic therapy is initiated and continued until adequate healing has occurred, usually in 6 weeks. If debridement is unsuccessful, inert substances must be completely removed and tissue debrided. Antibiotics should be placed in contact with the bone using a polymethylmethacrylate antibiotic (PMMA) bead chain or other biodegradable delivery system to achieve higher local antibiotic concentrations. The site needs to be stabilized with an external fixator, and staged reconstruction should be initiated.

PLAGUE

Method of

Nelson Iván Agudelo Higuaita, MD; and Douglas A. Drevets, MD

CURRENT DIAGNOSIS

- Plague should be suspected when a person develops abrupt onset of fever, lymphadenopathy, or sepsis and there is history of a flea bite or possible exposure to an infected animal or person.
- Yersinia pestis* is an aerobic gram-negative coccobacilli that exhibits bipolar staining with Giemsa, Wright's, and Wayson stains.
- Automated diagnostic systems may misidentify *Y. pestis* as other organism.

CURRENT THERAPY

- Timely and appropriate management is imperative for a good outcome.

TABLE 2 Antibiotics for Osteomyelitis

ORGANISM	PREFERRED DRUG	ALTERNATIVE DRUGS
Methicillin-sensitive <i>Staphylococcus aureus</i>	Nafcillin (Unipen) 2 g IV or IM q4h	Cefazolin, oxacillin, vancomycin, clindamycin, Trimethoprim-sulfamethoxazole (Bactrim)* 4 mg/kg of the trimethoprim component twice daily) with rifampin (Rifadin) 600 mg once daily.*
Methicillin-resistant <i>S. aureus</i>	Vancomycin (Vancocin) 30 to 40 mg/kg IV every 24 hours in two or three divided doses; not to exceed 2 g/dose	Trimethoprim-sulfamethoxazole (Bactrim)* 4 mg/kg of the trimethoprim component twice daily) with rifampin (Rifadin) 600 mg once daily.*
<i>Streptococcus pneumoniae</i> , group A β-hemolytic streptococci	Penicillin G (Pfizerpen)* 2 million units IV q4h	Cefazolin, vancomycin, clindamycin
Enterococci, <i>Haemophilus influenzae</i> β-lactamase negative	Cefotaxime (Claforan) 2 g q6h	Trimethoprim-sulfamethoxazole, ceftriaxone
<i>H. influenzae</i> β-lactamase positive, <i>Klebsiella pneumoniae</i>	Ceftriaxone (Rocephin) 2 g q24h	Trimethoprim-sulfamethoxazole, ciprofloxacin, piperacillin (Pipracil), imipenem (Primaxin)
<i>Escherichia coli</i>	Cefazolin (Ancef) 2 g q8h	Ciprofloxacin, ceftriaxone, imipenem
<i>Pseudomonas aeruginosa</i>	Ciprofloxacin (Cipro) 400 mg q8h ³	Piperacillin plus aminoglycoside, aztreonam (Azactam)*
<i>Salmonella</i>	Choose ampicillin, ceftriaxone, imipenem (Primaxin), or ciprofloxacin, depending on sensitivities	
<i>Bacteroides</i> spp.	Clindamycin (Cleocin) 600 mg q6h	Imipenem, metronidazole (Flagyl)
<i>Serratia marcescens</i>	Ceftriaxone (Rocephin) 2 g q24h	Imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin

(Modified from Cohen J, Powderly WG, editors. *Infectious Diseases*. 2nd ed. St. Louis: Mosby; 2003.)

*Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Surgery

Bones can heal in the presence of active infection. However, in the presence of obvious signs of infection, such as an abscess or Cierny-Mader stage 3 or 4 disease, acute surgical debridement and irrigation are warranted. The goals of surgery include drainage, debridement, and stabilization. After successful debridement and stabilization, antibiotic therapy is initiated and continued until adequate healing has occurred, usually in 6 weeks. If debridement is unsuccessful, inert substances must be completely removed and tissue debrided. Antibiotics should be placed in contact with the bone using a polymethylmethacrylate antibiotic (PMMA) bead chain or other biodegradable delivery system to achieve higher local antibiotic concentrations. The site needs to be stabilized with an external fixator, and staged reconstruction should be initiated.

PLAGUE

Method of

Nelson Iván Agudelo Higuaita, MD; and Douglas A. Drevets, MD

CURRENT DIAGNOSIS

- Plague should be suspected when a person develops abrupt onset of fever, lymphadenopathy, or sepsis and there is history of a flea bite or possible exposure to an infected animal or person.
- Yersinia pestis* is an aerobic gram-negative coccobacilli that exhibits bipolar staining with Giemsa, Wright's, and Wayson stains.
- Automated diagnostic systems may misidentify *Y. pestis* as other organism.

CURRENT THERAPY

- Timely and appropriate management is imperative for a good outcome.

- Despite their toxicities, aminoglycosides are the treatment agents of choice.
- Respiratory droplet precautions should be instituted when pneumonic plague is suspected.
- Postexposure prophylaxis is indicated for close contacts.

Historical descriptions indicate that *Yersinia pestis* probably caused Justinian's Plague (AD 541), which led into the first plague pandemic. The second plague pandemic, also known as the Black Death, began in Central Asia in 1347 and then spread to Europe, Asia, and Africa. It killed an estimated 50 million people. The current (third) plague pandemic began in China and then spread worldwide along shipping routes in 1899–1900. *Y. pestis* is a gram-negative, nonmotile, facultatively anaerobic, non-spore-forming coccobacillus that is approximately 0.5 to 0.8 μm in diameter and 1 to 3 μm in length. Genomic sequencing shows that *Y. pestis* is a recently emerged clone of *Y. pseudotuberculosis*.

Epidemiology

Plague is a zoonosis for which urban and sylvatic rodents (e.g., rats, prairie dogs, and marmots) are the most important enzootic reservoirs. Additionally, domestic cats and dogs have been linked to human disease. Human plague occurs in North and South America, Asia, and Africa. Recent outbreaks reported to the World Health Organization (WHO) have occurred in the Democratic Republic of Congo (2005, 2006), China (2009), and Peru (2010). Plague is endemic in Madagascar, and between 2004 and 2009, 30% of all human cases worldwide were reported from this country. A new epidemic was identified August 1, 2017, and contained November 27, 2017. A total of 2417 cases (77% pneumonic) with a 9% case fatality ratio were reported. From 2000 to 2009, a total of 21,725 cases of plague with a 7.4% fatality rate were reported worldwide. Between 2010 and 2015 another 3248 cases of plague were reported to the WHO. In North America, most human cases occur in New Mexico, Arizona, California, Colorado, and Texas. Between 1900 and 2012, 1006 confirmed or probable cases have occurred in the U.S. with over 80% of these attributable to bubonic plague.

Modes of Transmission

Most human infections are transmitted from rodent to humans via the bite of an infected flea. Infection also can be acquired by contact with body fluids from infected animals, such as during field dressing of game or by inhalation of respiratory droplets from animals, particularly cats, or humans with pneumonic plague.

Bioterrorism Threat

Plague was used as an agent of biowarfare by the Japanese in World War II and was a focus of intensive research and development in the former Soviet Union during the Cold War. Primary pneumonic plague is the most likely form of exposure because of biowarfare or bioterrorism. Recent increases in terrorism worldwide have increased the focus of public health management groups to develop comprehensive statements regarding plague as a biological weapon.

Pathogenesis and Clinical Syndromes

Transdermal inoculation of bacilli from the bite of an infected flea ultimately leads to infection of the regional lymph nodes in which massive replication of bacteria creates the bubo (derived from the Greek *bubon* or "groin"), a swollen, erythematous, and painful lymph node in the groin, axilla, or cervical region. Bacteremia and septicemia frequently develop and lead to secondary infection of other organs including the lungs, spleen, and central nervous system. Primary pneumonic plague is a rare natural occurrence and results from the inhalation of respiratory droplets containing *Y. pestis* bacilli from another case of pneumonic plague, usually in humans or in cats. Although plague in dogs is rare, human outbreaks have been traced to sick dogs with wildlife exposure. Secondary pneumonic plague results from seeding of the lungs by blood-borne bacteria in the setting of either bubonic or septicemic plague. Septicemic plague also begins with transdermal exposure

but manifests as primary bacteremia/septicemia without the bubo. Less common manifestations include meningitis, pharyngitis, and gastroenteritis.

Bubonic plague is an acute febrile lymphadenitis that develops 2 to 8 days after inoculation. Inflamed lymph nodes are usually 1 to 6 cm in diameter and painful. Abrupt onset of fever is an almost universal finding and occurs simultaneously with, or up to 24 hours before, the appearance of the bubo. Headache, malaise, and chills are frequent, along with nausea, vomiting, and diarrhea. Most patients are tachycardic, hypotensive, and appear prostrate and lethargic with episodic restlessness. Leukocytosis with a left shift is typical. Complications include pneumonia, shock, disseminated intravascular coagulation, purpuric skin lesions, acral cyanosis, and gangrene. The differential diagnosis of bubonic plague includes tularemia and Group A β -hemolytic streptococcal adenitis with bacteremia.

Symptoms of septicemic plague are similar to those caused by other gram-negative bacteria, and are very similar to those of bubonic plague except that abdominal pain is more common in septicemic plague. Septicemic plague must be differentiated from fulminating septicemia caused by other gram-negative bacteria. Primary pneumonic plague has an abrupt onset of fever and influenza-like symptoms 1 to 5 days after inhalation exposure. Symptoms include shortness of breath, cough, chest pain, and bloody sputum with rapid progression to fulminating pneumonia and respiratory failure. Patients with secondary pneumonic infection show respiratory symptoms in addition to those attributed to the bubo or sepsis. Radiographic findings include patchy bronchopneumonia, multilobar consolidations, cavitations, and alveolar hemorrhage and are not pathognomonic of *Y. pestis*. Plague pneumonia must be differentiated from severe influenza, inhalation anthrax, and overwhelming community-acquired pneumonia.

Diagnosis

Plague is diagnosed by demonstrating *Y. pestis* in blood or body fluids such as a lymph node aspirate, sputum, or cerebrospinal fluid. A tentative diagnosis of bubonic plague can be made rapidly with fluid aspirated from a bubo showing gram-negative coccobacilli with bipolar staining. It is important to remember that automated diagnostic systems might misidentify *Y. pestis*. In an outbreak in Colorado, the misidentification of *Y. pestis* as *Pseudomonas luteola* delayed the recognition of the outbreak. Serology showing a fourfold rise in antibody titers to F1 antigen or a single titer of more than 1:128 is also diagnostic. Rapid tests using monoclonal antibodies to detect *Y. pestis* F1 antigen in bubo aspirates and sputum have been developed and field tested. The use of mass spectrometry as a more rapid and cost-effective diagnostic tool has also been studied.

Treatment

The aminoglycosides (gentamicin¹ and streptomycin), the fluoroquinolones (ciprofloxacin [Cipro] moxifloxacin [Avelox] and levofloxacin [Levaquin]) and doxycycline (Vibramycin) are the first-, second-, and third-line classes of antibiotics, respectively. Typical minimal inhibitory concentrations for 90% (MIC₉₀) of tested strains for the fluoroquinolones are less than 0.03 to 0.25 $\mu\text{g}/\text{mL}$ compared with less than 1.0 $\mu\text{g}/\text{mL}$ and less than 1.0 $\mu\text{g}/\text{mL}$ to 4.0 $\mu\text{g}/\text{mL}$ for gentamicin and streptomycin, respectively, and less than 1.0 $\mu\text{g}/\text{mL}$ for doxycycline. Streptomycin (15 mg/kg up to 1 g intramuscularly [IM] every 12 hours) and gentamicin (5 to 7 mg/kg/day intravenously [IV]/IM in one or two doses daily) are the drugs of choice for severe infection. Standard fluoroquinolone dosing includes ciprofloxacin 400 mg IV/500 mg orally every 12 hours; levofloxacin 500–750 mg IV/orally daily; and moxifloxacin 400 mg IV/orally daily. Doxycycline is administered starting with a 200 mg loading dose followed by 100 mg IV/orally every 12 hours. Chloramphenicol (25 mg/kg IV/orally every 6 hours) can be used in select circumstances. Antibiotic therapy should be continued for a total of 10 days; some experts will extend the duration of therapy to 14 days when a bacteriostatic agent like a tetracycline is used.

¹Not FDA approved for this indication.

Prevention and Control

Standard infection control procedures should include a disposable surgical mask, latex gloves, devices to protect mucous membranes, and good hand washing. Hospitalized patients with known or suspected pneumonic plague should be isolated under respiratory droplet precautions for at least 48 hours after appropriate antibiotics are initiated. Patients without respiratory plague can be managed under standard precautions. Postexposure prophylaxis should be given to individuals with close contact (less than 2 meters) with an infectious case or who have had a potential respiratory exposure. The recommended adult antibiotics for prophylaxis are doxycycline or ciprofloxacin in the same doses used for treatment. Postexposure prophylaxis can be given orally and should be continued for 7 days following exposure. Currently, there is no licensed plague vaccine. An encapsulated *Y. pseudotuberculosis*, strain V674pF1⁵, is an efficient live oral vaccine against pneumonic plague in mice. Recently, flea resistance to insecticides such as DDT and Deltamethrin in Madagascar has prompted an immediate need for alternative insecticides to prevent future plague outbreaks.

⁵Investigational drug in the United States.

PSEUDOMEMBRANOUS COLITIS

Method of

Jeffery D. Semel, MD

CURRENT DIAGNOSIS

- *Clostridium difficile* infection is diagnosed by a combination of clinical and laboratory findings.
- Diagnosis requires a positive test for the presence of *C difficile* toxins.
- GDH, or glutamate dehydrogenase, produced by *C difficile*, can be detected in stool. However, it is not specific and can be produced by non-difficile *Clostridia* species.

- Enzyme immunoassay testing for toxin A and or B has a variable sensitivity and specificity and a turnaround time of about 24 hours and correlates well with disease activity.
- Polymerase chain reaction testing has a high sensitivity and specificity and a turnaround time of less than 4 hours; correlates less with disease activity, thus identifying patients with colonization as well as active infection. Increasingly, combination testing is being employed to improve diagnostic accuracy.
- Laboratory testing for *C difficile* toxins should only be performed on patients with ≥ 3 unformed stools per 24 hours, who are not on laxatives and is not useful as a test of cure.
- Pathologic findings can help to confirm diagnosis.

CURRENT THERAPY

- If possible, the clinician should first consider discontinuing concurrent antibacterial therapy.
- Treatment should be initiated only after a positive test result for *C difficile* toxin unless the patient is at high risk for *C difficile* infection or is severely ill, in which case empirical therapy is justified.
- Treatment recommendations depend on the severity of the disease and whether the patient has a first-time diagnosis or recurrence.
- Clinical parameters that guide treatment include increasing age, leukocytosis, elevation of serum creatinine, and presence of hypotension, shock, ileus, or megacolon.
- Oral vancomycin (Vancocin) or fidaxomicin (Dificid), are preferred for initial therapy. Metronidazole (Flagyl)¹ oral, can be used for non-severe disease if these are not available.
- Intravenous metronidazole¹ and or rectal vancomycin (enema)^{1,6} can be added for severe disease.
- FMT (fecal microbiota therapy) is a safe and effective option for recurrent disease.

¹Not FDA approved for this indication.

⁶May be compounded by pharmacists.

Pseudomembranous colitis is an inflammatory disease of the colon that is almost always associated with the toxin-producing bacteria *Clostridium difficile*. In very rare cases, other organisms can be responsible. In this article I discuss *C difficile* as an important cause of pseudomembranous colitis.

Epidemiology and Risk Factors

C difficile is the most common infectious cause of health care-associated diarrhea. Studies in US hospitals showed that mortality rates related to *C difficile* infection nearly quadrupled from 1999 through 2004. An active population and laboratory based study done by the US Centers for Disease Control and Prevention in 2011 suggested that 453,000 new cases occur in the United States annually; with a 30-day mortality rate of 6.4%. Higher rates of infection were found in whites, females, and those >65 years of age. A Canadian study in 2011 prospectively followed up 5422 hospitalized patients and showed that 7.4% had asymptomatic colonization only (60% of these were positive at the time of admission); 2.8% developed *C difficile* infection during hospitalization. Colonization of asymptomatic hospitalized patients with *C difficile* ranges from 0%–22% and is higher in residents of long-term care facilities.

Additional risk factors for the development of *C difficile* infection include antimicrobial or chemotherapeutic drug exposure, severe underlying illness, prior hospitalization (acute or long-term care), use of feeding tubes, recent gastrointestinal surgery, and use of proton pump inhibitors. Exposure to antibiotics has been shown to lead to an alteration in the type and quantity of bacterial species found in the normal human intestinal microbiome. Most

Prevention and Control

Standard infection control procedures should include a disposable surgical mask, latex gloves, devices to protect mucous membranes, and good hand washing. Hospitalized patients with known or suspected pneumonic plague should be isolated under respiratory droplet precautions for at least 48 hours after appropriate antibiotics are initiated. Patients without respiratory plague can be managed under standard precautions. Postexposure prophylaxis should be given to individuals with close contact (less than 2 meters) with an infectious case or who have had a potential respiratory exposure. The recommended adult antibiotics for prophylaxis are doxycycline or ciprofloxacin in the same doses used for treatment. Pseudomembranous colitis is an inflammatory disease of the colon that is almost always associated with the toxin-producing bacteria *Clostridium difficile*. In very rare cases, other organisms can be responsible. In this article I discuss *C difficile* as an important cause of pseudomembranous colitis.

Epidemiology and Risk Factors

C difficile is the most common infectious cause of health care-associated diarrhea. Studies in US hospitals showed that mortality rates related to *C difficile* infection nearly quadrupled from 1999 through 2004. An active population and laboratory based study done by the US Centers for Disease Control and Prevention in 2011 suggested that 453,000 new cases occur in the United States annually; with a 30-day mortality rate of 6.4%. Higher rates of infection were found in whites, females, and those >65 years of age. A Canadian study in 2011 prospectively followed up 5422 hospitalized patients and showed that 7.4% had asymptomatic colonization only (60% of these were positive at the time of admission); 2.8% developed *C difficile* infection during hospitalization. Colonization of asymptomatic hospitalized patients with *C difficile* ranges from 0%–22% and is higher in residents of long-term care facilities.

Additional risk factors for the development of *C difficile* infection include antimicrobial or chemotherapeutic drug exposure, severe underlying illness, prior hospitalization (acute or long-term care), use of feeding tubes, recent gastrointestinal surgery, and use of proton pump inhibitors. Exposure to antibiotics has been shown to lead to an alteration in the type and quantity of bacterial species found in the normal human intestinal microbiome. Most

antibiotics have been associated with *C difficile* infection. Increased antimicrobial duration and dosage appear to be associated with higher risk of *C difficile* infection.

Epidemic strains have been described by pulsed-field gel electrophoresis (NAP1,4,7,11 etc.) that are associated with decreased regulatory gene function and increased toxin production. The risk and severity of infection are increased after exposure to the NAP1 strains. Failure of standard first-line therapy for *C difficile* infection may increase to 10% to 35% during infection with NAP strains.

C difficile infection occurs rarely without prior antibiotic exposure. Healthy peripartum women, children, and postsurgical patients rarely have *C difficile* infection develop after a single dose of an antibiotic. Newborns have a higher rate of colonization but generally a low rate of *C difficile* infection.

Infection is costly. It is estimated that each episode costs the US health care system \$3,427–\$16,307 per episode or \$1.2 billion–\$5.9 billion per year.

Microbiology and Pathophysiology

C difficile is a gram-positive, spore-forming, anaerobic rod. *C difficile* can exist as either a spore or vegetative form. The vegetative form is highly oxygen sensitive; slight exposure can kill the bacteria. The spore form is highly heat-stable and can survive harsh conditions such as the high acidity of the stomach. Spores have been shown to resist many commercial disinfectants. *C difficile* reproduces in intestinal crypts and releases exotoxins A and B, leading to severe inflammation. Toxin A (enterotoxin) attracts neutrophils and monocytes, and toxin B (cytotoxin) degrades colonic epithelial cells. Most strains of *C difficile* produce both toxin A and B; however, toxin production, and thus detection may fluctuate during infection. Toxins disrupt cell membranes and cause shallow ulcerations on the intestine mucosal surface. Ulcer formation leads to the release of proteins, mucus, and inflammation manifesting as a pseudomembrane. A pseudomembrane is virtually pathognomonic for *C difficile* infection.

Transmission occurs via the fecal–oral route, person to person, or via fomites. Following exposure to antibiotics, the normal gut flora is altered (“dysbiosis”), allowing *C difficile* to become more dominant. Exposure to *C difficile* spores may result in no acquisition, asymptomatic colonization, mild diarrhea, or infection. The incidence of colonization increases at a steady rate during hospitalization, suggesting ongoing exposure to spores. A recent meta-analysis of 19 studies and more than 8700 patients suggests that colonization at the time of hospital admission is associated with an increased risk of subsequent *C difficile* infection. The risk of colonization was associated with hospitalization during the prior 3 months.

Evidence suggests that the host immune response to spore exposure is important in determining the clinical outcome. Approximately 60% of people have detectable levels of antibodies to toxin A and B. It is likely that prior exposure to *C difficile* spores or related clostridial species and subsequent colonization stimulates antibody production and immunity. *Clostridium difficile* has been found to be capable of creating a biofilm in vitro, which may impair the antibacterial activity of antibiotics such as metronidazole (Flagyl). Various studies are attempting to define the role of active or passive immunotherapy, including vaccination with nontoxigenic *C difficile*, to prevent *C difficile* infection.

Clinical Features

C difficile infection is diagnosed by a combination of clinical and laboratory findings. Diarrhea is defined as the passage of three or more unformed stools in a 24-hour period. Symptoms include fever, diarrhea, and cramplike abdominal pain. Patients can have nausea, vomiting, or hematochezia. In severe cases, abdominal tenderness and distention are present. Signs of septic shock can develop. The extent of leukocytosis frequently correlates with disease severity. Plain abdominal radiographs might show distended loops of bowel, ileus, or, in severe cases, toxic megacolon. Computed tomography (CT) image findings include colonic wall

thickening and dilatation, mesenteric edema, and, rarely, perforation. Endoscopy can reveal pseudomembranes. However, sigmoidoscopy or colonoscopy may be complicated by perforation in severely ill patients and should be performed with caution.

Differential Diagnosis

The differential diagnosis includes bacterial causes such as *Shigella*, *Salmonella*, or *Campylobacter* species, protozoan infections such as *Entamoeba histolytica* or *Strongyloides stercoralis* (immunosuppressed patients), inflammatory disorders such as ulcerative colitis or Crohn’s disease, drug toxicity (e.g., chemotherapeutic agents), and vascular disorders such as ischemic bowel disease.

Diagnosis

Various tests have been developed for the diagnosis of *C difficile* infection. Glutamate dehydrogenase (GDH) is produced by *C difficile* and can be detected in stool. It is very sensitive for *C difficile* but can be produced by other *Clostridia* sp. and thus is non-specific.

Enzyme immunoassays (EIA) for toxin A and or B detect toxin production. The sensitivity is 63%–94% and specificity is 75%–100%. The turnaround time is usually 24 hours. GDH and toxin assays correlate well with clinical disease activity.

Molecular tests such as polymerase chain reaction (PCR) can be performed in less than 4 hours. The sensitivity is approximately 93% and specificity is 97%. These tests target toxin genes and do not always correlate with clinical disease. Since the introduction of PCR, the number of cases diagnosed has increased further (though some may represent colonization). Thus positive *C difficile* testing must be correlated with clinical disease activity to determine if treatment is indicated. Increasingly, authors have recommended two-step testing using PCR and toxin EIA, or, GDH/toxin EIA, followed by PCR.

Treatment

If possible, the clinician should first consider discontinuing concurrent antibacterial therapy, unless there is a compelling clinical indication to continue. Antimotility agents should be avoided because decreased gut motility can increase the potential for tissue toxin exposure and toxic megacolon. Treatment for *C difficile* infection should be initiated only after a positive *C difficile* test result unless the patient is at high risk for *C difficile* infection or is severely ill, in which case empirical therapy is reasonable even with negative test results.

Antibacterials used to treat *C difficile* infection can be administered orally, intravenously, or rectally. Oral therapies are preferred. Oral vancomycin (Vancocin) is not absorbed in the gastrointestinal tract and is eliminated in the feces. Fidaxomicin (Dificid), a macrocyclic antibiotic, has been shown to have equal efficacy to vancomycin but with a potentially lower rate of *C difficile* recurrence. Fidaxomicin is approved for patients 18 years or older. Oral metronidazole (Flagyl), a nitroimidazole antibiotic, is eliminated primarily in the urine, although 6% to 15% is eliminated in the feces.

The Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA) published treatment guidelines in 2018. Recommendations for the treatment of *C difficile* infection depend on the severity of the disease. Clinical parameters that correlate with severity include increasing age, leukocytosis, and elevation of the serum creatinine.

For all patients with a first episode of *C difficile* infection vancomycin 125 mg four times daily or fidaxomicin 200 mg twice daily, by mouth (PO) for 10 to 14 days is recommended. If these drugs are not available, metronidazole (Flagyl)¹ 500 mg three times daily by mouth can be used but should be avoided if the disease is severe.

¹Not FDA approved for this indication.

A white blood cell count of at least 15,000 cells/ μ L or a serum creatinine at least 1.5 times the premorbid level suggests severe infection.

Patients with an initial episode that is complicated by hypotension, shock, ileus, or megacolon should be treated with vancomycin 500 mg PO 4 times per day, plus metronidazole 500 mg IV¹ every 8 hours. If the patient has a complete ileus, the clinician may consider adding a rectal instillation of vancomycin^{1,6} 500 mg every 6 hours.

Monitoring

The response to therapy should be monitored clinically. Reversal of hemodynamic instability, decreasing stool frequency, and a declining white blood cell count are objective measures of response. Stool tests for *C difficile* toxin are not valuable for monitoring disease elimination, because these tests can remain positive after improvement.

Complications and Recurrence

Another challenging problem in *C difficile* infection is recurrence. Recurrence is defined as another episode that occurs within eight weeks of the initial episode. Recurrence occurs in approximately 20% to 30% of cases following resolution of the initial episode. Continued use of antibacterials (other than treating agents), increased age, longer hospitalization, severe underlying disease, and inadequate antitoxin antibody response are risk factors for relapse. Even though treatment failure and relapse are common, resistance to metronidazole or vancomycin is uncommon.

For an initial recurrence, a tapered, pulsed dose regimen of vancomycin is often employed. This consists of vancomycin 125 mg PO 4 times per day for 2 weeks, followed by 125 mg PO 2 times per day for 1 week, followed by vancomycin 125 mg PO once daily for 1 week, followed by 125 mg PO once every 2 to 3 days for 2 to 8 weeks.

Fidaxomicin may be considered as an alternative to vancomycin for an initial recurrence.

Another option for recurrent *C difficile* infection is fecal reconstitution or fecal microbiota therapy (FMT). The goal is to reverse dysbiosis and restore normal colonic flora. Healthy donor stool is infused via colonoscopy, intraduodenal, or by frozen capsule. Numerous studies have shown the efficacy of FMT, although the exact place, timing and mode of installation continue to be under evaluation. Donor stool must be screened for infectious agents prior to installation. Additional promising options for prevention of recurrences include the addition of monoclonal antibodies directed against *C difficile* and the oral administration of non toxigenic *C difficile* strains. A monoclonal antibody, directed at toxin B, bezlotoxumab (Zinplava), is now available for prevention of recurrence in patients at high risk.

Probiotics⁷ are live organisms that seek to restore the normal gastrointestinal microflora. Most studies have used *Lactobacillus* species or *Saccharomyces boulardii* in an effort to prevent, or treat *C difficile* infection. A recent Cochrane analysis has shown that the use of probiotics during antimicrobial administration may decrease the subsequent development of *C difficile* colitis. The optimal probiotic formula, dosing, and side effect profile remains to be determined. Probiotics have not shown benefit during active infection. Occasional cases of fungemia or bacteremia have been reported in immunocompromised patients and those with central venous catheters treated with probiotics. Probiotics should be avoided in these patients.

Total colectomy is often considered as a last measure for patients who remain critically ill despite standard therapy. The exact indications for surgery are not clear, although refractory shock, signs of peritonitis, megacolon, and multiorgan failure are most often cited. As expected, the mortality rate after total colectomy is high,

ranging from 35% to 80%. Neal and colleagues reported that in a series of 42 patients, performance of a diverting loop ileostomy and intraoperative colonic lavage with polyethylene glycol, followed by postoperative antegrade vancomycin flushes, resulted in 19% mortality and 93% colon preservation.

Prevention

Given the current difficulties in controlling the spread of *C difficile*, prevention is critical. *C difficile* spores resist desiccation and can survive in the hospital environment for months. Environmental contamination is highest in and around the rooms of patients with *C difficile* infection. The risk of hospital-associated *C difficile* has been found to be increased for patients occupying the bed of a previous patient who received antibiotics. Items that have been found to harbor *C difficile* spores include clothing, blood pressure cuffs, telephones, toilets, doorknobs, oral and rectal thermometers, and other medical equipment. In addition, the hands of health care workers have been found to be a vehicle of transmission.

Current recommendations for prevention of transmission of *C difficile* include the following. Careful hand hygiene with soap and water is essential. Programs to monitor the compliance and technique of hand hygiene are recommended. Alcohol-based hand rubs, which are widely used, have been shown to be less effective at removing spores than conventional hand washing. Thus alcohol-based hand rubs should not be used for *C difficile* isolation when *C difficile* outbreaks are present. Barrier precautions with gowns and gloves should be used. Programs to ensure adequate and effective cleaning of health care facilities after use are recommended. Disposable electronic thermometers are recommended. Antimicrobial stewardship programs aimed at promoting the judicious use of antibacterial therapy have been found to be effective in reducing *C difficile* infection rates and should be used. In view of recent data that colonization at the time of admission increases the risk for *C difficile* infection, studies have been initiated to determine if contact isolation for *C difficile* colonized patients will be beneficial in decreasing transmission.

CURRENT DIAGNOSIS

- The key to successful management of psittacosis is to consider this diagnosis, particularly in cases of community-acquired pneumonia (CAP), especially given a history of bird contact.
- The typical clinical pictures are of CAP, influenza-like illness, or fever of unknown origin. Psittacosis causes 1% of incident CAP cases. Onset is usually sudden with fever, chills and a prominent headache. Consider this diagnosis in a patient with CAP unresponsive to β -lactam antibiotics.
- Investigation will typically reveal a normal or slightly elevated white blood cell count with a left shift or toxic changes, increase in C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR), mildly abnormal liver function tests, hyponatremia, and mild renal impairment. Chest x-ray may be more abnormal than examination alone would predict.
- Diagnosis can be confirmed with (ideally) paired serum samples: using either the complement fixation test (widely used but unable to differentiate between *Chlamydophila* species), or the microimmunofluorescence test, which is specific for individual *Chlamydophila* species. Either a single high titer or a fourfold rise in titer using samples collected at least 14 days apart are interpreted as positive. More recently, real-time polymerase chain reaction (rt-PCR) tests are used to detect specific DNA. These can provide a more rapid diagnosis, as well as subspecific genotype.

CURRENT THERAPY

- Therapy should commence when the diagnosis is suspected on clinical presentation and initial investigation.
- Tetracyclines are the drugs of choice; for example, doxycycline (Vibramycin) 100 mg bid for 10 to 14 days.
- Macrolides are suitable (but probably less effective) alternatives in those intolerant of tetracyclines (e.g., children and pregnant women).
- Notification to health authorities facilitates public health investigation and interventions to reduce transmission and control outbreaks.

Psittacosis is caused by infection with the bacterium *Chlamydophila psittaci* (formerly *Chlamydia psittaci*). It is twice as common in men than in women, and mainly affects adults typically aged 40 to 50 years. The main reservoir for psittacosis is birds, particularly psittacine birds (parrots, parakeets, budgerigars and cockatoos), but other bird species and mammals can be infected.

Risk Factors

The most common etiological factor is exposure to infected birds—especially a new, sick, or dead one—typically a pet or via occupational exposure (e.g., work as a veterinarian, zoo keeper, or poultry-worker). Most cases are sporadic, but outbreaks have occurred associated with pet shops, aviaries, and poultry-processing plants and with mowing lawns in areas with large numbers of psittacine birds. Person-to-person transmission is rare. Ingestion of poultry products is *not* a risk factor.

Pathophysiology

C. psittaci infection is via the respiratory tract and is typically thought to be by inhalation of an aerosol of dried feces or other

avian secretion. It then either travels via the blood to the liver and spleen (where it replicates, causing a secondary bacteremia) or directly infects respiratory epithelial cells.

Prevention

Prevention is aimed at controlling disease or colonization in susceptible host species: usually birds. This is facilitated by import restrictions including quarantine and treatment of suspected infections with tetracycline-impregnated feeds. Notification of health authorities is important for initiating public health investigations and interventions to reduce transmission and control of outbreaks.

Clinical Manifestations

The incubation period varies from 4 to 14 or more days. The typical presentation of psittacosis is of an influenza-like illness with sudden onset of fever, chills, and prominent headache, with or without rigors. A more gradual onset is also seen. A typically mild, dry cough usually starts later. There may also be diarrhea, pharyngitis, altered mental state, or shortness of breath. Chest examination is usually abnormal, but the findings are often minimal and less prominent than symptoms or x-ray findings would suggest. Pleural effusion is rare.

Patients might present with a fever of unknown origin without obvious respiratory involvement, or the disease can be misdiagnosed as meningitis because of prominent headache, sometimes with photophobia.

The white blood cell count is usually normal or slightly raised, but there is often a left shift or toxic changes. Increases in the C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are common. Mildly abnormal liver function tests, hyponatremia, and mild renal impairment are also common. The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal. The chest x-ray usually shows more (nonspecific) abnormality than examination findings might predict. The most common finding is lobar consolidation, but bilateral consolidation and interstitial opacities are also common.

Confirmation of diagnosis is more commonly performed using serology. The complement fixation (CF) test is widely used, but cannot differentiate between *Chlamydophila* species. A fourfold rise in titer, using samples collected at least 14 days apart, or a single titer of 1:128 or higher, is interpreted as positive, but this test is not widely available. Culture of *C. psittaci* is difficult and hazardous. Polymerase chain reaction (PCR) assays have been developed, but are not yet widely available for routine clinical use.

Diagnosis

Diagnosis is facilitated by eliciting a history of recent bird contact from a patient with a compatible clinical syndrome, most commonly an influenza-like presentation, community acquired pneumonia (CAP), or a fever of unknown origin. The diagnosis should be considered in a patient with CAP and prominent headache, splenomegaly, or failure to respond to β -lactam antibiotics.

Differential Diagnosis

Differential diagnosis of an atypical CAP, includes infection with *Legionella* species, *Mycoplasma pneumoniae*, or *Chlamydophila pneumoniae*.

Treatment

When the diagnosis is suspected on clinical presentation and initial investigations, empiric therapy should be commenced. Tetracyclines are the drugs of choice, for example doxycycline (Vibramycin) 100 mg bid for 10 to 14 days. Tetracycline treatment usually leads to improvement in symptoms (including fever) within 24 to 48 hours. Macrolides are usually recommended for pregnant women, children, and other patients intolerant of tetracyclines. However, erythromycin (Erythrocine)¹ has been shown to fail in situations where a tetracycline was effective, and there are few

¹Not FDA approved for this indication.

clinical data on the efficacy of the other agents in this class. Some data suggest that quinolones may be effective. Tetracycline hydrochloride or doxycycline (4.4 mg/kg/d divided into two infusions) may be given intravenously for critically ill patients.

Monitoring

Symptomatic improvement usually occurs within 24 to 48 hours of starting a tetracycline; typically including reduction of fever.

Complications

The degree of illness varies from asymptomatic to life threatening. Given appropriate antimicrobial therapy, subsequent case-fatality is less than 1%. Elderly persons and pregnant women are susceptible to more severe illness. Neurologic consequences (e.g., meningo-encephalitis) are recognized but rare. Other less-common sequelae include hemoptysis, proteinuria, hepatosplenomegaly, and encephalitis. Cardiac manifestations include relative bradycardia and, rarely, myocarditis, culture-negative endocarditis, and pericarditis. Erythema nodosum and other skin manifestations have also been described. *C psittaci* has been demonstrated by PCR to be present in ocular adnexal lymphoma (OAL) in parts of Eurasia. Up to one half of such cases respond to antibiotic treatment. However, studies elsewhere suggest that this organism might not commonly play a role in OAL. Recovery with minimal residual deficit is normal.

Q FEVER

Method of

Didier Raoult, MD, PhD

Q fever is a widespread zoonosis caused by *Coxiella burnetii*, a small, coccoid, strict intracellular gram-negative bacterium. It lives within the phagolysosome of its eukaryotic host cell at very low pH (4.5–4.8). It had previously been classified in the rickettsial family; however, recent phylogenetic data based on study of the 16S rRNA gene sequence have shown that it belongs to *Legionellales* with the *Legionella* species and *Francisella tularensis*.

The bacterium has a sporelike life cycle, which explains its marked resistance to physicochemical agents. In cultures, *C. burnetii* exhibits a phase variation (from virulent phase I to avirulent phase II) caused by a spontaneous chromosome deletion. The avirulent form paradoxically generates high antibody levels in patients, but only patients with chronic infection have high antiphase I immunoglobulin G (IgG) and IgA antibody titers.

The reservoir of *C. burnetii* is wide, and nearly all tested mammals, birds, and ticks can be infected. Outbreaks have also been reported in association with the birth products of mammals (including ungulates and pets), raw milk, slaughterhouses, and farm work. Laboratory outbreaks have been reported. The disease is prevalent

everywhere in the world but in New Zealand and South Pacific Islands, but because its clinical spectrum is wide and nonspecific, the observed incidence is directly related to physician interest in Q fever. A recent outbreak has been observed in the Netherlands.

Clinical Features

Q fever is a reportable disease in the United States. In humans, infection is symptomatic in only 50% of patients. Most symptomatic patients experience a flulike syndrome lasting 2 to 7 days and consisting of severe headaches and cough; 5% to 10% of infected patients may be sick enough to be investigated. They initially have high fever and one or several of pneumonia, hepatitis, meningo-encephalitis, rash, myocarditis, and pericarditis. Routine laboratory investigation commonly shows mildly elevated transaminase levels and mild thrombocytopenia.

In special hosts such as immunocompromised patients (specifically those with splenectomy), *C. burnetii* can cause endocarditis. In pregnant women it can lead to recurrent miscarriage, low-birth-weight offspring, and prematurity. *C. burnetii* could contribute to the evolution of lymphoma.

In patients with valvular heart disease and those with arterial aneurysms or a vascular prosthesis, it can cause chronic endocarditis or vascular infection in patients in the 2 years following primary infection. The clinical picture is that of a chronic blood culture-negative endocarditis; the modified Duke criteria are of diagnostic value in such cases. It is spontaneously fatal in most cases.

Diagnosis

Because Q fever is pleomorphic, the diagnosis is based mainly on comprehensive serum testing in patients with an unexplained infectious syndrome. Liver biopsy may be of diagnostic value, because the typical doughnut granuloma is quasispecific to acute Q fever. Valves obtained at surgery or autopsy can be used for culture, direct immunostaining, and polymerase chain reaction (PCR).

Three serologic techniques are used. Complement fixation lacks sensitivity, and one-third of patients with acute Q fever do not exhibit complement-fixing antibodies within 1 month after onset of the disease. However, a fourfold increase in antibodies to phase II antigen indicates acute Q fever, and antibody levels against phase I that are higher than 1:200 indicate persistent focalized Q fever. Indirect immunofluorescence assay is the reference method. A single titer of 1:200 for IgG antiphase II associated with a titer of 1:50 for IgM is diagnostic of acute infection. IgG antibody levels against phase I that are greater than 1:800 and IgA antibody levels greater than 1:50 are highly predictive of endocarditis or vascular infection. Enzyme-linked immunosorbent assay (ELISA) is useful for diagnosing acute infection in detecting IgM antiphase II.

PCR has recently been developed to detect *C. burnetii* DNA in the sera of patients with Q fever. Real-time PCR using multicopy gene *IS1111* is the more-sensitive technique. It is positive in the sera of patients with acute Q fever before IgG antibodies to *C. burnetii* become apparent. It is also positive in patients with untreated endocarditis. Contamination of PCR can occur, and many unconfirmed results are reported in the literature. Detection of patients at risk for endocarditis may be provided by systematic echocardiography in patients with acute Q fever specifically seeking for aortic bicuspidity and serologic follow-up at 3 and 6 months after acute infection. Antiphospholipid antibodies are relatively common during acute Q fever and predictive of endocarditis and deep vein thrombosis.

Use of a positron emission tomography (PET) scanner may help in the diagnosis of endocarditis (and may reveal mycotic aneurysms), vascular infection, and joint infection.

Treatment

To be active against Q fever, an antibiotic compound has to enter the cell, be effective at an acidic pH (where *C. burnetii* multiplies), and have activity against *C. burnetii*. No antibiotic is bactericidal,

clinical data on the efficacy of the other agents in this class. Some data suggest that quinolones may be effective. Tetracycline hydrochloride or doxycycline (4.4 mg/kg/d divided into two infusions) may be given intravenously for critically ill patients.

Monitoring

Symptomatic improvement usually occurs within 24 to 48 hours of starting a tetracycline; typically including reduction of fever.

Complications

The degree of illness varies from asymptomatic to life threatening. Given appropriate antimicrobial therapy, subsequent case-fatality is less than 1%. Elderly persons and pregnant women are susceptible to more severe illness. Neurologic consequences (e.g., meningo-encephalitis) are recognized but rare. Other less-common sequelae include hemoptysis, proteinuria, hepatosplenomegaly, and encephalitis. Cardiac manifestations include relative bradycardia and, rarely, myocarditis, culture-negative endocarditis, and pericarditis. Erythema nodosum and other skin manifestations have also been described. *C. psittaci* has been demonstrated by PCR to be present in ocular adnexal lymphoma (OAL) in parts of Eurasia. Up to one half of such cases respond to antibiotic treatment. However, studies elsewhere suggest that this organism might not commonly play a role in OAL. Recovery with minimal residual deficit is normal.

Q FEVER

Method of

Didier Raoult, MD, PhD

Q fever is a widespread zoonosis caused by *Coxiella burnetii*, a small, coccoid, strict intracellular gram-negative bacterium. It lives within the phagolysosome of its eukaryotic host cell at very low pH (4.5–4.8). It had previously been classified in the rickettsial family; however, recent phylogenetic data based on study of the 16S rRNA gene sequence have shown that it belongs to *Legionellales* with the *Legionella* species and *Francisella tularensis*.

The bacterium has a sporelike life cycle, which explains its marked resistance to physicochemical agents. In cultures, *C. burnetii* exhibits a phase variation (from virulent phase I to avirulent phase II) caused by a spontaneous chromosome deletion. The avirulent form paradoxically generates high antibody levels in patients, but only patients with chronic infection have high antiphase I immunoglobulin G (IgG) and IgA antibody titers.

The reservoir of *C. burnetii* is wide, and nearly all tested mammals, birds, and ticks can be infected. Outbreaks have also been reported in association with the birth products of mammals (including ungulates and pets), raw milk, slaughterhouses, and farm work. Laboratory outbreaks have been reported. The disease is prevalent

everywhere in the world but in New Zealand and South Pacific Islands, but because its clinical spectrum is wide and nonspecific, the observed incidence is directly related to physician interest in Q fever. A recent outbreak has been observed in the Netherlands.

Clinical Features

Q fever is a reportable disease in the United States. In humans, infection is symptomatic in only 50% of patients. Most symptomatic patients experience a flulike syndrome lasting 2 to 7 days and consisting of severe headaches and cough; 5% to 10% of infected patients may be sick enough to be investigated. They initially have high fever and one or several of pneumonia, hepatitis, meningo-encephalitis, rash, myocarditis, and pericarditis. Routine laboratory investigation commonly shows mildly elevated transaminase levels and mild thrombocytopenia.

In special hosts such as immunocompromised patients (specifically those with splenectomy), *C. burnetii* can cause endocarditis. In pregnant women it can lead to recurrent miscarriage, low-birth-weight offspring, and prematurity. *C. burnetii* could contribute to the evolution of lymphoma.

In patients with valvular heart disease and those with arterial aneurysms or a vascular prosthesis, it can cause chronic endocarditis or vascular infection in patients in the 2 years following primary infection. The clinical picture is that of a chronic blood culture-negative endocarditis; the modified Duke criteria are of diagnostic value in such cases. It is spontaneously fatal in most cases.

Diagnosis

Because Q fever is pleomorphic, the diagnosis is based mainly on comprehensive serum testing in patients with an unexplained infectious syndrome. Liver biopsy may be of diagnostic value, because the typical doughnut granuloma is quasispecific to acute Q fever. Valves obtained at surgery or autopsy can be used for culture, direct immunostaining, and polymerase chain reaction (PCR).

Three serologic techniques are used. Complement fixation lacks sensitivity, and one-third of patients with acute Q fever do not exhibit complement-fixing antibodies within 1 month after onset of the disease. However, a fourfold increase in antibodies to phase II antigen indicates acute Q fever, and antibody levels against phase I that are higher than 1:200 indicate persistent focalized Q fever. Indirect immunofluorescence assay is the reference method. A single titer of 1:200 for IgG antiphase II associated with a titer of 1:50 for IgM is diagnostic of acute infection. IgG antibody levels against phase I that are greater than 1:800 and IgA antibody levels greater than 1:50 are highly predictive of endocarditis or vascular infection. Enzyme-linked immunosorbent assay (ELISA) is useful for diagnosing acute infection in detecting IgM antiphase II.

PCR has recently been developed to detect *C. burnetii* DNA in the sera of patients with Q fever. Real-time PCR using multicopy gene *IS1111* is the more-sensitive technique. It is positive in the sera of patients with acute Q fever before IgG antibodies to *C. burnetii* become apparent. It is also positive in patients with untreated endocarditis. Contamination of PCR can occur, and many unconfirmed results are reported in the literature. Detection of patients at risk for endocarditis may be provided by systematic echocardiography in patients with acute Q fever specifically seeking for aortic bicuspidity and serologic follow-up at 3 and 6 months after acute infection. Antiphospholipid antibodies are relatively common during acute Q fever and predictive of endocarditis and deep vein thrombosis.

Use of a positron emission tomography (PET) scanner may help in the diagnosis of endocarditis (and may reveal mycotic aneurysms), vascular infection, and joint infection.

Treatment

To be active against Q fever, an antibiotic compound has to enter the cell, be effective at an acidic pH (where *C. burnetii* multiplies), and have activity against *C. burnetii*. No antibiotic is bactericidal,

TABLE 1 Treatment

Q FEVER	RECOMMENDED TREATMENT	ALTERNATIVE TREATMENT
Acute	Doxycycline (Vibramycin) 100 mg PO q12h × 14 d	Ofloxacin (Floxin) ¹ 200 mg PO q8h ³ × 14 d Cotrimoxazole (Bactrim) ¹ 160/800 mg/PO q12h × 14 d
Endocarditis	Doxycycline 100 mg PO q12h <i>plus</i> hydroxychloroquine (Plaquenil) ¹ 200 mg PO q8h ³ × 18–24 mo	Doxycycline 100 mg PO q12h <i>plus</i> ofloxacin ¹ 200 mg PO q8h ³ for 3 y to lifetime
Acute in a patient with a valvular lesion	Same as chronic Q fever for 12 mo	
In pregnancy	Cotrimoxazole (Bactrim) ¹ 160/800 mg PO q12h until term	

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

but bactericidal activity can be achieved by the addition of hydroxychloroquine (Plaquenil)¹ to doxycycline (Vibramycin).

For acute Q fever, the reference treatment is doxycycline 100 mg orally twice daily for 2 to 3 weeks. Other compounds have been reported to be effective, such as trimethoprim-sulfamethoxazole (TMP-SMX) (Bactrim)¹, Rifampin (Rifadin)¹ 300 mg twice daily, and ofloxacin (Floxin)¹ 200 mg twice daily. In the case of Q fever in pregnant women, one double-strength TMP-SMX tablet (trimethoprim 160 mg, sulfamethoxazole 800 mg)¹ twice daily until delivery prevents fetal death (Table 1).

Chronic endocarditis should be treated for 18 months to 2 years, and antibody levels should be monitored. Patients with prosthetic valves may be treated for 2 years. Two protocols have been evaluated: doxycycline 200 mg daily combined with ofloxacin¹ 400 mg daily for 4 years to lifetime, and doxycycline combined with hydroxychloroquine¹ for 1.5 to 2 years in an amount to achieve a 1 ± 0.20 µg/mL plasma concentration. Doxycycline serum levels greater than 4.5 µg/mL are associated with a more rapidly favorable outcome. This last regimen is apparently more efficacious in terms of relapse. However, regular ophthalmologic surveillance is critical to detect the accumulation of chloroquine in the retina. Both regimens expose the patient to a major risk of photosensitization.

The combination of doxycycline and hydroxychloroquine for 1 year has demonstrated efficacy in preventing endocarditis. Patients with high-level antiphospholipid antibodies may be treated by the same treatment until normalization of the antibody level.

Prevention

Prevention depends on avoiding exposure, particularly by pregnant women and patients with valvulopathy. No vaccine is currently available outside Australia.

¹Not FDA approved for this indication.

RABIES

Method of

Alan C. Jackson, MD

CURRENT DIAGNOSIS

- A history of animal bite or exposure is often absent in North America.
- Pain, paresthesias, and pruritus are early neurologic symptoms of rabies, probably reflecting infection in local sensory ganglia.
- Autonomic features are common including hypersalivation, gooseflesh, cardiac arrhythmias, and priapism.
- Hydrophobia is a highly specific feature of rabies.
- Paralytic features may be prominent, and the clinical presentation can resemble that of Guillain-Barré syndrome.
- Saliva samples for reverse transcription polymerase chain reaction (RT-PCR) and a skin biopsy should be obtained to detect rabies virus antigen to make a laboratory diagnosis of rabies.

CURRENT THERAPY

- Details of an exposure determine whether postexposure rabies prophylaxis should be initiated.
- Wound cleansing is important after potential rabies exposure.
- Active immunization with a schedule of four doses of rabies vaccine (RabAvert or Imovax) at intervals is recommended. The four-dose series is a new Centers for Disease Control and Prevention (CDC) recommendation and is not yet reflected in the package insert, which calls for five doses.
- Passive immunization (if previously the patient was not immunized) consists of infiltrating human rabies immune globulin (HyperRAB, Imogam Rabies) into the wound, with the remainder of the 20 IU/kg dosage given intramuscularly.

Rabies is an acute infection of the nervous system caused by rabies virus, which is a member of the family Rhabdoviridae in the genus *Lyssavirus*. Other lyssaviruses have only very rarely caused rabies in locations outside of the Americas.

Pathogenesis

Rabies virus is usually transmitted by bites from rabid animals. Transmission has rarely occurred through an aerosol route (in a laboratory accident or bat cave containing millions of bats) or by transplantation of infected organs or tissues (e.g., corneas). The virus is in the saliva of the rabid animal and is inoculated into subcutaneous tissues or muscles via a bite.

During most of the long incubation period (lasting 20–90 days or longer), the virus is close to the site of inoculation. The virus binds to the nicotinic acetylcholine receptor at the postsynaptic neuromuscular junction and travels toward the central nervous system (CNS) in peripheral nerves by retrograde fast axonal transport.

RABIES

Method of

Alan C. Jackson, MD

CURRENT DIAGNOSIS

- A history of animal bite or exposure is often absent in North America.
- Pain, paresthesias, and pruritus are early neurologic symptoms of rabies, probably reflecting infection in local sensory ganglia.
- Autonomic features are common including hypersalivation, gooseflesh, cardiac arrhythmias, and priapism.
- Hydrophobia is a highly specific feature of rabies.
- Paralytic features may be prominent, and the clinical presentation can resemble that of Guillain-Barré syndrome.
- Saliva samples for reverse transcription polymerase chain reaction (RT-PCR) and a skin biopsy should be obtained to detect rabies virus antigen to make a laboratory diagnosis of rabies.

CURRENT THERAPY

- Details of an exposure determine whether postexposure rabies prophylaxis should be initiated.
- Wound cleansing is important after potential rabies exposure.
- Active immunization with a schedule of four doses of rabies vaccine (RabAvert or Imovax) at intervals is recommended. The four-dose series is a new Centers for Disease Control and Prevention (CDC) recommendation and is not yet reflected in the package insert, which calls for five doses.
- Passive immunization (if previously the patient was not immunized) consists of infiltrating human rabies immune globulin (HyperRAB, Imogam Rabies) into the wound, with the remainder of the 20 IU/kg dosage given intramuscularly.

Rabies is an acute infection of the nervous system caused by rabies virus, which is a member of the family Rhabdoviridae in the genus *Lyssavirus*. Other lyssaviruses have only very rarely caused rabies in locations outside of the Americas.

Pathogenesis

Rabies virus is usually transmitted by bites from rabid animals. Transmission has rarely occurred through an aerosol route (in a laboratory accident or bat cave containing millions of bats) or by transplantation of infected organs or tissues (e.g., corneas). The virus is in the saliva of the rabid animal and is inoculated into subcutaneous tissues or muscles via a bite.

During most of the long incubation period (lasting 20–90 days or longer), the virus is close to the site of inoculation. The virus binds to the nicotinic acetylcholine receptor at the postsynaptic neuromuscular junction and travels toward the central nervous system (CNS) in peripheral nerves by retrograde fast axonal transport.

There is rapid dissemination throughout the CNS by fast axonal transport. Under natural conditions, degenerative neuronal changes are not prominent, and it is thought that the rabies virus induces neuronal dysfunction by mechanisms that are not well understood. In rabies vectors, the encephalitis is associated with behavioral changes that lead to transmission by biting. After the CNS infection is established, the virus spreads by autonomic and sensory nerves to multiple organs, including the salivary glands of rabies vectors in which the virus is secreted in saliva.

Clinical Features

In North America, where the bat is the most common rabies vector for human disease, a history of an animal bite is usually absent, and there may be no known contact with animals. The incubation period is usually between 20 and 90 days, but it occasionally lasts 1 year or longer. Prodromal features are nonspecific and include malaise, headache, and fever, and patients can also have anxiety or agitation. Approximately half of patients experience pain, paresthesias, or pruritus at the site of the wound, which has often healed, and these symptoms likely reflect infection and inflammation involving local sensory ganglia. Approximately 80% of patients with rabies have encephalitic rabies; approximately 20% have paralytic rabies.

In encephalitic rabies, there are characteristic periods of generalized arousal or hyperexcitability separated by lucid periods. Autonomic dysfunction is common and includes hypersalivation, gooseflesh, cardiac arrhythmias, and priapism. Hydrophobia is the most characteristic feature of rabies and occurs in 50% to 80% of patients; contractions of the diaphragm and other inspiratory muscles occur on swallowing. This can become a conditioned reflex, and even the sight or thought of water can precipitate the muscle contractions. Hydrophobia is thought to be caused by inhibition of inspiratory neurons near the nucleus ambiguus.

In paralytic rabies, prominent muscle weakness usually begins in the bitten extremity and progresses to quadriplegia; typically there is sphincter involvement. Patients have a longer clinical course than in encephalitic rabies. Paralytic rabies is often misdiagnosed as Guillain-Barré syndrome.

Coma subsequently develops in both clinical forms. With aggressive medical therapy, a variety of medical complications develop, and multiple organ failure is common. Survival is very rare and has usually occurred in the context of incomplete postexposure rabies prophylaxis that included administration of one or more doses of rabies vaccine.

Epidemiology

Worldwide about 60,000 human deaths per year are attributed to rabies. The impact is particularly significant in terms of years of life lost because children are commonly the victims. Most human rabies cases occur through transmission from dogs in developing countries with endemic dog rabies, particularly in Asia and Africa. In the United States and Canada, transmission of rabies virus occurs most commonly in human cases from insect-eating bats, and often there is no known history of a bat bite or exposure to bats. A bat bite might not be recognized. The rabies virus variant responsible for most human cases is found in silver-haired bats and tricolored bats. These are small bats not often in contact with humans. Other rabies vectors in North American wildlife include skunks, raccoons, and foxes, but these species are rarely responsible for transmission to humans. This is likely because of effective postexposure rabies prophylaxis after recognized exposures.

Diagnosis

Most cases of rabies can be diagnosed clinically or the diagnosis will be strongly suspected, which is particularly important so that appropriate barrier nursing techniques can be initiated to prevent exposures of many health care workers. Some patients are candidates for an aggressive therapeutic approach. A serum-neutralizing titer can be useful for diagnosis in a previously unimmunized person, but a positive titer might not develop until the second week of clinical illness, and the result of the test might not be readily

available. Detection of rabies virus antigen in a skin biopsy obtained from the nape of the neck using a fluorescent antibody technique is a useful diagnostic test. Detection of rabies virus ribonucleic acid (RNA) in saliva or in skin biopsies using RT-PCR amplification is an important recent advance for rapid rabies diagnosis. Rabies virus antigen can be detected in brain tissue obtained by brain biopsy or postmortem. Negative antemortem diagnostic laboratory tests do not exclude rabies and the tests may need to be repeated on subsequent samples.

Prevention

After a rabies exposure is recognized, rabies can be prevented with initiation of appropriate steps, including wound cleansing and active and passive immunization. After a human is bitten by a dog, cat, or ferret, the animal should be captured, confined, and observed for a period of at least 10 days; initiation of postexposure rabies prophylaxis is not necessary if the animal remains healthy. The animal should also be examined by a veterinarian prior to its release. If the animal is a stray, unwanted, shows signs of rabies, or develops signs of rabies during the observation period, the animal should be killed immediately, and its head should be transported under refrigeration for a laboratory examination. The brain should be examined via an antigen-detection method using the fluorescent antibody technique and viral isolation using cell culture or mouse inoculation.

The incubation period for animals other than dogs, cats, and ferrets is uncertain; these animals should be killed immediately after an exposure, and the head should be submitted for examination. If the result is negative, one may safely conclude that the animal's saliva did not contain rabies virus; if immunization has been initiated, it should be discontinued. If an animal escapes after an exposure, it should be considered rabid unless information from public health officials indicates this is unlikely, and rabies prophylaxis should be initiated. The physical presence of a bat might warrant postexposure prophylaxis when a person (such as a small child or sleeping adult) is unable to reliably report contact that could have resulted in a bite.

Local wound care should be given as soon as possible after all exposures, even if immunization is delayed, pending the results of an observation period. All bite wounds and scratches should be washed thoroughly with soap and water. Devitalized tissues should be debrided.

Purified chick embryo cell culture vaccine (RabAvert) and human diploid cell vaccine (Imovax) are licensed rabies vaccines in the United States and Canada. Other vaccines grown in either primary cell lines (hamster or dog kidney) or continuous cell lines (Vero cells) are also satisfactory and available in other countries. A regimen of four 1-mL doses of rabies vaccine should be given IM in the deltoid area (anterolateral aspect of the thigh is also acceptable in children). The four-dose series is a recent CDC recommendation and is an update from the five doses recommended in the current package insert. Ideally, the first dose should be given as soon as possible after exposure, but failing that, it should be given regardless of the length of a delay. Three additional doses should be given on days 3, 7, and 14. Pregnancy is not a contraindication for immunization. Live vaccines should not be given for 1 month after rabies immunization.

Local and mild systemic reactions are common. Systemic allergic reactions are uncommon, and anaphylactic reactions may be treated with epinephrine and antihistamines. Corticosteroids can interfere with the development of active immunity. Immunosuppressive medications should not be administered during postexposure therapy unless they are essential. The risk of developing rabies should be carefully considered before deciding to discontinue vaccination because of an adverse reaction. A serum-neutralizing antibody determination is necessary only after immunization of immunocompromised patients. Less-expensive vaccines derived from neural tissues are still used in some developing countries; these vaccines are associated with serious neuromuscular complications.

Human rabies immune globulin (Imogam Rabies or HyperRAB) should also be administered as passive immunization for protection

before the development of immunity from the vaccine. It should be given at the same time as the first dose of vaccine and no later than 7 days after the first dose. Rabies vaccine and human rabies immune globulin should never be administered at the same site or in the same syringe. The recommended dose of human rabies immune globulin is 20 IU/kg; larger doses should not be given because they can suppress active immunity from the vaccine. After wounds are washed, they should be infiltrated with human rabies immune globulin (if anatomically feasible), and the remainder of the dose should be given IM in the gluteal area. If the exposure involves a mucous membrane, the entire dose should be administered IM. With multiple or large wounds, the human rabies immune globulin might need to be diluted for adequate infiltration of all of the wounds. Adverse effects of human rabies immune globulin include local pain and low-grade fever.

After an exposure, a previously immunized patient should receive two 1-mL doses of rabies vaccine on days 0 and 3, but the patient should not receive human rabies immune globulin.

Management of Human Rabies

Only 16 people have survived rabies, and 15 received rabies vaccine prior to the onset of their disease. The possibilities for an aggressive approach were reviewed (see Jackson et al., 2003). There was one survivor in Wisconsin in 2004 who did not receive rabies vaccine. It is now doubtful whether the therapy she received played a significant role in her favorable outcome because a similar approach has failed in many cases (see Jackson, 2013), and there are concerns about its scientific rationale (see Zeiler and Jackson, 2016). Palliation is an important alternative approach and may be appropriate for many patients in whom rabies develops.

RAT-BITE FEVER

Method of

Jatin M. Vyas, MD, PhD

CURRENT DIAGNOSIS

- Exposure to rats is the major risk factor. Transmission can occur with simple contact with infected animals or excreta.
- A maculopapular rash and septic arthritis after initial symptoms of fever or sepsis should raise the suspicion of rat-bite fever.
- Clinicians must maintain a high index of suspicion for this diagnosis.
- Notify microbiology laboratory of clinical suspicion (slow growth, 5%–10% CO₂ microaerophilic conditions, 20% normal rabbit serum media supplementation, and avoidance of sodium polyanethol sulfonate when collecting blood cultures from the patient).

CURRENT THERAPY

Bite Site

- Clean and disinfect the bite site.
- Administer tetanus toxoid (tetanus-diphtheria toxoids, Td), if indicated.
- Postexposure rabies prophylaxis (Imovax Rabies) for animal bites should be considered in consultation with local public health authorities, though there are no reports of rat-to-human transmission of the rabies virus.

Established and Suspected Cases

- Give intravenous penicillin G at a dose of 1.2 million U/day for 5 to 7 days, followed by oral penicillin (PenVK)¹ or ampicillin (Omnipen)¹ 500 mg qid for an additional 7 days.
- For penicillin-allergic patients, consider doxycycline (Vibramycin)¹ 100 mg IV/PO twice daily or tetracycline (Achromycin)¹ 500 mg PO four times daily.
- *S. moniliformis* can be resistant to gentamicin (Garamycin),¹ tobramycin (Nebcin),¹ ciprofloxacin (Cipro),¹ and levofloxacin (Levaquin).¹

¹Not FDA approved for this indication.

Rat-bite fever (RBF) is a systemic, febrile disease caused by infection with *Streptobacillus moniliformis* or *Spirillum minus*. As the name implies, this infection is transmitted by a rat bite. However, the bacteria can also be transmitted by simple contact with infected rats or even through ingestion of food contaminated with rat excreta. Diagnosis can be difficult, and a high degree of suspicion is necessary to make a correct diagnosis. Recognition and early treatment are crucial, because case fatality is as high as 25% in untreated cases.

Epidemiology

S moniliformis is part of the normal respiratory flora of the rat. From 50% to 100% of healthy wild, laboratory, and pet rats harbor *S moniliformis* in the nasopharynx. *S moniliformis* is also excreted in the urine. *S minus* causes rat-bite fever mostly in Asia, but this organism is found worldwide. *S minus* has been demonstrated in rat conjunctival secretions and blood. Thus rat-bite fever can be transmitted not only from a bite but also through scratches, handling of dead rats, handling litter material, or by contamination of rat excreta.

Although the rat is the natural reservoir and major vector of the disease, *S moniliformis* has also been found in other rodents such as mice, squirrels, gerbils, and weasels. No precise data are available on the true incidence of rat-bite fever because it is not a reportable disease. It appears to be unusual in Western countries, a rarity that might reflect failed diagnosis, empiric treatment of infected bites and scratches caused by animals, or spontaneous recovery.

Risk Factors

The major risk factor is exposure to rats, either as an occupational hazard for persons such as laboratory workers, veterinarians, or pet shop employees, or for persons who have rats for pets or feed rats to snakes, especially children. Classically, homelessness and lower socioeconomic status were described as major factors, but most cases reported in the last few years have involved pet rats. Thirty percent of patients with rat-bite fever do not report any exposure to rats or other rodents. Therefore the lack of documented exposure does not exclude this diagnosis.

Pathophysiology

Very little is known about the pathophysiology of *S moniliformis* infections. Presumably, the failure of local control by dendritic cells, tissue macrophages, neutrophils, and other components of the innate immune system results in deeper infection, leading to

before the development of immunity from the vaccine. It should be given at the same time as the first dose of vaccine and no later than 7 days after the first dose. Rabies vaccine and human rabies immune globulin should never be administered at the same site or in the same syringe. The recommended dose of human rabies immune globulin is 20 IU/kg; larger doses should not be given because they can suppress active immunity from the vaccine. After wounds are washed, they should be infiltrated with human rabies immune globulin (if anatomically feasible), and the remainder of the dose should be given IM in the gluteal area. If the exposure involves a mucous membrane, the entire dose should be administered IM. With multiple or large wounds, the human rabies immune globulin might need to be diluted for adequate infiltration of all of the wounds. Adverse effects of human rabies immune globulin include local pain and low-grade fever.

After an exposure, a previously immunized patient should receive two 1-mL doses of rabies vaccine on days 0 and 3, but the patient should not receive human rabies immune globulin.

Management of Human Rabies

Only 16 people have survived rabies, and 15 received rabies vaccine prior to the onset of their disease. The possibilities for an aggressive approach were reviewed (see Jackson et al., 2003). There was one survivor in Wisconsin in 2004 who did not receive rabies vaccine. It is now doubtful whether the therapy she received played a significant role in her favorable outcome because a similar approach has failed in many cases (see Jackson, 2013), and there are concerns about its scientific rationale (see Zeiler and Jackson, 2016). Palliation is an important alternative approach and may be appropriate for many patients in whom rabies develops.

RAT-BITE FEVER

Method of

Jatin M. Vyas, MD, PhD

CURRENT DIAGNOSIS

- Exposure to rats is the major risk factor. Transmission can occur with simple contact with infected animals or excreta.
- A maculopapular rash and septic arthritis after initial symptoms of fever or sepsis should raise the suspicion of rat-bite fever.
- Clinicians must maintain a high index of suspicion for this diagnosis.
- Notify microbiology laboratory of clinical suspicion (slow growth, 5%–10% CO₂ microaerophilic conditions, 20% normal rabbit serum media supplementation, and avoidance of sodium polyanethol sulfonate when collecting blood cultures from the patient).

CURRENT THERAPY

Bite Site

- Clean and disinfect the bite site.
- Administer tetanus toxoid (tetanus-diphtheria toxoids, Td), if indicated.
- Postexposure rabies prophylaxis (Imovax Rabies) for animal bites should be considered in consultation with local public health authorities, though there are no reports of rat-to-human transmission of the rabies virus.

Established and Suspected Cases

- Give intravenous penicillin G at a dose of 1.2 million U/day for 5 to 7 days, followed by oral penicillin (PenVK)¹ or ampicillin (Omnipen)¹ 500 mg qid for an additional 7 days.
- For penicillin-allergic patients, consider doxycycline (Vibramycin)¹ 100 mg IV/PO twice daily or tetracycline (Achromycin)¹ 500 mg PO four times daily.
- *S. moniliformis* can be resistant to gentamicin (Garamycin),¹ tobramycin (Nebcin),¹ ciprofloxacin (Cipro),¹ and levofloxacin (Levaquin).¹

¹Not FDA approved for this indication.

Rat-bite fever (RBF) is a systemic, febrile disease caused by infection with *Streptobacillus moniliformis* or *Spirillum minus*. As the name implies, this infection is transmitted by a rat bite. However, the bacteria can also be transmitted by simple contact with infected rats or even through ingestion of food contaminated with rat excreta. Diagnosis can be difficult, and a high degree of suspicion is necessary to make a correct diagnosis. Recognition and early treatment are crucial, because case fatality is as high as 25% in untreated cases.

Epidemiology

S moniliformis is part of the normal respiratory flora of the rat. From 50% to 100% of healthy wild, laboratory, and pet rats harbor *S moniliformis* in the nasopharynx. *S moniliformis* is also excreted in the urine. *S minus* causes rat-bite fever mostly in Asia, but this organism is found worldwide. *S minus* has been demonstrated in rat conjunctival secretions and blood. Thus rat-bite fever can be transmitted not only from a bite but also through scratches, handling of dead rats, handling litter material, or by contamination of rat excreta.

Although the rat is the natural reservoir and major vector of the disease, *S moniliformis* has also been found in other rodents such as mice, squirrels, gerbils, and weasels. No precise data are available on the true incidence of rat-bite fever because it is not a reportable disease. It appears to be unusual in Western countries, a rarity that might reflect failed diagnosis, empiric treatment of infected bites and scratches caused by animals, or spontaneous recovery.

Risk Factors

The major risk factor is exposure to rats, either as an occupational hazard for persons such as laboratory workers, veterinarians, or pet shop employees, or for persons who have rats for pets or feed rats to snakes, especially children. Classically, homelessness and lower socioeconomic status were described as major factors, but most cases reported in the last few years have involved pet rats. Thirty percent of patients with rat-bite fever do not report any exposure to rats or other rodents. Therefore the lack of documented exposure does not exclude this diagnosis.

Pathophysiology

Very little is known about the pathophysiology of *S moniliformis* infections. Presumably, the failure of local control by dendritic cells, tissue macrophages, neutrophils, and other components of the innate immune system results in deeper infection, leading to

bacteremia. Studies using histologic analysis have revealed intravascular thrombosis near the port of entry.

Prevention

The role of prophylactic antibiotics is unknown, but some authors recommend the use of oral penicillin V (PenVK)¹ after documented exposure to rats and a break in the skin. Penicillin V should be given for 3 days at a dose of 2 g per day for adults. Primary prevention should be encouraged for patients with occupational risk by using protective gloves to handle animals or cages.

Clinical Manifestations

Rat-bite fever is a systemic febrile disease. Classically, following a rat bite and a short incubation of 2 to 10 days, systemic dissemination of the organism is associated with an abrupt onset with intermittent relapsing fever, rigors, myalgias, arthralgias, headache, sore throat, malaise, and vomiting. These symptoms are followed within the first week by the development of a maculopapular rash in 75% of patients. The rash can be pustular, purpuric, or petechial, and it typically involves the extremities, in particular the palms and soles. The bite site typically heals promptly, with minimal inflammation and no significant regional lymphadenopathy.

Following the rash, approximately 50% of infected patients develop an asymmetric migrating polyarthritis, which appears to be exceedingly painful and affects large and middle-sized joints. Joint effusion appears more common in adults. Infection can occur in any tissue. Although most cases of rat-bite fever resolve spontaneously, there have been reports of complications. These include meningitis, endocarditis (including prosthetic valve endocarditis), myocarditis, pericarditis, pneumonia, brain abscess, septic arthritis, DIC (disseminated intravascular coagulation), and infarcts of the spleen and kidneys. The mortality rate in untreated cases is around 10% to 15%, and it rises to more than 50% in the rare cases with cardiac involvement.

Two closely related variants have been described. In Haverrill fever, the organism is transmitted by ingestion of contaminated food. Haverrill fever tends to occur in epidemics and also causes rashes and arthritis, but upper respiratory tract symptoms and vomiting appear more prominent. It is important to note that these patients do not provide a history of exposure to rodents. Sodoku is a rat-bite fever caused by *S minus*; it is common in Japan. The course is more subacute, arthritic symptoms are rare, and if the bite initially heals, it then ulcerates and is associated with regional lymphadenopathy and a distinctive rash. *S minus* cannot be grown using synthetic media, and thus microbiologic diagnosis rests on visualization of these organisms in infected tissues.

Diagnosis

Diagnosis is difficult and requires a high clinical index of suspicion. The initial symptoms of rat-bite fever are nonspecific, triggering a broad differential diagnosis. Additionally, the fastidious nature of this organism makes isolation from blood cultures difficult. Clinicians should ask about rodent exposure when compatible symptoms are seen in patients. Rat-bite fever should not be ruled out in the absence of bite history, because transmission can occur without a bite, and pet owners or laboratory workers can minimize the significance of the bite, especially in the absence of a local reaction.

No reliable serologic test is available, and the definitive diagnosis requires isolation of *S moniliformis* from the wound, blood, or synovial fluid in patients with septic arthritis. The microbiology laboratory should be specifically notified of any clinical suspicion to enhance the chances of recovering the pathogen.

S moniliformis is a highly pleomorphic, nonencapsulated, nonmotile, gram-negative rod, which can stain positively on Gram stain (Figure 1). It is often dismissed as proteinaceous debris because of its numerous bulbous swellings with occasional clumping (*moniliformis* = “necklace-like”). It grows slowly and requires a microaerophilic environment with 5% to 10% CO₂ or anaerobic

Figure 1 Gram stain of *Streptobacillus moniliformis*. Gram stain of growth from anaerobic bottle, $\times 100$ magnification [microphotography]. (Reprinted with permission from Partners' Infectious Disease Images; accessed on August 11, 2016, from <http://www.idimages.org/images/detail/?imageid=373>.)

conditions and media supplementation with 20% normal rabbit serum. Cultures can take up to 7 days to turn positive. Some experts recommend holding blood cultures for 21 days to permit sufficient time to grow this organism. *S moniliformis* is also inhibited by sodium polyanethol sulfonate, a common adjunct in most commercial blood culture media at a concentration as low as 0.0125%. *S moniliformis* has been identified using polymerase chain reaction amplification and 16S ribosomal ribonucleic acid (rRNA) sequencing, which shows great promise though it is available at reference laboratories. Fatty acid profiles obtained by gas-liquid chromatography can also be used for identification.

S minus, the other etiologic agent of rat-bite fever, is a short, thick, gram-negative, tightly coiled spiral rod that measures 0.2 to 0.5 μm and has two to six helical turns.

Differential Diagnosis

Differential diagnosis for fever, rash, and polyarthritis is broad. Malaria, typhoid fever, and neoplastic disease can cause relapsing fevers, and the presence of a rash and polyarthritis might suggest viral and rickettsial diseases including Rocky Mountain spotted fever. An asymmetric oligoarthritis suggests disseminated gonococcal and meningococcal diseases in the context of cutaneous lesions on the palms and soles. Lyme disease, leptospirosis, or secondary syphilis can have a similar clinical presentation. Finally, when classic infectious symptoms such as fever or rash are missing, any causes of polyarthritis, from crystal-induced arthropathies to rheumatoid arthritis, should be considered.

Treatment

All established cases of rat-bite fever should be treated with antibiotics because of the associated mortality and potential for complications. Intravenous penicillin G at a dose of 1.2 million units per day should be initiated as soon as the clinical diagnosis is made. Empiric therapy is necessary and should not be delayed for laboratory confirmation of this bacterial infection. The intravenous treatment should continue for 5 to 7 days. After treatment with IV penicillin and suitable clinical response, therapy should be continued with oral penicillin (PenVK)¹ or ampicillin (Omnipen)¹ at a dose of 500 mg qid for an additional 7 days. For patients allergic to penicillin, intravenous doxycycline (Vibramycin)¹ at a dose of 100 mg every 12 hours or oral tetracycline (Achromycin)¹ at a dose of 500 mg four times a day can be used.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Streptomycin¹ and cephalosporins including cefotaxime (Clavan) have been reported to be potentially useful. Other antibiotics including azithromycin (Zithromax),¹ erythromycin,¹ carbapenems,¹ aztreonam (Azactam),¹ clindamycin (Cleocin),¹ vancomycin (Vancocin),¹ and nitrofurantoin (Macrochantin)¹ have shown efficacy in vitro, but they lack good clinical correlation to recommend them for routine use. Erythromycin has been associated with treatment failures. Trimethoprim-sulfamethoxazole (Bactrim),¹ polymyxin B,¹ gentamicin (Garamycin),¹ tobramycin (Nebcin),¹ ciprofloxacin (Cipro),¹ and levofloxacin (Levaquin)¹ should not be used because in vitro resistance has been demonstrated.

Typically, the bite site heals promptly. It should be cleaned and disinfected, as is typical for management of other wounds. Tetanus prophylaxis (tetanus-diphtheria toxoids, Td) administration is indicated as required by the patient's immunization record. Rabies prophylaxis (Imovax Rabies) is usually not required for rodent bite, but consultation with local public health authorities is encouraged. There are no reports of transmission of the rabies virus from rats to humans.

RELAPSING FEVER

Method of
Diego Cadavid, MD

CURRENT DIAGNOSIS

- There are two forms of relapsing fever: epidemic and endemic.
- Epidemic relapsing fever is transmitted from person to person by the body louse *Pediculus humanus*.
- Endemic relapsing fever is transmitted from rodent reservoirs to humans exposed to endemic areas by soft-bodied ticks of the genus *Ornithodoros*.
- The hallmark of relapsing fever is two or more febrile episodes separated by periods of relative well-being.
- The diagnosis is confirmed by visualization of the etiologic spirochetes in thin peripheral blood smears prepared at times of febrile peaks by phase-contrast or darkfield microscopy or light microscopy after Wright or Giemsa staining.

CURRENT THERAPY

- The antibiotic of choice for treatment of relapsing fever is doxycycline (Doryx) except in children or pregnant women. In children <8 years of age, erythromycin (E-Mycin)¹ or oral penicillin is used instead of tetracycline (Table 3).
- Relapsing fever, if severe or complicated with neuroborreliosis, requires treatment with the intravenous antibiotics ceftriaxone (Rocephin) or penicillin G (Table 3).
- The louse-borne epidemic form is treated with a single dose, whereas the endemic tick-borne form is treated with multiple doses for at least 1 week (Table 3).
- Antibiotic treatment of relapsing fever results in the Jarisch-Herxheimer reaction (JHR) in as many as 60% of cases, more often in the epidemic than in the endemic form. It is characterized by the sudden onset of tachycardia, hypotension, chills, rigors, diaphoresis, and high fever. To reduce the risk of JHR, antibiotics should be started between but not at times of febrile peaks.

¹Not FDA approved for this indication.

Relapsing fever is one of several diseases caused by spirochetes. Other human spirochetal diseases are syphilis, Lyme disease, and leptospirosis. Notable features of spirochetes are wavy and helical shapes, length-to-diameter ratios of as much as 100 to 1, and flagella that lie between the inner and outer cell membranes. The spirochetes that cause relapsing fever are in the genus *Borrelia*. Other *Borrelia* species cause Lyme disease, avian spirochetosis, and epidemic bovine abortion. Table 1 shows the main *Borrelia* species of relapsing fever, their vectors, and an estimate of their geographic ranges. In the United States, relapsing fever was considered a disease endemic only in the West. However, the recent finding of relapsing fever-like *Borrelia* in ticks and dogs in the eastern United States suggests that the risk of relapsing fever may extend into the East.

Epidemiology

There are two forms of relapsing fever: epidemic transmitted to humans by the body louse *Pediculus humanus* (louse-borne relapsing fever [LBRF]) and endemic transmitted to humans by soft-bodied ticks of the genus *Ornithodoros* (tick-borne relapsing fever [TBRF]). In LBRF, itching caused by skin infestation with lice leads to scratching, which may result in crushing of lice and release of infected hemolymph into areas of skin abrasion. Louse infestation is associated with cold weather and a lack of hygiene. Migrant workers and soldiers at war are particularly susceptible to this infection. Historically, massive outbreaks of LBRF occurred in Eurasia, Africa, and Latin America, but currently the disease is found only in Ethiopia and neighboring countries. However, immigrants can spread LBRF to other parts of the world.

The main risk factor for TBRF is exposure to endemic areas (Table 1). The risk of infection increases with outdoor activities in areas where rodents nest, like entering caves or sleeping in rustic cabins. *Ornithodoros* ticks are soft-bodied and feed for short periods of time (minutes), usually at night. They can live many years between blood meals and may transmit spirochetes to their offspring transovarially. Infection is produced by regurgitation of infected tick saliva into the skin wound during tick feeding. There are several natural vertebrate reservoirs for TBRF, but most common are rodents (deer mice, chipmunks, squirrels, and rats). In contrast, the body louse *Pediculus humanus* is a strict human parasite, living and multiplying in clothing. *Borrelia miyamotoi* is a spirochete closely related to the bacteria that cause TBRF. It is more distantly related to the bacteria that cause Lyme disease. First identified in 1995 in ticks from Japan, *B. miyamotoi* has since been detected in two species of North American ticks, the black-legged or "deer" tick (*Ixodes scapularis*) and the western black-legged tick

Streptomycin¹ and cephalosporins including cefotaxime (Claforan)¹ have been reported to be potentially useful. Other antibiotics including azithromycin (Zithromax),¹ erythromycin,¹ carbapenems,¹ aztreonam (Azactam),¹ clindamycin (Cleocin),¹ vancomycin (Vancocin),¹ and nitrofurantoin (Macrochantin)¹ have shown efficacy in vitro, but they lack good clinical correlation to recommend them for routine use. Erythromycin has been associated with treatment failures. Trimethoprim-sulfamethoxazole (Bactrim),¹ polymyxin B,¹ gentamicin (Garamycin),¹ tobramycin (Nebcin),¹ ciprofloxacin (Cipro),¹ and levofloxacin (Levaquin)¹ should not be used because in vitro resistance has been demonstrated.

Typically, the bite site heals promptly. It should be cleaned and disinfected, as is typical for management of other wounds. Tetanus prophylaxis (tetanus-diphtheria toxoids, Td) administration is indicated as required by the patient's immunization record. Rabies prophylaxis (Imovax Rabies) is usually not required for rodent bite, but consultation with local public health authorities is encouraged. There are no reports of transmission of the rabies virus from rats to humans.

¹Not FDA approved for this indication.

	<i>Borrelia crocidurae</i>	<i>Ornithodoros erraticus</i>	North and East Africa, Middle East, southern Europe
	<i>Borrelia duttoni</i>	<i>Ornithodoros moubata</i>	Sub-Saharan Africa
	<i>Borrelia persica</i>	<i>Ornithodoros tholozani</i>	Middle East, Greece, Central Asia
	<i>Borrelia uzbekistan</i>	<i>Ornithodoros pappilipes</i>	Tajikistan, Uzbekistan
Epidemic	<i>Borrelia recurrentis</i>	<i>Pediculus humanus</i>	Worldwide (recently only in East Africa including immigrants to Europe)

(*Ixodes pacificus*). These ticks are already known to transmit Lyme disease, anaplasmosis, and babesiosis.

Clinical Diagnosis

Relapsing fever should be suspected in any patient presenting with two or more episodes of high fever and constitutional symptoms spaced by periods of relative well-being. The index of suspicion increases if the patient has been exposed to endemic areas for TBRF or to countries where LBRF still occurs (Table 1). Whereas LBRF is usually associated with a single febrile relapse, TBRF usually has multiple relapses (up to 13). In LBRF the second episode of fever is typically milder than the first; in TBRF the multiple febrile periods are usually of equal severity. The febrile periods last from 1 to 3 days, and the intervals between fevers last from 3 to 10 days. During the febrile periods, numerous spirochetes are circulating in the blood. This is called *spirochetemia* and is sometimes unexpectedly detected during routine blood smear examinations. Between fevers, spirochetemia is not observed because the numbers are low. The fever pattern and recurrent spirochetemia are the consequences of antigenic variation of abundant outer membrane lipoproteins of relapsing fever *Borrelia* species that are the target for serotype-specific antibodies.

The mean latency between exposure to ticks in the endemic form or to lice in the epidemic form and onset of symptoms is 6 days (range, 3–18 days). Because *Ornithodoros* ticks feed briefly and painlessly at night, patients with TBRF may not be able to recall having been bitten by a tick. The clinical manifestations of TBRF and LBRF are similar, although some differences do exist. Table 2 lists the frequency of the most common manifestations of TBRF. The usual initial presentation is sudden onset of chills followed by high fever, tachycardia, severe headache, vomiting, myalgia and arthralgia, and often delirium. In the early stages, a reddish rash may be seen over the trunk, arms, or legs. The fever remains high for 3 to 5 days, and then it clears abruptly. After an asymptomatic period of 7 to 10 days, the fever and other constitutional symptoms can reappear suddenly. The febrile episodes gradually become less severe, and the person eventually recovers completely. As the disease progresses, fever, jaundice, hepatosplenomegaly, cardiac arrhythmias, and cardiac failure may occur, especially with LBRF. Jaundice is more common at times of relapses. Patients with LBRF are more likely to develop petechiae on the trunk, extremities, and mucous membranes; epistaxis; and blood-tinged sputum. Rupture of the spleen may rarely occur. Multiple neurologic complications can occur as a result of disseminated intravascular coagulation in LBRF and as a result of infection of the meninges and cranial and spinal nerve roots by spirochetes in TBRF. The most common neurologic complications of TBRF are aseptic meningitis and facial palsy. Relapsing fever in pregnant women can cause abortion, premature birth, and neonatal death. Sometimes patients can have nonfebrile relapses, consisting of periods of severe

headache, backache, weakness, and other constitutional symptoms without fever that occur at the time of expected relapses. Delirium may persist for weeks after the fever resolves, and, rarely, symptoms may be protracted.

Relapsing fever may be confused with many diseases that are relapsing or cause high fevers. These include typhoid fever, yellow fever, dengue, African hemorrhagic fevers, African trypanosomiasis, brucellosis, malaria, leptospirosis, rat-bite fever, intermittent cholangitis, cat-scratch disease, and echovirus 9 infection, among others. Relapsing fever *Borrelia* spp. have antigens that are cross reactive with Lyme disease *Borrelia* spp. and inasmuch as the endemic areas of relapsing fever and Lyme disease overlap to some extent, confusion between the two infections can be expected.

Laboratory Diagnosis

Although the pattern of recurring fever is the clue to diagnosing relapsing fever, confirmation of the diagnosis requires demonstration of spirochetes in peripheral blood taken during an episode of fever. The comparatively large number of spirochetes in the blood during relapsing fever provides the opportunity for the simplest method for laboratory diagnosis of the infection, light microscopy of Wright- or Giemsa-stained thin blood smears or darkfield or phase-contrast microscopy of a wet mount of plasma. The blood should be obtained during or just before peaks of body temperature. Between fever peaks, spirochetes often can be demonstrated by inoculation of blood or cerebrospinal fluid (CSF) into special culture medium (BSK-H with 6% rabbit serum available from Sigma) or experimental animals. Enrichment for spirochetes is achieved by using the platelet-rich fraction of plasma or the buffy coat of sedimented blood. In the United States the most common causes of relapsing fever are *Borrelia hermsii* and *Borrelia turicatae*; both grow in BSK-H medium and in young mice or rats. Whereas direct visual detection of organisms in the blood is the most common method for laboratory confirmation of relapsing fever, immunoassays for antibodies are the most common means of laboratory confirmation for Lyme disease. Although serologic assays have been developed for the agents of relapsing fever, these are not widely available and of dubious utility. The antigenic variation displayed by the relapsing fever species means there are hundreds of different “serotypes.” If a different serotype or species is used for preparing the antigen, only antibodies to conserved antigens may be detected. For this reason, a standardized enzyme-linked immunosorbent assay (ELISA) with Lyme disease *Borrelia* as antigen may be the best available serologic assay for relapsing fever. ELISA for *Borrelia burgdorferi* antibodies is routinely done across the United States and Europe. If a positive result for IgM or IgG antibodies is obtained, the Western blot for antibodies to *B. burgdorferi* antigens would be expected to discriminate current or past Lyme disease from relapsing fever, as well as from syphilis, another cause of false-positive Lyme disease ELISA results. Other frequent laboratory abnormalities can occur in relapsing fever but are not diagnostic. These include elevated white blood cell count with increased neutrophils, thrombocytopenia, increased serum bilirubin, proteinuria, microhematuria, prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT), and elevation of fibrin degradation products.

Treatment

Relapsing fever *Borrelia*s are very sensitive to several antibiotics, and antimicrobial resistance is rare. Table 3 summarizes the treatment options for adults and children younger than 8 years. Children older than 8 years can be treated with the same antibiotics as adults, but the doses should be adjusted by weight. Before antibiotics are given, the possibility of causing the Jarisch-Herxheimer reaction (JHR) should be considered (see later). The tetracycline antibiotics are most commonly used for treatment of LBRF and TBRF. The first antibiotic of choice in adults and children older than 8 years is doxycycline (Doryx). In general, shorter treatments are needed for LBRF than for TBRF. Single-dose therapy is usually recommended for LBRF. In contrast, in TBRF even multiple doses of tetracyclines for up to 10 days may fail to prevent relapses, and retreatment can be required. Physicians have successfully treated patients infected with *B. miyamotoi* with a 2 to 4-week course of doxycycline.

Alternative oral antibiotics to the tetracyclines are erythromycin (E-Mycin)¹, azithromycin (Zithromax)¹, amoxicillin (Amoxil)¹, penicillin¹, and chloramphenicol (Chloromycetin).¹ However, oral chloramphenicol is not available in the United States. Erythromycin, azithromycin, and penicillin do not appear as effective as the tetracyclines; however, they are recommended for children younger than 8 years and for pregnant women. Amoxicillin is another

TABLE 3 Treatment Options for Tick-Borne Relapsing Fever*

Adults

Nonsevere forms

1. Doxycycline (Doryx oral), 100 mg PO bid for 1–2 wk[†]
2. Tetracycline (Sumycin), 500 mg PO qid for 1–2 wk
3. Erythromycin (Erythrocin),¹ 500 mg PO tid for 1–2 wk

Severe forms

1. Ceftriaxone (Rocephin),¹ 2 g IV qd for 1–2 wk
2. Penicillin G parenteral aqueous (Pfizerpen),¹ 4 million U IV q4h for 1–2 wk

Children (≤8 y)

Nonsevere forms

1. Erythromycin suspension oral (EryPed),¹ 30–50 mg/kg/d divided tid for 1–2 wk
2. Azithromycin oral suspension (Zithromax),¹ 20 mg/kg on the first day followed by 10 mg/kg/d for 4 more days
3. Penicillin V (Pen-Vee K),¹ 25–50 mg/kg/d divided qid for 1–2 wk
4. Amoxicillin (Amoxil),¹ 50 mg/kg/d divided tid for 1–2 wk

Severe forms

1. Ceftriaxone (Rocephin),¹ 75–100 mg/kg/d IV for 1–2 wk
2. Penicillin G parenteral aqueous (Pfizerpen),¹ 300,000 U/kg/d given IV in divided doses q4h for 1–2 wk

Abbreviations: IV = intravenous; PO = orally.

[†]Not FDA approved for this indication.

*The same oral agents are used for treatment of louse-borne (epidemic) relapsing fever but given as a single dose.

[†]In general, treatment for 1 wk is recommended in early/milder cases and for up to 2 wk for more severe cases.

alternative for young children with early Lyme disease; however, it is ineffective for human granulocytic ehrlichiosis, which sometimes occurs as a co-infection with Lyme disease.

Although treatment with antibiotics is usually given orally, they may need to be given intravenously if severe vomiting makes swallowing impractical. If there are symptoms and signs of meningitis or encephalitis without clinical or radiologic signs of increased intracranial pressure, the CSF should be examined to rule out central nervous system (CNS) infection. The finding of elevation of CSF cells and protein demands the use of parenteral antibiotics, such as penicillin G¹ or ceftriaxone (Rocephin).¹ Optimally, antibiotic treatment should be started during afebrile periods when the spirochetemia is low. Starting therapy near the peak of a febrile period may induce JHR, in which high fever and a rise and subsequent fall in blood pressure, sometimes to dangerously low levels, may occur. Dehydration should be treated with fluids given intravenously. Severe headache can be treated with pain relievers such as codeine, and nausea or vomiting can be treated with prochlorperazine (Compazine).

Jarisch-Herxheimer Reaction

Antibiotic treatment of relapsing fever causes JHR in as many as 60% of cases. JHR is more common in LBRF than in TBRF. It is characterized by the sudden onset of tachycardia, hypotension, chills, rigors, diaphoresis, and high fever. Patients with JHR have said that they felt as if they were going to die. JHR is caused by the

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

rapid killing of circulating spirochetes 1 to 4 hours after the first dose of antibiotic, which results in the release of large amounts of *Borrelia* lipoproteins in the circulation followed by massive release of tumor necrosis factor and other cytokines. If possible, patients with JHR should be transferred to an intensive care unit for close monitoring and treatment. Over several hours, the temperature declines and the patient feels better. Large amounts of intravenous fluids (0.9% sodium chloride solution) may be required to treat hypotension. Steroids and nonsteroidal anti-inflammatory agents have no effect on the frequency or severity of the JHR. One study found that pretreatment with anti-TNF- α monoclonal antibody (Humira)¹ suppressed JHR after penicillin treatment for LBRF and reduced the associated increases in plasma cytokines. Death can occur as a result of JHR secondary to cardiovascular collapse in up to 5% of patients with treated LBRF and much less frequently in TBRF.

Outcome

Complete recovery occurs in 95% or more of adequately treated patients. The prognosis for untreated cases or if treatment is delayed varies. A mortality rate as high as 40% is reported in untreated epidemics of LBRF. Relapsing fever also has a high mortality rate in neonates. Some neurologic sequelae can occur in patients with TBRF complicated with neuroborreliosis.

Prevention

Prevention of TBRF involves avoidance of rodent- and tick-infested dwellings such as animal burrows, caves, and abandoned cabins. Wearing clothing that protects skin from tick access (e.g., long pants and long-sleeved shirts) is also helpful. Repellents and acaricides provide additional protection. Diethyltoluamide (DEET) repels ticks when applied to clothing or skin, but it must be used with caution. It loses its effectiveness within 1 to several hours when applied to skin and must be reapplied; it is absorbed through the skin and may cause CNS toxicity if used excessively. Picaridin (KBR 3023), which has been used as an insect repellent for years in Europe and Australia, is now available in the United States in 7% solution as Cutter Advanced Repellent (Spectrum Brands). The US Centers for Disease Control and Prevention (CDC) is recommending it as an alternative to DEET. Permethrin Insect Repellent, an acaricide, is more effective than DEET but should not be applied directly to skin. When applied to clothing, it provides good protection for 1 day or more. In LBRF, prevention can be achieved by promoting personal hygiene and by dusting undergarments and the inside of clothing with malathion¹ powder² or lindane¹ powder² when available. Widespread antibiotic use may be necessary to control epidemics of LBRF, using one or two doses of 100 mg doxycycline¹ given within 1 week of exposure.

RUBELLA AND CONGENITAL RUBELLA

Method of

Dee Ann Bragg, MD

CURRENT DIAGNOSIS

- Given its clinical overlap with other viral syndromes, suspected rubella infection must be confirmed with laboratory testing.
- Rubella serology or viral polymerase chain reaction (PCR) testing are available options for confirming a suspected diagnosis.

CURRENT THERAPY

- Rubella infection is largely self-limited with no specific treatment indicated.
- Infection during pregnancy should prompt further evaluation and counseling regarding risks and potential outcomes.
- Treatment of children with congenital rubella syndrome requires a multidisciplinary effort based on individual manifestations.
- Vaccination is essential in reducing the risk of rubella and congenital rubella syndrome.

Rubella typically presents in children and adults as a mild viral illness, but is one of the TORCH infections (toxoplasmosis, other, rubella, cytomegalovirus, herpes) known to cause congenital anomalies. Although vaccination efforts have led to the successful eradication of rubella in the United States, it remains a significant cause of morbidity and death worldwide. Its name is derived from Latin and means “little red.” Initially considered a variant of measles or scarlet fever, rubella was first described as its own entity in the German medical literature in 1814. Thus it is still often referred to as “German measles” in common nomenclature.

Pathophysiology and Virology

Rubella virus, a single-stranded RNA virus and the only member of the Rubivirus genus, is part of the Togaviridae family and is the causative agent of rubella infection. There are 13 recognized genotypes of rubella, each with minor differences in nucleotide sequencing and gene expression. Rubella typically presents as a mild and self-limited illness. During pregnancy, however, it can infect the placenta and disrupt organogenesis by creating systemic inflammation and inhibiting actin assembly. Outcomes of antenatal infection are variable but can include miscarriage, fetal death, and congenital rubella syndrome (CRS).

Multiple factors are involved in the pathogenesis of CRS. Rubella infection can cause necrosis of the chorionic epithelial and endothelial cells. These cells then enter fetal circulation and can incite thrombotic or ischemic lesions in the eyes, ears, brain, and heart. The virus also appears to trigger an immune-modulated upregulation of interferon and cytokines, which can alter the normal development and differentiation of fetal cells.

Epidemiology

Although rubella is less contagious than other viruses such as influenza or measles, large epidemics are associated with significant morbidity from complications including encephalitis, fetal loss, deafness, and blindness. Norman Gregg, an Australian ophthalmologist, was the first to recognize the teratogenic potential of rubella when in 1941 he noted an unusually high incidence of congenital cataracts after an area outbreak.

rapid killing of circulating spirochetes 1 to 4 hours after the first dose of antibiotic, which results in the release of large amounts of *Borrelia* lipoproteins in the circulation followed by massive release of tumor necrosis factor and other cytokines. RUBELLA AND CONGENITAL RUBELLA

Method of

Dee Ann Bragg, MD

CURRENT DIAGNOSIS

- Given its clinical overlap with other viral syndromes, suspected rubella infection must be confirmed with laboratory testing.
- Rubella serology or viral polymerase chain reaction (PCR) testing are available options for confirming a suspected diagnosis.

CURRENT THERAPY

- Rubella infection is largely self-limited with no specific treatment indicated.
- Infection during pregnancy should prompt further evaluation and counseling regarding risks and potential outcomes.
- Treatment of children with congenital rubella syndrome requires a multidisciplinary effort based on individual manifestations.
- Vaccination is essential in reducing the risk of rubella and congenital rubella syndrome.

Rubella typically presents in children and adults as a mild viral illness, but is one of the TORCH infections (toxoplasmosis, other, rubella, cytomegalovirus, herpes) known to cause congenital anomalies. Although vaccination efforts have led to the successful eradication of rubella in the United States, it remains a significant cause of morbidity and death worldwide. Its name is derived from Latin and means “little red.” Initially considered a variant of measles or scarlet fever, rubella was first described as its own entity in the German medical literature in 1814. Thus it is still often referred to as “German measles” in common nomenclature.

Pathophysiology and Virology

Rubella virus, a single-stranded RNA virus and the only member of the Rubivirus genus, is part of the Togaviridae family and is the causative agent of rubella infection. There are 13 recognized genotypes of rubella, each with minor differences in nucleotide sequencing and gene expression. Rubella typically presents as a mild and self-limited illness. During pregnancy, however, it can infect the placenta and disrupt organogenesis by creating systemic inflammation and inhibiting actin assembly. Outcomes of antenatal infection are variable but can include miscarriage, fetal death, and congenital rubella syndrome (CRS).

Multiple factors are involved in the pathogenesis of CRS. Rubella infection can cause necrosis of the chorionic epithelial and endothelial cells. These cells then enter fetal circulation and can incite thrombotic or ischemic lesions in the eyes, ears, brain, and heart. The virus also appears to trigger an immune-modulated upregulation of interferon and cytokines, which can alter the normal development and differentiation of fetal cells.

Epidemiology

Although rubella is less contagious than other viruses such as influenza or measles, large epidemics are associated with significant morbidity from complications including encephalitis, fetal loss, deafness, and blindness. Norman Gregg, an Australian ophthalmologist, was the first to recognize the teratogenic potential of rubella when in 1941 he noted an unusually high incidence of congenital cataracts after an area outbreak.

Rubella was successfully eradicated from the United States in 2004 due to widespread vaccination efforts, and most sporadic cases since that time have been documented in foreign-born young adults. In endemic areas, annual springtime outbreaks are common. However, sporadic cases can occur year-round in temperate climates. Outbreaks typically affect early school-aged children, and the mean age for an infected host is 5 to 9 years. Because lifelong immunity develops after natural infection, large cyclical epidemics tend to occur every 3 to 8 years as population immunity wanes.

Humans are the only known host of rubella infection, and the virus is transmitted from person to person through respiratory droplets. After transmission, rubella virus replicates in the respiratory mucosa and cervical lymph nodes before entering systemic circulation and spreading to target organs.

Clinical Manifestations

Acquired Rubella

After an incubation period of about 14 days (range, 12–23), a variety of clinical symptoms can appear. These are generally mild, and about 50% of cases are asymptomatic. In children, a skin rash is typically the initial manifestation of rubella. The rash usually appears on the face and then progresses downward from the head to the feet. It lasts about 3 days and is characteristically maculopapular, presenting with small pink non-coalescing papules that are occasionally pruritic. Bathing or showering in hot water tends to make the rash more evident.

Adults more often have a prodromal period of low-grade fever, malaise, and adenopathy lasting 1 to 5 days before the onset of skin findings. Lymphadenopathy may begin up to a week before the rash and can last for several weeks. The postauricular nodes are particularly commonly involved, and posterior cervical or suboccipital nodes may also be affected.

Sequelae

Polyarthritides and polyarthralgia are the most common complications of rubella, particularly in adult women, in whom they are seen up to 70% of the time. They appear with such frequency that they are often considered intrinsic to the virus itself rather than complications. Joint symptoms typically present around the same time or just after the onset of the rash. They usually last 3 to 4 days but can remain for up to 1 month. The most commonly affected joints are fingers, wrists, and knees. Chronic arthritis is rarely observed.

Other complications are uncommon but can carry a high degree of morbidity and death. Hemorrhagic events are more likely in children than adults and occur in about 1 in 3000 cases. They manifest as a result of vascular damage or thrombocytopenia. Skin purpura is the most common presentation, but gastrointestinal, cerebral, or intrarenal hemorrhage can occur. Encephalitis occurs in about 1 in 6000 cases, more commonly in adults than children. Rare complications include orchitis, neuritis, progressive panencephalitis, and Guillain-Barré syndrome.

Congenital Rubella Syndrome (CRS)

CRS can present transiently with low birth weight, thrombocytopenic purpura, or hemolytic anemia. However, permanent defects are the hallmark of CRS because it classically involves a triad of cataracts, cardiac anomalies, and sensorineural deafness. Of these, hearing loss is the most common and sometimes the only complication observed. Cardiac abnormalities can include patent ductus arteriosus, ventricular septal defect, pulmonary artery hypoplasia, and coarctation of the aorta. Other ocular defects such as glaucoma, retinopathy, and microphthalmia can also occur. Additional manifestations can include microcephaly, intellectual disability, psychomotor retardation, and delayed speech.

Notably, it can take 2 to 4 years for certain neurologic, endocrine, or cardiac abnormalities associated with CRS to manifest. Diabetes mellitus, thyroid disease, autism, and progressive panencephalopathy can all occur as late effects of CRS.

The risk of CRS and its associated congenital defects is greatest when infection occurs in the first trimester. Up to 85% of infants

born under these conditions are found to be affected, whereas defects are rare when infection occurs after 20 weeks' gestation.

Diagnosis

Given its nonspecific nature and similarity to other viral infections, clinical diagnosis of rubella is challenging and largely unreliable. Suspected infection should be confirmed by 1 of 3 diagnostic methods: (1) rubella immunoglobulin M (IgM) serology, (2) a demonstrated rise in rubella virus immunoglobulin G (IgG) between acute and convalescent phases, or (3) detection of rubella virus by PCR.

Among the existing options for laboratory diagnosis, rubella IgM is the most accessible and widely used. However, collection timing is important to consider. Rubella IgM will only be detectable in about 50% of cases on the day of rash appearance but will be present in nearly all cases by 7 to 10 days after the rash. It will then remain positive for 4 to 12 weeks. Importantly, serum IgM testing is most sensitive and specific in the setting of local outbreaks. False-positive results occur more frequently in sporadic cases, and in those instances, additional means of analysis should be performed to confirm diagnosis.

Rubella IgG testing can be used to diagnose acute rubella infection under two circumstances: either (1) a negative rubella IgG during acute infection followed by a positive IgG in the convalescent phase, or (2) a fourfold increase in IgG titer over 10 to 14 days. IgG avidity testing may also be useful. This measures the strength of antigen-antibody binding, which is typically weaker in acute infection and increases over time. Therefore a low avidity index would indicate a more recent infection.

Viral isolation of rubella by PCR is quite valuable for diagnostic confirmation and can be performed on samples obtained from throat or nasopharyngeal swabs. These tests are not as widely available in postvaccination settings and may need to be performed in conjunction with local health departments or national epidemiology centers.

Diagnosis of CRS in infants can similarly be confirmed by one of three methods: (1) rubella IgM detection in serum or cord blood, (2) persistence of rubella IgG >6 months of age (past the time frame of passive maternal immunity), or (3) PCR isolation of rubella virus from respiratory or urinary samples. Because both rubella virus and IgM remain positive for several months in patients with CRS, the time frame for testing is less crucial than in cases of postnatal infection.

Treatment

There is no specific treatment for rubella and, because acquired cases are generally mild and self-limiting, basic supportive care is recommended. Detection of rubella infection in pregnancies before 18 weeks' gestation should prompt further investigation including maternal-fetal medicine referral, detailed ultrasound examination, support for adverse outcomes including neonatal hospice services, and follow-up examination and screening of the newborn. Maternal infections after 18 weeks can be followed with routine ultrasound monitoring along with newborn evaluation and testing.

Prevention

Rubella Vaccine

The first rubella vaccines became available in 1969, and a number of strains have been developed since that time. Of these, the RA 27/3 vaccine has been the most enduring, and all other strains were discontinued at the time of its introduction in 1979. The RA 27/3 rubella vaccine is a live attenuated virus that is administered in conjunction with measles and mumps as MMR, or with measles, mumps, and varicella as MMRV (ProQuad). Single-antigen rubella vaccine is not available in the United States.

Vaccination against rubella is safe and effective. Adverse events such as fever and rash are mild and are generally attributable to the measles and mumps portions of the vaccines. After a single dose, more than 95% of those vaccinated have serologic confirmation of rubella immunity, with evidence of lifelong immunity in the vast majority of responders. MMR or MMRV is recommended for all

children at 12 months of age, followed by a second dose between 4 and 6 years of age. The second dose is generally indicated to stimulate measles and mumps immunity in those who did not respond to the first vaccine. MMR and MMRV are contraindicated in immunosuppression, pregnancy, and in patients with a history of anaphylaxis to neomycin or other vaccine components.

Preconception Counseling and Prenatal Care

Rubella immunity, defined as serum rubella IgG of 10 IU/mL or greater, should be documented in all women attempting to conceive. MMR vaccine should be given in cases of nonimmunity, and although it is recommended at least 4 weeks before conception, inadvertent vaccination after that time is unlikely to be associated with adverse events. Rubella IgG should likewise be checked in all pregnant females as part of routine obstetric care, and MMR should be administered postpartum to nonimmune women.

Eradication and Future Goals

Despite widely available effective vaccines and evidence of sustained eradication in the Western Hemisphere, there are still approximately 100,000 cases of CRS annually worldwide. Although some African and Asian nations have introduced routine rubella vaccination, public health efforts have been inconsistent in many developing countries. Dedicated personnel and funding will likely be necessary to decrease rubella and its complications on a global scale.

- The physician should avoid antimotility agents for diarrhea presenting with fever or with mucus and blood present.
- More than 95% of patients with nontyphoid salmonellosis *will get better* on their own.
- Fluoroquinolone antibiotics should be reserved for when they are truly indicated clinically.
- Increasing resistance mandates sensitivity testing (including tests for ESBL) to guide therapy of bacteremia and its complications.
- Do not prescribe *prophylactic* antibiotics to prevent diarrhea in travelers.
- Stress personal hygiene and prudent food choice with proper preparation.

Abbreviation: ESBL = extended spectrum beta lactamases.

Salmonellosis refers to a group of infections caused by members of the genus *Salmonella*. This genus is named after Salmon, a pathologist who first isolated the organism, later designated as *Salmonella choleraesuis*, from the intestine of pigs with diarrhea. *Salmonellae* are widely distributed throughout nature and are adapted to a myriad of warm and cold-blooded hosts. In humans there are four main clinical presentations:

1. Acute gastroenteritis
2. Bacteremia
3. Focal extraintestinal infection
4. Chronic carriage (Table 1)

Microbiology

Salmonellae are motile, gram-negative, nonspore-forming bacilli that are differentiated from other *Enterobacteriaceae* by inability to ferment lactose and sucrose while producing acid, hydrogen sulfide, and gas (except *Salmonella typhi*). Members of the genus were more accurately classified into serotypes using the Kauffman-White schema, which differentiated and grouped them serologically dependent on their lipopolysaccharide somatic (O) and flagellar (H) antigens.

More recently, DNA analysis has divided the genus into two species. Initially the first of the two species was named *Salmonella choleraesuis* and was divided into six subspecies, each of which was then divided into more than 2400 serotypes (serovars) by Kauffman-White methodology. The second species, *Salmonella bongori*, is inconsequential. Serotypes were named historically from the host or the geographic locale of the first isolate, such as *Salmonella typhimurium* or *Salmonella dublin*. However, under the new DNA division, *choleraesuis* was both a species and a

SALMONELLOSIS

Method of

Arvid E. Underman, MD

CURRENT DIAGNOSIS

- More than 95% of nontyphoid salmonellosis presents as uncomplicated acute gastroenteritis.
- The clinical presentation of different causes of gastroenteritis and diarrhea overlaps significantly.
- The physician should be familiar with groups of patients at risk for complicated salmonellosis.
- Specific diagnosis requires culture of the stool or blood.
- Focal complications are always suspect in high-risk patients who are blood culture positive for nontyphoid *Salmonellae* (e.g., aortitis or mycotic aneurysm in patients older than age 60 years with atherosclerosis).

CURRENT THERAPY

- Fluid and electrolyte replacement is of paramount importance.
- The physician should avoid routine empiric antibiotic in acute uncomplicated patients.

TABLE 1 Clinical Presentations of Salmonellosis

Acute gastroenteritis (90%–95% of cases)

Bacteremia (< 5% of cases)

- Transient during acute gastroenteritis
- Enteric fever (nontyphoid)
- Persistent or recurrent (especially HIV)

Focal complications following bacteremia

- Bronchopneumonia, empyema, chest wall abscess
- Aortitis with mycotic aneurysm
- Prosthetic graft or valve infection
- Endocarditis, endarteritis
- Osteomyelitis (especially with sickle cell anemia)
- Septic arthritis
- Soft tissue abscess
- Hepatic or splenic abscess
- Meningitis or brain abscess
- Suppurative urogenital disease

Carriage (asymptomatic)

- Convalescent excretors (<2 mo)
- Convalescent carriers (2–12 mo)
- Chronic carriers (>12 mo)

children at 12 months of age, followed by a second dose between 4 and 6 years of age. The second dose is generally indicated to stimulate measles and mumps immunity in those who did not respond to the first vaccine. MMR and MMRV are contraindicated in immunosuppression, pregnancy, and in patients with a history of anaphylaxis to neomycin or other vaccine components.

Preconception Counseling and Prenatal Care

Rubella immunity, defined as serum rubella IgG of 10 IU/mL or greater, should be documented in all women attempting to conceive. MMR vaccine should be given in cases of nonimmunity, and although it is recommended at least 4 weeks before conception, inadvertent vaccination after that time is unlikely to be associated with adverse events. Rubella IgG should likewise be checked in all pregnant females as part of routine obstetric care, and MMR should be administered postpartum to nonimmune women.

Eradication and Future Goals

Despite widely available effective vaccines and evidence of sustained eradication in the Western Hemisphere, there are still approximately 100,000 cases of CRS annually worldwide. Although some African and Asian nations have introduced routine rubella vaccination, public health efforts have been inconsistent in many developing countries. Dedicated personnel and funding will likely be necessary to decrease rubella and its complications on a global scale.

serotype. To avoid confusion the name *Salmonella enterica* has been widely adopted. The first of the six subspecies (Group I) is also named *enterica*. It contains the more than 1400 serotypes that occur in warm-blooded animals. Using nomenclature employed by the United States Centers for Disease Control (CDC) and the World Health Organization (WHO), the species and subspecies name is understood and the serotype is capitalized. Thus, the formal *S. enterica* subspecies *enterica* serotype *typhimurium* becomes simply *S. Typhimurium*, which except for the capital *T* is where we started!

Epidemiology

In the last 25 years, the incidence of nontyphoid salmonellosis has increased two- to threefold, with approximately 1.5 million cases occurring annually in the United States. This is an underestimate because most cases are sporadic (endemic) and go unreported. Children younger than 5 years of age have the highest incidence of gastroenteritis and constitute the greatest number of cases.

Animals are the source of nontyphoid salmonella infection in humans. Infection occurs from food of animal origin such as meat, poultry, eggs, and dairy products. Contamination may occur during the production, slaughter, processing, or distribution of these products. Outbreaks have been associated with eggs, ice cream, and processed meats. Increasingly there have been outbreaks associated with raw vegetables (e.g., scallions) that are crosscontaminated during growth and distribution. Restaurant or home outbreaks occur in the context of improper preparation, cooking, and refrigeration. Most of the outbreaks can be attributed to centralized mass production and preparation of food along with globalization of the food trade. Novel sources of human salmonella include pet turtles, lizards, iguanas, African hedgehogs, rattlesnakes, and even marijuana contaminated by manure.

Emergence of antibiotic resistant species is a formidable problem. It is believed that resistance is driven worldwide by improper antibiotics use. However, in developed countries it is attributable to widespread use in animal feeds. Large numbers of transferable-resistance plasmids have been described. Resistance rates of more than 50% to ampicillin, chloramphenicol (Chloromycetin), and trimethoprim-sulfamethoxazole (TMP-SMZ) (Bactrim) occur in parts of Asia, Africa, and Latin America. One strain of *S. Typhimurium* (DT104) is resistant to five antimicrobials; the three mentioned previously plus tetracycline and streptomycin. This organism has spread widely in livestock throughout the United States, Canada, the United Kingdom, Europe, and the Middle East. Likewise, resistance to third-generation cephalosporins is increasing and is mediated by plasmids producing both regular and extended-spectrum beta-lactamases (ESBLs). Even more disturbing is fluoroquinolone resistance caused by mutated DNA gyrase, topoisomerase IV, or efflux pumps. The latter literally expel the quinolone from the bacterium before it can act on its target. Fluoroquinolone resistance is most pronounced in Southeast Asia, Europe, and the Middle East.

Pathogenesis

Human infection usually requires 10^6 organisms. Fewer organisms may cause disease in patients who have hypochlorhydria or achlorhydria, have impaired cellular immunity, are at the extremes of age, or are taking certain drugs (Table 2). *Salmonellae* predominately infect the terminal ileum and proximal colon through attachment. Initially, host response is by neutrophils followed by lymphocytes and macrophages. Strains vary genetically in their virulence and invasiveness. The organisms can survive intracellularly, thus avoiding antibiotic agents that lack intracellular penetration. Bacteria that are not contained regionally in the gut or lymph nodes may enter the blood. There are many predisposing factors associated with this and subsequent focal complications (see Table 2).

Clinical Presentation

Gastroenteritis

Acute gastroenteritis is by far the most common clinical presentation of salmonellosis. It should be emphasized that there is

TABLE 2 Predisposing Factors for Salmonellosis

Gastrointestinal
• Achlorhydria
• Gastric surgery
• Inflammatory bowel disease
Immune or structural compromise
• Age (<6 mo, >60 y)
• Lymphoma
• Splenectomy
• Cirrhosis with portal hypertension
• Diabetes mellitus
• Chronic uremia
• Hemolytic anemia (iron overload)
• Sickle cell (bone infarct, autosplenectomy)
• Systemic lupus
• Atheromata, aortic aneurysm
Infections
• HIV/AIDS (decreased T-cells)
• Malaria
• Bartonellosis
• Schistosomiasis
Drugs
• H ₂ -blockers, H ⁺ proton pump inhibitors
• Antibiotic administration
• Antimotility agents
• Chemotherapy
• Corticosteroids
• Transplant antirejection agents

considerable overlap in its presentation with other infectious intestinal pathogens such as *Campylobacter* species. Given this, the incubation ranges from 6 to 96 hours but most commonly occurs between 12 and 48 hours. Initial symptoms include nausea and vomiting, followed by headaches, myalgias, malaise, chills, low-grade fever, abdominal cramps, and diarrhea. High temperatures (40°C [104°F]) should alert the clinician to invasive disease. Stools may be merely loose or profuse and watery. On direct examination, they may or may not contain polymorphonuclear leukocytes or occult blood. The presence of mucus or gross blood in the absence of hemorrhoids or fissures should alert the clinician to organisms causing dysentery such as *Shigella* species. The white blood cell count is most often normal or slightly elevated, with a left shift containing 10 to 15 bands. Low white blood cell counts with greater numbers of bands should alert the clinician to possible bacteremia or enteric fever. The diagnosis can be confirmed only by stool or blood culture. Serum serology examinations are not helpful. Most healthy adults have a self-limited, uncomplicated course, with resolution of symptoms without treatment within 48 to 72 hours.

Treatment

Fluid and Electrolyte Replacement

The sine qua non in the treatment of diarrhea is fluid and electrolyte replacement. In most cases increased oral intake of bland juices coupled with clear broth and temporary elimination of lactose-containing foods will suffice. Commercial electrolyte solutions (Pedialyte) may be useful. Although not readily available in the United States, rehydration salts are widely employed in many developing countries. WHO distributes packets containing its recommended formula of 90 mmol sodium, 20 mmol potassium, 80 mmol chloride, 30 mmol bicarbonate, along with 111 mmol glucose to dissolve in 1 L sterile or boiled water. This mixture should be consumed at a rate sufficient to compensate for diarrheal losses while maintaining an adequate output of dilute-appearing urine. Within 24 to 48 hours, the diet can be supplemented with bland, soft foods given in small, frequent feedings. If the patient has profuse vomiting or severe dehydration as determined by orthostatic changes in blood pressure, parenteral rehydration should be used. Frequently, this can be accomplished as an outpatient in an infusion room or with a home agency rather than

through admission to hospital. When there is persistent emesis, profuse diarrhea, systemic toxicity, or abnormalities in serum electrolytes, parenteral rehydration in hospital is prudent.

Antimotility and Antinausea Agents

The use of agents such as atropine-diphenoxylate (Lomotil) or loperamide (Imodium) should be discouraged. Although they may result in symptomatic improvement in cramps and diarrhea, they can increase complications and even predispose to bacteremia. In general, if the patient has a fever and the diarrhea contains blood or mucus, their use should be eschewed. Most pediatricians feel they should never be used in children younger than 5 years of age. An alternative is bismuth subsalicylate (Pepto-Bismol). The adult dose is 1 ounce (2 tablespoons) or 2 tablets (262.5 mg) every 30 minutes for 8 hours. The pediatric dose is 1.1 mL/kg at 4-hour intervals for up to 5 days. Although nausea and vomiting are occasional presenting symptoms with enterocolitis, they rarely persist. Prochlorperazine (Compazine) or trimethobenzamide (Tigan) may be helpful. Both are available in oral, suppository, or parenteral form, even though injectable prochlorperazine (Compazine) has been in short supply. Suppositories usually stimulate further diarrhea. Vomiting may preclude oral administration. A singular muscular injection of prochlorperazine (Compazine) 5 to 10 mg, is often all that is needed. This may be repeated every 4 to 6 hours as needed. Promethazine hydrochloride (Phenergan) is more frequently used in children and may be used orally (0.5 mg/pound or 1 mg/kg every 6 hours) or intramuscularly in the same doses. A 5-HT₃ receptor antagonist such as ondansetron (Zofran)¹ is expensive and inefficacious.

Antibiotics

The routine empiric use of antibiotics, especially fluoroquinolones, for any and all cases of diarrhea is not only unjustifiable but should be decried. Certainly antibiotics are not needed in the treatment of uncomplicated *Salmonella* gastroenteritis in otherwise healthy children or adults. Studies have shown that they neither shorten the course nor improve symptoms. No doubt some of this usage is patient driven. However, overuse is contributing to the emergence of resistance, and may increase risk of symptomatic and bacteriologic relapse. Indeed, antibiotic use may actually prolong the convalescent excretion or contribute to chronic carriage of the organism. Postponing antibiotic therapy until the return of a stool culture often provides the physician with a way to avert the frequent demand for antibiotic therapy. Often patients are better by the time results become available. Nevertheless, high-risk patients, as previously identified (see Table 2), should receive treatment to prevent potential complications from bacteremia. Additionally, if patients are sick enough to require hospitalization, antibiotic therapy should be considered.

Appropriate antibiotic therapy should be guided by susceptibility testing. Initially, TMP-SMZ (cotrimoxazole, Bactrim, or Septra)¹ may be administered to the nonsulfonamide-sensitive patient. The dose is 5 to 8 mg/kg trimethoprim every 12 hours for children or 1 double-strength tablet (160 mg trimethoprim/800 mg sulfamethoxazole) every 12 hours for adults. Although widely used, trimethoprim-sulfamethoxazole has not yet received FDA approval. If the organism is susceptible, ampicillin, 50 mg/kg orally to 100 mg/kg/day intravenously, each in four divided doses for children, or 2 to 4 g/day in four divided doses for adults, may be administered. Amoxicillin (Amoxil)¹ in equivalent oral dosage may be substituted. The duration of therapy is generally 5 days.

Newer fluoroquinolone antibiotics, such as ciprofloxacin,¹ ofloxacin,¹ and norfloxacin,¹ are among the most effective agents, with excellent oral bioavailability and intracellular concentration. They are contraindicated in prepubertal children and pregnant women. Adult doses are ciprofloxacin (Cipro), 500 mg twice daily; ofloxacin (Floxin), 400 mg twice daily; or norfloxacin (Noroxin), 400 mg twice daily. It must be emphasized that the trend in the

United States to use these agents empirically for all suspected bacterial diarrhea should be vigorously resisted by the thoughtful clinician.

Bacteremia and Focal Infection

Bacteremia in acute uncomplicated *Salmonella* gastroenteritis is infrequent. Therefore, blood cultures are not routinely necessary except for patients who are in high-risk categories. Shaking chills or high fever (40°C [104°F]) should alert the clinician to possible bacteremia. Focal suppurative infection following bacteremia is also infrequent but may occur at any site. Thus, *Salmonella* has been associated with bronchopneumonia, soft tissue infection, aortic mycotic aneurysms, endocarditis, septic arthritis, splenic or hepatic abscesses, meningitis, and osteomyelitis. The clinician should suspect an endovascular mycotic aneurysm in all blood culture-positive patients older than 50 years of age. *Salmonella* should always be suspected in individuals with sickle cell disease in whom bone and joint infection is the most frequent cause of extraintestinal infection. Meningitis occurs primarily in infants younger than 5 months of age. The diagnosis of a *Salmonella* bacteremia in HIV patients will almost always be accompanied by recurrent episodes.

Treatment

Antibiotics

Bacteremia and localized suppurative infection require antibiotic therapy. The choice of effective treatment is less predictable with the emergence of resistance. Therapy must be altered according to the results of susceptibility testing. Therefore the recovery of the organism is extremely important, and adequate cultures of blood or infected material must be obtained before initiation of therapy.

Parenteral ampicillin, 100 to 200 mg/kg/day divided into four doses, or TMP/SMZ,¹ 8 to 10 mg/kg of trimethoprim per day in three divided doses, may be used. In the case of resistance or allergy to the foregoing, third-generation cephalosporins such as cefotaxime (Claforan) or ceftriaxone (Rocephin) have reasonable activity, but intracellular concentrations are not optimal. Cefotaxime, 1 to 2 grams every 6 to 8 hours for adults, or 100 to 200 mg/kg/day in three or four divided doses for children, has been found effective in bacteremia, osteomyelitis, septic arthritis, and a variety of other focal *Salmonella* infections. The use of chloramphenicol (Chloromycetin) is not recommended, but a preparation of it in oil (Typhomycin)² is in use in developing countries. Ciprofloxacin (Cipro)¹ 7.5 mg/kg intravenously twice daily is becoming a favored agent; not only is it effective, but oral bioequivalence facilitates the change to 500 to 750 mg by mouth twice daily. If fluoroquinolone resistance is encountered, imipenem (Primaxin)¹ may be tried. Efficacy data for it or other agents such as azithromycin (Zithromax)¹ are scant.

Surgery

Focal infection often requires surgery. Often this is as simple as the drainage of localized suppuration or lavage of a septic joint. However, in the case of infected aortic aneurysms, extensive resection and vascular reconstruction are required. Infected prosthetic grafts must be removed in nearly all cases, with courses of antibiotics before and after surgery.

The duration of therapy for simple bacteremia is 10 to 14 days. Septic arthritis is usually treated for 4 weeks whereas osteomyelitis and endovascular infections require 6 weeks. Oral fluoroquinolones such as ciprofloxacin (Cipro), 500 mg twice daily, may be helpful in treating osteomyelitis. TMP-SMZ (Bactrim)¹ can also be used in this manner. Both have adequate blood levels after oral administration. I have had to use continuous prophylaxis of either TMP-SMZ or ciprofloxacin in several HIV patients to prevent recurrent bacteremia. Because prophylactic TMP-SMZ is used chronically for *Pneumocystis*, it may be preferred.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

²Not available in the United States.

Enteric Fever

The clinical picture of nontyphoid *Salmonella* enteric fever is indistinguishable from that of typhoid fever, which is discussed elsewhere in this publication. However, the following discussion also applies to enteric fever caused by nontyphoid *Salmonellae*.

Treatment

The adjunct and antibiotic therapy of nontyphoid enteric fever parallels that of the treatment of typhoid. Antibiotics should be adjusted and altered once the results of susceptibility testing are available. Acceptable regimens include ampicillin, amoxicillin,¹ and TMP-SMZ (Bactrim),¹ along with third-generation cephalosporins and fluoroquinolone antibiotics. My preference was cefotaxime (Claforan)¹ in the same doses as for bacteremic salmonellosis. The duration is 10 to 14 days. Relapse rates are low, and relapse is seen within 2 to 6 weeks. Relapse requires an equivalent course of therapy in both dose and duration. Currently, I prefer ciprofloxacin (Cipro)¹ intravenously 7.5 mg/kg every 12 hours continued until the patient is afebrile and clinically able to start taking it orally. Comparative studies are ongoing, using both third-generation cephalosporins, such as ceftriaxone (Rocephin)¹ or cefixime (Suprax),¹ and oral fluoroquinolones in short-course therapy of typhoid as well as nontyphoid enteric fever. Although these show some promise, they are currently not the standard of practice in the United States. Nevertheless, a strong case can be made for oral fluoroquinolones use, with obvious cost saving. Otherwise healthy young adults may be treated orally as outpatients. This advantage, if for no other reason, should prevent the physician from prescribing quinolones for uncomplicated gastroenteritis or other self-limited diarrheas of bacterial origin.

Adjunctive measures are of importance, including attention to fluid and electrolyte balance and nutrition. As in typhoid, the routine use of corticosteroids is controversial. Use in patients who are steroid dependent or believed to be hypoadrenal is indicated. In those who are delirious, obtunded, comatose, or in shock it may be warranted, but there are little supportive data. It has been my overall impression that nontyphoid enteric fever is somewhat milder than typhoid itself, and complications such as gastrointestinal bleeding or ileal perforation are exceedingly rare.

Carrier State

Asymptomatic excretion of organisms invariably occurs following clinical *Salmonella* gastroenteritis. It exceeds 8 weeks in 5% to 10% of patients. Chronic carriage, either in the stool or urine, is defined as excretion of the organism for more than 1 year. Its incidence is stated to be 1% in adults and 5% in children younger than 5 years of age. This is somewhat less than that seen with *S. typhi*. Convalescent excretors need only maintain strict personal hygiene to prevent transmission of the organism. Those involved in food preparation or in child care and health care should be kept off work until three successive cultures are negative at intervals required by the public health department. It goes without saying that all positive cases of salmonellosis are reportable by law to local public health authorities.

Recently, oral quinolones have been used (ciprofloxacin [Cipro],¹ 500 to 750 mg twice daily for 5 to 14 days) to curtail institutional outbreaks, as in nursing homes or psychiatric facilities. Although this may be expeditious, eliminating or preventing the source of the outbreak in a prospective fashion is preferable. In the case of food handlers and health care or child care workers, some feel that quinolone therapy eliminates the problem of convalescent excretion, hence individuals may return to work without delay. The data are debatable and the successive negative stool requirement will not be obviated.

The management of the chronic carriage of nontyphoid salmonellosis is the same as that of *S. typhi*, which is discussed in detail elsewhere. A 4- to 6-week course of oral antibiotics may be tried when no evidence of gallbladder disease exists. However, if chronic

cholecystitis and/or cholelithiasis are present, cholecystectomy is almost always necessary. Despite cholecystectomy, a certain number of individuals will continue to excrete organisms thought to be of hepatobiliary origin. Chronic carriage is seen, albeit rarely, in the United States with either *Schistosoma mansoni* or *Schistosoma haematobium*. When these parasites are treated, subsequent therapy of the *Salmonella* results in termination of the stool or urinary carrier state.

Prevention

Prevention of salmonellosis has both personal and public health dimensions. Food and leftovers should be rapidly refrigerated. I recommend separate plastic (not wood) cutting boards for meats and vegetables and washing them after each use. Spillage of raw animal juices should be immediately cleaned. All preparation surfaces should be washed and dried after each meal. Detergent rather than antibacterial cleaners should be used; bleach is beautiful.

Public health surveillance is essential via regular inspection of restaurants, food retailers, and industrial food processors. National efforts to coordinate and computerize surveillance systems such as FoodNet should be expanded and fully funded so as to guarantee our food supply. Preservation technologies, including irradiation, need study.

Finally, the practicing physician should take the time to reiterate to patients with HIV or malignancies or other immune-compromised patients (see Table 2) how they can avoid food-borne pathogens.

SEVERE SEPSIS

Method of

Jerome Larkin, MD; and Marisa Holubar, MD

CURRENT DIAGNOSIS

Systemic Inflammatory Response Syndrome (SIRS)

- Diagnosis is based on the presence of two or more of the following:
 - Temperature >38°C or <36°C
 - Pulse >90 beats/min
 - Respirations >20 breaths/min or arterial partial pressure of carbon dioxide (Paco₂) <32 mm Hg
 - White blood cell count >12,000 or <4000 cells/mm³ or >10% bands

Sepsis

- Diagnosis is based on a finding of SIRS plus proven or suspected infection as the cause.

Severe Sepsis

- Diagnosis is based on a finding of sepsis plus organ dysfunction of one or more major systems (typically kidney, lung, or heart; less often, central nervous system).

¹Not FDA approved for this indication.

Enteric Fever

The clinical picture of nontyphoid *Salmonella* enteric fever is indistinguishable from that of typhoid fever, which is discussed elsewhere in this publication. However, the following discussion also applies to enteric fever caused by nontyphoid *Salmonellae*.

Treatment

The adjunct and antibiotic therapy of nontyphoid enteric fever parallels that of the treatment of typhoid. Antibiotics should be adjusted and altered once the results of susceptibility testing are available. Acceptable regimens include ampicillin, amoxicillin,¹ and TMP-SMZ (Bactrim),¹ along with third-generation cephalosporins and fluoroquinolone antibiotics. My preference was cefotaxime (Claforan)¹ in the same doses as for bacteremic salmonellosis. The duration is 10 to 14 days. Relapse rates are low, and relapse is seen within 2 to 6 weeks. Relapse requires an equivalent course of therapy in both dose and duration. Currently, I prefer ciprofloxacin (Cipro)¹ intravenously 7.5 mg/kg every 12 hours continued until the patient is afebrile and clinically able to start taking it orally. Comparative studies are ongoing, using both third-generation cephalosporins, such as ceftriaxone (Rocephin)¹ or cefixime (Suprax),¹ and oral fluoroquinolones in short-course therapy of typhoid as well as nontyphoid enteric fever. Although these show some promise, they are currently not the standard of practice in the United States. Nevertheless, a strong case can be made for oral fluoroquinolones use, with obvious cost saving. Otherwise healthy young adults may be treated orally as outpatients. This advantage, if for no other reason, should prevent the physician from prescribing quinolones for uncomplicated gastroenteritis or other self-limited diarrheas of bacterial origin.

Adjunctive measures are of importance, including attention to fluid and electrolyte balance and nutrition. As in typhoid, the routine use of corticosteroids is controversial. Use in patients who are steroid dependent or believed to be hypoadrenal is indicated. In those who are delirious, obtunded, comatose, or in shock it may be warranted, but there are little supportive data. It has been my overall impression that nontyphoid enteric fever is somewhat milder than typhoid itself, and complications such as gastrointestinal bleeding or ileal perforation are exceedingly rare.

Carrier State

Asymptomatic excretion of organisms invariably occurs following clinical *Salmonella* gastroenteritis. It exceeds 8 weeks in 5% to 10% of patients. Chronic carriage, either in the stool or urine, is defined as excretion of the organism for more than 1 year. Its incidence is stated to be 1% in adults and 5% in children younger than 5 years of age. This is somewhat less than that seen with *S. typhi*. Convalescent excretors need only maintain strict personal hygiene to prevent transmission of the organism. Those involved in food preparation or in child care and health care should be kept off work until three successive cultures are negative at intervals required by the public health department. It goes without saying that all positive cases of salmonellosis are reportable by law to local public health authorities.

Recently, oral quinolones have been used (ciprofloxacin [Cipro],¹ 500 to 750 mg twice daily for 5 to 14 days) to curtail institutional outbreaks, as in nursing homes or psychiatric facilities. Although this may be expeditious, eliminating or preventing the source of the outbreak in a prospective fashion is preferable. In the case of food handlers and health care or child care workers, some feel that quinolone therapy eliminates the problem of convalescent excretion, hence individuals may return to work without delay. The data are debatable and the successive negative stool requirement will not be obviated.

The management of the chronic carriage of nontyphoid salmonellosis is the same as that of *S. typhi*, which is discussed in detail elsewhere. A 4- to 6-week course of oral antibiotics may be tried when no evidence of gallbladder disease exists. However, if chronic

cholecystitis and/or cholelithiasis are present, cholecystectomy is almost always necessary. Despite cholecystectomy, a certain number of individuals will continue to excrete organisms thought to be of hepatobiliary origin. Chronic carriage is seen, albeit rarely, in the United States with either *Schistosoma mansoni* or *Schistosoma haematobium*. When these parasites are treated, subsequent therapy of the *Salmonella* results in termination of the stool or urinary carrier state.

Prevention

Prevention of salmonellosis has both personal and public health dimensions. Food and leftovers should be rapidly refrigerated. I recommend separate plastic (not wood) cutting boards for meats and vegetables and washing them after each use. Spillage of raw animal juices should be immediately cleaned. All preparation surfaces should be washed and dried after each meal. Detergent rather than antibacterial cleaners should be used; bleach is beautiful.

Public health surveillance is essential via regular inspection of restaurants, food retailers, and industrial food processors. National efforts to coordinate and computerize surveillance systems such as FoodNet should be expanded and fully funded so as to guarantee our food supply. Preservation technologies, including irradiation, need study.

Finally, the practicing physician should take the time to reiterate to patients with HIV or malignancies or other immune-compromised patients (see Table 2) how they can avoid food-borne pathogens.

SEVERE SEPSIS

Method of

Jerome Larkin, MD; and Marisa Holubar, MD

CURRENT DIAGNOSIS

Systemic Inflammatory Response Syndrome (SIRS)

- Diagnosis is based on the presence of two or more of the following:
 - Temperature >38°C or <36°C
 - Pulse >90 beats/min
 - Respirations >20 breaths/min or arterial partial pressure of carbon dioxide (Paco₂) <32 mm Hg
 - White blood cell count >12,000 or <4000 cells/mm³ or >10% bands

Sepsis

- Diagnosis is based on a finding of SIRS plus proven or suspected infection as the cause.

Severe Sepsis

- Diagnosis is based on a finding of sepsis plus organ dysfunction of one or more major systems (typically kidney, lung, or heart; less often, central nervous system).

¹Not FDA approved for this indication.

Septic Shock

- Diagnosis is based on a finding of severe sepsis plus persistent hypotension despite aggressive fluid resuscitation (i.e., vasopressors are required to maintain mean arterial pressure >65 mm Hg).

Supportive Laboratory Findings

- Hyperglycemia
- Lactic acidosis
- Hyperbilirubinemia
- Acute renal failure
- Thrombocytopenia
- Coagulopathy
- Leukocytosis or leukopenia
- Elevated erythrocyte sedimentation rate or C-reactive protein

Supportive Physical Findings

- Decreased capillary refill or mottling of skin
- Mental status changes or obtundation
- Tachypnea or respiratory failure
- Tachycardia
- Anuria or oliguria
- Edema

**CURRENT THERAPY****Initial 6 Hours**

- Initiate fluid resuscitation with crystalloid or colloid to achieve central venous pressure of 12 mm Hg (or 15 mm Hg if intubated).
- Add dopamine (Intropin) or norepinephrine (Levophed) for persistent hypotension (mean arterial pressure <65 mm Hg).
- Obtain blood, urine, and other appropriate cultures (cerebrospinal fluid, abscess drainage, catheter tip, tissue, sputum).
- Administer empiric antimicrobial therapy.
- Perform appropriate imaging studies with urgent source control as indicated and allowed by clinical status; remove potentially infected foreign bodies.
- All interventions should be undertaken simultaneously and initiated within 1 hour after making a presumptive diagnosis of sepsis.

Subsequent Interventions

- Maintain glycemic control with a target blood glucose level of less than 150 mg/dL.
- Use unfractionated or low-molecular-weight heparin for prophylaxis against deep venous thrombosis.
- Use a histamine 2 (H₂) blocker or proton pump inhibitor for gastric ulcer prophylaxis.
- Initiate therapy with dobutamine (Dobutrex) for low cardiac output in the face of adequate filling pressures.
- Consider therapy with activated protein C (drotrecogin alfa [Xigris]) for patients with an Acute Physiology and Chronic Health Evaluation (APACHE) II score of 25 or greater.
- Consider therapy with hydrocortisone (Solu-Cortef)¹ for patients with continued hypotension despite adequate fluid resuscitation and vasopressors.
- Achieve adequate sedation.

¹Not FDA approved for this indication.

Epidemiology

The true prevalence and incidence of sepsis remain unknown. A study by Martin and colleagues in 2003 analyzed data from the National Hospital Discharge Survey from 1979 to 2000. Although some limitations apply, particularly shifts in the understanding of and use of coding, their findings have the advantage of assessing a

large sample size over a prolonged period of observation. The most striking finding was a rise in the incidence of sepsis in the United States over this period, from an annual occurrence of 164,000 cases in 1979 to 660,000 cases in 2000. This reflects an average annual increase of 8.7% for more than 20 years. Coincident with this increase was a rise in the percentage of patients with a diagnosis of sepsis due to fungal organisms (4.6% in 2000). Gram-positive organisms supplanted gram-negative organisms as the largest group of pathogens after 1987 (52% vs. 37%).

Mortality was highest among African American men and was associated with failure of three or more organs. Men were more likely to become septic than women (relative risk, 1.90). In-hospital mortality fell from 27.8% to 17.9% between 1995 and 2000. Total mortality increased, most likely as a result of the increase in the total burden of disease. This increase, although perhaps in part attributable to greater use of the diagnostic code for sepsis, is thought to have resulted from a combination of aging of the population, greater numbers of immunosuppressed individuals surviving longer, greater use of prosthetic devices, and greater numbers of and more invasive medical interventions. Diabetes, hypertension, chronic obstructive pulmonary disease, congestive heart failure, and HIV infection all increased as a proportion of medical conditions contributing to sepsis, whereas the proportion of patients with cancer and that of pregnant patients declined. The percentage of patients with one or more organs failing (i.e., severe sepsis) increased from 17% to 35% of all patients with a diagnosis of sepsis.

A study by Dombrovskiy and associates described an even greater increase in the proportion of severe sepsis, from 25.6% in 1993 to 43.8% in 2003. They also found an absolute increase in the number of cases of sepsis, as well as an increase in total mortality, again likely due to increased incidence. Case-fatality rates fell from 45.8% to 37.8%, but mortality was substantially higher at both the beginning and the end of their study period than was described by Martin et al. These findings suggest acceleration in both severity and incidence of severe sepsis and septic shock.

Sepsis is the tenth most common cause of death in the United States. The incidence is highest during the winter, most likely reflecting increased respiratory viral infections that precede the development of community-acquired pneumonia, which is itself a medical condition with increased risk of developing severe sepsis.

A remarkable aspect of sepsis, severe sepsis, and septic shock is the relatively small number of associated pathogens out of the more than 1000 microorganisms known to cause human disease. *Staphylococcus aureus*, streptococci, enterococci, and gram-negative rods are the most commonly isolated species. *Escherichia coli*, *Klebsiella*, *Pseudomonas*, *Serratia*, *Acinetobacter*, *Enterobacter*, *Citrobacter*, and *Neisseria meningitidis* (a gram-negative coccus) constitute the most common gram-negative pathogens. This relative paucity of etiologic bacterial pathogens has implications for empiric antimicrobial therapy. The emergence of resistant organisms, particularly methicillin-resistant *S. aureus* (MRSA) and gram-negative bacteria harboring extended-spectrum β -lactamases, increases the risk of antibiotic failure and attendant mortality. Fungal pathogens, particularly non-candidal species, continue to increase in incidence. This is most likely the result of better empiric management of gram-negative and candidal sepsis in patients with hematologic malignancies.

Although sepsis is most typically a disease of the elderly, the immune suppressed, and those with chronic medical problems, otherwise young and healthy individuals can also be stricken with no clear cause or known risk factor, such as in meningococcemia, toxic shock syndrome, and necrotizing fasciitis.

Definitions

The term *sepsis* derives from a Greek word that generally implies putrefaction. It also has a colloquial meaning, understood by most laypeople to mean a serious, potentially overwhelming infection. Historically, it has been intuitively understood by physicians to mean an infection, once localized, that has now disseminated and is life threatening. Bacteremia is implied if not always proven.

Sepsis was usually fatal in the preantibiotic era, and its morbidity and mortality remain substantial.

In 2001, a consensus conference, sponsored by the American College of Chest Physicians and the Society of Critical Care Medicine and involving the European Society of Intensive Care Medicine, the Surgical Infection Society, and the American Thoracic Society, was convened to arrive at a specific definition of sepsis. Achieving such a definition is critically important to ongoing research on interventions aimed at improving mortality. Their deliberations, building on the work of a previous conference and published in 2003, elaborated several key concepts. They defined systemic inflammatory response syndrome (SIRS) as a state of immune activation characterized by the findings of fever with tachycardia, tachypnea, and/or leukocytosis or leukopenia. Although sensitive, this definition is so overly broad as to be rather unhelpful to an experienced clinician who would not need to resort to such terms to understand that a patient is seriously ill. Nonetheless, it provides a useful construct in beginning to arrive at a specific definition of sepsis. Both infectious and noninfectious processes—severe burns and pancreatitis being the most notable examples of the latter—can cause SIRS.

Sepsis is defined as the finding of SIRS in the presence of known or suspected invasion by a microbe into a normally sterile body site. Severe sepsis is sepsis that has become more generalized. The cardinal finding is organ dysfunction that is unrelated to the primary site of infection. Other typical findings include hyperglycemia, thrombocytopenia, hyperbilirubinemia, acidosis, coagulopathy, edema, oliguria, hypotension, ileus, hypoxia, and poor perfusion. Heart, kidney, and respiratory failure are the most common forms of organ dysfunction. Altered sensorium is also common. Septic shock refers to the presence of hypotension with systolic blood pressure lower than 90 mm Hg or mean arterial pressure lower than 60 mm Hg despite adequate fluid resuscitation. These terms (sepsis, severe sepsis, and septic shock) are all part of a continuum, implying a progressively graver degree of illness with associated increasing mortality. No single symptom, physical finding, organ dysfunction, or laboratory abnormality serves to make or exclude the diagnosis, although isolation of a microorganism in the setting of such findings is highly suggestive. Increasing numbers of physical findings and other abnormalities correlate with an increasing likelihood of the diagnosis of sepsis.

The consensus conference put forward a staging system for sepsis based on host predisposition, nature of infection, host response, and organ dysfunction (mnemonic: PIRO). By this, it is understood that a given patient may be predisposed to infection based on medical conditions such as diabetes, vascular disease, sickle cell anemia, or inherited or acquired immunodeficiencies. Additionally, there are likely to be more subtle genetic predispositions to the development of sepsis, as well as age-related factors. The nature of infection in terms of the site, inoculum, and virulence of the infecting organism clearly plays a role in determining the development of sepsis. The host response—ranging from localization and clearing of the infection without deleterious effect on the host to a state of immunologic dissonance whereby the inflammatory response is itself the driver of pathology—is signaled by the development of organ dysfunction. This staging system allows patients to be stratified at different points and serves as a template for evaluating the efficacy of various interventions as the characterization of sepsis and research into novel therapies progresses.

Pathophysiology

Infection of the immunocompetent host by a microorganism typically leads to immune activation. This serves to isolate the site and source of infection. Local tissue is often damaged, but eventually the infection is cleared, and repair and regeneration occur. This process is highly regulated, with a number of different cell types and mediators involved, all in delicate balance between proinflammatory and antiinflammatory effects. The patient may have few or no symptoms, or there may be systemic evidence of infection (i.e., SIRS). Sepsis is the failure of localization such that the process becomes generalized and leads to tissue destruction remote from the site of

infection. Why the immune system enters this state of dysregulation remains unknown, although an enormous amount of research over the past 4 decades has elucidated many of the pathways and mediators involved. Tumor necrosis factor, platelet-activating factor, interleukins, eicosanoids, interferons, and nitric oxide are among the biologically active molecules characterized to date. Particular microbes also contribute to this process through the elaboration of toxins (typically by gram-positive organisms) and endotoxins (gram-negative–derived lipopolysaccharide). These events lead to tissue destruction as a result of ischemic insult, direct cytotoxicity, and accelerated apoptosis. The characterization of inflammatory mediators has led to attempts to modify the immune response through the use of novel therapies such as monoclonal antibodies directed against tumor necrosis factor. To date such attempts have not met with success, and investigation continues.

Diagnosis

The diagnosis of sepsis ultimately relies on the clinical suspicion of infection in the setting of SIRS. A constellation of other supportive evidence establishes a greater or lesser likelihood of the presence of sepsis (see the [Current Diagnosis](#) box). It is rare that specific microbiologic evidence for infection is available in a manner timely enough to determine that sepsis is present or to help guide the initial, typically urgent, therapy. When it is available, it usually is a Gram stain or other type of specialized microbiology stain that confirms the presence of a potential pathogen in a site where none should be (e.g., gram-positive cocci in cerebrospinal fluid). Early therapy therefore relies on aggressive resuscitative measures and the administration of empiric antibiotics.

Treatment

Early Goal-Directed Resuscitation: The First 6 Hours

Initial treatment of sepsis should focus on correction of hemodynamic parameters, early administration of antibiotics, and source control of potential sites of infection. The 2008 guidelines from the Surviving Sepsis Campaign, an international initiative to improve sepsis outcomes, emphasized the importance of aggressive fluid resuscitation. Therapy should be implemented according to a protocol directed at achieving the following specific goals:

- Central venous pressure 8 to 12 mm Hg, or 12 to 15 mm Hg in those who are mechanically ventilated or have decreased left ventricular compliance
- Central venous or mixed venous oxygen saturation 70% or greater
- Mean arterial pressure (MAP) 65 mm Hg or greater
- Urine output 0.5 mL/kg/hr or greater

Administration of fluid boluses of 1000 mL or more of crystalloids or 300 to 500 mL of colloids over 30 minutes should begin as soon as hypoperfusion is recognized. There is no evidence that one type of fluid is superior to the other, although crystalloid is substantially cheaper. In cases of profound intravascular volume depletion, more rapid and more frequent fluid administration may be needed. Hemodynamic improvement (decreased heart rate, increased blood pressure, increased urine output) and the goal of optimizing central venous pressure should direct the need for continued infusion of fluid while avoiding the development of volume overload and pulmonary edema. Transfusion of packed red blood cells should be considered if anemia is present, with a goal of achieving a hemoglobin level of 7.0 to 9.0 g/dL. If tissue hypoperfusion or hypoxia persists (central mixed venous oxygen saturation <70%) despite achieving a central venous pressure of 12 mm Hg, therapy with dopamine (Intropin) or norepinephrine (Levophed) should be initiated with a goal of achieving a MAP of 65 mm Hg. There is no role for the use of low-dose dopamine for renal protection. An arterial line for more precise and continuous measurement of blood pressure should be inserted as soon as possible after the initiation of vasopressor therapy. Ideally, vasopressors should not be introduced to increase MAP until after the fluid deficit has been corrected. However, in cases of severe shock, vasopressor therapy may be needed early in the resuscitation effort to improve perfusion to the peripheral vascular beds. If there is no response to dopamine

and norepinephrine, the patient should be treated with epinephrine (Adrenalin).¹

Appropriate antibiotics should be administered within 1 hour after diagnosis of severe sepsis or septic shock, because mortality increases in a linear fashion with each hour of delay. All efforts should be made to obtain appropriate cultures, in particular at least two sets of blood cultures. At least one of these should be peripheral, with the second from any long-term (>48 hours) vascular device. Cultures of urine, sputum, wounds, abscesses, and cerebrospinal fluid should also be obtained as appropriate and before the administration of antibiotics, assuming that such specimens can be obtained during the first hour. Specific antibiotic choices are discussed later.

Source Control

A survey for potential sources of infection should be performed, and early resuscitation efforts should occur concomitantly. Elimination of the source of infection is critical to reversing septic shock. Conditions that require emergent intervention, such as necrotizing fasciitis, cholangitis, and intestinal infarction, should be ruled out within the first 6 hours after presentation. Potentially infected indwelling devices should be removed as soon as possible. Necrotic tissue should be debrided and abscesses drained if either condition is detected. Practitioners must consider the risks and benefits of the specific invasive procedures and the timing of such interventions for each patient individually. Every effort should be made to limit the invasiveness of necessary procedures, to avoid further stress in patients with an already hemodynamically fragile state. Imaging studies such as computed tomography of the head, chest, abdomen, and pelvis are necessary to identify or rule out potential sources of infection. An exception to the mandate to drain or debride infected collections is the presence of infected pancreatic necrosis, in which case surgical intervention should be delayed.

Other Interventions

After hemodynamic parameters have been stabilized with fluid and vasopressors, cultures have been obtained, antibiotics have been administered, and initial source control of infected foci has been achieved, other interventions may be appropriate. Many of these are typical components of good critical care.

Cardiac Dysfunction. Patients who have adequate left ventricular filling pressures (as determined by a central venous pressure ≥ 12 mm Hg) but low cardiac output may benefit from therapy with dobutamine (Dobutrex) to increase cardiac output and improve tissue perfusion.

Corticosteroid Therapy. Activation of the hypothalamic-pituitary axis and the consequent increase in serum cortisol levels are vital aspects of the body's acute stress response to shock. Recent data suggest that critical illness-related corticosteroid insufficiency is more prevalent in septic shock than previously thought, with rates as high as 60%. Therapy with corticosteroids is indicated only for those patients who have continued hypotension in the face of adequate fluid resuscitation and vasopressor support. Hydrocortisone (Solu-Cortef)¹ should be administered intravenously 200–300 mg/day for 7 days, either divided every 6 hours or as a continuous infusion. Dexamethasone (Decadron)¹ should not be used unless hydrocortisone is not available. Because of the unclear long-term benefits and the known immunosuppressive side effects of corticosteroids, patients should be weaned from hydrocortisone as soon as vasopressors are no longer necessary. If another form of corticosteroid other than hydrocortisone is used, then fludrocortisone (Florinef)¹ at a dose of 50 mcg/day should be added for mineralocorticoid effect.

Activated Protein C. Patients who are at increased risk of death with Acute Physiology and Chronic Health Evaluation (APACHE) II scores of 25 or higher and those with multiple organ dysfunction may benefit from infusion of activated protein C (drotrecogin alfa [Xigris]). This drug has numerous contraindications, including

current active bleeding, recent (within 3 months) hemorrhagic stroke, recent (within 2 months) severe head trauma or intracranial or intraspinal surgery, trauma with a risk of life-threatening bleeding, presence of an epidural catheter, and intracranial neoplasm or mass lesion or evidence of herniation. It is not recommended for use in children. It is given as a 96-hour continuous infusion.

Glycemic Control. Maintenance of the blood glucose concentration lower than 150 mg/dL is associated with decreased mortality and length of stay in the intensive care unit. Control should be achieved with intravenous insulin, paying close attention to serum glucose levels every 1 to 2 hours until stable, with adjustments made on the basis of a validated protocol. Patients receiving intravenous insulin should simultaneously receive some form of glucose as a calorie source to minimize the risk of hypoglycemia.

Sedation and Paralytics. Sedation and treatment of pain should be aggressively managed according to validated protocols. Daily interruption of sedation allows for more accurate titration of drug and decreases the total time of mechanical ventilation. Paralytics should be avoided or used only briefly if required.

Anticoagulation. Patients should receive prophylaxis for deep venous thrombosis with either low-molecular-weight heparin or unfractionated heparin unless contraindicated by severe thrombocytopenia, recent intracranial bleeding, or coagulopathy. Those patients who cannot receive heparin should receive prophylaxis with graduated compression stockings or intermittent compression devices. Patients who are at especially high risk for deep venous thrombosis (e.g., prior history of clot, orthopaedic surgery, trauma) should receive both pharmacologic and mechanical prophylaxis. Low-molecular-weight heparin is preferred to unfractionated heparin in high-risk patients.

Ulcer Prophylaxis. Patients should receive prophylaxis with a proton pump inhibitor or a histamine 2 (H_2) blocker to prevent upper gastrointestinal bleeding.

Bicarbonate Therapy. There is no role for the administration of bicarbonate to correct acidosis or improve hemodynamic status.

Antibiotics

Antibiotic choices should take into account the most likely pathogens for the suspected site or process. In general, initial empiric therapy (Table 1) should be broad, with an intention to narrow therapy once a microorganism has been isolated or a more precise clinical diagnosis has been made. Such a reevaluation should take place approximately 72 hours after the initiation of therapy. Numerous studies have documented the mortality associated with initial therapy that did not include agents active against the pathogen eventually isolated. In general, drugs from the β -lactam and related classes of antibiotics should be preferred for at least a part of most empiric regimens.

Special considerations include patients with neutropenia and fever, who should always be treated with at least one agent active against *Pseudomonas*. Some debate continues regarding the use of two anti-pseudomonal drugs as part of the initial antibiotic regimen. Given the possibility of resistance on the part of this pathogen, it would seem reasonable to use two drugs initially, until *Pseudomonas* has been isolated (if present) and its susceptibilities are known, allowing coverage to be narrowed. The Surviving Sepsis Campaign guidelines advocate this approach. There is no benefit in treating with two drugs known to be active in an attempt to achieve a supposed synergy.

Patients with hematologic malignancies are at increased risk for sepsis from fungal organisms. Severe sepsis or septic shock in such patients warrants empiric treatment with an echinocandin, a broad-spectrum azole such as voriconazole (Vfend) or posaconazole (Noxafil), or amphotericin (Fungizone).

MRSA continues to increase in incidence nationally and is now common as a community-acquired pathogen. It is also to be suspected as a cause of postinfluenza bacterial pneumonia. Empiric treatment with an antibiotic active against this bacterium, such as vancomycin (Vancocin), linezolid (Zyvox), or daptomycin (Cubicin), should be strongly considered in septic patients in communities where the rate of MRSA in bloodstream infections

¹Not FDA approved for this indication.

TABLE 1 Empiric Antibiotic Choices for Severe Sepsis*

SOURCE	ANTIBIOTIC AND DOSE	COMMENTS
Community-acquired pneumonia	Ceftriaxone (Rocephin) 2 g q24h <i>plus</i> azithromycin (Zithromax) 500 mg q24h	Should include atypical coverage; alternative is moxifloxacin (Avelox)
Health care–associated pneumonia	Piperacillin/tazobactam (Zosyn) 4.5 g q6h <i>or</i> meropenem (Merrem) ¹ 2 g q8h <i>plus</i> vancomycin (Vancocin) ¹ 1 g q12h	Should cover for <i>Pseudomonas</i> and other resistant gram-negative rods
Neutropenia/fever	Piperacillin/tazobactam ¹ 4.5 g q6h <i>or</i> meropenem ¹ 2 g q8h ³	Consider empiric fungal coverage for prolonged neutropenia
Abdominal sepsis	Ampicillin/sulbactam (Unasyn) 3 g q6h <i>or</i> piperacillin/tazobactam 4.5 g q6h	Consider coverage for yeast, MRSA
Urosepsis	Ampicillin/sulbactam ¹ 3 g q6h <i>or</i> piperacillin/tazobactam ¹ 4.5 g q6h	Obtain imaging and decompression as appropriate
Foreign body/vascular catheter–related sepsis	Piperacillin/tazobactam ¹ 4.5 g q6h <i>or</i> meropenem ¹ 2 g q8h ³ <i>plus</i> vancomycin 1 g q12h	Vascular catheters or other foreign bodies should be removed urgently
Meningitis	Ceftriaxone 2 g q12h <i>plus</i> vancomycin ¹ 750 mg q8h <i>plus</i> rifampin (Rifadin) ¹ 600 mg q24h	Consider steroid therapy before or simultaneously with administration of antibiotics
Soft-tissue infection	Cefazolin (Ancef) 2 g q8h <i>plus</i> vancomycin 1 g q12h	Image for abscess with débridement as appropriate
Necrotizing fasciitis	Ampicillin/sulbactam 3 g q6h <i>plus</i> vancomycin 1 g q12h <i>plus</i> clindamycin (Cleocin) 900 mg q8h	Obtain urgent surgical consultation
Unknown	Piperacillin/tazobactam 4.5 g q6h <i>or</i> meropenem 2 g q8h ³ <i>plus</i> vancomycin 1 g q12h <i>plus</i> tobramycin (Tobrex) 7 mg/kg q24h	Obtain appropriate imaging studies, especially of abdomen, pelvis, central nervous system

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

*In all cases, prior antimicrobial therapy, kidney and liver dysfunction, and the probable source of sepsis should be carefully considered. Always consider coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) in areas where incidence in bloodstream isolates is >10%.

exceeds 10%. This pathogen should always be considered in a patient with a long-term intravenous catheter, prosthetic device, or other indwelling foreign body. Although vancomycin-resistant *S. aureus* is extremely rare, caution should be taken when using daptomycin and linezolid as empiric therapy, because resistance has been reported.

Prior administration of antibiotics and the attendant risk of infection by a pathogen resistant to the previous therapy should be considered in arriving at a course of empiric therapy. A typical scenario is a patient who presents with a catheter-related bloodstream infection while taking vancomycin. One would expect a gram-negative bacterium, a fungal organism, or, potentially, a vancomycin-resistant enterococcus as the pathogen. Recent hospitalization or residence in a nursing home places patients at risk for colonization and subsequent infection with resistant gram-negative rods.

Prognosis and Limits of Care

Patients who present with severe sepsis or septic shock often have substantial prior medical morbidity, decreasing their chances of survival. The overall mortality rate remains between 20% and 40%. Patients often have expressed wishes regarding limits of care to family members or others close to them before becoming ill. It is always appropriate to discuss goals of therapy, possible and probable outcomes, and plans for further evaluation and treatment with patients (if possible) and their proxies in all instances. Decisions to proceed with or limit care should be made within the context of a patient's expressed or expected wishes and should take into account unfolding clinical data and circumstances. Time spent in this endeavor can substantially decrease the amount of futile care rendered to a patient and lead to care that more truly reflects the patient's wishes regarding life-prolonging measures. The stress and anxiety experienced by family members may also be reduced.

Substantial progress has been made in the past 3 decades in decreasing the mortality associated with severe sepsis and septic shock. Nevertheless, the mortality rate remains unacceptably high, and the overall incidence and severity of disease appear to be

increasing, by as much as 1.5% annually by some estimates. The risk of death for an individual patient appears to stabilize approximately 6 months after the original illness. Many patients who do survive remain with the same risk factors (e.g., diabetes, vascular disease, prosthetic devices, immunosuppression) that contributed to their infection and therefore are at risk for recurrence. Moreover, certain organisms, such as MRSA, resistant gram-negative rods, and fungi, remain difficult to treat, and success rates are relatively low despite aggressive, timely, and prolonged therapy.

There is some cause for optimism. The Surviving Sepsis Campaign has now entered phase III. This is a program in which a core set of recommendations, described in the guidelines, is being implemented with opportunities to measure outcomes, assess physician behavior, and provide feedback to improve survival through evidence-based interventions. This effort involves more than 12,000 patients in 239 hospitals in 17 countries and will undoubtedly change the future course of this lethal disease.

SMALLPOX

Method of

Raul Davaro, MD

Smallpox, a disease unique to humans, is one of the oldest recorded infections affecting humankind. In endemic forms and in epidemic waves, smallpox killed and disfigured millions of people throughout history. This viral infection, spread by respiratory droplets, continued to have worldwide distribution at the beginning of the 20th century. Because smallpox confers immunity in the survivors of an attack, its persistence depends on contact of nonimmune persons with infected persons in the initial 2 weeks of acquiring the infection.

Centuries ago, physicians realized that inoculating smallpox matter into nonimmune persons conferred partial or total immunity against smallpox. This practice was known in India and China as *variolation*. Variolation was introduced in England in 1721 by the wife of Ambassador Montagu, Lady Montagu, who herself was disfigured by smallpox. The practice spread rapidly in England despite skepticism from the scientific community and resistance from the Church. Variolation was risky and sometimes fatal. In 1783 Octavius, the son of King George III, died as a result of complications from variolation. Benjamin Franklin was an ardent supporter of variolation in the American colonies.

In 1778, Edward Jenner, an English physician, reported that milkmaids infected with cowpox were immune to smallpox during epidemics. In 1796 he decided to test his hypothesis by injecting cowpox material into James Phipps. Phipps developed no signs or symptoms of smallpox 2 months after the inoculation, when he had variolation. This experiment was the birth of vaccination (Latin *vacca*, “cow”) against smallpox. With the support of King George IV, vaccination was implemented in England, and variolation was slowly abandoned and finally declared illegal in 1840. Vaccination was introduced in the United States in 1800 by Dr. Benjamin Waterhouse, a Harvard physician, and supported by President Thomas Jefferson, who immunized members of his household. The last-documented natural case of smallpox in the United States was documented in 1947.

The World Health Organization (WHO) designed an Intensified Eradication Program based on a ring vaccination strategy that began in 1966 and eradicated smallpox from humans in an unprecedented effort in less than 10 years. The last natural case was documented in Somalia in 1977. Routine immunization against smallpox ceased in the United States in 1972 and worldwide in 1980. It was thought that without a human reservoir, reemergence of this infection would not occur.

Smallpox virus stocks are still available in the United States at the CDC in Atlanta, Georgia, and in Russia at the State Center for Virology and Biotechnology in Novosibirsk, Siberia. These stocks are maintained under strict bio-containment measures. In the aftermath of the terrorist attacks on September 11, 2001 and the deliberate distribution of *Bacillus anthracis* afterwards, President Bush announced plans to immunize health care workers and first responders against smallpox by 2003. Although the plan fell short of its goals, 40,000 first responders and health care workers were vaccinated by the end of 2003.

The Agent

Smallpox is a single, linear double-stranded DNA virus that belongs to the *Orthopoxvirus* genus, family Poxviridae. The poxviruses replicate in cell cytoplasm. They are brick-shaped and measure about 300 by 250 by 200 nm.

Epidemiology

The natural reservoir of smallpox is the patient suffering from the disease. Smallpox spreads from person to person through droplet nuclei or fine-particle aerosols released from the pharynx of infected persons. Smallpox can also be transmitted by fomites such as clothing and bedding. Smallpox patients are not infectious until the third day of the clinical disease, typically 1 day before the skin eruption. The secondary attack rate of smallpox is 37% to 88% among unvaccinated contacts, depending on many variables.

Clinical Presentation

Smallpox occurs as either variola major or variola minor (Alastrim). Variola major had a mortality rate of 30% compared with 1% for variola minor.

After an incubation period of 10 to 14 days, the illness begins with intense prostration and high fever lasting 4 to 6 days (Figure 1). Headache, photophobia, and vomiting are noted. During the prodrome phase most patients are bedridden. Around the fourth day the fever breaks and the patient feels better.

The eruptive phase is signaled by an enanthem involving the buccal mucosa and pharynx and a centrifugal exanthem that begins on the face and forearms. The initial rash is macular and turns pustular in 1 to 2 days. Within 2 days the papules evolve into vesicles that become cloudy and pustular. Most patients exhibit lesions on their soles and palms. A typical feature of variola is that the exanthem everywhere is in the same state of evolution, unlike the exanthem of chickenpox, in which lesions exhibit all stages of evolution. At the end of day 8 to 10 the skin rash crusts and dries; it takes 3 to 4 weeks from the onset of the disease for all the scabs to fall off. The period of contagiousness ends when the last scab falls off. Scarring and pitting of the skin are common sequelae.

Patients with hemorrhagic disease develop severe prostration, high fever, abdominal pain, petechiae, and extensive cutaneous ecchymoses. In the malignant or flat form, the lesions fail to progress to the pustular stage. In the hemorrhagic and the malignant forms, death invariably occurs within 1 week.

History of smallpox vaccination modifies the course of the disease. Vaccinated persons who contract smallpox have fewer skin lesions and an accelerated clinical course.

Complications

Bacterial infections of the skin and other organs are common. Ocular involvement may result in blindness. Encephalitis (one in 500 cases of variola major) is a devastating complication.

Differential Diagnosis (Figure 2)

Many rashes can be confused with smallpox, especially at the outset of the eruption, when the rash is maculopapular. Herpes zoster, chickenpox, herpes simplex, impetigo, scabies, erythema multiforme, and syphilis are some of the conditions that can be confused with smallpox (Box 1). When smallpox was endemic, chickenpox was the most common condition confused with smallpox. The most useful clinical points of smallpox are the following:

- Centrifugal distribution of the lesions
- All the lesions in the same stage of development
- Progression of the rash from the face to the arms, trunk and legs
- A severe prodrome phase that lasts 4 days
- In an epidemic, known contact with an active case

Diagnosis

The identification of a suspected case of smallpox should be treated as an international health emergency. Clinical samples may be collected from vesicular or pustular fluid, blood, tonsillar swabs, and skin biopsy and must be transported to a Biosafety level 4 facility for processing and testing with real-time polymerase chain reaction (PCR) assays to detect virus DNA.

Lesions of varicella zoster virus (chickenpox, herpes zoster) demonstrate multinucleated giant cells on Tzanck smears; lesions of smallpox do not. Serology or electronic microscopy are not

BOX 1 Conditions that Might Be Confused with Smallpox

Maculopapular Stage

Measles
Rubella
Drug eruptions
Secondary syphilis
Erythema multiforme
Scabies, insect bites
Acne
Scarlet fever

Vesicular/Pustular Stage

Chickenpox
Disseminated herpes zoster
Disseminated herpes simplex virus
Drug eruptions
Contact dermatitis
Erythema multiforme (including Stevens-Johnson syndrome)
Enteroviral infections
Secondary syphilis
Acne
Generalized vaccinia
Monkeypox
Impetigo
Scabies, insect bites
Disseminated molluscum contagiosum

recommended for the diagnosis of smallpox because these modalities cannot distinguish among different Orthopoxviruses.

Treatment

A suspected case of smallpox should be placed in a negative-pressure room with strict respiratory and contact isolation precautions. Ideally to minimize the risk of contagion in health care personnel, patient with smallpox should be assisted by providers documented to have been immunized against this condition. Patients with smallpox require careful care of their eyes to avoid complications and this is accomplished with daily eye rinsing. Patients must receive adequate nutrition and hydration. Skin and soft tissue infections must be treated with an antistaphylococcal β -lactams, and initially pending results of cultures, with an antimicrobial with activity against methicillin-resistant *Staphylococcus aureus*. There is no antiviral drug with demonstrated activity against smallpox.

Vaccines and Vaccination

Sanofi's U.S.-licensed ACAM2000, a second-generation vaccine, was made from cell culture-derived vaccinia virus found in Dryvax,

a first-generation vaccine that is no longer produced. ACAM2000 is indicated for active immunization of people who are determined to be at high risk for smallpox. A two-pronged stainless steel (or bifurcated) needle is dipped into the vaccine solution and the skin is pricked several times in the upper arm with a droplet of the vaccine. The virus begins growing at the injection site causing a localized infection or "pock" to form. A red, itchy sore spot at the site of the vaccination within 3–4 days is an indicator that the vaccination was successful; that is, there is "a take." A blister develops at the vaccination site and then dries up forming a scab that falls off in the third week, leaving a small scar. If no evidence of vaccine take is apparent after 7 days, the person can be vaccinated again.

The vaccine causes local and systemic symptoms. There is an eruption at the injection site with redness and pain, systemic symptoms such as fever, and headaches. Swelling and tenderness of regional lymph nodes begin 3 to 10 days after vaccination and can last up to a month.

Complications

Adverse events of vaccinia have been reviewed extensively and include postvaccinal encephalitis, progressive vaccinia, eczema vaccinatum, and generalized vaccinia (Table 1). The most common complication is inadvertent autoinoculation causing self-limited satellite lesions. Generalized vaccinia results from viremia and may be life threatening in immunocompromised patients. Progressive vaccinia is characterized by necrosis at the inoculation site and distal sites such as bones and internal organs. Progressive vaccinia is often a fatal complication. Myopericarditis was observed with the use of adult vaccines in the United States in 2002 (Table 1).

Contraindications to Vaccination

Persons who are immune compromised or who have severe eczema or who are pregnant should not receive Post-exposure vaccination against smallpox. However, in the event of exposure to a patient with smallpox, no absolute contraindication is applicable.

Control of Outbreaks

As soon as a diagnosis of smallpox is considered, suspected persons should be isolated and close contacts should be immunized. Post-exposure vaccination within the first 4 days can greatly mitigate subsequent illness. Contact isolation and ring vaccination are the strategies of choice to contain an outbreak of smallpox.

Use in Warfare

During the 15th century, variola-laden clothing and blankets were distributed by Europeans among Native Americans to spread smallpox in the local population. British soldiers used variola-contaminated blankets among the natives supporting the French during the French and Indian wars. The use of infectious agents in warfare is not new, and the potential use of smallpox as a

wepan increased when routine immunization against smallpox ceased and worldwide immunity waned.

Because natural smallpox has been eradicated, the only possibility of a smallpox outbreak is the deliberate release of smallpox in a population by a nation or a terrorist group to inflict casualties in a civilian population. Preemptive vaccination of first responders and ring immunization of those exposed are the means available to avoid massive propagation of smallpox.

TETANUS

Method of

Dilip R. Karnad, MD

Tetanus is a potentially fatal illness caused by the neurotoxin produced by the spore-bearing anaerobic bacterium *Clostridium tetani*. As the causative organism and its spores are ubiquitous, nonimmune individuals in any part of the world may get tetanus unless they are protected by the highly effective vaccine.

Epidemiology

As a result of effective universal immunization, tetanus is rare in the developed world. Twenty to 40 cases of tetanus occur annually in the United States and 12 to 15 cases per year have been reported from the United Kingdom in the last 10 years. Although progressively declining in the developing world due to improved immunization coverage, according to WHO figures, more than 500 cases were reported in 2012 from each of these nations: Angola, Bangladesh, Congo, India, and Uganda. While tetanus may affect individuals of all ages, a significant number of cases in developed countries are elderly people who did not receive a primary immunization or lacked the booster dosage needed to maintain protective immunity. In developing countries, most cases are neonates (*tetanus neonatorum*), children who are born to nonimmunized mothers and thus lack transplacentally acquired passive immunity. Infection of the umbilical stump due to poor hygiene results in severe tetanus that has mortality in excess of 60%.

The infection is caused by the gram-positive, spore-bearing bacterium *C. tetani*, the spores of which exist in the soil, in animal feces, and even in the human gastrointestinal tract. Spores remain dormant and viable for several months and are destroyed by autoclaving at 1 atmosphere pressure at 120°C for 15 minutes. When inoculated into human or animal tissues, they transform into motile bacilli in an anerobic environment that produce a potent exotoxin, tetanospasmin, which produces the manifestations of tetanus. It must be emphasized that tetanus is not transmitted from human to human, and patients do not require isolation.

Risk Factors

Elderly individuals are at increased risk, as they may not have received adequate immunization or may have waning immunity. Other predisposed groups include immigrants from countries with

an unreliable immunization program, immunosuppressed individuals (with HIV infection or receiving immunosuppressive drugs), and intravenous drug addicts. Local factors include wounds with crushed, devitalized tissue or contaminated by dirt or rust, such as open fractures, punctures, and abscesses. However, even scratches, chronic ulcers, or tattooing may cause tetanus. In developing countries, unsafe practices related to termination of pregnancy may cause maternal tetanus; newborn babies born outside of medical facilities are at risk of neonatal tetanus.

Pathophysiology

Tetanospasmin is a highly toxic protein released by *C. tetani*. It is absorbed into the circulation and reaches the ends of motor axons all over the body, from where it is transported proximally along the axonal cytoplasm to motor nuclei in the brainstem and spinal cord at a rate of 3 to 13 mm/hour. A fragment of the toxin then binds inhibitory interneurons that produce gamma-aminobutyric acid (GABA) and glycine and inactivates synaptobrevin, a protein that is essential for the release of these neurotransmitters from presynaptic vesicles.

The loss of normal inhibition at motor and autonomic neurons results in spontaneous discharge of nerve impulses as well as exaggerated responses to stimuli manifesting as tonic muscle contraction with superadded intermittent muscle spasms. As tetanospasmin reaches the motor nuclei of the shortest motor axons first, muscles innervated by motor cranial nerves are affected first, followed by trunk muscles, and finally the extremities. Autonomic overactivity results in severe tachycardia, swings in blood pressure, profuse sweating, and (rarely) ileus. An exaggerated startle-like response to stimuli with motor and autonomic components is also typical. Generalized spasms may mimic tonic seizures.

Clinical Manifestations

An attempt should be made to locate the predisposing wound, such as cuts, abrasions, burns, puncture wounds, and other skin lesions. Uncommon causes include needle-sticks in intravenous drug abusers, ulcerated malignant tumors, and chronic middle-ear infection in children (otogenic tetanus). In up to 30% of patients, no site of infection is discovered. The incubation period is the interval between the injury and the onset of symptoms and can range from a few days to a few months (usually 3–21 days). A short incubation period (<7 days) suggests the likelihood of developing severe tetanus; however, a long incubation period does not necessarily indicate a milder disease. The period of onset (the interval between the first symptom and first paroxysmal muscle spasm) is a better predictor of severity: early elective tracheal intubation and mechanical ventilation are usually required if the interval is <48 hours.

Generalized Tetanus

Initial symptoms include an inability to open the mouth (lockjaw or trismus), difficulty in chewing and swallowing, and stiffness of neck muscles. The contraction of facial muscles produces the characteristic sneering smile (*risus sardonius*) (Figure 1). In severe cases, intermittent spasms are provoked by attempts to speak or swallow. Pooled saliva from hypersalivation and dysphagia may trigger cough and laryngeal spasms; if prolonged, these may prove fatal. Rigidity of paraspinal muscles follows, and hyperextension of the spine results in opisthotonus (Figure 2). Finally, proximal muscles of the extremity are also affected. Deep tendon reflexes are always exaggerated and ankle clonus is common. Tonic muscle spasms may affect head and neck muscles and laryngeal muscles, or may be generalized. Paroxysmal spasms occur spontaneously or in response to loud noise, bright lights, or attempts to speak or swallow. Prolonged spasms may compromise breathing.

The Ablett classification is commonly used to grade the severity of tetanus. Grade I (mild) tetanus is characterized by moderate trismus and general spasticity without spasms, dysphagia, or respiratory distress. Grade II (moderate) tetanus has severe trismus, intermittent short spasms, mild tachypnea, and dysphagia. Grade III (severe) tetanus is associated with severe rigidity, prolonged

wepan increased when routine immunization against smallpox ceased and worldwide immunity waned.

Because natural smallpox has been eradicated, the only possibility of a smallpox outbreak is the deliberate release of smallpox in a population by a nation or a terrorist group to inflict casualties in a civilian population. Preemptive vaccination of first responders and ring immunization of those exposed are the means available to avoid massive propagation of smallpox.

TETANUS

Method of

Dilip R. Karnad, MD

Tetanus is a potentially fatal illness caused by the neurotoxin produced by the spore-bearing anaerobic bacterium *Clostridium tetani*. As the causative organism and its spores are ubiquitous, nonimmune individuals in any part of the world may get tetanus unless they are protected by the highly effective vaccine.

Epidemiology

As a result of effective universal immunization, tetanus is rare in the developed world. Twenty to 40 cases of tetanus occur annually in the United States and 12 to 15 cases per year have been reported from the United Kingdom in the last 10 years. Although progressively declining in the developing world due to improved immunization coverage, according to WHO figures, more than 500 cases were reported in 2012 from each of these nations: Angola, Bangladesh, Congo, India, and Uganda. While tetanus may affect individuals of all ages, a significant number of cases in developed countries are elderly people who did not receive a primary immunization or lacked the booster dosage needed to maintain protective immunity. In developing countries, most cases are neonates (*tetanus neonatorum*), children who are born to nonimmunized mothers and thus lack transplacentally acquired passive immunity. Infection of the umbilical stump due to poor hygiene results in severe tetanus that has mortality in excess of 60%.

The infection is caused by the gram-positive, spore-bearing bacterium *C. tetani*, the spores of which exist in the soil, in animal feces, and even in the human gastrointestinal tract. Spores remain dormant and viable for several months and are destroyed by autoclaving at 1 atmosphere pressure at 120°C for 15 minutes. When inoculated into human or animal tissues, they transform into motile bacilli in an anerobic environment that produce a potent exotoxin, tetanospasmin, which produces the manifestations of tetanus. It must be emphasized that tetanus is not transmitted from human to human, and patients do not require isolation.

Risk Factors

Elderly individuals are at increased risk, as they may not have received adequate immunization or may have waning immunity. Other predisposed groups include immigrants from countries with

an unreliable immunization program, immunosuppressed individuals (with HIV infection or receiving immunosuppressive drugs), and intravenous drug addicts. Local factors include wounds with crushed, devitalized tissue or contaminated by dirt or rust, such as open fractures, punctures, and abscesses. However, even scratches, chronic ulcers, or tattooing may cause tetanus. In developing countries, unsafe practices related to termination of pregnancy may cause maternal tetanus; newborn babies born outside of medical facilities are at risk of neonatal tetanus.

Pathophysiology

Tetanospasmin is a highly toxic protein released by *C. tetani*. It is absorbed into the circulation and reaches the ends of motor axons all over the body, from where it is transported proximally along the axonal cytoplasm to motor nuclei in the brainstem and spinal cord at a rate of 3 to 13 mm/hour. A fragment of the toxin then binds inhibitory interneurons that produce gamma-aminobutyric acid (GABA) and glycine and inactivates synaptobrevin, a protein that is essential for the release of these neurotransmitters from presynaptic vesicles.

The loss of normal inhibition at motor and autonomic neurons results in spontaneous discharge of nerve impulses as well as exaggerated responses to stimuli manifesting as tonic muscle contraction with superadded intermittent muscle spasms. As tetanospasmin reaches the motor nuclei of the shortest motor axons first, muscles innervated by motor cranial nerves are affected first, followed by trunk muscles, and finally the extremities. Autonomic overactivity results in severe tachycardia, swings in blood pressure, profuse sweating, and (rarely) ileus. An exaggerated startle-like response to stimuli with motor and autonomic components is also typical. Generalized spasms may mimic tonic seizures.

Clinical Manifestations

An attempt should be made to locate the predisposing wound, such as cuts, abrasions, burns, puncture wounds, and other skin lesions. Uncommon causes include needle-sticks in intravenous drug abusers, ulcerated malignant tumors, and chronic middle-ear infection in children (otogenic tetanus). In up to 30% of patients, no site of infection is discovered. The incubation period is the interval between the injury and the onset of symptoms and can range from a few days to a few months (usually 3–21 days). A short incubation period (<7 days) suggests the likelihood of developing severe tetanus; however, a long incubation period does not necessarily indicate a milder disease. The period of onset (the interval between the first symptom and first paroxysmal muscle spasm) is a better predictor of severity: early elective tracheal intubation and mechanical ventilation are usually required if the interval is <48 hours.

Generalized Tetanus

Initial symptoms include an inability to open the mouth (lockjaw or trismus), difficulty in chewing and swallowing, and stiffness of neck muscles. The contraction of facial muscles produces the characteristic sneering smile (*risus sardonius*) (Figure 1). In severe cases, intermittent spasms are provoked by attempts to speak or swallow. Pooled saliva from hypersalivation and dysphagia may trigger cough and laryngeal spasms; if prolonged, these may prove fatal. Rigidity of paraspinal muscles follows, and hyperextension of the spine results in opisthotonus (Figure 2). Finally, proximal muscles of the extremity are also affected. Deep tendon reflexes are always exaggerated and ankle clonus is common. Tonic muscle spasms may affect head and neck muscles and laryngeal muscles, or may be generalized. Paroxysmal spasms occur spontaneously or in response to loud noise, bright lights, or attempts to speak or swallow. Prolonged spasms may compromise breathing.

The Ablett classification is commonly used to grade the severity of tetanus. Grade I (mild) tetanus is characterized by moderate trismus and general spasticity without spasms, dysphagia, or respiratory distress. Grade II (moderate) tetanus has severe trismus, intermittent short spasms, mild tachypnea, and dysphagia. Grade III (severe) tetanus is associated with severe rigidity, prolonged

Figure 1 Typical facial expression with the sneering smile (*risus sardonicus*), wrinkled forehead, narrow palpebral fissures, and “crow’s feet” at the lateral palpebral margins from the tonic contraction of muscles of facial expression in moderate tetanus.

Figure 2 Spasm of paraspinal muscles, producing the hyperextended opisthotonic posture in severe tetanus.

spasms, severe dysphagia, tachypnea, apneic spells, and tachycardia. The presence of additional violent autonomic disturbances with persistent or intermittent episodes of severe hypertension and tachycardia alternating with hypotension and bradycardia is classified as Grade IV (very severe) tetanus. Cardiac arrhythmias, peripheral vasoconstriction, and sudden asystole may also occur in very severe tetanus.

Despite the use of antitetanus immune globulin (HyperTET) to neutralize circulating tetanus toxin, the disease may progress for up to 2 weeks as more intraaxonal toxin continues to reach the central nervous system. Manifestations persist for another 2 to 3 weeks before gradually subsiding. During this period, an apparently stable patient is at risk of developing sudden asphyxia due to severe generalized or laryngeal spasms. Patients may develop fever, rhabdomyolysis, and hyperthermia due to excessive muscular activity.

Cephalic Tetanus

Following injuries to the head or face, in some patients, the toxin reaches the local motor nuclei earlier and produces a combination of partial paralysis and overactivity—more severely affected motor neurons stop functioning while the remaining fibers are overactive and cause muscle spasm (Figure 3).

Localized Tetanus

In this rare form of tetanus, manifestations are restricted to muscles in the region of the wound. These patients have a good prognosis.

Diagnosis

C. tetani can be isolated from the wound in <30% of cases, and microbiological and other laboratory tests do not help in

Figure 3 Cephalic tetanus: This 6-year-old child developed mild tetanus 3 weeks after a wound on his right cheek was sutured. He had cephalic tetanus characterized by partial paralysis of the right facial nerve along with overactivity of the unaffected nerve fibers. **A**, Note the overactivity of the facial muscles with a narrow palpebral and prominent nasolabial fold on the same side as the injury. On asking him to shut his eyes tight (**B**), weakness of the orbicularis oculi and other facial muscles on the right side become manifest.

confirming the diagnosis. The diagnosis is entirely clinical. In an individual with a predisposing injury, the presence of trismus, rigidity of neck, abdominal and paraspinal muscles, and severe hyperreflexia are suggestive. The spatula test is a useful bedside test: A spatula (tongue depressor) is inserted into the mouth to touch the posterior pharyngeal wall. Normally, a gag reflex is activated in an attempt to expel the spatula. In tetanus, severe spasms of the masseters results in the patient biting on the spatula, making it difficult to withdraw—a positive test. In one study, the spatula test was positive in 94% of patients with tetanus and in none without tetanus. The electromyogram shows the continuous discharge of motor units in moderate tetanus and the absence of the normal silent period.

Differential Diagnosis

While the diagnosis of tetanus is easy in severe tetanus, it may be mistaken for other conditions in its initial stages (Table 1). The spatula test is negative in other conditions causing trismus. Abdominal muscles usually relax after adequate sedation. As in spasticity due to cord compression, deep reflexes are exaggerated; however, the plantar response, which is extensor in spinal cord disorders, is always flexor with tetanus. Unlike seizures or other intracranial diseases, the patient with tetanus is always fully alert and awake.

Treatment

In patients with life-threatening spasms, prompt, adequate sedation is the first step in management. Patients must be observed in an intensive care unit because the disease may rapidly worsen. They should be nursed in a quiet, dimly lit room in order to keep external stimuli to a minimum—this is difficult in modern intensive care units.

TABLE 1 Conditions that Mimic Clinical Manifestations of Tetanus

CLINICAL FEATURE	DIFFERENTIAL DIAGNOSIS
Trismus	Acute tonsillar abscess, temporomandibular joint disease, extrapyramidal reaction to drugs, dental pathology
Neck stiffness	Cervical spine disease; extrapyramidal reaction to drugs such as antipsychotics, antiemetics, or metoclopramide; meningitis; subarachnoid hemorrhage
Abdominal rigidity	Acute abdomen
Dysphagia	Myasthenia gravis, acute bulbar paralysis, rabies
Muscle spasms	Seizures, spasticity due to spinal cord disease, stiff man syndrome

Neutralization of Toxin

Although unsupported by randomized studies, human tetanus immune globulin (HyperTET) (3000–6000 units) is administered intramuscularly to neutralize the circulating toxin. This does not bind to the toxin that has already entered neurons. There is insufficient evidence favoring intrathecal administration¹ of tetanus immune globulin over the usual intramuscular route, although one randomized study showed a shortening of the course of tetanus. Equine antiserum² (10,000–20,000 units) may be administered after skin testing for hypersensitivity. Though rarely used today due to the risk of anaphylaxis or serum sickness, it has the advantage of being administered intravenously.

Control of Clostridial Infection

Benzylpenicillin (Penicillin G) in a dose of 10 to 12 million units per day is given intravenously for 10 days. In one study, metronidazole (Flagyl) (500 mg every 6 hours for 10 days) was superior to procaine penicillin (Wycillin),¹ presumably because procaine and penicillin are GABA antagonists and may worsen manifestations of tetanus. However, a more recent study showed that a single intramuscular injection of 1.2 million units of benzathine penicillin (Bicillin LA)¹ was as effective as benzylpenicillin or metronidazole. Fortunately, resistance to these antibiotics has not been reported. Debridement of the infected wound and abscess drainage should be performed after spasms have been adequately controlled.

Control of Muscle Spasms

Benzodiazepines (diazepam [Valium] or lorazepam [Ativan]¹) are the preferred drugs and act by enhancing the effect of GABA on its receptor on the postsynaptic membrane, thus potentially antagonizing the effect of tetanospasmin. However, as very little GABA is released in tetanus, large doses (up to 1000 mg/day³) of diazepam may be required to achieve adequate sedation and muscle relaxation. Diazepam may be administered intravenously (10–30 mg in 5 mg boluses every 5 minutes)³ or through a nasogastric tube (10–40 mg every 1 to 2 hours).³ Barbiturates and chlorpromazine (Thorazine)¹ are alternative agents. Other sedative hypnotic agents such as midazolam (Versed)¹ and propofol (Diprivan)¹ have also been used with good effect. In mild to moderate tetanus, drug doses can be titrated to achieve moderate sedation and control rigidity and spasms without causing respiratory depression. In severe cases, however, spasms may not be controlled despite large doses, increasing the risk of severe central nervous system (CNS) depression. In these patients, heavy sedation combined with

neuromuscular blockade and mechanical ventilation is required. In about 10% of cases, benzodiazepines may produce paradoxical excitation instead of sedation; increasing doses make the patient more wakeful, agitated, and delirious, with increased spasms. Discontinuation of diazepam and the use of barbiturates and chlorpromazine may prevent the need for paralysis and mechanical ventilation. Pancuronium (Pavulon),¹ vecuronium (Norcuron),¹ and rocuronium (Zemuron)¹ are often used for neuromuscular blockade. Atracurium (Tracrium)¹ could also be used but may have unfavorable cardiovascular effects. Intravenous and intrathecal baclofen (Lioresal Intrathecal)¹ have been used in some case.

Airway Management

Tracheostomy or endotracheal intubation is required in moderate and severe tetanus to prevent respiratory failure due to laryngeal spasm and aspiration of oropharyngeal secretions. In most developing countries, elective tracheostomy is performed early in severe tetanus. In countries with superior intensive care facilities, heavy sedation, neuromuscular blockade, endotracheal intubation, and mechanical ventilation are preferred, with tracheostomy being reserved for those who need prolonged ventilation.

Control of Autonomic Disturbances

With good intensive care, mortality due to respiratory failure has been drastically reduced. Autonomic dysfunction is now the major challenge in patients with severe tetanus; it is common even in sedated and paralyzed patients. Various measures to control autonomic fluctuations include intravenous fluid loading, oral and parenteral beta-blockers, alpha-blockers, centrally acting sympatholytics such as clonidine (Catapres)¹ or dexmedetomidine (Precedex),¹ and epidural or spinal bupivacaine (Marcaine).¹ More recently, infusion of dexmedetomidine has been used by some authors. Many patients may develop sudden asystole, possibly due to sudden parasympathetic discharge, catecholamine-induced myocardial damage, or sudden loss of sympathetic drive. Consequently, the use of long-acting antiadrenergic drugs should be avoided. Increasing the level of sedation itself is also effective, to a significant extent.

The agent most frequently used for autonomic dysfunction is intravenous magnesium sulfate.¹ A randomized controlled trial in Vietnamese patients showed that magnesium sulfate did not decrease mortality, ICU stay, or the need for mechanical ventilation but did reduce the dose of sedatives and neuromuscular blocking drugs required. This study used a loading dose of 40 mg/kg over 30 minutes, followed by intravenous infusion of 2 g/hour in patients >45 kg and 1 to 5 g/hour in patients ≤45 kg. Infusion was titrated to maintain serum magnesium levels between 2 and 4 mmol/L.

Other Measures

Continuous muscle hyperactivity and spasms greatly increase caloric requirements. Most patients require nasogastric tube feeding because of trismus and dysphagia. A catabolic state similar to sepsis may develop in very severe tetanus. Consequently, patients lose up to 15% of their body weight during the illness. Good nursing care is essential to prevent pressure sores, deep vein thrombosis, stress ulcers, and aspiration pneumonia. Urinary catheterization is required in most patients as urinary retention is common and distension of the urinary bladder may provoke spasms and autonomic overactivity. All patients should be started on a primary immunization schedule against tetanus.

Complications

Respiratory failure may occur due to laryngeal obstruction, prolonged spasm of respiratory muscles, aspiration pneumonia, or sedative drugs. Severe spasms may result in tongue-bite, compression fractures of midthoracic vertebrae, rhabdomyolysis, myoglobinuria, and renal failure. Rarely, patients may develop acute

¹Not FDA approved for this indication.

²Not available in the United States.

³Exceeds dosage recommended by the manufacturer.

¹Not FDA approved for this indication.

respiratory distress syndrome (ARDS) either due to tetanus itself or as a result of secondary bacterial sepsis. Cardiac arrhythmias and sudden asystole are common in patients with autonomic dysfunction. Acute myocardial infarction may occur in elderly patients with underlying coronary artery disease due to sympathetic overactivity. Deep vein thrombosis and pressure sores are preventable complications. The overall mortality ranges from 40% to 60% in countries with inadequate health care facilities. With good intensive care, mortality as low as 10% is reported in some series. Mortality is higher in neonates, the elderly, and patients with a short incubation period and period of onset.

Prevention

Adsorbed tetanus toxoid (Tt), derived from formaldehyde-treated tetanus toxin, is extremely effective in inducing active immunity. It is available as a single-antigen preparation or in combination with diphtheria toxoid as pediatric diphtheria-tetanus toxoid (DT) or adult tetanus-diphtheria (Td), and with both diphtheria toxoid and acellular pertussis vaccine as DTaP (Infanrix, Tripedia) or Tdap (Adacel, Boostrix) (lower-case alphabets indicate lower doses of antigens). Pediatric vaccines (DT and DTaP) contain identical amounts of tetanus toxoid as adult vaccines, but three to four times as much diphtheria toxoid. The usual schedule for primary immunization in children <7 years consists of four doses of DTaP or DT at age 2, 4, 6, and 15 to 18 months. A booster dose is recommended at 4 to 6 years of age. In individuals aged 7 years or older, three doses of the adult formulation are administered; the second dose is given 4 to 8 weeks after the first, and the third dose after another 4 to 6 months. Further booster doses are needed every 10 years to maintain antibody titers above the protective level of 0.1 IU/mL.

After administration of Tt to individuals with wounds, protective titers of antibody are achieved after at least 2 weeks. Consequently, passive immunization with 250 units of human tetanus immune globulin (HyperTET) or 1500 units of equine antitetanus serum² administered intramuscularly is needed to confer protection during these initial few weeks. This is especially required in individuals with tetanus-prone wounds who have not received at least three doses of tetanus toxoid in the past. Previously unimmunized individuals with clean, minor, nontetanus prone wounds do not need any passive immunization, but should receive active immunization. Passive immunization is not necessary in those who have received three or more doses of the toxoid. These individuals should receive a dose of Tt (or Td) if more than 10 years have elapsed since the last booster dose and they have nontetanus prone wounds or if >5 years have elapsed after the booster dose and they have a tetanus-prone wound. In countries where neonatal tetanus is common, primary immunization of women during pregnancy has been advocated as a public health program to prevent neonatal tetanus.

²Not available in the United States.

TICKBORNE RICKETTSIAL DISEASES (ROCKY MOUNTAIN SPOTTED FEVER AND OTHER SPOTTED FEVER GROUP RICKETTSIOSES, EHRLICHIOSES, AND ANAPLASMOSIS)

Method of
Robert Wittler, MD

CURRENT DIAGNOSIS

- Early diagnosis of Rocky Mountain spotted fever (RMSF) and other tickborne rickettsial diseases is made clinically. RMSF should be considered in the setting of fever, headache, rash, and a history of possible tick exposure. The rash is not always present and typically occurs 2 to 4 days after the onset of fever.
- Diagnostic laboratory tests for rickettsial diseases, particularly RMSF, are usually not helpful in making a timely diagnosis during the initial states of illness.
- Tickborne rickettsial diseases can be confirmed by polymerase chain reaction (PCR) during the acute stage if readily available (whole blood for ehrlichiosis and anaplasmosis and skin biopsy or whole blood for RMSF) or at later stages by subsequently demonstrating a fourfold increase between acute and convalescent (ideally 2 to 4 weeks apart) serum immunoglobulin G (IgG) indirect immunofluorescence antibody titers. PCR of whole blood for RMSF has low sensitivity, although sensitivity increases in patients with severe disease.
- Typical findings of ehrlichiosis and anaplasmosis include fever, headache, malaise, leukopenia, thrombocytopenia, and elevated serum transaminases. Rash is often not present.

CURRENT THERAPY

- Treatment of choice for all tickborne rickettsial diseases in patients of all ages (including children less than 8 years of age) is doxycycline (Vibramycin).
- The dose for doxycycline is 100 mg twice daily (intravenously [IV] or orally depending on severity of illness) for adults. For children weighing <45 kg,¹ the recommended dose is 2.2 mg/kg/dose IV or orally twice daily.
- Delay in recognition and appropriate treatment is the most important factor associated with death from RMSF. Empiric treatment within 5 days of the onset of symptoms with doxycycline is the best way to prevent morbidity and death. Treatment decisions should never be delayed while awaiting laboratory confirmation, nor should treatment be discontinued solely on the basis of a negative test result with an acute-phase specimen.
- Although optimal duration of therapy has not been well studied, a common treatment course for RMSF and ehrlichiosis is at least 3 days after the patient defervesces (typically the minimum total course is 5–7 days) or longer for severe illness. Anaplasmosis should be treated for 10 days to provide appropriate therapy for possible coinfection with *Borrelia burgdorferi*.
- Historically chloramphenicol has been recommended for the treatment of RMSF during pregnancy based on adverse effects of older tetracycline drugs (but not specifically doxycycline). Although there is limited evidence, doxycycline has not been associated with teratogenicity or maternal hepatic toxicity during pregnancy, and doxycycline has been used successfully to treat tickborne rickettsial disease in several pregnant women without adverse effects.

respiratory distress syndrome (ARDS) either due to tetanus itself or as a result of secondary bacterial sepsis. Cardiac arrhythmias and sudden asystole are common in patients with autonomic dysfunction. Acute myocardial infarction may occur in elderly patients with underlying coronary artery disease due to sympathetic overactivity. TICKBORNE RICKETTSIAL DISEASES (ROCKY MOUNTAIN SPOTTED FEVER AND OTHER SPOTTED FEVER GROUP RICKETTSIOSES, EHRLICHIOSES, AND ANAPLASMOSIS)

Method of
Robert Wittler, MD

CURRENT DIAGNOSIS

- Early diagnosis of Rocky Mountain spotted fever (RMSF) and other tickborne rickettsial diseases is made clinically. RMSF should be considered in the setting of fever, headache, rash, and a history of possible tick exposure. The rash is not always present and typically occurs 2 to 4 days after the onset of fever.
- Diagnostic laboratory tests for rickettsial diseases, particularly RMSF, are usually not helpful in making a timely diagnosis during the initial states of illness.
- Tickborne rickettsial diseases can be confirmed by polymerase chain reaction (PCR) during the acute stage if readily available (whole blood for ehrlichiosis and anaplasmosis and skin biopsy or whole blood for RMSF) or at later stages by subsequently demonstrating a fourfold increase between acute and convalescent (ideally 2 to 4 weeks apart) serum immunoglobulin G (IgG) indirect immunofluorescence antibody titers. PCR of whole blood for RMSF has low sensitivity, although sensitivity increases in patients with severe disease.
- Typical findings of ehrlichiosis and anaplasmosis include fever, headache, malaise, leukopenia, thrombocytopenia, and elevated serum transaminases. Rash is often not present.

CURRENT THERAPY

- Treatment of choice for all tickborne rickettsial diseases in patients of all ages (including children less than 8 years of age) is doxycycline (Vibramycin).
- The dose for doxycycline is 100 mg twice daily (intravenously [IV] or orally depending on severity of illness) for adults. For children weighing <45 kg,¹ the recommended dose is 2.2 mg/kg/dose IV or orally twice daily.
- Delay in recognition and appropriate treatment is the most important factor associated with death from RMSF. Empiric treatment within 5 days of the onset of symptoms with doxycycline is the best way to prevent morbidity and death. Treatment decisions should never be delayed while awaiting laboratory confirmation, nor should treatment be discontinued solely on the basis of a negative test result with an acute-phase specimen.
- Although optimal duration of therapy has not been well studied, a common treatment course for RMSF and ehrlichiosis is at least 3 days after the patient defervesces (typically the minimum total course is 5–7 days) or longer for severe illness. Anaplasmosis should be treated for 10 days to provide appropriate therapy for possible coinfection with *Borrelia burgdorferi*.
- Historically chloramphenicol has been recommended for the treatment of RMSF during pregnancy based on adverse effects of older tetracycline drugs (but not specifically doxycycline). Although there is limited evidence, doxycycline has not been associated with teratogenicity or maternal hepatic toxicity during pregnancy, and doxycycline has been used successfully to treat tickborne rickettsial disease in several pregnant women without adverse effects.

- Chloramphenicol is not an alternative treatment for human monocytic ehrlichiosis (HME) or HGA. Chloramphenicol treatment of RMSF has been associated with a greater risk of death compared with doxycycline treatment.
- Limited case report data suggest that rifampin¹ can be used as an alternative to doxycycline for the treatment of confirmed (RMSF ruled out) mild anaplasmosis during pregnancy or with documented tetracycline allergy.

¹Not FDA approved for this indication.

Tickborne rickettsial diseases in humans often share clinical features but are epidemiologically and etiologically distinct. In the United States included diseases are (1) Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii*; (2) other spotted fever group (SFG) rickettsioses, caused by *Rickettsia parkeri* and *Rickettsia* species 364D; (3) *Ehrlichia chaffeensis* ehrlichiosis, also called human monocytic ehrlichiosis (HME); (4) other ehrlichioses, caused by *Ehrlichia ewingii* and *Ehrlichia muris*-like agent; and (5) anaplasmosis, caused by *Anaplasma phagocytophilum*, also called human granulocytic anaplasmosis (HGA). The reported incidence of tickborne rickettsial diseases has increased in the United States. Tickborne rickettsial diseases, especially RMSF, continue to cause severe illness and death in otherwise healthy adults and children, despite the availability of effective antibiotic therapy. SFG rickettsioses (including RMSF), ehrlichioses, and anaplasmosis are nationally notifiable diseases in the United States. Providers report potential cases to state or local health departments. In 2010, the reporting category of RMSF was changed to spotted fever rickettsiosis, as serology does not readily distinguish RMSF from other SFG rickettsioses.

Epidemiology

Tickborne rickettsial pathogens are maintained in natural cycles involving domestic or wild vertebrates and ticks. The epidemiology of each disease reflects the geographic distribution and seasonal activities of the tick vectors and the natural vertebrate hosts, as well as the human activities resulting in tick exposure. Although cases have been reported in every month, most cases occur during April to September, coincident with peak levels of tick host-seeking activity.

RMSF is the rickettsiosis in the United States that is associated with the highest rates of severe and fatal outcomes. The case-fatality rate in the preantibiotic era was ~25%. Current case-fatality rates are estimated at 5% to 10%. From 2008–2012, the estimated average annual incidence from passive surveillance of SFG rickettsioses was 8.9 cases per million persons. Reported annual incidence has increased during the past two decades. The highest incidence occurs in persons aged 60 to 69 years, and the highest case-fatality rate is among children aged <10 years. Additional epidemiologic risk factors for fatal RMSF include age ≥40 years, alcohol abuse, and glucose-6-phosphate dehydrogenase deficiency. From 2008 to 2012, 63% of reported SFG rickettsiosis cases came from Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee. SFG rickettsiosis has been reported from all the contiguous 48 states and the District of Columbia.

In the United States, the tick species most frequently associated with transmission of *R. rickettsii* is the American dog tick, *Dermacentor variabilis*, which is found primarily in the eastern, central, and Pacific Coast regions. The Rocky Mountain wood tick, *Dermacentor andersoni*, is associated with transmission in the western United States. Larval and nymphal stages of most *Dermacentor* spp ticks usually do not bite humans. Adult *D. variabilis* and *D. andersoni* ticks bite humans, but the principal hosts are deer, dogs, and livestock.

The brown dog tick, *Rhipicephalus sanguineus*, which is located throughout the United States, is an important vector in parts of Arizona and along the United States–Mexico border. All stages (larvae, nymphs, and adults) of *R. sanguineus* bite humans and can transmit *R. rickettsia*. Domestic dogs are the preferred host. On

Arizona tribal lands, the warm climate and proximity of ticks to domiciles (tick-infested dogs) provide a suitable environment for *R. sanguineus* to remain active year-round, resulting in cases of RMSF in Arizona every month of the year.

Rickettsia parkeri is transmitted by the Gulf Coast tick, *Amblyomma maculatum*. *R. parkeri* rickettsiosis cases have not been documented in children, and no fatal cases have been reported. The first confirmed case of *Rickettsia* species 364D was in 2010 and likely transmitted by the Pacific Coast tick, *Dermacentor occidentalis*. All reported cases have been from California.

The average annual incidence of ehrlichiosis from 2008 to 2012 was 3.2 cases per million persons, with the most common cause being *E. chaffeensis*. The highest incidence is in persons aged 60 to 69 years. The case fatality rate is ~3% and is highest among children aged <10 years, adults aged ≥70 years, and immunosuppressed persons. *E. chaffeensis* is transmitted to humans by the lone star tick, *Amblyomma americanum*, which is the most commonly encountered tick in the southeastern United States, with a range that extends into areas of the Midwest and New England. Arkansas, Delaware, Missouri, Oklahoma, Tennessee, and Virginia have the highest reported incidence. The white-tailed deer is an important natural reservoir for *E. chaffeensis*, and most cases occur during May to August.

The principal vector for *E. ewingii* ehrlichiosis is also *A. americanum*. Cases have primarily been reported from Missouri. No fatal cases of *E. ewingii* ehrlichiosis have been reported. *Ehrlichia muris*-like agent (EML) has recently been recognized as a human pathogen. Reported cases have been from Minnesota and Wisconsin. The blacklegged tick, *Ixodes scapularis*, is an efficient vector for EML in experimental studies. EML agent DNA has been detected in *I. scapularis* collected in Minnesota and Wisconsin but has not been detected in *I. scapularis* from other states.

The incidence of human anaplasmosis during 2008–2012 was 6.3 cases per million persons. Incidence is highest in the northeastern and upper midwestern states, and the geographic range seems to be expanding. The case fatality rate is <1%. *I. scapularis* is the vector for *Anaplasma phagocytophilum* in the northeastern and midwestern United States, whereas the western blacklegged tick, *Ixodes pacificus*, is the principal vector along the West Coast. The seasonality is bimodal, with the first peak June–July and a smaller peak in October, corresponding to the emergence of the adult stage of *I. scapularis*. *I. scapularis* also transmits *Borrelia burgdorferi* (Lyme disease), *Babesia microti* (babesiosis), *Borrelia miyamotoi* (tickborne relapsing fever), and deer tick virus (a cause of tickborne encephalitis). Simultaneous infections with *A. phagocytophilum* and *B. burgdorferi* or *B. microti* have occurred.

Pathophysiology

The agents causing RMSF, ehrlichiosis, and anaplasmosis are all obligate intracellular pathogens, but the target host cells they infect and subsequent pathology vary by organism.

R. rickettsii is transmitted from the tick to humans via a painless bite, which often goes unrecognized. The organism resides in the salivary gland of the tick and is passed during acquisition of a blood meal. *R. rickettsii* can be transmitted as early as 10 to 24 hours after tick attachment. When transmitted to a human host, *R. rickettsia* localize and multiply in vascular endothelial cells, and, less commonly, underlying smooth muscle cells of small and medium vessels, resulting in vasculitis. The vasculitis is the underlying mechanism for most of the clinical features and laboratory abnormalities of RMSF. Injury to the vascular endothelium results in increased capillary permeability, microhemorrhage, and platelet consumption. Late-stage complications of pulmonary edema (acute respiratory distress syndrome) and cerebral edema are consequences of the microvascular leakage.

E. chaffeensis predominantly infects monocytes and tissue macrophages and replicates in cytoplasmic vacuoles called morulae. Unlike RMSF, direct vasculitis and endothelial injury are rare in human monocytic ehrlichiosis. Frequent pathologic findings

include granuloma formation, myeloid hyperplasia, and megakaryocytosis in the bone marrow. The severe pathology and multiorgan involvement in severe and fatal HME in immunocompetent patients is believed to be due to dysregulation of the host immune response that leads to tissue damage and eventually multiorgan failure. *E. ewingii* has a predilection for neutrophils, and morulae can be observed in granulocytes of the blood, cerebrospinal fluid (CSF), and bone marrow.

A. phagocytophilum is found predominantly in neutrophils in the peripheral blood and tissues from infected individuals. *A. phagocytophilum* has the unique ability to selectively survive and multiply within cytoplasmic vacuoles (morulae) of polymorphonuclear cells by delaying their apoptosis. Infection with *A. phagocytophilum* induces a systemic inflammatory response, which is believed to be the mechanism for tissue damage. Pathologic findings with human granulocytic anaplasmosis include normocellular or hypercellular bone marrow, erythrophagocytosis, hepatic apoptosis, focal splenic necrosis, and mild interstitial pneumonitis and pulmonary hemorrhage.

Clinical Manifestations

A detailed history should include information about known tick bites or activities that might be associated with tick exposure. Unrecognized tick bites are common. A history of a tick bite within 14 days of illness onset is reported in only 50% to 60% of RMSF cases and 68% of ehrlichiosis cases. Absence of a tick bite should never dissuade providers from considering tickborne rickettsial disease in the appropriate clinical context. Contact with pets, especially dogs, and a history of tick attachment or recent tick removal from pets can be useful in assessing human tick exposure.

Tickborne rickettsial diseases commonly have nonspecific clinical signs and symptoms early in the course of disease. Although there is overlap in the clinical presentations of tickborne rickettsial diseases, the frequency of certain associated signs and symptoms (e.g., rash and other cutaneous findings) and typical laboratory findings differ by pathogen and assist providers in developing a differential diagnosis, beginning appropriate antibacterial treatment, and ordering confirmatory diagnostic tests.

Symptoms of RMSF typically begin 3 to 12 days after the bite of an infected tick or 4 to 8 days after discovery of an attached tick. The incubation period is generally shorter (≤ 5 days) in patients who develop severe disease. Initial symptoms are often nonspecific and include the sudden onset of fever, chills, malaise, and myalgia. Clinical suspicion for RMSF should be maintained in cases of non-specific febrile illness and sepsis of unclear cause, particularly during the spring and summer months.

The classic triad of fever, rash, and reported tick bite is present in only a minority of RMSF patients during the initial presentation to health care; therefore it is crucial not to wait for development of this triad before considering a diagnosis of RMSF and beginning treatment. A rash typically occurs 2 to 4 days after the onset of fever; however, many patients initially seek medical care before the rash. In one large series of patients with RMSF, 88% of patients had a rash, but only 49% had a rash in the first 3 days. Children more frequently have rash (97%) and develop the rash earlier. The rash typically begins as small, blanching macules on the ankles, wrists, or forearms that then spreads to the palms, soles, arms, legs, and trunk, usually sparing the face. The generalized petechial rash appears later (day 5 or 6) and is indicative of advanced disease. An inoculation eschar is rarely present with RMSF. In addition to rash, the most frequent clinical findings at any point in the illness are fever (99%), headache (91%), and myalgia (82%).

The total white blood cell count is typically normal or mildly increased with RMSF, and increased numbers of immature neutrophils are often present. Thrombocytopenia, slight elevations of AST or ALT, and hyponatremia might be present, particularly as the disease advances. Laboratory values cannot be relied on to guide early treatment decisions because they are often within or slightly deviated from normal reference values early in the course.

When CSF is obtained, a lymphocytic (less commonly neutrophilic) pleocytosis can be present, along with a moderately elevated CSF protein. CSF glucose is generally normal.

R. parkeri rickettsiosis is a milder illness compared with RMSF; no severe manifestations or death has been reported. Symptoms develop a median of 5 days (range, 2–10 days) after the bite of an infected tick. The first manifestation in nearly all patients is an inoculation eschar, which generally is nonpruritic, nontender or mildly tender, and surrounded by an indurated, erythematous halo and occasionally a few petechiae. Shortly after the onset of fever (0.5–4 days later), a nonpruritic maculopapular or vesicopustular rash develops in 90% of patients. The rash primarily involves the extremities and trunk and in ~half of patients involves the palms and soles. Headache (86%) and myalgia (76%) are common. Laboratory findings include modest elevation of hepatic transaminases (78%), mild leukopenia (50%), and thrombocytopenia (40%).

Few patients with *Rickettsia* species 364D have been reported, so the full clinical spectrum has yet to be described. It does appear to be relatively mild and characterized by an eschar or ulcerative skin lesion with regional lymphadenopathy. Fever, headache, and myalgia occur, but rash has not been a notable feature.

Symptoms of *E. chaffeensis* ehrlichiosis typically occur a median of 9 days (range, 5–15 days) after an infected tick bite. Fever (96%), headache (72%), malaise (77%), and myalgia (58%) are common. Abdominal pain, vomiting, and diarrhea can occur, particularly in children. Rash (maculopapular, petechial, or diffuse erythema) occurs in approximately one-third of patients and is more frequent in children. The rash occurs a median of 5 days after illness onset and can involve the palms and soles. Neurologic manifestations are present in ~20% of patients. Characteristic laboratory findings in the first week include leukopenia, thrombocytopenia, and elevated levels of hepatic transaminases. *Ehrlichia ewingii* and *Ehrlichia muris*-like agent ehrlichiosis have similar clinical and laboratory features as *E. chaffeensis* ehrlichiosis, although rash and gastrointestinal symptoms are less common.

Symptoms of human granulocytic anaplasmosis typically occur 5 to 14 days after an infected tick bite. Fever (92%–100%), headache (82%), malaise (97%), and myalgia (77%) are common. Rash is present in <10% of patients, and central nervous system involvement is rare. Laboratory findings are similar to ehrlichiosis.

Diagnosis

Early diagnosis and initiation of treatment of tickborne rickettsial diseases is based on clinical and epidemiologic findings, as rapid confirmatory assays are often not available or reliable to guide treatment decisions early in the clinical course. Confirmatory diagnostic tests are serologic assays, nucleic acid detection, immunostaining of biopsy tissue, blood-smear microscopy, and culture.

Assays using paired acute and convalescent sera (ideally collected 2–4 weeks apart) are the standard for serologic confirmation. Assays are insensitive during the first week of rickettsial infection. After 7 days of illness, the sensitivity increases. Assays are highly sensitive 2 to 3 weeks after illness onset. Early therapy with doxycycline may diminish or delay the development of antibodies in RMSF.

A diagnosis of tickborne rickettsial diseases is confirmed with a \geq fourfold increase in antibody titer in patients with a clinically compatible acute illness. A single IgG antibody reciprocal titer ≥ 64 is supportive of, but not confirmatory for, the diagnosis. In the United States, *R. rickettsia*-reactive IgG antibody reciprocal titers ≥ 64 can be found in 5% to 10% of the population who do not acutely have RMSF. Some laboratories also perform assays for IgM antibodies. However, because of the lower specificity of IgM compared with IgG assays, IgM titers should not be used as a stand-alone method for diagnosis.

PCR amplification of DNA from whole blood specimens collected during the acute stage of illness is particularly useful for confirming *E. chaffeensis*, *A. phagocytophilum*, *E. ewingii*, and EML agent infections due to the tropism of those organisms for circulating cells. PCR detection of *R. rickettsia* in whole blood is less

sensitive, as low numbers of rickettsiae typically circulate in the blood in the absence of advanced disease. Tissue specimens such as a skin biopsy are a more useful source of SFG rickettsial DNA compared with blood samples. Doxycycline treatment decreases the sensitivity of PCR. Obtaining blood before treatment is recommended to decrease false-negative results.

Immunostaining of a skin punch biopsy is useful for diagnosing RMSF with 100% specificity and 70% sensitivity. Microscopic examination of blood smears or buffy-coat preparations during the first week of illness may reveal leukocyte morulae in patients infected with *E. chaffeensis* or anaplasmosis, although it is relatively insensitive, and accuracy is dependent on having experienced microscopists. Culture is the reference standard for microbiologic diagnosis, but the agents that cause tickborne rickettsial diseases require cell culture techniques that are not widely available.

Differential Diagnosis

The differential diagnosis of fever and rash is broad, and during the early stages of illness tickborne rickettsial diseases can be indistinguishable from many viral exanthams, particularly in children. In addition to viral infections, conditions that should be considered include meningococcemia, Kawasaki disease, secondary syphilis, disseminated gonococcal infection, bacterial endocarditis, scarlet fever, leptospirosis, typhoid, drug eruptions, Stevens-Johnson syndrome, toxic shock syndrome, and thrombotic thrombocytopenic purpura.

Treatment

Doxycycline is the drug of choice for treatment of all tickborne rickettsial diseases in patients of all ages and should be initiated immediately in persons with signs and symptoms suggestive of rickettsial disease. Treatment decisions should never be delayed awaiting laboratory confirmation. Multiple studies have noted a delay in appropriate treatment of tickborne rickettsial diseases, particularly after the fifth day of illness for RMSF, to be a significant potentially preventable risk factor for severe disease, increased mortality rates, and long-term sequelae. Because of the nonspecific signs and symptoms of tickborne rickettsial diseases, concomitant empiric treatment for other conditions in the differential diagnosis should be administered (e.g., treatment with ceftriaxone for meningococcemia).

The recommended dose of doxycycline is 100 mg twice daily (IV or oral) for adults and 2.2 mg/kg twice daily (IV or oral) for children weighing <45 kg.¹ Oral therapy is appropriate for patients with early-stage disease who can be treated as outpatients. The recommended duration of therapy for RMSF and ehrlichiosis is at least 3 days after fever resolves and until evidence of clinical improvement is noted; typically, the minimum total course is 5 to 7 days. Severe or complicated disease could require a longer course. HGA should be treated for 10 days to provide appropriate therapy for possible coinfection with Lyme disease.

The use of doxycycline to treat children with suspected tickborne rickettsial disease should no longer be a subject of controversy. The American Academy of Pediatrics and CDC recommend doxycycline as the treatment of choice for children of all ages with suspected tickborne rickettsial disease. Doxycycline used at the recommended dose and duration for RMSF in children aged <8 years, even after multiple courses, has not resulted in tooth staining or enamel hypoplasia.

Chloramphenicol in the past was used as an alternative drug for treating RMSF. However, chloramphenicol has been associated with a higher risk of death compared to patients treated with a tetracycline; in vitro evidence indicates that chloramphenicol is not effective treatment for ehrlichiosis or anaplasmosis. Chloramphenicol is no longer available in the oral form in the United States, and the IV form is not readily available at all institutions.

Chloramphenicol has been recommended for the treatment of RMSF during pregnancy based on adverse effects of older tetracycline drugs (but not specifically doxycycline). Although there is limited evidence, doxycycline has not been associated with teratogenicity or maternal hepatic toxicity during pregnancy, and doxycycline has been used successfully to treat tickborne rickettsial diseases in several pregnant women without adverse effects.

Rifamycins demonstrate in vitro activity against *E. chaffeensis* and *A. phagocytophilum*. Case reports document favorable outcomes in small numbers of pregnant women treated with rifampin for anaplasmosis. Rifampin¹ could be an alternative for treatment of confirmed mild anaplasmosis (RMSF ruled out) during pregnancy or documented allergy to tetracycline-class drugs. Rifampin is not acceptable treatment for RMSF or potential coinfection with *B. burgdorferi*.

Treatment of symptom-free persons seropositive for tickborne rickettsial disease is not recommended, regardless of past treatment, because antibodies can persist for months to years after infection.

Monitoring and Complications

Fever with tickborne rickettsial diseases typically subsides within 24 to 48 hours when treated with doxycycline in the first 4 to 5 days of illness. Lack of a clinical response within 48 hours of early treatment with doxycycline could indicate the illness is not a tickborne rickettsial disease, and alternative diagnoses or coinfection should be considered. Severely ill patients may require >48 hours of treatment before clinical improvement is noted. Patients with mild disease treated on an outpatient basis need close follow-up to ensure they are responding appropriately.

Patients with evidence of organ dysfunction, severe thrombocytopenia, mental status changes, or the need for supportive therapy should be hospitalized. Other considerations for hospitalization include the likelihood and ability to take oral medication and existing comorbid conditions, including the patient's immune status. Infection with RMSF and to a somewhat lesser extent HME are most likely to have a severe disease or death. Severe, late-stage manifestations of RMSF include meningoencephalitis, acute respiratory distress syndrome (ARDS), acute renal failure, arrhythmia, and seizures. Severe manifestations of HME include ARDS, shock-like syndromes, renal failure, hepatic failure, coagulopathies, and hemorrhagic complications.

Severe or life-threatening manifestations are less frequent with anaplasmosis than with RMSF or HME. Predictors of a more severe course of anaplasmosis include advanced age, immunosuppression, comorbid medical conditions, and delay in diagnosis and treatment. Confirmed *A. phagocytophilum* coinfection has been reported in <10% of patients with Lyme disease. Response to treatment can provide clues to possible coinfection with Lyme disease or babesiosis. If the clinical response to treatment with doxycycline is delayed, coinfection or an alternate infection should be considered. Conversely, if Lyme disease is treated with a beta-lactam antibiotic in a patient with unrecognized *A. phagocytophilum* infection symptoms could persist.

Prevention

The best prevention for all the tickborne rickettsial diseases is to avoid tick bites, perform regular tick checks on humans and pets, and promptly remove attached ticks. Longer periods of tick attachment increase the probability of transmission of tickborne diseases. Repellents and protective clothing can reduce the risk for tick bites. Products containing 20% to 30% N,N-Diethyl-meta-toluamide (DEET) effectively repel ticks and can be applied directly to the skin. DEET is not recommended for use on infants younger than 2 months. Permethrin-treated or -impregnated clothing can significantly reduce tick bites. Prophylactic treatment is not recommended in persons who have had recent tick bites and are well.

TOXIC SHOCK SYNDROME

Method of

Julius Larioza, MD; and Richard B. Brown, MD

KEY DIAGNOSTIC AND THERAPEUTIC POINTS

- Toxic shock syndrome (TSS) secondary to *Staphylococcus aureus* and *Streptococcus pyogenes* (Group A Streptococcus [GAS]) is an acute-onset illness causing systemic symptoms of fever, hypotension, and desquamative rash with the potential for high morbidity and rapid mortality. Clostridium species TSS may lack fever and rash but is often fatal.
- TSS secondary to staphylococcus and streptococcus is associated with elaboration of bacterial toxins, with a resultant vigorous cytokine cascade leading to multiorgan failure. Clostridium species toxins have a direct cellular effect on vascular endothelium.
- Diagnosis of TSS is based on fulfillment of criteria that involve identification of a constellation of clinical and laboratory data.
- A strong suspicion, early recognition, and aggressive management may decrease overall mortality and morbidity. Treatment consists of strategies to control the source of infection, decrease toxin production, and provide appropriate antibiotic therapy, surgical intervention, and clinical support with close monitoring of end-organ function. Three major causes of TSS have been identified. Those caused by toxin-producing strains of *Staphylococcus aureus* and *Streptococcus pyogenes* produce an acute, desquamative febrile illness. Clostridium species (*Clostridium sordellii*, *Clostridium perfringens*) TSS lacks the febrile illness or rash but may rapidly lead to multiorgan system failure with substantial morbidity and mortality.

Epidemiology

Staphylococcal toxic shock syndrome (TSS) was first reported in 1978 in previously healthy children with *Staphylococcus aureus* infection. Estimated incidence peaked in the early 1980s, with between 6.2 and 12.3 cases per 100,000 population. Ninety percent of cases were associated with tampon use in healthy, young menstruating women. With a decrease in tampon absorbency, changes in tampon composition and usage patterns, standardized labeling, and greater awareness among women and physicians, incidence fell to about 1 case per 100,000 population in the United States. By 1986 rates of menstrual and nonmenstrual TSS cases

were 1 and 0.3 per 100,000, respectively. Menstrual TSS declined from 91% of all TSS cases (1979–1980) to 59% (1987–1996). Of nonmenstrual causes, almost 20% were reported following surgery, 11.5% were postpartum or postabortion, and 23% were associated with nonsurgical cutaneous lesions. Incidence of postoperative cases of TSS following all types of surgery was estimated to be 3 per 100,000 population and was higher following ear, nose, and throat surgery, likely related to nasal packing. The latest population-based report of incidence between 2000 and 2006 in Minneapolis–St. Paul showed menstrual cases at 0.69 and nonmenstrual cases at 0.32 per 100,000 population. The crude mortality rate from staphylococcal TSS is 5% to 8%, with acute respiratory distress syndrome being a major cause of death.

The incidence of streptococcal TSS corresponds to that of invasive group A streptococcal (GAS) disease. In the United States approximately 10,000 cases of invasive GAS occur each year, with an annual incidence of 3 to 3.5 cases per 100,000 population. TSS complicates 10% to 15% of cases. The crude mortality rate is significantly higher than with staphylococcal TSS and reaches 30% to 80% in adults and 5% to 10% in children.

The current passive surveillance system for TSS is limited given the complexity of the clinical diagnosis and lack of a single test. Because studies related to incidence of both staphylococcal and streptococcal TSS use the Centers for Disease Control and Prevention (CDC) case definition that identifies the most severe cases, they may underestimate the total TSS disease burden.

Clostridium species are uncommon causes of TSS but have been reported to cause fatal disease after medical or spontaneous abortion. These organisms are found in the vaginal tract of pregnant women and likely ascend to cause disease after abortion with or without cervical instrumentation. There are no available incidence data for clostridium species TSS, but it has been reported in case series and is associated with a case fatality rate of at least 70%.

Risk Factors

In patients with staphylococcal TSS, previous antibiotic treatment and hospital exposure may predispose to colonization with toxigenic strains of *Staphylococcus aureus*. Primary staphylococcal infections such as pneumonia, postsurgical state, disruption of skin or mucous membranes, abscesses or burns, and foreign body placement have also been noted as risk factors. The absence of protective antitoxin antibodies may be a predisposing factor.

A major risk factor for streptococcal TSS is extremes of age. This is more common in persons ≥ 65 years old, followed by those < 2 years old. Higher incidence was also observed in persons with underlying chronic illnesses, in pregnancy as well as childbirth, after varicella infection, and with use of nonsteroidal antiinflammatory drugs. Any disease or injury compromising the mucosal surface or skin barrier may predispose a patient to streptococcal TSS. Transfer of the disease from one individual to another may also occur, as clusters of GAS infections have been described in nursing homes and among health-care workers and family members.

Main risk factors of clostridium species TSS are pregnancy, abortion, injection drug use, recent trauma, or (less commonly) cadaveric musculoskeletal graft surgery.

Pathophysiology

The hypothesis for the development of TSS is that infection with *Staphylococcus aureus* or *Streptococcus pyogenes* results in the production of toxins that act as superantigens. Staphylococcal TSS is normally associated with TSST-1, staphylococcal enterotoxin (SE) serotype B (SEB) or serotype C (SEC). Most cases of streptococcal TSS have been associated with streptococcal pyrogenic exotoxin (SPE) serotypes A (SPE A) and C (SPE C). These proteins share the ability to trigger excessive T-cell activation. Whereas conventional antigens stimulate on the order of 1 in 10,000 T cells, superantigens may stimulate over 20% of all T cells. This large expansion of T cells is believed to be responsible for severe clinical consequences such as capillary leakage leading to hypotension, shock, multiorgan failure, and death.

Estimated incidence peaked in the early 1980s, with between 6.2 and 12.3 cases per 100,000 population. Ninety percent of cases were associated with tampon use in healthy, young menstruating women. With a decrease in tampon absorbency, changes in tampon composition and usage patterns, standardized labeling, and greater awareness among women and physicians, incidence fell to about 1 case per 100,000 population in the United States. By 1986 rates of menstrual and nonmenstrual TSS cases

were 1 and 0.3 per 100,000, respectively. Menstrual TSS declined from 91% of all TSS cases (1979–1980) to 59% (1987–1996). Of nonmenstrual causes, almost 20% were reported following surgery, 11.5% were postpartum or postabortion, and 23% were associated with nonsurgical cutaneous lesions. Incidence of postoperative cases of TSS following all types of surgery was estimated to be 3 per 100,000 population and was higher following ear, nose, and throat surgery, likely related to nasal packing. The latest population-based report of incidence between 2000 and 2006 in Minneapolis–St. Paul showed menstrual cases at 0.69 and nonmenstrual cases at 0.32 per 100,000 population. The crude mortality rate from staphylococcal TSS is 5% to 8%, with acute respiratory distress syndrome being a major cause of death.

The incidence of streptococcal TSS corresponds to that of invasive group A streptococcal (GAS) disease. In the United States approximately 10,000 cases of invasive GAS occur each year, with an annual incidence of 3 to 3.5 cases per 100,000 population. TSS complicates 10% to 15% of cases. The crude mortality rate is significantly higher than with staphylococcal TSS and reaches 30% to 80% in adults and 5% to 10% in children.

The current passive surveillance system for TSS is limited given the complexity of the clinical diagnosis and lack of a single test. Because studies related to incidence of both staphylococcal and streptococcal TSS use the Centers for Disease Control and Prevention (CDC) case definition that identifies the most severe cases, they may underestimate the total TSS disease burden.

Clostridium species are uncommon causes of TSS but have been reported to cause fatal disease after medical or spontaneous abortion. These organisms are found in the vaginal tract of pregnant women and likely ascend to cause disease after abortion with or without cervical instrumentation. There are no available incidence data for clostridium species TSS, but it has been reported in case series and is associated with a case fatality rate of at least 70%.

Risk Factors

In patients with staphylococcal TSS, previous antibiotic treatment and hospital exposure may predispose to colonization with toxigenic strains of *Staphylococcus aureus*. Primary staphylococcal infections such as pneumonia, postsurgical state, disruption of skin or mucous membranes, abscesses or burns, and foreign body placement have also been noted as risk factors. The absence of protective antitoxin antibodies may be a predisposing factor.

A major risk factor for streptococcal TSS is extremes of age. This is more common in persons ≥ 65 years old, followed by those < 2 years old. Higher incidence was also observed in persons with underlying chronic illnesses, in pregnancy as well as childbirth, after varicella infection, and with use of nonsteroidal antiinflammatory drugs. Any disease or injury compromising the mucosal surface or skin barrier may predispose a patient to streptococcal TSS. Transfer of the disease from one individual to another may also occur, as clusters of GAS infections have been described in nursing homes and among health-care workers and family members.

Main risk factors of clostridium species TSS are pregnancy, abortion, injection drug use, recent trauma, or (less commonly) cadaveric musculoskeletal graft surgery.

Pathophysiology

The hypothesis for the development of TSS is that infection with *Staphylococcus aureus* or *Streptococcus pyogenes* results in the production of toxins that act as superantigens. Staphylococcal TSS is normally associated with TSST-1, staphylococcal enterotoxin (SE) serotype B (SEB) or serotype C (SEC). Most cases of streptococcal TSS have been associated with streptococcal pyrogenic exotoxin (SPE) serotypes A (SPE A) and C (SPE C). These proteins share the ability to trigger excessive T-cell activation. Whereas conventional antigens stimulate on the order of 1 in 10,000 T cells, superantigens may stimulate over 20% of all T cells. This large expansion of T cells is believed to be responsible for severe clinical consequences such as capillary leakage leading to hypotension, shock, multiorgan failure, and death.

Clostridium sordellii and *C. perfringens* secrete lethal and hemorrhagic toxins. Unlike staphylococcal or streptococcal TSS, these toxins do not act as superantigens. Rather, they are large molecular weight proteins that have glycosyl transferase activity, modifying members of the Rho GTPase superfamily to disrupt crucial cell processes that particularly affect vascular endothelial cells. These culminate in vascular leak and are suggested to be the main virulence factors that lead to rapid progression to shock and death.

Clinical Manifestations

Staphylococcal TSS typically presents abruptly with an influenza-like prodrome consisting of fever, gastrointestinal upset, and myalgia, followed commonly by confusion, lethargy, and agitation. Symptoms of hypovolemia are common. If present, a focus of infection is more likely to be superficial, may complicate burns or a surgical wound, or may result from a foreign body. Desquamation is a characteristic late feature. Blood cultures are positive in <5% of cases. After the onset of symptoms, progression is rapid and multi-organ failure can present in 8 to 12 hours.

Streptococcal TSS more commonly arises from deep-seated, invasive, soft-tissue infections such as necrotizing fasciitis and myositis. An influenza-like illness is also common in the early stage with fever, sore throat, swollen lymph nodes, and gastrointestinal upset. Local pain may be severe and is one of the most common reasons for seeking medical attention. Patients with a defined entry site may have early and visible signs of inflammation. In the absence of a definite portal of entry, clinical evidence of a deep infection becomes more obvious as the illness progresses. The initiating injury may be blunt trauma, muscle strain, and hematoma or joint effusion and may seem trivial. Like staphylococcal TSS, hypotension and organ dysfunction are rapidly progressive but unlike it, most (60%) patients with streptococcal TSS have positive blood cultures. Bacteremia alone, however, is not sufficient to explain the complications and increased mortality associated with streptococcal TSS.

Clostridium species toxic shock was suggested in previously healthy women with recent mifepristone (Mifeprex) and misoprostol (Cytotec) pregnancy termination. Women were noted to have nonspecific complaints of sudden onset of weakness, nausea, vomiting, diarrhea, and abdominal pain. A rapid sequence of progressive hypotension and local and spreading edema was associated with severe hemoconcentration and marked leukemoid reaction. The syndrome was described with the identification of *Clostridium sordellii* or *C. perfringens* and exclusion of a staphylococcal cause of the rapidly progressive shock. Absence of fever, presence of refractory tachycardia, local edema at the infected site, and subsequent pleural and peritoneal effusions are seen.

Diagnosis

The diagnostic criteria for TSS are based on the clinical case definitions updated by the CDC in 2010 and 2011 for streptococcal TSS and staphylococcal TSS, respectively. They are presented in Table 1.

Additional laboratory abnormalities include an increase in bands, anemia, hypocalcemia, and hypoproteinemia. Cultures from sites of infection are usually positive and should be sought.

In clostridium species TSS, case definition is incomplete. The clinical manifestations as described should be confirmed by additional laboratory tests such as anaerobic culture of the cervix, histopathologic, immunohistochemical, and molecular studies of surgical or autopsy tissue to confirm necrotizing endometritis, and presence of clostridium species.

Differential Diagnoses

TSS can be confused with acute pyelonephritis, acute rheumatic fever, acute viral syndrome such as measles, Legionnaire disease, leptospirosis, Lyme disease, pelvic inflammatory disease, osteomyelitis, scarlet fever, typhus, meningococemia, Rocky Mountain spotted fever, ehrlichiosis, and gram-negative sepsis. Noninfectious illnesses that lead to septic shock, severe drug reactions, Kawasaki

TABLE 1 Diagnostic Criteria for Toxic Shock Syndrome (TSS)

CASE DEFINITION	
STAPHYLOCOCCAL TSS (2011)	STREPTOCOCCAL TSS (2010)
Clinical Manifestation	Clinical Manifestation
Fever: temperature $\geq 102^{\circ}\text{F}$ Rash: diffuse macular erythroderma Desquamation: 1–2 weeks after onset of rash Hypotension: systolic blood pressure ≤ 90 mm Hg for adults or <5 th percentile by age for children <16 years old Multisystem involvement (three or more of the following organ systems): Gastrointestinal: vomiting or diarrhea at onset of illness Muscular: severe myalgia or creatinine phosphokinase level at least twice the upper limit of normal Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal or urinary sediment with pyuria (≥ 5 leukocytes per high-power field) in the absence of urinary tract infection Hepatic: total bilirubin, alanine aminotransferase enzyme (ALT), or aspartate aminotransferase (AST) enzyme levels at least twice the upper limit of normal Hematologic: platelets $<100,000/\text{mm}^3$ Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent	Hypotension Multisystem involvement (two or more of the following organ systems): Renal: creatinine ≥ 2 mg/dL for adults or greater than twofold the upper limit of normal for age. In patients with preexisting renal disease, a greater than twofold elevation over baseline level Coagulopathy: platelets $<100,000/\text{mm}^3$ or disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and presence of fibrin degradation products Hepatic: ALT, AST, or total bilirubin levels more than twice the upper limit of normal for the patient's age. In a patient with preexisting liver disease, a greater than twofold increase over the baseline level Acute respiratory distress syndrome: defined by acute onset of diffuse pulmonary infiltrated and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia A generalized erythematous macular rash that may desquamate Soft-tissue necrosis, including necrotizing fasciitis or myositis, or gangrene
Laboratory Criteria	Laboratory Criteria
Negative results on the following tests, if obtained: Blood or cerebrospinal fluid (CSF) cultures (blood cultures may be positive for <i>Staphylococcus aureus</i>) Negative serologies for Rocky Mountain spotted fever, leptospirosis, or measles	Isolation of group A <i>Streptococcus</i>
Case Classification	Case Classification
Probable: meets the laboratory criteria and with four of the five clinical findings shown above present Confirmed: meets the laboratory criteria and with all five of the clinical findings above present including desquamation, unless the patient dies before desquamation occurs	Probable: meets the clinical case definition in the absence of another identified etiology for the illness and with isolation of group A <i>Streptococcus</i> from a nonsterile site Confirmed: meets the clinical case definition and with isolation of group A <i>Streptococcus</i> from a normally sterile site (e.g., blood or CSF or, less commonly, joint, pleural, or pericardial fluid)

disease (in children), flares of autoimmune illnesses such as systemic lupus erythematosus, tumors, and hemolytic uremic syndrome may also mimic the syndrome.

Therapy

Poor outcome is due in part to the nonspecific features at presentation leading to missed or delayed diagnosis and underestimation of the aggressive nature of the infection delaying treatment. Highest probability for successful outcome lies with early identification and a therapeutic strategy that involves hemodynamic stabilization and specific antibiotics to eradicate the bacteria and control toxin synthesis. Vigorous attempts at source control are mandatory. Timely management of hypovolemic shock is critical. Microbial documentation is rarely available at the onset of management; thus early antimicrobial therapy should be broad. At present the best empiric choices for serious gram-positive infections include vancomycin (Vancocin), linezolid (Zyvox), daptomycin (Cubicin), and tigecycline (Tygacil). The dosing schedule is summarized in Table 2. Antimicrobial coverage may then be narrowed as the clinical picture and culture results become available to the clinician.

Semisynthetic penicillins and cephalosporins increase TSST-1 in culture, probably by lysis or increased cell membrane permeability. In the setting of increasing incidence of methicillin-resistant *Staphylococcus aureus*, these drugs should be avoided as empiric therapy. There is no obvious direct effect of vancomycin on toxin production while clindamycin has been shown to reduce TSST-1 by 90%. Thus, use of clindamycin in combination with a second agent such as vancomycin results in a potentially beneficial effect by decreasing the synthesis of TSST-1.

For streptococcal TSS, clindamycin is more effective because its antimicrobial activity is not affected by the inoculum size or dependent on penicillin-binding proteins; because it acts by inhibiting protein synthesis, it also inhibits the synthesis of antiphagocyte M protein and bacterial toxins (SPEs), subsequently reducing the superantigenicity of SPEs. It has a longer postantibiotic effect than

β -lactams. Thus clindamycin is recommended although not as empiric monotherapy because up to 20% of GAS are resistant to it. Linezolid also has the ability to suppress toxin synthesis and may be an alternative as monotherapy or in combination with vancomycin.

Antimicrobial therapy should be continued for at least 10 to 14 days to eradicate the organism and prevent recurrences. The total duration should be based on the usual duration established for the underlying focus of infection.

A thorough and continuous search for possible sites of infection is key to eliminate any preformed toxin and to prevent further synthesis of toxins. Removal of suspect foreign bodies especially tampons is mandatory. Surgical wounds should be considered as possible reservoirs of infection, even if no superficial signs of local infection or purulent discharge are present. Infected wounds should be inspected, any packing should be removed, and abscesses should be drained and irrigated. Culture specimens from all possible sites should be obtained. Patients suspected of having necrotizing fasciitis should have urgent surgical intervention for fasciotomy and debridement.

With clostridium species, the presence of an anaerobic environment enhances growth and toxin production. Thus drainage and aggressive removal of necrotic tissue is important. Older literature suggests that total hysterectomy is often required. Antimicrobial agents with anaerobic coverage should be foremost for gram-positive infection. Inhibitors of protein synthesis such as clindamycin, linezolid, and fluoroquinolones may be of additional benefit.

Intravenous immunoglobulin (IVIG)¹ may be of value when given in addition to appropriate antimicrobial therapy. The neutralizing and protective activity against the superantigenic toxins has been reviewed but results appear variable. There are no current guidelines for the use of IVIG, but it may be used for TSS resulting from an infection refractory to several hours of aggressive therapy.

Monitoring

Control and monitoring of shock and individual organ dysfunction are best achieved in the setting of the intensive-care unit. There, active fluid resuscitation, early use of vasopressors or inotropes, or both, and mechanical ventilation if required are done. Appropriate management of associated problems such as renal failure and adult respiratory distress syndrome must be addressed. Monitoring of hemodynamic status and constant surveillance by repeated clinical examination and laboratory investigation searching for evidence of increasing burden of toxin production and subsequent clearance of the source of infections provide the highest chances of survival and equally prevention of further comorbidities related to irreversible organ system damage. Table 3 summarizes the characteristics of TSS by organism.

TABLE 2 Empiric Antibiotics for Gram-Positive Infections

AGENT	DOSE (ADJUST FOR RENAL DYSFUNCTION)
Vancomycin* (Vancocin)	15–20 mg/kg q12h (up to 4 g daily) ³
Tigecycline (Tygacil)	Start with 100 mg \times 1, then 50 mg q12h
Daptomycin* (Cubicin)	6–8 mg/kg q24h ³
Clindamycin (Cleocin)	900 mg q8h
Linezolid (Zyvox)	600 mg q12h

³Exceeds dosage recommended by the manufacturer.

*Requires renal adjustment.

TOXOPLASMOSIS

Method of

Carlo Contini, MD

CURRENT DIAGNOSIS

- The diagnosis of *Toxoplasma gondii* infection mostly relies on serologic detection of specific IgM and IgG antibodies.
- Specific IgM antibodies with low IgG (IgG-avidity testing) are consistent with recent infection in immunocompetent persons. Positive IgG antibodies in the absence of IgM in healthy persons indicate past infection and resistance to reinfection.
- Amniocentesis and polymerase chain reaction (PCR)-based analysis on amniotic fluid (AF) [past 18 weeks' gestation] are useful to establish a certain or presumed seroconversion in pregnancy and to determine whether the infection was transmitted to the offspring.
- IgM, IgA, or both at birth indicate probable congenital infection.
- Serologic testing is not useful for the diagnosis of TE in AIDS patients, who should instead undergo computed tomography (CT) or magnetic resonance imaging (MRI), cerebrospinal fluid (CSF)-*T-gondii* DNA PCR testing, or demonstration of tachyzoites by histology.
- Serologic screening is helpful in identifying transplant patients at risk, especially seronegative recipients with seropositive donors, and can help in establishing the diagnosis by showing seroconversion. Serologic follow-up combined with PCR after allogeneic hematopoietic stem cell transplantation (HSCT) is recommended in all patients at risk for toxoplasmosis.

TOXOPLASMOSIS

Method of

Carlo Contini, MD

CURRENT DIAGNOSIS

- The diagnosis of *Toxoplasma gondii* infection mostly relies on serologic detection of specific IgM and IgG antibodies.
- Specific IgM antibodies with low IgG (IgG-avidity testing) are consistent with recent infection in immunocompetent persons. Positive IgG antibodies in the absence of IgM in healthy persons indicate past infection and resistance to reinfection.
- Amniocentesis and polymerase chain reaction (PCR)-based analysis on amniotic fluid (AF) [past 18 weeks' gestation] are useful to establish a certain or presumed seroconversion in pregnancy and to determine whether the infection was transmitted to the offspring.
- IgM, IgA, or both at birth indicate probable congenital infection.
- Serologic testing is not useful for the diagnosis of TE in AIDS patients, who should instead undergo computed tomography (CT) or magnetic resonance imaging (MRI), cerebrospinal fluid (CSF)-*T-gondii* DNA PCR testing, or demonstration of tachyzoites by histology.
- Serologic screening is helpful in identifying transplant patients at risk, especially seronegative recipients with seropositive donors, and can help in establishing the diagnosis by showing seroconversion. Serologic follow-up combined with PCR after allogeneic hematopoietic stem cell transplantation (HSCT) is recommended in all patients at risk for toxoplasmosis.

CURRENT THERAPY

- All immunocompetent patients, as well as nonpregnant women with acute toxoplasmosis presenting with lymphadenitis and fever, generally do not require specific antimicrobial treatment because the infection is self-limited and usually subclinical.
- Pyrimethamine (Daraprim) plus sulfadiazine¹ plus folinic acid (Leucovorin)¹ is the standard and preferred regimen against toxoplasmosis. It is recommended for acute *T gondii* infection in immunocompetent adults with acute illness; pregnant women who acquire the infection after 18 weeks' gestation or in whom fetal infection is documented (positive PCR-AF); and immunosuppressed patients, including AIDS patients. Patients who do not tolerate the standard regimen should be given alternative drugs such as clarithromycin (Biaxin),¹ azithromycin (Zithromax),¹ atovaquone (Mepren),¹ and dapsone.¹
- Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim)¹ has been shown to have efficacy similar to pyrimethamine-sulfadiazine and may be used as an alternative if patients do not have sulfa allergy and pyrimethamine is not tolerated or is not available.
- Oral spiramycin (Rovamycin)² is the drug most often used in the prenatal therapy of congenital toxoplasmosis (before 18 weeks of gestation) because of high concentration in placenta without crossing it and of its relative lack of toxicity compared with the teratogenic effects of pyrimethamine. Spiramycin is more efficacious when administered early after maternal seroconversion.
- TMP-SMX¹ should be given as a prophylaxis to HIV-positive patients who have CD4⁺ cell counts that are less than 100/mm³ and IgG *T gondii* antibodies and who are not already receiving a PCP prevention regimen, as well as to patients with active toxoplasmosis, transplant patients, and workers after accidental laboratory exposure.
- In ocular toxoplasmosis, corticosteroid therapy, if given, should be always monitored to prevent severe tissue destruction.
- Universal prophylaxis with TMP/SMX in allo pre-HCTSP patients should be implemented by all transplantation programs.

¹Not FDA approved for this indication.

²Not commercially available in the United States.

Toxoplasma gondii is a ubiquitous protozoan parasite that is extremely widespread and of great medical importance, infecting all mammalian cells and responsible for human and veterinary diseases. It was initially described in Tunis by Nicolle and Manceaux (1908) in the tissues of the rodent gundi (*Ctenodoactylus gundi*) and later in Brazil by the microbiologist Alfonso Splendore (1908) in the rabbit. Its identification was rapidly followed by the recognition that it was a human pathogen. In this regard, the Italian bacteriologist Castellani (1914) was probably the first to describe a *T gondii*-like parasite in smears of blood and spleen from a 14-year-old Singhalese boy who died of a disease characterized by severe anemia, fever, and splenomegaly. However, it was not until the 1960s and 1970s that the parasite was identified as a coccidian and the cat recognized as the definite host.

Toxoplasma belongs to the phylum *Apicomplexa*, which contains many other protozoan pathogens of human and veterinary importance, such as *Plasmodium* spp. (malaria), *Cryptosporidium* spp. (cryptosporidiosis), and *Eimeria* spp. (poultry coccidiosis).

Disease can occur through acute infection after recent contact with *T gondii* cysts or oocysts or through endogenous reactivation. Primary infection is usually subclinical, but in some patients cervical or occipital lymphadenopathy or ocular disease is present. Infection acquired during pregnancy can cause severe damage to the fetus if *Toxoplasma* crosses the placental barrier, and it causes abortion or congenital birth defects if the mother becomes infected for the first time shortly before or during pregnancy.

In patients with AIDS and others who are immunocompromised, reactivation of latent disease can cause life-threatening encephalitis.

Ocular infection by *Toxoplasma* is a major cause of retinochoroiditis in several geographic areas in both immunocompetent and immunocompromised persons. Due to the heterogeneous parasitologic outcomes and limited immunological data, the role of aging in toxoplasmosis evolution remains poorly understood.

Epidemiology and Risk Factors

Toxoplasmosis is a cosmopolitan zoonotic disease that has important implications for public health because it affects one-third of the world's population. It is also a significant veterinary pathogen that can infect many species of warm-blooded animals. *T gondii* is one of the world's most successful parasites, in part because of its ability to infect and persist in most warm-blooded animals. In general, the prevalence in animals is much higher than that in humans. In China, among the major animals monitored, pigs were the most frequently infected by *T gondii*, reaching 70% in some areas and farms. This high *T gondii* prevalence increases the risks of human infection through meat consumption, because pork is the main meat Chinese people consume. Among other meat-producing animals, sheep and chickens have also high *T gondii* infection rates, and economic losses caused by abortions and other diseases from sheep toxoplasmosis are predicted to be huge in the forthcoming decades.

In humans, the incidence of positive serology for *Toxoplasma* varies greatly around the world and is influenced by different cultures. In Colombia, approximately half of the women of child-bearing age have *T gondii* antibodies, and the clinical disease in congenitally infected children is more severe than in Europe. In humans, seroprevalence of *T gondii* infection rises with age; does not vary greatly between sexes; and is lower in cold regions, hot and arid areas, and at high elevations. Prevalence rates, which range worldwide from <10% to >60%, are thought to depend on food production and harvesting practices, water treatment, environment, climate, and exposure to soil or sand. In the United States, the seroprevalence of *T gondii* appears to be declining. Seroprevalence in Europe is high, up to 54% in southern European countries; it decreases with increasing latitude to 5% and 10% in northern Sweden and Norway, respectively. As is the case of most other protozoa, the prevalence of *Toxoplasma* is higher in Africa, South America, and in developing areas of the world. In Brazil, there is a higher prevalence of *T gondii* infection among male patients (79.0%) than among female patients (63.4%), according to data obtained from a blood bank.

The sexual cycle of *T gondii* occurs in felines. The estimated seroprevalence for *T gondii* in domestic cats (*Felis catus*), worldwide, is 30% to 40%. Most feline infections occur postnatally through ingestion of infected tissue cysts or rarely oocysts, although congenital infections occur. Tens of millions of unsporulated oocysts may be released in the feces of a single cat in a day, depending on the stage of *T gondii* ingested. These sporulate in 1 to 21 days and are highly infectious to the parasite's intermediate hosts (asexual cycle), which include almost any warm-blooded animal, such as birds, humans, and sea otters.

Sporulated oocysts are very resistant to environmental conditions and to disinfectants; however, they are killed within 1 to 2 minutes by heating to 55°C to 60°C, and the risk of infection is reduced by deep-freezing meat (−12°C or lower) before cooking.

Feline infections are typically subclinical. Common symptoms of *T gondii* infection in cats can include fever, ocular inflammation, anorexia, lethargy, abdominal discomfort, and neurologic abnormalities. Occasionally, pneumonia, liver damage, and loss of vision develop. Why only some cats show symptoms is not known.

Identification of locally prevalent risk factors is critical for health education, and it is generally important for policy. The most important recognized factors influencing the risk of *T gondii* infection are having a cat or a dog, doing household work, having a lower education level, having poor hygiene habits, eating raw vegetables, and working in contact with soil.

Most people are infected inadvertently, and thus the specific route of transmission usually cannot be established. Contact with

this obligate intracellular protozoan can occur through the ingestion of oocysts containing sporozoites or cysts containing bradyzoites in contaminated food or water. The major risk factors for *T gondii* exposure are directly related to exposure to cats and more specifically to cat feces, which represent the source of ingestion of sporozoites from the environment. Because cats are the primary host for *T gondii*, cats in the house or stray cats in and around the house or property are considered a primary risk factor for acquiring this parasite during pregnancy. Moreover, any job or activity that puts a pregnant woman in direct contact with soil, sand, or materials such as fruit, vegetables, or drinking water that could have been contaminated by cat feces puts her at risk for being infected. In this setting, rain and surface water can transport infectious oocysts into drinking water supplies and irrigation waters. Coprophagous insects that can contaminate food and fertilizer also contribute to the spread of oocysts. Climate plays an indirect role in allowing better (in the case of moist and hot climate) or worse (in the case of dry and cold climate) survival of oocysts in the environment.

Consumption of undercooked meat of secondary hosts such as pigs and sheep is also a major route of transmission of the disease to humans. The ingestion of undercooked or raw meat during pregnancy is also an important risk factor, because the tissue can contain *T gondii* cysts that, unless destroyed by cooking or by food-preparation practices, could infect a pregnant woman. Heating at 60°C to 100°C for 10 minutes, freezing at either -10°C for 3 days or -20°C for 2 days, or irradiation at doses of 75 to 100 kilo rad is sufficient to kill tissue cysts. Tissue cysts are also killed by gamma irradiation at a dose of 1.0 kGy, but irradiation of meat has not been approved in the European Union (EU). Neither cooking in a microwave oven nor chilling at 5°C for 5 days is sufficient to kill tissue cysts.

The risk of infection rises also in women who taste meat when preparing meals or who eat raw or undercooked beef, lamb, or other meats, but not pork. Eating raw horsemeat imported from non-EU countries can expose consumers to high inocula of highly virulent atypical *T gondii* strains, which can cause a life-threatening primary infection or severe congenital toxoplasmosis with atypical outcome. Transmission during breast-feeding or direct human-to-human transmission other than from mother to fetus (discussed later in the chapter) has not been recorded. Drinking unpasteurized milk and consuming milk products also correlates with increased risk of infections. Although oral transmission is considered the main route of infection, it does not explain the common occurrence of toxoplasmosis in a variety of hosts, such as herbivorous animals, birds, and wild rodents. In this regard, *T gondii* infection has been discovered in particular ticks (i.e., *Haemaphysalis longicornis*) that could serve as a reservoir for secondary toxoplasmosis transmission to other common hosts, if ingested. Other routes are transplacental infection of the fetus, transfusion of white blood cells, and organ transplantation from a seropositive donor to a seronegative recipient.

It is not uncommon for health care professionals, laboratory workers, pet lovers (especially cat owners), butchers, cooks (those handling raw meat), veterinarians, and farmers to acquire acute toxoplasmosis.

Finally, an interesting hypothesis suggested that toxoplasmosis may be transmitted from infected men to noninfected women during unprotected sexual intercourse, resulting in the most dangerous form of disease, the congenital toxoplasmosis. *T gondii* tachyzoites in fact, are present in the seminal fluid and tissue of the testes of various animals including humans.

Dogs can also have a role in the transmission of toxoplasmosis as a mechanical vector by rolling in foul-smelling substances and by ingesting fecal material. Unlike in cats, *T gondii* does not replicate in the dog's gut and no cysts are shed. In areas where dogs and cats are plentiful, immunocompromised persons and pregnant women should be warned of the possibility of acquiring *T gondii* from dogs, as well as from soil contaminated by cats. People should be encouraged to wash their hands after contact with soil, dogs, or cats, as well as before eating.

Pathophysiology

Disease can occur through acute infection after recent contact with *T gondii* cysts or oocysts or through endogenous reactivation. After ingestion, the sporozoites or bradyzoites invade the intestinal epithelium and differentiate to tachyzoites, which disseminate in the blood and replicate within the new host. The parasite translocation into the blood stream may be a possible consequence of localized intestinal inflammation and enteropathy generated by the parasite, which collectively results in impaired integrity of the intestinal mucosa and gut-blood barrier. Transport of the parasite via the bloodstream can occur intracellularly within dendritic cells or monocytes or as a free tachyzoite. Certain *Toxoplasma* surface antigens aid in the interaction between the tachyzoite and the host cell. One is the perforin-like protein 1 (PLP-1) forming pores in the host cell membrane after binding, as well as playing a role in egress. The success of *Toxoplasma* as a widespread pathogen is due to the effortlessness with which it can be transmitted among the intermediate hosts. Once inside a host, the parasite develops powerful tools to modulate its host cell and to develop into a chronic infection, undergoing bradyzoite development that can evade the host's immune system as well as, in contrast with acute toxoplasmosis, all known antitoxoplasmic drugs.

Host protection from *T gondii* results from a complex cell-mediated immune response involving inflammatory cells, lymphocytes and macrophages, and cytokines. Inoculum size, parasite virulence (strain), genetic background, time of infection (congenital versus postnatal contamination), and sex also contribute to affect the course of infection in human beings and animal models of toxoplasmosis. In particular, the *T gondii* genotype affects its replication rate, migration, and tendency to differentiate to bradyzoites, virulence, and epidemiologic pattern of occurrence. Type II genotypes (most strains isolated from AIDS patients and newborns with congenital disease) and type III genotypes (mostly isolated from animals) are generally less virulent and more cystogenic compared with type I genotypes (also found in congenital disease). Ocular toxoplasmosis in humans is associated with type I but not type II or III genotypes.

Other than the three major *Toxoplasma* clonal lineages designated as types I, II and III, which are only predominant in Europe and North America (mostly type 2 strain), there are highly polymorphic strains referred to as atypical in South America and Africa, termed Africa 1, 2, and 3.

Genetic background also plays a significant role in increased susceptibility to *T gondii* in humans; HLA-DQ3 appears to be a genetic marker associated with susceptibility to development of TE in patients with AIDS. The mechanisms by which *T gondii* invades host cells and forms an intracellular niche have been extensively reviewed, and several aspects of this process are directly relevant to immunity and pathogenesis. During invasion, three successive waves of proteins are secreted from parasite organelles, (the micronemes, dense granules, and rhoptries) into the host cell. Rhoptry proteins are the major virulence factors of *T gondii* and are located in different parts of the host cells. Blocking the cell intrinsic defense mechanisms of the host lets *T gondii* invade, parasitize, and proliferate in the host successfully. These proteins can alter host cell function and inhibit the immune response directed toward the parasite.

During infection in the intermediate host, *T gondii* undergoes stage conversion between the rapidly dividing tachyzoite that is responsible for acute toxoplasmosis and the slowly replicating, encysted bradyzoite stage. This process of tachyzoite-bradyzoite interconversion is central to the pathogenesis and longevity of infection. In normal conditions, the tachyzoite stage is thwarted by the prompt and efficient interferon- γ -dependent cell-mediated immune response, which eventually kills off the majority of the disseminating tachyzoites before eventually entering the persistent form, the bradyzoite. Bradyzoites are encysted within various tissues, most notably the brain but also muscle, eye, and lung, and are infectious to another intermediate host or the cat if eaten. Cell-mediated immune mechanisms thus play a major role in the

control of *T gondii* infection because the parasite is exclusively localized intracellularly.

After infection, *T gondii* evokes a powerful and persistent T-helper-1 (Th1) response (dendritic cell activated) together with neutrophils, inflammatory monocytes, and macrophages. The response is characterized by production of proinflammatory cytokines, including interleukin (IL)-12, INF- α and tumor necrosis factor (TNF)- α , which, together with other immunologic mechanisms, protect the host against rapid replication of tachyzoites and subsequent pathologic changes. The outcome of toxoplasmic infection depends on a balance between proinflammatory (IL-12, TNF- α) and downregulatory (IL-10, IL-27) cytokines that suppress parasite proliferation and control the inflammatory response, respectively.

Clinical Presentation in the Immunocompetent

Acute acquired toxoplasmosis has traditionally been considered an oligosymptomatic and self-limited infection in previously healthy patients. The typical clinical presentation of acute *T gondii* infection is a short flulike or mononucleosis-like illness that includes prolonged fever, headache, persistent enlarged but firm lymph nodes (rarely painful but initially tender) unattached to the overlying skin, and, occasionally, myalgia and gastrointestinal symptoms that rarely need treatment. Other infectious or noninfectious diseases cause similar symptoms and should always be included in the differential diagnosis: mononucleosis, cat scratch disease, tuberculosis, primary HIV infection, sarcoidosis, metastatic cancer, and lymphoma. In these cases, serologic testing is the initial and primary method of diagnosis.

Lymph node biopsy should be reserved for when *Toxoplasma* serology is uncertain and all other infectious serologic investigations are negative. Hepatomegaly and hepatitis with a moderate increase in liver enzyme levels (a 5- to 10-fold elevation) are common. Lymphocytosis and atypical lymphocytes are other laboratory hallmarks of toxoplasmosis. The spleen appears to be involved early in toxoplasmosis, but palpable splenomegaly is uncommon.

Pneumonia as well as myocarditis, polymyositis, or encephalitis are rarely described in immunocompetent hosts.

Although malaria and dengue are the most common causes of fever in travelers, toxoplasmosis should be considered in the differential diagnosis of fever, particularly in travelers with nonspecific symptoms such as fatigue, fever, headache and lymphadenopathy.

Latent toxoplasmosis is characterized by the lifelong presence of cysts of the parasite in different host tissues, including the nervous system, and by the presence of anamnestic *T gondii* immunoglobulin (Ig) G antibodies in the serum. Long considered asymptomatic, latent toxoplasmosis might increase the risk of schizophrenia and Parkinson's disease; influence human personality and behavior; impair psychomotor performance and increase the risk of suicide (suicide rates have been shown higher in countries with greater *T gondii* prevalence, regardless of national wealth or gross domestic product), traffic accidents, and the probability of the birth of male offspring. Recent studies have also hypothesized that *T gondii* is a risk factor for increasing aggressiveness as well as a murder behavior in women.

Higher rates of *T gondii* seropositivity have been reported for several psychiatric conditions affecting neurotransmitters, especially dopamine, that are implicated in the emergence of psychosis and behavioral *Toxoplasma*-induced abnormalities and in inducing brain inflammation by the direct stimulation of inflammatory cytokines in the central nervous system. Also, there is increasing evidence for a prominent role of immune dysregulation in psychosis and bipolar disorders. Accumulating evidence suggests that a permeabilized gut-blood barrier is present in psychiatric disorders, as demonstrated through studies of microbial translocation and microbiome sequencing that seem to indicate an actively dysbiotic environment in subsets of individuals with psychiatric disorders. RhD phenotype seems to play an important role in the strength and direction of association between latent toxoplasmosis and personality and intelligence.

Toxoplasmosis should also be regarded as an epilepsy risk factor. Epileptogenic mechanisms are probably multifactorial (direct lodgment of parasite, direct modulation of neuronal functions, abnormalities in GABA, role of calcium, etc.), etc. Recently, it was suggested that chronic latent neuroinflammation caused by the parasite may be responsible for the development of several neurodegenerative diseases manifesting with the loss of smell. Olfactory dysfunction reported in Alzheimer's disease, multiple sclerosis, and schizophrenia was frequently associated with the significantly increased serum anti-*T gondii* immunoglobulin G antibody levels.

In addition to above-mentioned manifestation, several recent studies performed in human and animal models have demonstrated that latent or acute toxoplasmosis is associated with reproductive organs disorders, infertility, sperm abnormalities, behavioral changes, and neurological disorders in pregnant women and other people.

A meta-analysis also suggested chronic toxoplasmosis as a possible risk factor for type 2 diabetes mellitus. However, more accurate studies are needed to better understand this association.

A very important aspect that has emerged in recent years concerns the possible occurrence of toxoplasmosis in patient receiving biotherapies, particularly anti-TNF- α agents for the treatment of rheumatologic diseases and other conditions that need biotechnological drugs. *Toxoplasma* serology should be performed in patients before treatment with TNF- α antagonists is initiated, and patients should be advised to avoid situations that increase risk of exposure to *Toxoplasma*.

Clinical Presentation in Immunocompromised Patients

The presence of latent bradyzoite cysts, along with the ability of bradyzoites to reconvert into the active and rapidly growing tachyzoites that can result in often fatal injury, explains the high incidence of acute toxoplasmosis often observed in immunocompromised persons. In immunocompromised hosts and in patients with AIDS, the central nervous system (CNS) is the site most typically affected by infection, and toxoplasmic encephalitis (TE) is the most common manifestation, which typically consists of single or multiple brain lesions. In individuals with AIDS and a CD4 T-cell count <100 cells/ μ L, the incidence of TE is 28% in seropositive patients not taking prophylaxis. Ocular and pulmonary diseases are the most common extracerebral sites of infection. For *Toxoplasma*, various mechanisms have been proposed for CNS entry, including the so-called "Trojan horse" mechanism, whereby an infected immune cell crosses the BBB, bringing the intracellular parasite with it. TE is also the third most common condition associated with AIDS in Brazil, still accounting for high mortality and morbidity rates despite free access to antiretroviral therapy (ART). However, as in transplant patients or those with malignant hemolymphopathies or solid tumors, other organs such as the lungs or eyes may be involved. Most of these cases result from reactivation of latent infection, although reinfection with a different *T gondii* strain in the transplanted organs can also occur. Although the mortality rate of pulmonary toxoplasmosis was high before the advent of ART, patients with AIDS and recipients of bone marrow transplants are also at risk for development of pulmonary toxoplasmosis, especially patients with very low CD4 cell counts. The clinical manifestations are nonspecific and are similar to those of *Pneumocystis jirovecii*.

In immunocompromised patients with suspected pulmonary toxoplasmosis, conventional staining is the most appropriate method to diagnose for experienced microbiology laboratories, whereas *T gondii*-specific PCR may be useful for laboratories with less experience in parasitology.

The predictive value of elevated blood levels of lactate dehydrogenase is of uncertain value. Patients with TE typically present with headache, confusion, altered mental status, and motor weakness. Focal neurologic deficits or seizures, weakness, sensory abnormalities, cerebellar signs, and neuropsychiatric manifestations are also common. Fever is usually, but not reliably, present. Accompanying nausea or vomiting usually indicates elevated intracranial pressure.

Computed tomography (CT) scan or magnetic resonance imaging (MRI) of the brain typically shows multiple contrast-enhancing lesions, often with associated edema. These should be distinguished from other infectious or noninfectious CNS diseases in the course of AIDS.

In immunocompromised patients, the infection can disseminate rapidly and manifests with nonspecific symptoms such as fever and malaise. It can affect a number of organs, including the brain, cerebellum (an uncommon presentation), eye, liver, and lungs, as well as skeletal muscle, bone marrow, bladder, and spinal cord. Cardiac toxoplasmosis can occur during the course of multivisceral dissemination. However, in patients with AIDS, it is usually asymptomatic and found only at autopsy, typically in the setting of widely disseminated infection. Acquired toxoplasmosis with cutaneous involvement can also occur in the pediatric population, particularly in immunocompromised patients after stem cell transplantation. Early diagnosis and treatment of this life-threatening opportunistic infection may improve patient outcomes.

Toxoplasmosis of the Eye

Ocular toxoplasmosis is the major cause of visual impairment in high *T gondii* endemic regions of the United States and Europe, where it accounts for 30% to 50% of the infectious posterior uveitis. Toxoplasmosis can affect the retina and the underlying choroid, causing retinochoroiditis, the most common manifestation of ocular toxoplasmosis, which consists in an acute focal-necrotizing retinochoroiditis often adjacent to an old chorioretinal scar. Although the inner retina is the primary site of infection, vitreous, choroid, and sometimes sclera are secondarily affected. Many lesions are self-limiting and heal, forming characteristic unilateral or bilateral pigmented scars in the retina, where *Toxoplasma* cysts are found. Ocular lesions can recur in adolescence and adulthood, even after treatment in infancy. The severity of the disease is mainly a function of the parasite genotype and the host's immune status. Diagnosis in immunocompetent patients is based on the findings of typical ocular manifestations, including eye pain and decreased visual acuity, and may be confirmed by biologic tools applied to intraocular samples for antibody detection (local synthesis of specific antibodies), although PCR is becoming more widely available for direct identification of the parasite DNA in the vitreous and aqueous humor, especially with new methods of detection that can improve its sensitivity. When the clinical symptoms first manifest in immunocompetent patients, the intraocular inflammatory response may reduce the parasitic burden in the aqueous humor and vitreous, thus decreasing the amount of target DNA for PCR amplification. Secretory IgA antibodies in tears have been suggested as a reliable marker of acute ocular toxoplasmosis. Symptoms and signs in immunocompromised patients do not distinguish ocular toxoplasmosis from other ocular infections in HIV, including tuberculosis, *P jirovecii* pneumonia, and CMV retinitis. Toxoplasmic chorioretinitis appears as raised yellow-white, cottony lesions in a nonvascular distribution, unlike the perivascular exudates of CMV retinitis. Vitreal inflammation is usually present, in contrast to ocular toxoplasmosis in immunocompetent patients. Up to 63% of AIDS patients with *Toxoplasma* chorioretinitis have concurrent CNS lesions.

Maternal Infection and Congenital Toxoplasmosis

Infection with *T gondii* is particularly dangerous for pregnant women because it can lead to the transplacental passage of the parasite from the circulation of the primarily infected mother. Successful pregnancy involves an elegant equilibrium in organizing the immune system at the fetal-maternal and uteri milieu resulting in tolerance (TH2) of the fetus and defense (TH1) against the pathogenic agents. The placenta also plays an important role in trans-placental transmission, as it is a natural barrier to protection of the fetus against infectious agents and also a target tissue for parasite multiplication. In fact, the placental barrier is more efficient to inhibit the tachyzoites transmission at the beginning of gestation, but becomes more permeable at the end of pregnancy.

As tachyzoites bypass the placental blood barrier and invade the fetal organs, they propagate and compromise the embryonic developmental process.

During pregnancy, the prevalence of toxoplasmosis increases throughout the second and third quarter of gestation; simultaneously, progesterone and 17 β -estradiol also increase and can aggravate or reduce parasite reproduction. Infection of the placenta is a prerequisite for congenital transmission. More than 60% of infected pregnant women do not experience any symptoms or signs, and the clinical features, when present, are the same as in other immunocompetent persons.

Currently, congenital toxoplasmosis is the second most common intrauterine infection and remains a public health problem throughout the world. The global annual incidence of congenital toxoplasmosis has been estimated to be 190,100 cases (95% credible interval, CI: 179,300–206,300). This is equivalent to a burden of 1.20 million DALYs (95% CI: 0.76–1.90). High burdens are seen in South America and in some Middle Eastern and low-income countries. The risk of transmission of *T gondii* to the fetus ranges from 0.6 to 1.7 per 1000 pregnant women.

According to Massachusetts Department of Health (United States), about 1 case of congenital toxoplasmosis occurs for every 10,000 live births. Moreover, from 4,000,000 live births each year in the United States, 400 have acquired congenital toxoplasmosis. This rate is markedly higher for other developing countries. In France, about 300 cases are reported each year to the National Reference Center. The frequency of transmission and severity of disease are inversely related.

The development of possible consequences depends on many factors, including the degree of parasitemia in the mother, the maturity of the placenta, the age of the fetus, and immunologic maturity. Early maternal infection (first trimester) can cause severe congenital toxoplasmosis and can result in death of the fetus in utero and spontaneous abortion. Clinical manifestations of congenital toxoplasmosis observed in infancy are numerous and include jaundice, rash, hepatosplenomegaly, anemia, thrombocytopenia, hydrocephalus, microcephalus, intracranial calcifications, convulsions, psychomotor and mental retardation, chorioretinitis, microphthalmia, blindness, strabismus, visual and auditory inflammatory disorders, cardiovascular abnormalities, and pains. All these signs and symptoms are included in the general workup of suspected congenital TORCH infections: toxoplasmosis, other (syphilis, varicella-zoster, parvovirus B19, HIV infection, listeriosis, hepatitis B, Zika virus), rubella, cytomegalovirus, and herpes. The classic triad of bilateral chorioretinitis, hydrocephalus, and cerebral calcifications is exceptional.

Fetal infection at the second trimester results in milder complications, which include splenomegaly, hepatomegaly, cerebral calcifications, pneumonitis, anemia, epilepsy, thrombocytopenia-induced petechiae, rash, and retinochoroiditis. When maternal infection occurs during the third trimester, most of neonates (more than 80%) are asymptomatic; however, retinochoroiditis and neurologic deficits in newborn who may be at high risk for seizures, mental retardation, or delay in growth, as well as in early adulthood, might be developed if these newborns are not treated appropriately in early age. In multiparous women, the risk of infections has been shown twice as high as in nulliparas.

The clinical course of the disease in a child with congenital toxoplasmosis is not influenced by whether the mother showed any clinical symptoms of the disease or was entirely asymptomatic. Infants born to women infected simultaneously with HIV and *T gondii* should be evaluated for congenital toxoplasmosis, considering the increased risk of reactivation of parasitemia and disease in these mothers.

Diagnosis in the Immunocompetent

In immunocompetent persons, confirmation of acute infection can exclude other potentially more serious etiologies. In other clinical settings where *Toxoplasma* infection can result in severe sequelae, the interpretation of laboratory findings poses significant challenges. The parasite can in fact be present in acute, chronic, latent,

or reactivated form. Thus, discrimination of these forms is often crucial in understanding clinical relevance. A schematic diagnostic pathway that can be followed for the diagnosis of toxoplasmosis is shown in Figure 1. Methodical serologic screening for *T gondii* IgG and IgM antibodies in adult symptomatic immunocompetent persons, in pregnant women as early in gestation as possible (preferably in first trimester), and in seronegative women each month or trimester thereafter is optimal. Such screening allows detection of seroconversion and early initiation of treatment.

The laboratory tests used most commonly for initial investigation are serologic, targeting detection of IgG, IgM, and IgA specific for *T gondii* by available commercial kit. In addition to confirming infection, these tests can aid in determining prognosis, influence management, and assist in monitoring response to treatment. Typically, acute-phase IgM appears first about 1 to 2 weeks after infection, closely followed by IgA and IgE. Generally, IgM peaks at about 2 months. The time at which immunoglobulins can no longer be detected is highly variable depending on the test employed, usually about 6 to 9 months. In a small minority of cases IgM can persist at high levels for up to 18 months or for years, leading to an inaccurate assessment of when the exposure occurred. This

circumstance can be problematic because congenital toxoplasmosis can occur if the mother was infected during her pregnancy, and it is thus important to ascertain in which trimester of pregnancy the infection occurred. IgA antibodies are considered to be a marker of acute toxoplasmosis as their kinetics are faster than those of IgM antibodies; however, they can also persist for more than a year, and their detection, together with IgM detection, strongly suggests neonatal infection. IgE serology is highly specific in pregnant women but has low sensitivity, remaining detectable for less than 4 months after infection; moreover, it is not useful in samples from newborns.

To date, an IgM test is still used by most laboratories to determine if a patient has been infected recently or in the distant past, but confirmatory testing (double sandwich or capture IgM-ELISA [enzyme-linked immunosorbent assay] kits and the immunosorbent agglutination assay [IgM-ISAGA]) should always be performed owing to the difficulties in interpreting a positive IgM test result for the relatively high incidence of false-positive results (due to the rheumatoid factor and antinuclear antibodies in some IgM-IFA tests). Thus, a positive IgM test result in a single serum sample can be interpreted as a true-positive result in the setting

All Persons With Suspected Toxoplasmosis, Including Pregnant Women: First Visit

First-level *T. gondii* Diagnostic Test

Detection of serum anti-*T. gondii* IgM and IgG in first trimester

- If IgM and IgG negative: absence of specific immunity; mother prophylaxis, monthly serologic control*
- If only IgG is detected: infection likely took place 6–12 months before or before pregnancy; immunity
- If only IgM is detected: initial phase seroconversion of false IgM positivity†
- If IgM and IgG are detected: possible recent infection; consider a more thorough workup (reference laboratory) to try to determine the time of infection in the mother‡

Second-level Diagnostic Test

IgG avidity assay

- If negative (high avidity): infection occurred 3–5 months before testing
 - If positive (low avidity): probable recent *T. gondii* infection; repeat serology 3 weeks after the first sample; start spiramycin, ecographic surveillance
- Try to establish a certain or presumed seroconversion in pregnancy and to determine whether the infection was transmitted to the product of conception.

Third-level Diagnostic Tests (further maternal and fetal assessment)

In the mother

Detection of *T. gondii*-specific DNA by PCR-AF at 18 weeks of gestation§

- If positive: the fetus has been infected; consider starting treatment and monthly fetal ultrasound examination to detect abnormalities; start pyrimethamine-sulfadiazine||
- If negative: fetus unaffected; *T. gondii* has not crossed the placental barrier; continue spiramycin¶
- Parasite isolation on tissue culture: mouse inoculation**

In the newborn

Detection of serum anti-*T. gondii* IgM and IgA††

- If IgM and/or IgA are present at birth: probable congenital infection
- If IgM and/or IgA are not present at birth: monthly control

Western blot assay of serum IgG and IgM from mother-baby pairs‡‡

- If positive: confirmation of early postnatal diagnosis; therapy and serological control§§
- If negative: monthly control for the first 3 months

Figure 1 A schematic diagnostic pathway for the diagnosis of toxoplasmosis. *No treatment is required. †Repeat the tests weekly to detect the appearance of IgG antibodies to confirm the seroconversion. ‡Given that IgM may persist for several months, try to date the beginning of infection through education and counseling to guide the prenatal diagnosis of the patient. §PCR sensitivity is significantly higher for infections occurred between the 17th and 21st week of gestation. ||If ecographic abnormalities, consider abortion. ¶A negative PCR cannot completely rule out congenital infection; consider follow-up through ultrasounds and continue prophylaxis with spiramycin (Rovamycin) until delivery and neonatal testing. **For confirmation of PCR results; however, they are complex, expensive, and relatively insensitive. ††Limitations because IgA antibodies may persist for several months and are not always produced. ‡‡This test is not widely used mainly because of its technical complexity and high price. §§Administer pyrimethamine (Daraprim)-sulfadiazine therapy and serologic controls after cessation of therapy and every 6 months for the first 2 years.

of a recently acquired infection, a true-positive result in the setting of an infection acquired in the distant past, or a false-positive result. IgM levels decline more rapidly than IgG antibodies, which typically reach maximal levels at about 4 months, then decline to a lower level over the next 12 to 24 months but persist for decades. Elevated IgG levels confirm if a patient has been exposed to the parasite, but they do not differentiate between a recent or past exposure, because IgG persists at a low level throughout the life of the patient. The absence of IgG antibodies in early pregnancy indicates that women are at risk for acquiring toxoplasmosis.

The most commonly used tests for the measurement of IgG antibody are the Sabin-Feldman dye test (still considered the gold standard diagnostic test; it measures primarily IgG antibodies to *T gondii*, but it requires viable *Toxoplasma* organisms), the ELISA, the IFA, and the modified direct agglutination test. Other immunological methods, including chemiluminescence assays (CLIA), enzyme-linked fluorescence assay (ELFA), and immunochromatographic test (ICT), have been developed to improve the ability of diagnosis of *T gondii* infection.

Depending on the method used, the avidity tests currently available (serum IgG avidity test and immunosorbent agglutination assays (ISAGA) are helpful primarily to rule out that a patient's infection occurred within the prior 4 to 5 months and that the fetus is not at risk for congenital toxoplasmosis. The avidity test that shows low IgG values in a recent *T gondii* infection is most important when only a single serum sample is available at the time when critical decisions must be made. A major problem with this test is that the maturation of the IgG response after a primary *Toxoplasma* infection varies considerably among patients; in fact, low-avidity results can persist for as long as 1 year, and substantial numbers of patients have borderline or equivocal results. These equivocal cases require that in addition to a more careful interpretation of all laboratory test results in conjunction with other clinical findings, other serologic methods should then be undertaken in serology reference laboratories. Recently, a growing number of studies have demonstrated the potential advantages of chimeric or synthetic peptide antigens (EC2 (containing MIC1 and MIC2 antigenic regions) and EC3 (containing M2AP, GRA3 and GRA7 antigenic regions) for the serological diagnosis of toxoplasmosis.

The employment of polymerase chain reaction (PCR) to identify *T gondii* DNA in amniotic fluid (AF) obtained by amniocentesis at 18 weeks and later represents a milestone in the early diagnosis of intrauterine *T gondii* infection, thereby avoiding the use of more invasive procedures on the fetus. Sensitivity and specificity of PCR may even increase when performed on AF samples obtained from the sixteenth week of pregnancy onward. The specificity and positive predictive value of PCR on AF samples is close to 100%, although different protocols influence its sensitivity and specificity. PCR is generally carried out with various gene targets, of which the most widely used is the 35-fold repetitive gene B1. Following it, several multicopy targeting genes including 18S rRNA-, P30-, B1-genes, 529-bp repeat fragment or the AF146527 element have been used for the detection of *T gondii* in different biologic samples. In particular, PCR with the 529-bp RE gene is 10–100 times more sensitive than the B1 gene.

Results of studies indicated that loop-mediated isothermal amplification (LAMP) and real-time-PCR using AF and CSF are more sensitive and specific methods in congenital infection and immunocompromised patients, respectively, and could be used for early diagnosis of infection and also in follow-up after treatment. Moreover, LAMP on cord blood or whole blood is highly sensitive, specific, and easy to perform, as it doesn't require expensive equipment.

However, a definitive correlation between the number of *Toxoplasma* organisms in AF and the severity of congenital infection has not yet been demonstrated. PCR should be considered for pregnant women (without a contraindication for the procedure) with positive diagnostic serology or highly suggestive of an infection because of ultrasonographic abnormalities in the fetus acquired during gestation or shortly before conception. If the PCR-AF test result is

negative, the fetus should be unaffected, presumably because *T gondii* has not yet crossed the placental barrier even if it is theoretically possible that fetal infection can occur later in pregnancy from a placenta that was infected earlier in gestation. Samples obtained by cordocentesis, funipuncture, or periumbilical fetal blood sampling should not be used, because fetal risk of contamination with maternal blood is higher than with amniocentesis, and cordocentesis is less sensitive.

In the newborn, diagnosis of infection is based on detection of serum anti-*Toxoplasma* IgM and IgA antibodies that do not cross the placenta, unlike maternal IgG antibodies. Better results are obtained if the ISAGA method is used. Maternal IgG antibodies present in the newborn can reflect either past or recent infection in the mother and require serologic follow-up of the newborn for the 1st year of life until the complete disappearance of these antibodies. A negative *T gondii*-specific IgG test result at 1 year of age essentially rules out congenital toxoplasmosis. Detection of IgG in oral fluid appears to be a promising tool for monitoring infants with suspected congenital toxoplasmosis.

Detection of specific IgA antibodies appears to be more sensitive than detection of IgM antibodies for establishing infection in the newborn, because these antibodies may be present when there is no *T gondii*-specific IgM, and the converse can also occur. However, transmission of maternal IgM or IgA antibodies can occur during the birth process. Because of the relatively brief half-life of IgM and IgA, positive tests for these antibodies usually must be confirmed by repeat testing at 2 to 4 days of life in the case of IgM antibodies and at 10 days of life for IgA antibodies.

Evaluation of infants with suspected congenital toxoplasmosis should always include ophthalmologic examination, electroencephalogram, hearing test, blood tests, non-contrast CT scanning or ultrasound of the brain, and examination of CSF. Although CT scanning is the first-line diagnostic method used in the United States to detect CNS abnormalities caused by toxoplasmosis, ultrasound can be used as an alternative diagnostic method to avoid the effects of radiation in the neonatal period. Ultrasound is recommended for women with suspected or diagnosed acute infection acquired during or shortly before gestation. This technique can reveal fetal abnormalities, including hydrocephalus, brain or hepatic calcifications, splenomegaly, and ascites. Because most infants do not show signs of toxoplasmosis at birth, a negative ultrasound does not rule out the possibility of infection and might need to be followed by a CT scan for confirmation, because ultrasound results can vary depending on the examiner and technology used. Newborns thus need a thorough examination after birth and follow-up blood tests during the first year of life.

Diagnosis in the Immunocompromised

In immunocompromised persons and AIDS patients with TE, indirect serologic methods widely used in immunocompetent patients are unreliable because they fail to produce significant titers of specific antibodies. Although incidence of TE among HIV-infected persons directly correlates with the prevalence of anti-*T gondii* antibodies, the absence of IgG antibody makes a diagnosis of toxoplasmosis unlikely, but not impossible. Anti-*Toxoplasma* IgM antibodies are usually absent. CSF findings are normal or show nonspecific alterations such as lymphocytic pleocytosis and discrete CSF hyperproteinorrachia.

In clinical practice, the diagnosis of TE is presumptive and mainly based on clinical presentation, imaging, and laboratory test results. Imaging includes CT or MRI, preferably with gadolinium contrast, and shows isodense or hypodense single or multiple lesions with a mass effect, taking up the contrast dye in a ringlike or nodular manner in more than 90% of cases. However, as neither CT nor MRI can reliably distinguish CNS infections, such as toxoplasmosis, from lymphoma in HIV-1-positive patients, the use of FDG-PET has been shown to offer better sensitivity to noninvasively differentiate cerebral toxoplasmosis and other infectious diseases from primary CNS lymphoma. Laboratory results include the

presence of serum-specific *T gondii* IgG antibodies. Diagnosis is also made from an objective response, on the basis of clinical and radiographic improvement, to specific anti-*T gondii* therapy in the absence of a likely alternative diagnosis. In general, the occurrence of low CD4⁺ T-cell count (less than 150–200/mm³) and the presence of *T gondii* IgG antibody is habitually accepted as being a good predictor of TE reactivation, although less than 6% of TE patients show negative tests. If the suspected diagnosis of toxoplasmosis is correct, clinical or radiographic improvement should become evident by more than 50% within 7 to 14 days. If symptoms persist, a brain biopsy should be performed. This should be considered in immunocompromised patients with presumed CNS toxoplasmosis with a single MRI lesion, absence of IgG antibodies, or an unsatisfactory clinical response to specific anti-*T gondii* treatment.

Diagnosis of TE is crucial because other brain diseases—such as CNS lymphoma, bacterial abscess, progressive multifocal leukoencephalopathy, viral or fungal encephalitis, neurotuberculosis, cytomegalovirus encephalitis, and focal lesions caused by fungi (*Cryptococcus neoformans*, *Aspergillus* spp., and *Nocardia* spp.)—could share similar clinical and CT scan signs. In general, no imaging technique is completely specific. Thallium single-photon emission computed tomography (SPECT) and positron emission tomography (PET) can be useful in distinguishing toxoplasmosis or other infections from CNS lymphoma. CNS lymphoma has greater thallium uptake on SPECT and greater glucose and methionine metabolism on PET than neurotoxoplasmosis or other infections.

Definitive diagnosis of TE is made by pathologic examination of brain tissue obtained by open or stereotactic CT-guided brain biopsy, although there is morbidity and even death associated with the biopsy procedure. Tachyzoites are demonstrated on hematoxylin and eosin stains or immunoperoxidase staining, which can increase diagnostic sensitivity, or by Giemsa on cytocentrifuged CSF samples. Toxoplasma organisms must be distinguished from other intracellular organisms such as *Histoplasma*, *Trypanosoma cruzi*, and *Leishmania*.

Since the turn of the twenty-first century, molecular techniques have allowed significant improvement and have been shown to be an important diagnostic tool in laboratory diagnosis of TE. Their use is principally appropriate for immunocompromised patients because these techniques are not affected by the immunologic status of the host. PCR-based assays, in particular, have been shown to be rapid, sensitive, and specific enough to be used as a front-line test for detecting CSF *T gondii* DNA in most patients with CNS infection, thus avoiding invasive and expensive brain biopsy procedures. However, results usually are negative once specific anti-*Toxoplasma* therapy has been started. Moreover, parasite levels in blood and CSF may be very poor in some patients and cause difficulties in interpreting the PCR product. For this reason, a number of quantitative real-time PCRs with specific *T gondii* genome sequence have been developed in the last decade and used in patients with AIDS and CNS damage with different rates of sensitivity and specificity. In this setting, the recent sensitive and specific real-time PCR technique targeting the 529-bp repeat fragment of the *AF146527* element repeated 300 times in the genome of *T gondii* has been demonstrated to exactly quantify the parasite load, allowing correlation with clinical symptoms and impact of treatment. Moreover, the use of real-time PCR with primers targeting the genes *SAG4* and *MAG1* (located in the bradyzoites) and *SAG1* (located in tachyzoites) has shown to be useful to identify relapses of TE in patients in whom the use of PCR with B1 gene failed to detect DNA, in AIDS patients and other immunocompromised patients especially, when prophylaxis or treatment has been started.

Diagnosis of TE in AIDS patients can also be supported by demonstration of intrathecal antibody production based on detection of oligoclonal bands in CSF with antibody-specific index (ASI) and affinity-mediated immunoblot (AMI) techniques. This approach has also been shown to discriminate TE from other opportunistic CNS infections in AIDS.

In non-AIDS-immunocompromised patients, regular PCR follow-up of allogeneic hematopoietic stem-cell transplant (allo-HSCT) patients could guide preemptive treatment and improve outcome.

Treatment

An ideal treatment for toxoplasmosis should achieve therapeutic, systemic brain and eye concentrations to be effective in the organs where the majority of disease occurs and should be active against both the acute replicating tachyzoite and latent bradyzoite stages of the parasite. However, current treatments are only capable of suppressing the rapidly dividing tachyzoite stage of the organism. The main goal of treatment is to interrupt the replication of the parasite and prevent further damage to the organs involved. Nonpregnant immunocompetent patients with acute toxoplasmosis plus lymphadenitis generally do not require antimicrobial therapy because the infection is self-limiting and usually subclinical. Chronic lymphadenopathy accompanied by fever and marked weakness can be cured with specific therapy. Patients whose *T gondii* infection occurred during laboratory accidents or blood transfusions need specific treatment. Pregnant women must be treated to reduce the risk and severity of congenital infection. Immunocompromised patients, including patients with AIDS and transplant recipients, should always be treated with antitoxoplasmic agents. For eye disease, treatment usually includes anti-*Toxoplasma* agents plus systemic corticosteroids. The most important treatment and prophylactic regimens for the therapy of toxoplasmosis are shown in *Tables 1 and 2*.

The folate synthesis pathway being the best-known therapeutic target against *Toxoplasma*, the main enzymes targeted by pharmaceuticals are the dihydropteroate synthase and dihydrofolate reductase. Since the dihydropteroate enzyme is not found in mammalian cells, it provides a specific target against *Toxoplasma*. The standard pyrimethamine (Daraprim) and trimethoprim (Trimrex)¹ are the most widely used dihydrofolate reductase inhibitors. Pyrimethamine, however, is more effective than trimethoprim and is usually administered in conjunction with a dihydropteroate synthase inhibitor (sulfonamide compounds such as sulfadiazine and sulfamethoxazole).

First-line therapy for acquired toxoplasmosis in both immunocompetent and immunodeficient patients consists of the synergistic combination of pyrimethamine and sulfadiazine. Pyrimethamine plus sulfadiazine¹ plus folinic acid (Leucovorin)¹ to prevent hematologic toxicity is the preferred regimen. Azithromycin (Zithromax)¹ or atovaquone (Mepron)¹ may be used as alternate therapy in combination with pyrimethamine or sulfonamides for the treatment and prophylaxis of toxoplasmosis when first-line line therapy is contraindicated. Both compounds have been shown to be partially effective against tissue cysts in experimental studies. More recently, however, the search for new and efficient pharmacologic treatments directed against proliferating tachyzoites or the tissue cyst of *Toxoplasma* is under intense and frequent evaluation.

Treatment During Pregnancy

Management of maternal and fetal infection of *T gondii* varies considerably between different countries and even centers in the same country. According to the European Multicentre Study on Congenital Toxoplasmosis (EMSCOT) data, which suffer from the lack of a large-scale controlled clinical trial, treatment for the fetus should be started immediately (within 3 weeks of infection) after diagnosis of recently acquired maternal infection. This has been shown to significantly reduce sequelae and to have a beneficial effect when therapy is begun soon after birth. Later treatment has been shown to have no effect.

The macrolide antibiotic spiramycin (Rovamycin)² is prescribed immediately after diagnosis of maternal infection in most centers in Europe and the United States, and there has been no

¹Not FDA approved for this indication.

²Not commercially available in the United States.

TABLE 1 Treatment Regimens for Toxoplasmosis

PATIENTS	DRUG OF CHOICE	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION	ADVERSE EFFECTS
Acute infection in <i>T gondii</i> seropositive pregnant patients with undocumented fetal infection	Spiramycin (Rovamycine) ²	1000 mg PO q8h (without food)	Throughout pregnancy or until fetal infection is documented	Mild GI disturbances, possible skin eruptions
Acute infection in a pregnant patient with documented fetal infection (positive PCR-AF)	Pyrimethamine (Daraprim) [*] <i>plus</i>	Loading dose, 50 mg PO q12h × 2 d, then 50 mg PO daily	Throughout pregnancy; avoid before 18th wk of gestation because of high risk of teratogenesis	Pyrimethamine is a potential teratogen (kidney and heart malformation) and should be used only after the first trimester
	Sulfadiazine ¹ <i>plus</i>	Loading dose 75 mg/kg PO, then 50 mg/kg q12h (max 4 g daily)	Throughout pregnancy; do not administer before 18th wk of gestation [†]	Sulfadiazine can cause crystal-induced nephropathy [‡]
	Folinic acid (Leucovorin) ¹	10–20 mg PO daily	During and for 1 wk after pyrimethamine use	Complete regimen: rash, fever and dose-dependent myelosuppression; weekly monitoring of blood cell counts
Congenital infection in the infant	Pyrimethamine <i>plus</i>	Loading dose 2 mg/kg PO daily × 2 d; then 1 mg/kg PO daily × 2–6 mo; then 1 mg/kg tiw	1 y	Same as above
	Sulfadiazine ¹ <i>plus</i>	50 mg/kg PO q12h	1 y	
	Folinic acid ¹	10 mg/kg PO tiw	During and for 1 wk after pyrimethamine use	
Acute <i>T gondii</i> infection in adult immunocompetent patients and in pregnant patients infected > 6 mo before conception	Treatment not recommended or, if acutely ill: Pyrimethamine <i>plus</i>	Loading dose 200 mg PO daily in 2 divided doses, then 0.5–1 mg/kg/d (max 50 mg/d; 75 mg (if > 60 kg))	4–6 wk, or 1–2 wk after resolution of symptoms	Same as above
Chorioretinitis in immunocompetent patients	Sulfadiazine ¹ <i>plus</i>	1000–1500 mg PO q6h	During and 1 wk after pyrimethamine use	Same as above
	Folinic acid ¹	5–20 mg PO tiw	1–2 wk after resolution of symptoms	
	Pyrimethamine ^{§,1} <i>plus</i>	200 mg loading dose, then 50–75 mg PO daily		
	Sulfadiazine ^{§,1} <i>plus</i>	1000–1500 mg PO q6h	1–2 wk after resolution of symptoms	
	Folinic acid ¹ <i>plus</i>	5–20 mg PO tiw	During and for 1 wk after pyrimethamine use	
	Prednisone	1 mg/kg daily in 2 divided doses	Until resolution of signs and symptoms	
<i>Alternatives</i>				
	TMP-SMX (Bactrim) ¹ <i>or</i>	160–800 mg q12h	6 wk	Skin rash, fever, leukopenia, thrombocytopenia, hepatotoxicity; also available as an IV formulation Not reported
	Azithromycin (Zithromax) ¹ alone or associated with pyrimethamine <i>or</i>	500 mg/d	5 wk	
	Intravitreal clindamycin (Cleocin) ¹ -dexamethasone (Decadron)	One injection 1–400 mcg	Not reported	Not reported
<i>For untreatable cases only</i>				
	Photocoagulation	Not usually done	Not reported	Not reported
Immunocompro-mised patients and patients with TE	Pyrimethamine <i>plus</i>	Loading dose 200 mg PO, then 50–75 mg PO daily	At least 4–6 wk after signs and symptoms resolve	Same as above
	Folinic acid ¹ <i>plus either</i>	10–20 mg PO or IV or IM daily (max 50 mg daily)		

Continued

TABLE 1 Treatment Regimens for Toxoplasmosis—cont'd

PATIENTS	DRUG OF CHOICE	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION	ADVERSE EFFECTS
	Sulfadiazine or Clindamycin ^{1,†} plus Prednisone	1000–1500 mg PO q6h 600 mg PO or IV q6h (max 1200 mg q6h) 1 mg/kg daily in 2 divided doses	During and for 1 wk after pyrimethamine use At least 4–6 wk after signs and symptoms resolve Until improvement of edema or mass effect related to focal lesion	Rash, fever, diarrhea, hepatotoxicity Fever, rash, diarrhea, hepatotoxicity
	<i>Alternatives</i> TMP-SMX ¹ alone or	5 mg/kg TMP PO or IV q12h (max 15–20 mg/kg/d)	Same as above	Same as above
	Pyrimethamine plus folinic acid ¹ plus one of the following:	Same as above pyrimethamine and folinic acid doses 500 mg PO q12h	Same as above	Same as above
	Clarithromycin (Biaxin) ¹	750 mg PO q6h	At least 4–8 wk after resolution of signs and symptoms	
	Atovaquone (Mepron) ¹	1200–1500 mg PO daily	Not reported	Atovaquone can increase LFTs and skin rash Take with a meal to enhance absorption
	Azithromycin ¹ Dapsone ¹ Atovaquone (Mepron) ¹ alone or with sulfadiazine	100 mg PO daily 750 mg PO q6h 1000–1500 mg PO q6h	Not reported Not reported Not reported	
Acute infection in patients with <i>T gondii</i> and HIV infection ^{**}	Spiramycin ² (as for immunocompetent pregnant women)	1,000 mg PO q8h (without food)	Throughout pregnancy or until fetal infection is documented	

¹Not FDA approved for this indication.²Not commercially available in the United States.

*Take with food to minimize gastrointestinal adverse effects.

[†]This might change in some European countries.[‡]Should be taken on an empty stomach with adequate water.[§]Take both for 3 weeks followed by 1 week off; repeat for 3 or 4 cycles.^{||}After initial phase of therapy, maintenance therapy must be continued as long as the patient remains immunocompromised.[¶]Clindamycin can be used instead of sulfadiazine in patients intolerant to sulfonamides.^{**}Amniocentesis should be avoided because of the risk of transmitting HIV infection to the fetus.

Abbreviations: GI, gastrointestinal; LFT, liver function test; PCR-AF, polymerase chain reaction testing of amniotic fluid; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 2 Prophylaxis Regimens for Toxoplasmosis

PATIENTS WHO SHOULD RECEIVE PROPHYLAXIS	DRUG OF CHOICE*	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION
Primary prophylaxis for immunocompromised patients, including advanced pregnant HIV-positive women (CD4 ⁺ count < 100 cells/mm ³ and <i>T gondii</i> IgG positive)	First choice: TMP-SMX (Bactrim) ¹ <i>Alternatives</i> Pyrimethamine (Daraprim) ¹ plus Dapsone ¹ plus Folinic acid ¹ or Pyrimethamine-sulfadoxine (Fansidar) ¹ plus Folinic acid ¹ or Atovaquone (Mepron) ¹	1 DS tab 160–800 mg PO daily 50–75 mg/wk 50 mg/d 25 mg/wk 1 tab twice weekly 25 mg/wk 1,500 mg PO daily	For life or until immunoreconstitution has occurred [†] Same as above Same as above Same as above
Secondary prophylaxis for immunocompromised patients after primary or induction treatment	Same regimen used in the acute phase: TMP-SMX ¹	Half doses of those used in the acute phase 2.5 mg/kg TMP PO or IV q12h, max 15–20 mg/kg/d	For life or until immunoreconstitution has occurred [†]

TABLE 2 Prophylaxis Regimens for Toxoplasmosis—cont'd

PATIENTS WHO SHOULD RECEIVE PROPHYLAXIS	DRUG OF CHOICE	RECOMMENDED DOSAGE	LENGTH OF ADMINISTRATION
Prophylaxis in adults receiving heart, lung, or liver transplant, especially in the case of a seropositive donor (D +) and seronegative recipient (R –) [‡]	First choice: TMP-SMX ¹ <i>Alternative</i> Pyrimethamine ¹ plus Folinic acid ¹	80 mg TMP/400 mg SMX (1 tab single-strength Bactrim) twice daily 50–75 mg PO daily 5–10 mg PO daily	For 6 wk after transplant Same as above During and for 1 wk after pyrimethamine use
Prophylaxis in adults receiving bone marrow and allogeneic stem cell transplants [§]	First choice: TMP-SMX ¹ <i>Alternatives¹</i> : Pyrimethamine ¹ plus Clindamycin (Cleocin) ¹ plus Folinic acid ¹ Pyrimethamine ¹ plus Sulfadiazine ¹ plus Folinic acid ¹	Same as above Not standardized Same as for acute infection ^{**}	For more than 6 mo Not reported 2 wk
Prophylaxis for accidental laboratory exposure and blood transfusions			

¹Not FDA approved for this indication.

*For side effects, see Table 1.

[‡]In patients with AIDS, primary and secondary prophylaxis are generally discontinued when the patient's CD4⁺ cell count has returned to more than 200 cells/μL and HIV PCR peripheral blood viral load has been reasonably controlled for at least 6 months following ART.[§]Preemptive antiparasite treatment should be considered for all symptomatic, seropositive, immunocompromised patients in whom toxoplasmosis is suspected.[§]There are no clear recommendation for anti-*T gondii* prophylaxis in allogeneic stem cell transplantation, because the optimal regimen has not yet been determined.^{||}Not specifically codified.[¶]Alternative regimen in sulfonamide-allergic patients.^{**}Presumptive therapy should be given with the same dosages as for acute infection and monitored serologically for several months after the exposure or until seroconversion is noted; that is, testing immediately after the exposure, weekly for at least 1 month, and at least monthly thereafter. Seroconversion can occur despite presumptive therapy. Although presumptive therapy typically prevents disease or at least substantial morbidity, it does not necessarily prevent infection.

Abbreviations: ART, highly active retroviral therapy; PCR, polymerase chain reaction; TMP-SMX, trimethoprim-sulfamethoxazole.

evidence that this drug is teratogenic. Spiramycin does not cross the placenta but is concentrated in the placenta and protects the fetus from contact with the parasite. It has been estimated to reduce the incidence of vertical transmission of *T gondii* by about 60%. It is used 1 g every 8 hours in many EU countries, especially France, and in Asia and South America and does not seem to have any fetal effects, although a small percentage of women have developed gastrointestinal side effects.

Spiramycin should be continued as prophylaxis until delivery, along with periodic ultrasound examination, because the placenta could have been infected earlier in gestation.

In the case of positive PCR-AF at or immediately after 18 weeks' gestation, or with high probability of fetal infection acquired late in the second trimester (after 18 weeks) or during the third trimester of gestation (because of ultrasound abnormalities), and in women who cannot undergo amniocentesis, the spiramycin regimen should be replaced with the drug combination of sulfadiazine¹ and pyrimethamine plus folinic acid (Leucovorin).¹ This treatment strategy varies in some U.S. and European centers. Folinic acid prevents the toxicity of pyrimethamine without activity against *Toxoplasma*. This combination therapy is used only after confirmed or strongly suspected fetal infection and is never administered in the first trimester of pregnancy due to its teratogenic and hematological adverse effects, in addition to symptoms of nausea in the mother.

Throughout the pregnancy, therapy with pyrimethamine in conjunction with folinic acid should be continued to prevent hematologic toxicities, along with monitoring of blood cell counts and rigorous periodic ultrasound examination. Because spiramycin does not readily cross the placenta, it is not reliable for the treatment of infection in the fetus. In the absence of clinical and

laboratory signs suggestive of congenital toxoplasmosis, therapy is not indicated in infants, but it is necessary to inform the specialist and to plan, with the specialist, periodic clinical and serologic controls. In symptomatic infants, the combination of pyrimethamine plus sulfadiazine plus leucovorin is recommended. The duration of this treatment is not specifically defined, but it must be continued for up to a year, possibly alternating cycles of antifolate for 4 weeks with spiramycin cycles of equal duration.

Ocular Toxoplasmosis

In immunocompetent patients, *Toxoplasma*-related chorioretinitis is usually a self-limited infection and generally may resolve spontaneously in a period of 4 to 8 weeks. However, treatment is recommended for lesions within the vascular arcades, adjacent to the optic disk, or larger than 2 optic disk diameters to reduce the chance of vision loss. In general, pyrimethamine, sulfadiazine¹ plus folinic acid¹, and corticosteroids form the most common drug combination currently used to treat ocular toxoplasmosis. Patients may also be treated with TMP-SMX,¹ which appears to be a safe and effective substitute for pyrimethamine, sulfadiazine, and folinic acid, or with azithromycin¹ or intravitreal clindamycin (Cleocin)¹ and prednisone for 4 to 6 weeks. Pyrimethamine plus azithromycin is another drug combination that is similar to the standard treatment and can be considered an acceptable alternative treatment for sight-threatening ocular toxoplasmosis. *Toxoplasma* retinochoroiditis in immunocompromised patients requires immediate treatment. Atypical presentations also warrant treatment.

Recurrent toxoplasmic retinochoroiditis, probably related to the rupture of the dormant retinal cyst or *Toxoplasma* circulating in peripheral blood, remains a major health crisis and can be associated with severe morbidity if the disease extends to structures

¹Not FDA approved for this indication.¹Not FDA approved for this indication.

critical for vision, including the macula and optic disk. Severe morbidity can also occur if there is damage to the eye from inflammation or if there are complications such as retinal detachment or neovascularization. In patients with frequent recurrences, the rate of recurrent toxoplasmic retinochoroiditis can be significantly reduced by long-term intermittent treatment with TMP-SMX 160 mg/800 mg (Bactrim DS)¹, with one tablet administered three times a week as a prophylactic regimen. Intravitreal clindamycin¹ injection and possibly steroids may be an acceptable alternative to the classic treatment in ocular toxoplasmosis. It can offer the patient more convenience, a safer systemic side effect profile, greater availability, and fewer follow-up visits and hematologic evaluations. Although research has identified wide variation in practices regarding the use of corticosteroids, a recent Cochrane review did not identify evidence from randomized controlled trials for the role of corticosteroids in the management of ocular toxoplasmosis. The question of foremost importance, however, is whether they should be used as adjunct therapy (that is, in addition) to antiparasitic agents. There is no evidence to support that one antibiotic regimen is superior to another, so choice needs to be informed by the safety profile. Intravitreal clindamycin with dexamethasone¹ seems to be as effective as systemic treatments. There is currently level I evidence that intermittent trimethoprim-sulfamethoxazole prevents recurrence of the disease.

Toxoplasmosis in Immunosuppressed Patients

With the advent of the ART, the natural course of HIV infection has markedly changed, and opportunistic infections including toxoplasmosis have declined and changed in presentation, outcome, and incidence. However, TE is a major cause of morbidity and mortality, especially in resource-poor settings, and it is a common neurologic complication in some countries despite the availability of ART and effective prophylaxis. The initial therapy of choice in TE patients consists of the combination of pyrimethamine, which is able to penetrate the brain parenchyma efficiently even in the absence of inflammation, plus sulfadiazine or clindamycin¹ plus folinic acid.¹

Adjunctive corticosteroids should be administered when clinically indicated only for treatment of a mass effect associated with focal lesions or associated edema and for a short time because of their potential immunosuppressive effects. Patients receiving corticosteroids should be closely monitored for the development of other effects, including CMV retinitis and tuberculosis. Anticonvulsants should be administered to patients with a history of seizures, but should not be administered prophylactically to all patients. Drug interactions between anticonvulsants and antiretroviral agents should be carefully evaluated, and doses should be adjusted according to established guidelines. The preferred alternative regimen for patients unable to tolerate or who fail to respond to first-line therapy is pyrimethamine plus clindamycin¹ plus leucovorin.¹

Common clindamycin toxicities include fever, rash, nausea, diarrhea (including pseudomembranous colitis or diarrhea related to *Clostridium difficile* toxin), and hepatotoxicity. Other alternative regimens shown in Table 1 are active in the treatment of TE and may be used in sulfa-intolerant patients or those who have not responded to treatment, although their relative efficacy compared with the previous regimens is unknown.

The combination of atovaquone (Mepron)¹ with either pyrimethamine or sulfadiazine has demonstrated utility for the treatment of acute TE in patients with a Karnofsky Performance Status Score greater than 30, which combines the ability to work, to undertake normal activities without external assistance, and to take care of personal needs. Acute therapy should be continued for at least 6 weeks, if there is clinical and radiologic improvement. This should be followed by maintenance therapy (lifelong secondary prophylaxis), usually with the same regimen that was used in the acute phase but at half doses (see Table 2).

Recent findings indicate that daily pyrimethamine-based maintenance therapy is likely more efficacious in preventing TE relapse compared with intermittent therapy. Moreover, the likelihood of relapse associated with pyrimethamine-based therapy in patients with HIV and TE decreased after the introduction of HAART to approximately 11%. Relapse may thus affect a patient's disease severity and prognosis, increase utilization of health care resources, and result in additional health care expenditure. Currently, maintenance treatment should be continued for the life of the patient or until underlying immunosuppression has ceased (immune reconstitution resulting from ART). Adult and adolescent patients appear to be at low risk for recurrence of TE when they have successfully completed initial therapy, remain asymptomatic with respect to signs and symptoms, and have a sustained (i.e., more than 6 months) increase in their CD4⁺ T-lymphocyte counts to greater than 200 cells/ μ L on ART. AIDS patients with CD4⁺ T-cell counts less than 100/ μ L and IgG *Toxoplasma* antibody should receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of one double-strength tablet of TMP/SMX (Bactrim DS) used for *Pneumocystis jirovecii* prophylaxis provides adequate primary protection against toxoplasmosis. Secondary prophylaxis for toxoplasmosis may be discontinued in the setting of effective ART and when CD4⁺ T-cell counts increase to more than 200/ μ L for 6 months.

Prophylaxis and treatment measures of disease in bone marrow transplant recipients as well as in those receiving organ transplantation are shown in Table 2. Universal prophylaxis with TMP/SMX in allo pre-hematopoietic cell transplant seropositive recipients (HCTSP) should be implemented by all transplant programs. Preemptive treatment with routine blood PCR monitoring is an option if prophylaxis cannot be used.

T gondii Infection During Pregnancy in HIV-Positive Women

Immunocompromised women with chronic infection do rarely transmit the parasite to the fetus, resulting in congenital infection. This includes women with AIDS, as well as those on immunosuppressive treatment. Vertical transmission occurs in up to 4% of cases, particularly when the CD4⁺ count is less than 100/mm³. The risk of transmission is low when the CD4⁺ count is greater than 200/mm³ (see Table 2).

Consideration should be given to screening all immunosuppressed women for evidence of maternal *T gondii* serologic status to establish an early diagnosis of reactivation. Seropositive women with low CD4 counts should receive TMP-SMX (Bactrim)¹ to prevent reactivation of *Toxoplasma*. Because of reports of congenital toxoplasmosis in mildly or moderately immunosuppressed women, it is recommended that immunocompromised women not infected with HIV and women who are infected with HIV and who have CD4 counts less than 200/mm³ be treated with spiramycin (Rovamycin)² for the duration of the pregnancy. A non-pregnant woman who has been diagnosed with an acute *T gondii* infection should be counseled to wait 6 months before attempting to become pregnant. Each case should be considered separately in consultation with an expert.

Detailed ultrasound examination of the fetus specifically evaluating for hydrocephalus, cerebral calcifications, and growth restriction should be done for HIV-1-infected women with suspected primary or symptomatic reactivation of *T gondii* during pregnancy.

Prevention

Strategies for the primary prevention of toxoplasmosis in pregnant women and in immunosuppressed patients with negative serology are shown in Box 1.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

²Not commercially available in the United States.

- Check immunity to toxoplasmosis. If the patient has no protection (absence of anti-*Toxoplasma* IgG), take direct or indirect prophylactic measures against cats, food, and water.
- Universal prophylaxis with TMP/SMX¹ in all pre-HCTSP patients should be implemented by all transplant programs. Preemptive treatment with routine blood PCR monitoring is an option if prophylaxis cannot be used.
- Avoid contact with food (including unwashed fruit or vegetables) or water potentially contaminated with cat feces. Wash before consuming.
- Avoid any job or activity that requires contact with dirt, soil, or other material potentially contaminated with cat feces (e.g., gardening or handling cat litter). Wear gloves when gardening or handling cat litter.
- Keep cats inside. Do not adopt or handle stray cats. Do not feed cats raw or undercooked meat but only canned or dried commercial food or well-cooked food. Do not obtain a new kitten or cat during pregnancy.
- Disinfect the cat litter box with near-boiling water for 5 minutes before handling.
- Wash hands thoroughly after contact with raw meat.
- Kitchen surfaces and utensils that have come in contact with raw meat should be washed.
- Avoid ingesting raw or dried meat, raw eggs, or unpasteurized milk.
- Avoid eating raw oysters, clams, or mussels.
- Protect foods from flies, cockroaches, and other insects.
- Avoid touching the eyes or face or any mucous membrane during or immediately after preparing food.
- Cook meat thoroughly. Pork, lamb, beef, veal, and poultry should be cooked until the meat reaches 80°C in the center.
- Refrain from skinning animals.
- Avoid children's sandboxes.
- Avoid contact with stray dogs (xenosmophilia); if this is not possible, wash your hands after contact.

¹Not FDA approved for this indication.

Screening

Secondary prevention by serologic monitoring of seronegative pregnant women should be closely connected with detailed primary prevention. Routine toxoplasmosis screening programs for pregnant women have been established in France, Austria, and Brazil. In France, guidelines recommend that nonimmune pregnant women be tested monthly throughout pregnancy to detect seroconversion to *Toxoplasma* infection. In the United States, routine serologic screening is not performed. In Italy, serologic screening is recommended to prevent congenital toxoplasmosis as part of the antenatal care protocol (TORCH). Serologic screening of women should begin before conception, with follow-up monthly tests during pregnancy to detect seroconversion. This is the basis for the French screening program and the Austrian Toxoplasmosis Prevention Program, which recommend routine serologic testing. Treatment is recommended if one of the tests suggests definite or probable primary maternal infection.

Vaccine

Vaccination is one of the most efficient strategies to prevent and control the spread of toxoplasmosis by immunization of humans and animals (the source of infection). To date, there is much debate about whether a human vaccine is feasible. Costs, target population, method for testing the vaccine, and risks associated with the vaccine are important factors affecting development of the

vaccine. Much of the work has been focused on SAG1, a surface antigen expressed on tachyzoites, in attempts to induce protective immune response when introduced to the host with various adjuvants. SAG1 is primarily involved in adhesion, signal transduction, invasion, material transport and host immune responses. Thus, this protein may be crucial for both the diagnosis of *T gondii* infection and the ability to immunize against this parasite.

In general, a simpler route to prevent human disease would be to vaccinate animals (cats and intermediate hosts) that are responsible for transmission to humans, as demonstrated using a live attenuated vaccine developed for the prevention of chronic infection in sheep. However, it cannot be used in humans because of the risk of reversion to a pathogenic form. Vaccine development to prevent feline oocyst shedding is ongoing, mostly involving live vaccines. More recently, *T gondii* dense granule proteins including GRA-6, a secretory vesicular organelle that produces proteins that participate in the modification of the parasitophorous vacuole, have been shown to be suitable as possible DNA vaccines for immunity against toxoplasmosis. Recombinant rhostry effector protein 54 (ROP54) plasmid has demonstrated to provide partial protection against acute and chronic toxoplasmosis. Finally, aspartic protease 1 (Asp 1) has also shown to play an essential role in the *T gondii* lifecycle, thus being a potential vaccine candidate against toxoplasmosis.

In summary, the immune evasive nature and complex life cycle of *T gondii* has made the design of immunotherapeutics aimed at providing complete protection, a discouraging challenge. Generally, vaccine studies thus far have shown that multi-antigenic formulations confer better protection than single-subunit vaccines.

TREATMENT AND PREVENTION OF HIV INFECTION

Method of

Allison K. Cormier, MD; Tyler K. Liebenstein, PharmD; and Ryan P. Westergaard, MD, PhD, MPH

CURRENT DIAGNOSIS

- National guidelines recommend universal screening for HIV infection for all adult and adolescent patients in all health care settings, after notification that testing will be done, unless the patient specifically declines (opt-out testing). Patients with behavioral risk factors, sexually transmitted diseases, or tuberculosis should be screened annually.
- Revised HIV testing algorithms reflect the increased sensitivity of newer diagnostic assays during early infection, such as fourth-generation HIV-1/2 antigen/antibody combination immunoassays.
- Acute HIV infection is recognized as a variable syndrome including fever, pharyngitis rash, and arthralgias. As many as half of patients may be asymptomatic during seroconversion and early infection.

CURRENT THERAPY

- Combination antiretroviral therapy (ART) should be offered to all patients with HIV infection, regardless of CD4+ cell count.
- Initial ART regimens preferred for most patients include a combination of two nucleoside analog reverse transcriptase inhibitors (NRTIs) and an integrase strand transfer inhibitor (INSTI), which are often co-formulated into single-tablet preparations that can be administered once daily.
- While antiretroviral treatment decisions are often made by providers with specialized training, all providers caring for people living with HIV should be aware of the risk of antiretroviral drug interactions, particularly those involving the pharmacokinetic enhancing agents: ritonavir (Norvir) and cobicistat (Tybost).
- Since 2014, coformulated emtricitabine-tenofovir disoproxil fumarate (Truvada) has been approved for daily oral administration for pre-exposure prophylaxis (PrEP) as an HIV prevention strategy for people at elevated risk of HIV transmission.

Introduction

Remarkable advances in therapeutics, leading to the development of antiretroviral therapy (ART), have transformed HIV infection from an almost universally fatal illness to a chronic disease that can be managed over decades with an enlarging repertoire of treatment options. Further developments in antiretroviral therapy have also provided opportunities for preventing HIV infection in high-risk individuals. This chapter provides an overview of the current understanding of HIV pathogenesis, epidemiology, and reviews guidelines for the initial evaluation and long-term management of HIV infection in adult patients.

Pathophysiology

HIV is an enveloped, single-stranded RNA virus belonging to the family Retroviridae. It was recognized as the causative agent of AIDS within 3 years after the initial description of the syndrome in 1981, and ongoing characterization of its molecular biology has provided the identification of multiple targets for drug development. Two human immunodeficiency viruses exist: HIV-1 and HIV-2. HIV-1 has worldwide distribution, accounts for most infections outside western Africa, and is the focus of this chapter.

HIV-2 infection is endemic in West Africa and has limited spread outside this area. It should be considered in infections in patients of West African origin or those who have had sexual contact or shared needles with people of West African origin. HIV-2 generally has a longer asymptomatic stage, lower plasma HIV-2 viral loads, and overall lower mortality rate. Approximately 25–30% of patients with HIV-2 not receiving ART will have HIV-2 RNA levels below the rate of detection and some will also have clinical progression and CD4 cell count decline. HIV-2 can progress to AIDS over time. HIV-1 and HIV-2 coinfection may occur and should be a consideration in patients from HIV-2 high-prevalence areas. Patients diagnosed with HIV-2 infection should be managed by an HIV specialist.

Genetic heterogeneity of HIV-1 is reflected in categorization of the virus into three groups (M, O, and N) and several clades (e.g., B, C, D, AE, CRF01_AE), some of which have overlapping geographic distribution around the world. Subtype C is prevalent in southern and eastern Africa, China, India, South Asia, and Brazil and accounts for 50% of HIV subtypes, whereas subtype B, the most common subtype in the United States, accounts for 12%.

The HIV viral genome is encoded in single-stranded RNA, packaged in core protein structures, and surrounded by a lipid bilayer envelope that is derived from the cell membrane of the host cell as the virus buds from the cell surface after replication. This outer viral membrane contains HIV-specific glycoproteins, including gp120 and gp41, which facilitate attachment and entry into host cells through interaction with the cell surface receptor, CD4, and coreceptors CCR5 and CXCR4. CD4+ helper T lymphocytes are the predominant host cell affected by HIV; this molecular tropism explains the immune system destruction manifested in chronic HIV infection and provides the rationale for clinical staging of HIV infection using CD4+ T-cell counts. After host cell entry, the key enzyme responsible for viral replication is reverse transcriptase, an RNA-dependent DNA polymerase that is packaged within the virion core. This enzyme facilitates conversion of the HIV genome into a double-stranded DNA intermediate molecule. The second key enzymatic step is integration of this intermediate nucleic acid product into the host genome, which is facilitated by the viral protein integrase. Protein synthesis with packaging of new viral particles ensues, utilizing an HIV-specific protease. The integrase inhibitor class of drugs acts by blocking this step of integration.

Natural History

Within 1 to 4 weeks after the initial HIV infection, seroconversion may be accompanied by a nonspecific, self-limited illness, often referred to as the acute retroviral syndrome. This illness has variable manifestations but may include fever, malaise, myalgias, arthralgias, generalized lymphadenopathy, pharyngitis, and rash. The associated rash may be maculopapular, urticarial, or roseola-like. An illness resembling acute infectious mononucleosis syndrome, similar to that caused by Epstein-Barr virus or cytomegalovirus (CMV), and aseptic meningitis have been described. Diagnosis of acute HIV infection requires a high index of suspicion, which does not commonly occur unless the patient reports a recent history of a high-risk exposure.

During the acute phase of infection, high levels of viremia are present (often exceeding 10 million copies/mL) as HIV becomes widely disseminated throughout the body and the host defenses begin to counteract circulating virus through cell-mediated and

Further developments in antiretroviral therapy have also provided opportunities for preventing HIV infection in high-risk individuals. This chapter provides an overview of the current understanding of HIV pathogenesis, epidemiology, and reviews guidelines for the initial evaluation and long-term management of HIV infection in adult patients.

Pathophysiology

HIV is an enveloped, single-stranded RNA virus belonging to the family Retroviridae. It was recognized as the causative agent of AIDS within 3 years after the initial description of the syndrome in 1981, and ongoing characterization of its molecular biology has provided the identification of multiple targets for drug development. Two human immunodeficiency viruses exist: HIV-1 and HIV-2. HIV-1 has worldwide distribution, accounts for most infections outside western Africa, and is the focus of this chapter.

HIV-2 infection is endemic in West Africa and has limited spread outside this area. It should be considered in infections in patients of West African origin or those who have had sexual contact or shared needles with people of West African origin. HIV-2 generally has a longer asymptomatic stage, lower plasma HIV-2 viral loads, and overall lower mortality rate. Approximately 25–30% of patients with HIV-2 not receiving ART will have HIV-2 RNA levels below the rate of detection and some will also have clinical progression and CD4 cell count decline. HIV-2 can progress to AIDS over time. HIV-1 and HIV-2 coinfection may occur and should be a consideration in patients from HIV-2 high-prevalence areas. Patients diagnosed with HIV-2 infection should be managed by an HIV specialist.

Genetic heterogeneity of HIV-1 is reflected in categorization of the virus into three groups (M, O, and N) and several clades (e.g., B, C, D, AE, CRF01_AE), some of which have overlapping geographic distribution around the world. Subtype C is prevalent in southern and eastern Africa, China, India, South Asia, and Brazil and accounts for 50% of HIV subtypes, whereas subtype B, the most common subtype in the United States, accounts for 12%.

The HIV viral genome is encoded in single-stranded RNA, packaged in core protein structures, and surrounded by a lipid bilayer envelope that is derived from the cell membrane of the host cell as the virus buds from the cell surface after replication. This outer viral membrane contains HIV-specific glycoproteins, including gp120 and gp41, which facilitate attachment and entry into host cells through interaction with the cell surface receptor, CD4, and coreceptors CCR5 and CXCR4. CD4+ helper T lymphocytes are the predominant host cell affected by HIV; this molecular tropism explains the immune system destruction manifested in chronic HIV infection and provides the rationale for clinical staging of HIV infection using CD4+ T-cell counts. After host cell entry, the key enzyme responsible for viral replication is reverse transcriptase, an RNA-dependent DNA polymerase that is packaged within the virion core. This enzyme facilitates conversion of the HIV genome into a double-stranded DNA intermediate molecule. The second key enzymatic step is integration of this intermediate nucleic acid product into the host genome, which is facilitated by the viral protein integrase. Protein synthesis with packaging of new viral particles ensues, utilizing an HIV-specific protease. The integrase inhibitor class of drugs acts by blocking this step of integration.

Natural History

Within 1 to 4 weeks after the initial HIV infection, seroconversion may be accompanied by a nonspecific, self-limited illness, often referred to as the acute retroviral syndrome. This illness has variable manifestations but may include fever, malaise, myalgias, arthralgias, generalized lymphadenopathy, pharyngitis, and rash. The associated rash may be maculopapular, urticarial, or roseola-like. An illness resembling acute infectious mononucleosis syndrome, similar to that caused by Epstein-Barr virus or cytomegalovirus (CMV), and aseptic meningitis have been described. Diagnosis of acute HIV infection requires a high index of suspicion, which does not commonly occur unless the patient reports a recent history of a high-risk exposure.

During the acute phase of infection, high levels of viremia are present (often exceeding 10 million copies/mL) as HIV becomes widely disseminated throughout the body and the host defenses begin to counteract circulating virus through cell-mediated and

humoral (antibody-mediated) immune mechanisms. Antibodies against HIV usually become detectable between 2 to 4 months after infection. The initial, high-level viremia plateaus and then begins a decline as neutralizing antibodies are established. Ongoing replication is partially controlled by the immune response, resulting in a steady-state level of viremia. This virologic level differs from patient to patient and is one of the determinants of the rate of disease progression. A small number of HIV-infected persons are able to control viral replication to levels below the limit of detection, and they tend to have a more benign course of disease. In these patients, designated elite suppressors by researchers, HIV replication continues to occur, and HIV RNA can be isolated from latently infected cells by means of specialized laboratory techniques.

After the establishment of HIV infection and seroconversion, a period of asymptomatic infection ensues, during which patients are free of evidence of immune suppression and opportunistic infections (OIs) are uncommon. This phase of clinical latency lasts a median of 8 to 10 years, based on observational studies from the pre-ART era. Ongoing viral replication leads to gradual decline in CD4 counts.

The symptomatic stage of HIV infection can begin at any time after infection, but clinical manifestations become more likely as the CD4 count falls farther below the normal range of 800 to 1200 cells/mm³. For example, *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia (PJP) usually occurs in patients with a CD4 count of less than 200 cells/mm³ or a percentage of less than 10%. CMV retinitis occurs almost exclusively in patients with a CD4 count of less than 50 cells/mm³ or a percentage of less than 5%. Mucocutaneous candidiasis (oral thrush), herpes zoster, HIV-associated nephropathy, peripheral neuropathy, tuberculosis, and community-acquired bacterial pneumonia occur with increased frequency at earlier stages of infection and less reliably predicted by CD4⁺ cell measurement.

Diagnosis

The current recommended testing algorithm incorporates fourth-generation antigen/antibody combination HIV-1/2 immunoassay with a confirmatory HIV-1/HIV-2 antibody differentiation immunoassay. The fourth-generation assay detects both HIV-1 and HIV-2 antibodies and HIV p24 antigen. It has increased sensitivity due to its ability to diagnose acute/early infection as HIV p24 antigen is detected before seroconversion has occurred. If the fourth-generation combination assay is positive, the HIV-1 and HIV-2 antibody differentiation immunoassay both confirms the positive result and determines if the patient is infected with HIV-1 or HIV-2. If the fourth-generation assay is positive but the confirmatory antibody differentiation immunoassay is indeterminate or negative, a plasma HIV RNA level should be obtained.

In facilities where fourth-generation testing is not available, a two-step approach is utilized via enzyme-linked immunosorbent assay (ELISA) to detect HIV antibodies with subsequent confirmation using HIV-1/HIV-2 differentiation assay. ELISA detects HIV IgM and IgG antibodies as early as 3 weeks after virus exposure. This modality has excellent sensitivity and specificity for diagnosing chronic HIV infection; however, diagnosis may be missed in patients with early HIV infection who have not yet had seroconversion. If concern exists for acute/early HIV infection, plasma HIV RNA can be assessed.

Uncommonly, false-negative and false-positive tests occur. False-negative screening tests can occur with ELISA-only testing during acute/early HIV infection. This occurs less often using the fourth-generation antigen/antibody assay, which is more sensitive in detecting early HIV infection by identifying the p24 antigen. False-positive screening test results can occur for several non-HIV reasons, including cross-reaction from alloantibodies in pregnant females, autoantibodies from autoimmune diseases or malignancy, and the influenza vaccine. False-positive results in both screening and confirmatory testing are exceptionally uncommon.

Indeterminate test results occur when the initial screening test is positive and subsequent confirmatory testing is indeterminate or negative. In the event of a positive fourth-generation antigen/antibody test and negative HIV differentiation assay, the detection of p24 antigen would yield a positive result but the differentiation assay would be negative, as no antibody is present. In all patients with indeterminate test results, a plasma HIV RNA should be obtained, as viremia is present prior to antibody seroconversion. A detectable plasma HIV RNA level is diagnostic of HIV infection. If HIV RNA is negative, the patient should be reassured that HIV infection is unlikely. A repeat screening test can be repeated after 3 months for further reassurance. If the patient had a recent high-risk exposure, another plasma HIV RNA can be performed in 1–2 weeks. All patients with indeterminate testing should be counseled to avoid activities with potential to transmit HIV to others until evaluation is completed.

Consent

HIV screening should be voluntary and pursued only after discussion with the patient regarding testing. In the United States, written consent is no longer obligatory in any state, but individual states may have policies regarding documentation of the consent process and related counseling. Confidentiality, access to post-testing counseling, and services to support prompt linkage to HIV care for patients with positive results are important resources in HIV testing settings.

Screening

Early detection of HIV infection and subsequent initiation of antiretroviral therapy can dramatically reduce morbidity and mortality of affected patients. A relatively normal life span is obtainable in patients in the United States who are diagnosed early in their infection and successfully treated. It also can reduce the transmission of HIV. One-time testing is recommended for patients without high-risk factors for HIV exposure in patients 13–75 years of age. Pregnant women should be screened for HIV early in their pregnancy even if they have been screened during prior pregnancies.

In patients with elevated risk of HIV exposure, more frequent testing is recommended. Men who have sex with men, with sexual partners who have HIV, or those with unknown serostatus may benefit from HIV screening at least every 6 months. This is especially important in patients ages 13–24 years, as this demographic has experienced the highest rate of new infections in recent years. Other high-risk groups include patients who use injection drugs and sex workers.

Approach to the Patient With HIV Infection

HIV patient care is an ever-changing field, with routinely updated professional guidelines and new medications. The quality of care received by patients with HIV has been shown to correlate with the health care provider's experience and comfort in treating these patients. Referral to an HIV specialist is recommended for new HIV diagnoses, complications of HIV or antiretroviral drugs, and for treatment failure.

All patients with HIV should have a comprehensive history, physical examination, and laboratory evaluation when establishing care. This baseline evaluation can help establish and define the patient's goals and plan of care. In a patient who has already established treatment with ART and presents for initial evaluation with a new health care provider, it is important to document their complete antiretroviral history and drug resistance testing results if available.

Patients with HIV are often faced with many medical, psychiatric, and social issues. These are best addressed through a patient-centered, multidisciplinary approach. In a patient with a new diagnosis of HIV, it is important to counsel the patient regarding HIV infection and assess their understanding of about the disease and its transmission. They should also be assessed for readiness to initiate ART, potential high-risk behaviors, mental illness, substance abuse, social support, medical comorbidities, and/or

economic factors, as these are potential issues that may impair adherence to ART.

Antiretroviral Therapy

There are currently six major classes of antiretroviral medications used to treat patients with HIV. Though there are dozens of medications available, only a small selection of agents are currently preferred as initial treatment regimens (Table 1). For most patients, ART includes a combination of two nucleoside analogue reverse transcriptase inhibitors (NRTIs) plus a third medication from a different class.

When to Initiate Antiretroviral Therapy

Combination ART first became available in the mid-1990s and provided life-saving therapy for millions of patients suffering from HIV and AIDS. While the early ART regimens were effective in helping patients with AIDS recover, they were also associated with many toxicities and side effects. In 2006, the U.S.

Department of Health and Human Services, the International AIDS Society—USA, and the British HIV Society recommended CD4 counts of 200 cells/mm³ as the threshold for initiating ART treatment in asymptomatic patients. In the last decade, the paradigm has shifted toward earlier initiation of ART based on accumulating evidence for the beneficial effects of treatment initiation earlier in the course of infection. Antiretroviral therapies have advanced significantly since their conception, consisting of multiple drug classes, less toxicities, less pill burden, and overall improved tolerance. Failure to suppress viral loads on these medications is more likely to be due to therapy nonadherence than medication failure.

HIV patients are now achieving normal life spans, and non-AIDS-defining illnesses are becoming more prominent. Cardiovascular, renal, and hepatic disease complications are lower in patients who started ART at higher CD4 thresholds (>350 cells/mm³). Earlier initiation of ART is also associated with reduced risk of transmission and improved immune restoration.

TABLE 1 Preferred Initial Antiretroviral Medication Regimens for Most Patients

Generic name (trade name) and recommended adult dosing	Single tablet regimen?	Important points
INSTI + 2 NRTIs		
Bictegravir/emtricitabine/tenofovir alafenamide (Biktarvy®) 50/200/25 mg – 1 tablet by mouth once daily	Yes	Bictegravir has been shown to raise serum creatinine from baseline by a median 0.1mg/dL due to inhibition of creatinine secretion, not a true reduction in GFR Bictegravir has a drug interaction with metformin. The magnitude of this effect may be less than dolutegravir (Tivicay), but there is no guidance for metformin dose adjustment. The risks and benefits of this combination should be weighed if using concomitantly.
Dolutegravir/abacavir/lamivudine (Triumeq®) 50/600/300 mg – 1 tablet by mouth once daily	Yes	Dolutegravir has been shown to raise serum creatinine from baseline by a mean of 0.1 mg/dL due to inhibition of creatinine secretion, not a true reduction in GFR Dolutegravir has a drug interaction with metformin (maximum daily metformin dose is 1000 mg) Must be confirmed HLA-B*5701 negative before starting to avoid abacavir hypersensitivity reaction
Dolutegravir (Tivicay®) 50 mg - 1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy®) 25/200 mg - 1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada®) 300/200 mg - 1 tablet by mouth once daily	No	Dolutegravir has been shown to raise serum creatinine from baseline by a mean of 0.1 mg/dL due to inhibition of creatinine secretion, not a true reduction in GFR Dolutegravir has a drug interaction with metformin (maximum daily metformin dose is 1000 mg) Descovy® generally preferred over Truvada® due to fewer bone and kidney toxicities
Elvitegravir/cobicistat/tenofovir alafenamide/emtricitabine (Genvoya®) 150/150/10/200 mg – 1 tablet by mouth once daily OR Elvitegravir/cobicistat/tenofovir disoproxil fumarate/emtricitabine (Stribild®) 150/150/300/200 mg – 1 tablet by mouth once daily	Yes	Genvoya® generally preferred over Stribild® due to fewer bone and kidney toxicities Drug interactions with other medications are prevalent with both products due to cobicistat, a CYP3A4 inhibitor
Raltegravir (Isentress HD®) 600 mg – 2 tablets by mouth once daily OR Raltegravir (Isentress®) 400 mg – 1 tablet by mouth twice daily PLUS Tenofovir alafenamide/emtricitabine (Descovy®) 25/200 mg - 1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada®) 300/200 mg - 1 tablet by mouth once daily	No	Isentress HD® generally preferred over Isentress® due to once daily dosing Descovy® generally preferred over Truvada® due to fewer bone and kidney toxicities

Current Recommendations for Antiretroviral Therapy

ART should be offered to all patients with HIV infection, regardless of CD4 count. The goal of ART is to prevent morbidity, mortality, and transmission associated with HIV. This is accomplished by maximally inhibiting HIV replication to achieve an undetectable HIV viral load. Based on guidelines from the U.S. Department of Health and Human Services, integrase strand transfer inhibitors (INSTI)-based regimens are

currently the first-line recommendation as initial therapy for most patients with HIV based on high rates of virologic suppression and tolerability demonstrated in large clinical trials. Non-nucleoside reverse transcriptase (NNRTI)- and protease inhibitor (PI)-based regimens are recommended in certain clinical situations (Table 2). Monotherapy with any antiretroviral drug is not recommended due to increased risk of drug resistance and therapy failure.

TABLE 2 Alternative Initial Antiretroviral Medication Regimens Appropriate for Some Patients

Generic name (trade name) and recommended adult dosing	Single tablet regimen?	Important points
INSTI + 2 NRTIs		
Raltegravir (Isentress HD [®]) 600 mg – 2 tablets by mouth once daily OR Raltegravir (Isentress [®]) 400 mg – 1 tablet by mouth twice daily PLUS Abacavir/Lamivudine (Epzicom [®]) 600/300 mg - 1 tablet by mouth once daily	No	Isentress HD [®] generally preferred over Isentress [®] due to once daily dosing Must be confirmed HLA-B*5701 negative before starting to avoid abacavir hypersensitivity reaction
NNRTI + 2 NRTIs		
Rilpivirine/tenofovir alafenamide/emtricitabine (Odefsey [®]) 25/25/200 mg – 1 tablet by mouth once daily OR Rilpivirine/tenofovir disoproxil fumarate/emtricitabine (Complera [®]) 25/300/200 mg – 1 tablet by mouth once daily	Yes	Rilpivirine should only be used if HIV RNA <100,000 copies/mL and CD4 >200 cells/mm ³ Odefsey [®] generally preferred over Complera [®] due to fewer bone and kidney toxicities PPIs contraindicated with rilpivirine. H2 blockers may be used once daily, but must be spaced 12 hours apart from rilpivirine. Should be taken with food
Efavirenz/tenofovir disoproxil fumarate/emtricitabine (Atripla [®]) 600/300/200 mg – 1 tablet by mouth once daily	Yes	High rates of neuropsychiatric adverse effects (e.g., vivid dreams, depression, suicidal ideation)
Boosted PI + 2 NRTIs		
Darunavir/cobicistat (Prezcobix [®]) 800/150 mg – 1 tablet by mouth once daily OR Darunavir (Prezista [®]) 800mg – 1 tablet by mouth once daily + Ritonavir (Norvir [®]) 100 mg – 1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy [®]) 25/200 mg - 1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada [®]) 300/200 mg - 1 tablet by mouth once daily OR Abacavir/Lamivudine (Epzicom [®]) 600/300 mg - 1 tablet by mouth once daily	No	Prezcobix [®] generally preferred over the combination of Prezista [®] and Norvir [®] due to single tablet and potentially fewer GI side effects and drug interactions Drug interactions with other medications are prevalent with both cobicistat and ritonavir due to CYP3A4 inhibition. Ritonavir also inhibits and induces several other CYP enzymes. Careful attention should be given to manage drug interactions. Descovy [®] generally preferred over Truvada [®] due to fewer bone and kidney toxicities If using Epzicom [®] , must be confirmed HLA-B*5701 negative before starting to avoid abacavir hypersensitivity reaction
Atazanavir/cobicistat (Evotaz [®]) 300/150 mg – 1 tablet by mouth once daily OR Atazanavir (Reyataz [®]) 300 mg – 1 tablet by mouth once daily + Ritonavir (Norvir [®]) 100 mg – 1 tablet by mouth once daily PLUS Tenofovir alafenamide/emtricitabine (Descovy [®]) 25/200 mg - 1 tablet by mouth once daily OR Tenofovir disoproxil fumarate/emtricitabine (Truvada [®]) 300/200mg - 1 tablet by mouth once daily OR Abacavir/Lamivudine (Epzicom [®]) 600/300 mg - 1 tablet by mouth once daily	No	Evotaz [®] generally preferred over the combination of Reyataz [®] and Norvir [®] due to single tablet and potentially fewer GI side effects and drug interactions Drug interactions with other medications are prevalent with both cobicistat and ritonavir due to CYP3A4 inhibition. Ritonavir also inhibits and induces several other CYP enzymes. Careful attention should be given to manage drug interactions. Descovy [®] generally preferred over Truvada [®] due to fewer bone and kidney toxicities If using Epzicom [®] , must be confirmed HLA-B*5701 negative before starting to avoid abacavir hypersensitivity reaction

^bAbbreviations: INSTI = integrase strand transfer inhibitor; NRTI = nucleoside reverse transcriptase inhibitor; HLA = human leukocyte antigen; NNRTI = non-nucleoside reverse transcriptase inhibitor; PPI = proton pump inhibitor; H2 = histamine H2 receptor; PI = protease inhibitor; CYP3A4 = cytochrome P450 3A4.

Selection of an Antiretroviral Regimen

ART regimens should be individualized based on a regimen's side effect profile, pill burden, potential drug interactions, virologic efficacy, cost, and resistance test results. Before starting ART in any patient with HIV, the following factors must be considered:

- Pretreatment HIV RNA level
- Pretreatment CD4 count
- HIV genotypic drug resistance testing results
- HLA-B*5701 status (if planning to use abacavir-based ART regimen)
- A patient's individual preference
- Anticipated medication adherence

Other factors that are important to consider when choosing an initial regimen include the patient's medical comorbidities (cardiovascular, renal, psychiatric disease), pregnancy or the potential to become pregnant, and co-infections with tuberculosis, hepatitis C virus, and hepatitis B virus.

The currently recommended ART for treatment-naïve patients usually includes two NRTIs, abacavir/lamivudine (ABC/3TC, Epzicom), or either tenofovir alafenamide/emtricitabine (TAF/FTC, Descovy) or tenofovir disoproxil fumarate (TDF/FTC, Truvada), plus an agent from one of the following classes: INSTI, NNRTI, or a PK-enhanced PI. These recommendations are based on regimens that are well tolerated, have convenient dosing, and provide excellent virologic suppression.

The NRTI combinations of ABC/3TC, TAF/FTC, and TDF/FTC are available as fixed-dose combination tablets. The 3TC and FTC components have few adverse effects. The main differences between these combinations involve ABC, TAF, and TDF. The advantages of TAF and TDF include activity against hepatitis B virus, and HLA-B*5701 testing is not required prior to use. TDF has some association with lower lipid levels when compared to TAF, but also may cause decline in renal function and reduced bone mineral density. TAF is associated with less bone and kidney toxicity and its use is preferred in patients with underlying bone and kidney disease or those at risk for these conditions. The advantage of ABC is that it has less bone mineral loss and less nephrotoxicity than TDF and

does not require dose adjustment in patients with renal insufficiency. A potential drawback to ABC is an observed association with cardiovascular events in some observational studies.

Once the combination NRTI backbone has been chosen, a third drug from either the INSTI, PI, or NNRTI drug classes must be added to the regimen. Current recommendations for most treatment-naïve HIV patients favor the INSTI class due to its high efficacy, fewer side effects, and no significant CYP3A4-associated drug interactions.

Darunavir (DRV, Prezista)-based regimens may still be preferred in certain patients with difficulty maintaining medication adherence, and a high genetic barrier to resistance is favored or in a situation when ART should be initiated prior to receipt of resistance test results. Darunavir boosted with ritonavir (Norvir) (DRV/r) has a low rate of transmitted PI resistance, high genetic barrier to resistance, and a low rate of treatment-emergent resistance. Dolutegravir (DTG, Tivicay) is also a consideration for patients in whom it is necessary to initiate ART prior to resistance testing results due to its high barrier of resistance.

NNRTI-based regimens include efavirenz (EFV, Sustiva) or rilpivirine (RPV, Edurant) and may be appropriate choices in certain patients with good medication adherence. These medications have a low genetic barrier to resistance. EFV has minimal PK interactions with rifamycins, which makes it an excellent option in patients requiring treatment for tuberculosis. EFV has a high rate of central nervous system-related side effects, which lowers its overall tolerability for some patients. RPV has fewer side effects than EFV, but its virologic efficacy is reduced in patients with high baseline HIV RNA and low CD4 counts.

Monitoring Response to Antiretroviral Therapy

HIV disease progression and response to ART can be monitored via CD4 T lymphocyte (CD4) cell count and HIV RNA (viral load). CD4 count should be measured prior to initiation of ART and provides information regarding the patient's immune function and risk of opportunistic infection. Recommendations for monitoring viral load and CD4 count are shown in [Table 3](#).

TABLE 3 Recommendations on the Indications and Frequency of Viral Load and CD4 Count

CLINICAL SCENARIO	VIRAL LOAD MONITORING	CD4 COUNT MONITORING
Before initiating ART	At entry into care If ART initiation is deferred, repeat before initiating ART. In patients not initiating ART, repeat testing is optional.	At entry into care If ART is deferred, every 3–6 months
After initiating ART	Preferably within 2–4 weeks (and no later than 8 weeks) after initiation of ART; thereafter, every 4–8 weeks until viral load is suppressed.	3 months after initiation of ART
After modifying ART because of drug toxicities or for regimen simplification in a patient with viral suppression	4–8 weeks after modification of ART to confirm effectiveness of new regimen.	Monitor according to prior CD4 count and duration on ART, as outlined below.
After modifying ART because of virologic failure	Preferably within 2–4 weeks (and no later than 8 weeks) after modification; thereafter, every 4–8 weeks until viral load is suppressed. If viral suppression is not possible, repeat viral load every 3 months or more frequently if indicated.	Every 3–6 months
During the first 2 years of ART	Every 3–4 months	Every 3–6 months
After 2 years of ART (VL consistently suppressed, CD4 consistently 300–500 cells/mm ³) After 2 years of ART (VL consistently suppressed, CD4 consistently >500 cells/mm ³)	Can extend to every 6 months for patients with consistent viral suppression for greater than or equal to 2 years.	Every 12 months Optional
While on ART with detectable viremia (VL repeatedly >200 copies/mL)	Every 3 months or more frequently if clinically indicated.	Every 3–6 months
Change in clinical status	Every 3 months.	Perform CD4 count and repeat as clinically indicated

TABLE 4 Monitoring Recommendations for Antiretroviral Toxicity of Selected Drugs

DRUG	TOXICITY	MONITORING
NRTIs		
Abacavir (Ziagen)	Liver Abacavir hypersensitivity syndrome	LFTs Screening for HLA-B*5701 (should be confirmed negative prior to abacavir initiation) Symptoms of abacavir hypersensitivity may include fever, rash, nausea, vomiting, diarrhea, abdominal pain, malaise, fatigue, or respiratory symptoms such as sore throat, cough, or shortness of breath
Emtricitabine (Emtriva)	Minimal toxicity Liver Hyperpigmentation/skin discoloration	Serum creatinine LFTs Hepatitis B (prior to initiation of therapy) Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue emtricitabine. In patients where discontinuation of tenofovir is necessary, ensure an agent active against HBV is administered.
Lamivudine (Epivir)	Minimal toxicity Liver	Serum creatinine LFTs Hepatitis B (prior to initiation of therapy) Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue lamivudine. In patients where discontinuation of tenofovir is necessary, ensure an agent active against HBV is administered.
Tenofovir (disoproxil fumarate [Viread], alafenamide [Vemlidy])	Renal toxicity (tubulopathy) Decreases in bone mineral density Liver	Serum creatinine Urine glucose and protein (prior to initiation and as clinically indicated during therapy) Serum phosphorus (in patients with chronic kidney disease) Bone mineral density testing (if history of bone fracture or risk factors for bone loss) LFTs Hepatitis B (prior to initiation of therapy) Tenofovir alafenamide (Vemlidy) is associated with lower rates of bone and kidney toxicity compared to tenofovir disoproxil fumarate Severe acute exacerbation of hepatitis may occur in patients with HBV/HIV coinfection who discontinue tenofovir. In patients where discontinuation of tenofovir is necessary, ensure an agent active against HBV is administered.
All others		Put lactic acidosis, hepatic steatosis, lipodystrophy, insulin resistance in the text
NNRTIs		
Efavirenz (Sustiva)	Rash Neuropsychiatric symptoms Hyperlipidemia Hepatotoxicity QT interval prolongation	LFTs Lipid panel (prior to therapy periodically during) Signs and symptoms of neuropsychiatric effects (e.g., vivid dreams, depression, suicidal ideation)
Rilpivirine (Edurant)	Rash Depression, insomnia, Headache Hepatotoxicity QT interval prolongation	LFTs Lipid panel
PIs		
All	GI intolerance, nausea, vomiting, diarrhea Hyperglycemia Insulin resistance Hepatotoxicity Fat maldistribution Hyperlipidemia	Serum glucose LFTs (at baseline and as clinically indicated thereafter)
Atazanavir (Reyataz)	Indirect hyperbilirubinemia	Bilirubin
Darunavir (Prezista)	Skin rash	Darunavir contains a sulfonamide moiety; Stevens-Johnson syndrome, toxic epidermal necrolysis, acute generalized exanthematous pustulosis, and erythema have been reported. Risk of cross-reactivity between darunavir and sulfonamide medications is very low. However, use caution in patients with severe sulfonamide allergies.

Continued

TABLE 4 Monitoring Recommendations for Antiretroviral Toxicity of Selected Drugs—cont'd

DRUG	TOXICITY	MONITORING
INSTIs		
All	INSTIs typically well tolerated for most patients GI intolerance Insomnia Headache Depression and suicidal ideation (rare, usually in patients with pre-existing psychiatric conditions) CPK elevation, muscle weakness, and rhabdomyolysis (primarily reported with raltegravir [Isentress])	LFTs Serum creatinine (dolutegravir [Tivicay] and bictegravir) CPK (if signs of muscle toxicity)

^aAdapted from: Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents Living with HIV. Department of Health and Human Services. Available at <http://aidsinfo.nih.gov/contentfiles/lvguidelines/AdultandAdolescentGL.pdf>. Section accessed April 19, 2018 [Appendix B, tables 1-4].

^bAbbreviations: NRTI = nucleoside reverse transcriptase inhibitor; LFT = liver function test; HLA = human leukocyte antigen; HBV = hepatitis B virus; HIV = human immunodeficiency virus; NNRTI = non-nucleoside reverse transcriptase inhibitor; PI = protease inhibitor; GI = gastrointestinal; INSTI = integrase strand transfer inhibitor; CPK = creatinine phosphokinase.

Table is not all inclusive.

CD4 counts can be highly variable, and significant change is only considered with 30% difference in absolute count or an increase or decrease in CD4 percentage by 3 percentage points. CD4 cell recovery is most rapid in the first 3 months after initiating ART, later followed by more gradual increases. For most patients on ART, adequate response is considered as an increase in CD4 count in the range of 50–150 cells/mm³ during the first year of treatment. Subsequent increases may average 50–100 cells/mm³ per year until a steady-state level is reached. Peripheral blood CD4 cell counts in most HIV patients will continue to increase over a decade as long as viral suppression is maintained. Most individuals will eventually recover CD4 counts within the normal range (>500 cells/mm³). For approximately 15–20% of patients, especially those that initiate ART at very low CD4 counts (<200 cells/mm³), low CD4 counts may persist, which is associated with increased morbidity and mortality. These patients should be evaluated for reversible causes of CD4 cell lymphopenia, including offending medications, untreated co-infections, and underlying malignancy. In patients with appropriate virologic suppression, addition of more antiretroviral agents or transitioning to a different ART regimen has not been demonstrated to improve CD4 cell recovery.

CD4 counts should be repeated 3 months after ART initiation to monitor immune reconstitution and can be monitored in many patients at 3-to-6 month intervals for the first 2 years of ART. In virally suppressed patients with consistent CD4 counts between 300 and 500 cells/mm³ for at least 2 years, CD4 can be checked annually. While ART is recommended for all patients with HIV, patients who remain untreated should have CD4 counts monitored every 3–6 months to assess for the need for OI prophylaxis.

Viral load functions as a marker for ART response and should be monitored at initiation of therapy and regularly thereafter. Pre-treatment viral load can also provide useful information regarding selection of an initial ART. Commercially available HIV-1 RNA assays do not detect HIV-2 viral load. Decreases in viral load following ART initiation are associated with reduction in risk of disease progression to AIDS or death. Optimal viral suppression is defined as a viral load persistently below the level of detection. Low-level viremia refers to a patient with confirmed detectable HIV RNA <200 copies/mL. This may be detected using real-time polymerase chain reaction (PCR) assays and may be predictive of developing viral rebound. Viral rebound, or virologic failure, is considered to occur when a patient with confirmed virologic suppression has HIV RNA greater than or equal to 1,000 copies/mL. If virologic suppression occurs and the patient is found to have a single isolated detectable HIV RNA level with return to virologic suppression in subsequent tests, this is referred to as a virologic blip. This is not usually associated with

virologic failure and they do not require a change in ART. Acute illness, stress, and recent immunizations are a few potential causes of virologic blips. A repeat viral load can be rechecked in 3 months to confirm return to appropriate viral suppression.

If a patient has a very high HIV viral load at the time of ART initiation, it may take several weeks for a measurable virologic response to occur. Certain ART regimens may also have slower rates of virologic suppression than others. A patient who has received ART for at least 24 weeks and has not yet had documented virologic suppression should be evaluated for antiretroviral drug resistance.

Treatment Failure

Patients receiving ART who do not achieve HIV RNA levels below the lower limit of detection or who are shown to have sustained virologic rebound are at risk for developing resistance mutations to their current ART regimen, especially at HIV RNA levels >500 copies/mL. Virologic failure has a strong association with suboptimal medication adherence and drug intolerance/toxicity leading to self-discontinuation of ART.

Some factors that may increase the risk of ART nonadherence include active substance use, neurocognitive impairment, and mental health disorders. Unstable housing and other socioeconomic and psychosocial factors can make ART adherence particularly difficult. The patient's inability to afford the medication may lead to intermittent adherence or nonadherence. Some patients will stop taking ART due to adverse effects of their regimen. Others may not be able to adhere to a high pill burden or frequency of dosing.

Less common causes of treatment failure include existing or newly developed drug resistance. Patients with HIV-2 or HIV-1/HIV-2 coinfection can have innate resistance to certain ART regimens. Others may have adverse drug–drug interactions with other medications, suboptimal virologic potency, or error in their medication prescription.

If a patient is experiencing virologic failure, it is important to determine the cause because there is potential for choosing a subsequent therapy regimen that promotes better adherence. Management of a patient experiencing treatment failure is often complex and benefits from consultation with an HIV specialist.

Drug Resistance and Resistance Testing

Two types of resistance assays exist to assess viral strains and direct treatment strategies: genotypic and phenotypic. These assays provide useful information regarding resistance to NRTIs, NNRTIs, PIs, and INSTIs. In some settings, INSTI resistance tests must be ordered separately. In patients with newly diagnosed HIV infection, resistance

testing can guide therapy selection to optimize virologic response. Genotypic assays detect drug resistance mutations by sequencing reverse transcriptase, protease, and integrase genes. Interpreting these test results requires knowledge of the mutations selected by different antivirals and the potential for cross-resistance to other drugs. Clinical trials have shown that consulting with HIV specialists regarding drug resistance interpretation improves virologic outcomes.

Adverse Drug Reactions and Drug-Drug Interactions

All providers caring for patients who receive ART should be aware of the possibility of antiretroviral drug interactions. The use of the pharmacokinetic enhancing agents, ritonavir (Norvir) and cobicistat (Tybost), in many combination ART regimens can pose serious risks to patients receiving other drugs metabolized through the cytochrome P450 pathway, including numerous anticoagulant drugs and synthetic glucocorticoids. When prescribing or altering one or more drugs in an ART regimen, the potential for drug interactions must be explored. It is critical to carefully review the patient's other medications for potential interactions. If multiple drugs with similar or conflicting metabolic pathways are prescribed, health care providers should carefully monitor for appropriate therapeutic efficacy and concentration-related toxicities.

Viral Hepatitis Coinfection

Approximately 5–10% of patients with HIV in the United States have co-infection with chronic hepatitis B virus (HBV). Disease progression to cirrhosis, end-stage liver disease, and hepatocellular carcinoma is more rapid in these patients. Some antiretroviral toxicities and complications may be attributed to flares of HBV after initiation or discontinuation of ART.

FTC, 3TC, TDF, and TAF are approved for treatment of HIV and are also active against HBV. Discontinuation of these drugs can potentially cause significant hepatic damage due to reactivation of HBV. The anti-HBV drug entecavir (Baraclude) has activity against HIV. When entecavir is used to treat HBV in patients with HBV/HIV coinfection who are not taking ART, the drug can select for M184V mutation, resulting in HIV resistance to 3TC and FTC. When 3TC is the only active drug used to treat HBV in coinfecting patients, 3TC resistance develops in approximately 40–90% of patients after 2–4 years on 3TC monotherapy.

Before ART is initiated, all patients who test positive for HBV surface Ag (HBsAg) should also be tested for HBV DNA using a quantitative assay. This test should be repeated every 3–6 months to ensure effective HBV suppression. In patients with HBV/HIV coinfection, immune reconstitution following initiation of treatment for HIV, HBV, or both can be associated with elevated transaminases.

Complications

Diagnosis and Management of Opportunistic Infections (OI)

Widespread availability and use of ART has significantly reduced OI-related mortality in persons with HIV infection. OIs continue to cause considerable morbidity and mortality, however, due to the increasing number of undiagnosed cases of HIV and those with known HIV infection but who are not on ART or unable to maintain adherence to ART.

Pneumocystis pneumonia (PJP) is an infection caused by a ubiquitous fungus, *Pneumocystis jirovecii*. Most cases occur in patients with an advanced compromised immune system (CD4 count <100 cells/mm³). The most common manifestations are dyspnea, fever, nonproductive cough, and chest discomfort. Onset of symptoms is usually subacute and progressive over days to weeks. Mild cases may present with normal pulmonary physical exam findings at rest but develop dyspnea, tachycardia, and rales with exertion. Hypoxemia is often present to varying severity. Lab findings are consistent with lactate dehydrogenase levels >500 mg/dL and elevated serum 1,3 beta-d-glucan. Chest radiography may show diffuse, bilateral, ground-glass interstitial infiltrates, but chest radiography can appear unremarkable in patients with early disease. In patients with normal chest plain films, computed tomography (CT) of the chest can show underlying abnormalities consistent with PJP. HIV-

infected patients, including pregnant women and those on ART, should receive PJP chemoprophylaxis if they have CD4 counts <200 cells/mm³. Patients receiving pyrimethamine (Daraprim)-sulfadiazine for treatment or suppression of toxoplasmosis do not require additional prophylaxis for PJP. Trimethoprim-sulfamethoxazole (TMP-SMX, Bactrim) is the first-line prophylactic agent at one double-strength tablet daily (which also confers prophylaxis against toxoplasmosis¹) or three times weekly. In those who cannot tolerate TMP-SMX, alternative prophylactic options include dapsone¹, dapsone plus pyrimethamine¹ plus leucovorin¹, aerosolized pentamidine (Nebupent), and atovaquone (Mepron).

Toxoplasma gondii is a protozoan infection and is associated with reactivation of latent tissue cysts. Patients at greatest risk have CD4 counts <50 cells/uL. Clinical disease is rare in patients with CD4 counts >200 cells/uL. In patients with AIDS, the typical presentation of infection is focal encephalitis including headache, confusion, focal motor weakness, and fever. In the absence of treatment, disease progression may lead to seizures, coma, and death. CT and MRI of the brain may show multiple contrast-enhancing lesions within the gray matter of the cortex or basal ganglia, often with associated edema. HIV-infected patients with toxoplasma encephalitis are usually seropositive for *Toxoplasma* IgG antibodies. Definitive diagnosis requires the combination of clinical presentation, identification of one or more mass lesions via CT or MRI, and detection of the organism in a sample, with brain biopsy being the most preferred method. Therapy of choice includes pyrimethamine plus sulfadiazine plus leucovorin¹.

Disseminated *Mycobacterium avium* Complex (MAC) disease typically occurs in patients with CD4 counts <50 cells/mm³. Other factors associated with increased susceptibility to MAC disease include HIV RNA levels >100,000 copies/mL, previous opportunistic infections, and previous colonization of the respiratory or gastrointestinal tract with MAC. In HIV-infected patients with AIDS who are not on ART, MAC disease usually presents as a disseminated, multi-organ infection. Symptoms may be minimal at first but may include fever, night sweats, weight loss, diarrhea, fatigue, and nonspecific abdominal pain. Lab abnormalities may include anemia out of proportion for that expected from HIV alone and an increase in liver alkaline phosphatase. Physical exam or imaging may note nonspecific hepatomegaly, lymphadenopathy, and/or splenomegaly. Diagnosis is based on a combination of clinical symptoms and the isolation of MAC from cultures obtained from blood, lymph nodes, bone marrow, or other sterile sites. Initial treatment should consist of at least two antimycobacterial medications in an effort to prevent development of resistance. Infectious disease specialists should be consulted regarding treatment. MAC isolates should be tested for susceptibility to clarithromycin (Biaxin) and azithromycin (Zithromax).

Cryptococcus neoformans meningitis occurs more commonly in patients with CD4 counts <100 cells/uL. It can present as a subacute or acute meningoencephalitis associated with fever, headache, and malaise. Classic meningeal symptoms may be absent. Disseminated disease is usually present when diagnosed in a patient with HIV infection and can involve virtually any organ. Diagnosis of meningitis via cerebral spinal fluid (CSF) often demonstrates elevated opening pressure, elevated protein, low-to-normal glucose, and lymphocytic pleocytosis. Numerous yeast forms may be visualized on Gram stain or India ink preparations of CSF. CSF Cryptococcal antigen (CrAg) is often positive. Serum CrAg may be positive in both meningeal and non-meningeal involving infections and its presence can be detected weeks to months prior to the onset of symptoms. A positive serum CrAg should proceed to lumbar puncture to rule out meningeal disease. Treatment of cryptococcosis occurs in three stages: induction, consolidation, and maintenance therapy.

Cytomegalovirus (CMV) disease can cause disseminated and localized end-organ damage in HIV-infected patients with

¹Not FDA approved for this indication.

suppressed immune states with CD4 counts <50 cells/mm³. Clinical disease is usually the result of reactivation of latent infection. Risk factors include not receiving/failure to respond to ART, previous OIs, high level of CMV viremia, and high HIV viral load ($>100,000$ copies/mL). Retinitis is the most common clinical manifestation of CMV end-organ disease and is often unilateral but can progress to bilateral if therapy or immune recovery are not pursued. Retinitis may present with floaters, scotomata, or peripheral visual field defects. Colitis is another manifestation of CMV disease and may be associated with weight loss, abdominal pain, significant diarrhea, and malaise. Hemorrhage and bowel perforation can be life-threatening. CMV viremia can be measured via PCR and is usually present in end-organ disease.

Mucocutaneous candidiasis of the oropharynx and esophagus occurs commonly in HIV-infected patients and is often an indication of underlying immune suppression (CD4 count <200 cells/mm³). Oropharyngeal candidiasis is usually painless and affects the oropharyngeal mucosa and tongue surface. Esophageal candidiasis may be associated with retrosternal discomfort and odynophagia. Oropharyngeal candidiasis is usually diagnosed clinically. Diagnosis of esophageal candidiasis is made based on symptoms, response to therapy, or visualization of mucosal lesions on examination.

Many treatment guidelines recommend initiating ART within 2 weeks for most diagnosed OI. In patients with cryptococcal meningitis and possible tuberculous meningitis, ART should be deferred due to the risks of serious immune reconstitution syndrome outweighing the benefits of ART. In patients with AIDS-associated OI for which no effective therapy exists (e.g., progressive multifocal leukoencephalopathy, cryptosporidiosis, microsporidiosis), improvement in immune function with ART can potentially improve disease outcomes.

Neurologic

Both central nervous system disease and peripheral nerve abnormalities are common in advanced AIDS. HIV infection can directly cause distal sensory neuropathy, which may manifest as dysesthesia or hypersensitivity, decreased reflexes, and chronic neuropathic pain. Inflammatory demyelinating polyneuropathy (e.g., Guillain-Barré syndrome), which has known associations with some enteric pathogens, causes ascending motor weakness, typically without sensory involvement. CMV infection may cause polyradiculopathy, transverse myelitis, and encephalitis/ventriculitis in patients with CD4 counts lower than 50 cells/mm³. CMV end-organ disease, including retinitis (a vision-threatening condition), requires prompt diagnosis and initiation of appropriate anti-CMV therapy.

Focal central nervous system lesions can arise from infectious and malignant conditions. Cerebral toxoplasmosis usually occurs in patients with prior exposure to *Toxoplasma gondii* who develop reactivation disease when the CD4 count is lower than 100 cells/mm³. The main differential diagnosis for one or several enhancing brain lesions includes toxoplasmosis and primary central nervous system lymphoma (PCNSL). PCNSL is associated with Epstein-Barr virus, and detection of nucleic acid for Epstein-Barr virus in cerebrospinal fluid carries a high specificity for this condition in the proper radiographic context. Progressive multifocal leukoencephalopathy (PML), a rare and potentially devastating demyelinating condition, is caused by reactivation of JC virus and can manifest as focal neurologic deficit, seizures, or cognitive dysfunction. *Cryptococcus neoformans* is a common cause of meningitis in AIDS patients and may manifest with central nervous system mass lesions, pulmonary disease, or gastrointestinal disease. Worldwide, tuberculosis accounts for a large proportion of HIV-associated meningitis; less commonly, it can manifest as single or multiple focal lesions (tuberculomas). Neurosyphilis should be considered in patients with unexplained neurologic disease and sexual risk factors.

Respiratory Complications

Respiratory illnesses are among the most common causes of morbidity in HIV-infected patients. Community-acquired bacterial pneumonia occurs at a significantly higher rate in HIV-infected

compared with HIV-noninfected patients, regardless of CD4 count, and is one of the most common reasons for hospitalization. *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia (PCP) manifests with fever, cough, and dyspnea. Findings on physical examination and chest radiography can be variable, making the diagnosis difficult in the absence of high clinical suspicion. Elevated lactate dehydrogenase and oxygen desaturation with ambulation can be diagnostic clues. More than 90% of cases occur among patients with CD4 counts lower than 200 cells/mm³. The diagnosis is established by visualization of organisms in induced sputum (sensitivity, 50%–90%) or in bronchoalveolar lavage specimens (sensitivity, 90%–99%), most commonly with the use of immunofluorescent staining.

The risk of reactivation of latent TB is increased 100-fold in patients with HIV infection. Patients with HIV infection who are latently infected have a 10% annual risk of developing symptomatic tuberculosis, compared with a 10% lifetime risk among the general population. The risk of reactivation increases with decreasing CD4 count, and patients with counts lower than 350 cells/mm³ are more likely to have atypical radiographic presentations, including middle- and lower-lobe infiltrates without cavitation. Patients with low CD4 counts are more likely to have extrapulmonary tuberculosis. Diagnostic approaches to tuberculosis are similar in patients with HIV infection than in those without. Tuberculin skin testing can be used to diagnose latent tuberculosis infection, although the recommended cutoff for a positive test is 5 mm of induration. Treatment of co-infection with *Mycobacterium tuberculosis* and HIV requires consultation with experienced clinicians and pharmacists because of extensive drug–drug interactions among antiretroviral drugs and rifamycins.

Gastrointestinal Complications

Oropharyngeal candidiasis (thrush) commonly manifests as white plaques on the tongue, palate, or buccal mucosa that are painless and are easily scraped off. Although thrush is typically uncomplicated and easily treatable with topical preparations such as nystatin (Mycostatin) and clotrimazole (Mycexel troches), in the proper clinical setting it can alert the clinician to the presence of esophageal candidiasis. Esophageal involvement should be suspected in patients with dysphagia and odynophagia; retrosternal chest pain may also be present. Thrush is usually present but is not required for the diagnosis, which is often made on clinical grounds rather than being confirmed with endoscopy. Patients with esophageal candidiasis typically respond after several days of treatment, and 7 to 14 days of antifungal therapy is usually sufficient. For cases not responsive to empiric treatment for candidiasis, referral for endoscopy should be considered. Esophagitis caused by CMV or herpes simplex virus requires a histopathologic diagnosis.

Acute diarrhea, defined as three or more loose or watery stools per day for 3 to 10 days, is common among patients with HIV infection, and more than 1000 different enteric pathogens have been described. Data from a large cohort indicate that the most common pathogens isolated are *Clostridium difficile*, *Shigella* spp., *Campylobacter jejuni*, *Salmonella* spp., *Staphylococcus aureus*, and MAC. Culture of the stool can yield a microbiologic diagnosis in many cases, particularly for acute diarrheal illnesses caused by *Campylobacter*, *Yersinia*, *Salmonella*, and *Shigella* species. Infection with *C. difficile*, the most common bacterial enteric pathogen in the United States for both HIV-infected and HIV-uninfected persons, is diagnosed in most settings by detection of cytotoxin in the stool by EIA or PCR, although the more laborious tissue culture is considered the gold standard. Enteric viruses are present in 15% to 30% of HIV-infected persons with acute diarrhea. Definitive diagnosis is not feasible in most clinical laboratories; viral enteritis should be suspected in the setting of community outbreaks because of the high transmissibility of viral pathogens. Treatment is supportive with fluid resuscitation and antimotility agents.

Chronic diarrhea (duration >30 days) was a common manifestation of advanced-stage AIDS in the pre-HAART era. Most pathogens that cause acute gastroenteritis can also cause chronic symptoms. Pathogens that should be suspected in cases of chronic

watery diarrhea include protozoa such as *Cryptosporidium parvum*, *Isospora belli*, and *Microsporidia* spp. These entities are self-limited in the absence of severe immunosuppression. In advanced HIV infection, pathogen-specific antimicrobial therapy is infrequently effective, and symptoms commonly do not improve without immune reconstitution in response to ART. *Giardia lamblia* causes watery diarrhea, abdominal bloating, and occasionally malabsorption syndrome and can occur at any CD4 count. CMV infection can affect any segment of the gastrointestinal tract and is a common cause of chronic diarrhea. Diagnosis of gastrointestinal CMV disease is difficult without biopsy. Detection of CMV viremia with PCR does not correlate well with presence of CMV disease in HIV-infected patients, and CMV can be undetectable in serum in patients with extensive gastrointestinal disease.

Other Conditions

ART has dramatically increased the survival of individuals living with HIV, and the HIV elderly population is expanding. There are few clinical trials or studies systematically focused on this cohort. Older adults with HIV may develop comorbidities that can complicate their HIV management. ART-related CD4 cell recovery in older patients has been observed to be slower and with lower magnitude than in younger patients. Hepatic and renal functions decrease as the body ages and may lead to impaired drug elimination and increased drug exposure in older patients.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a collection of inflammatory disorders often associated with paradoxical worsening of preexisting infectious diseases after initiation of ART. IRIS is usually accompanied by an increase in CD4 count and can occur at any CD4 count. It usually occurs between the first 4–8 weeks after initiation of ART. Clinical features are often associated with the type and location of the preexisting OI and can be localized or systemic. Patients should continue on ART and should receive treatment for the underlying OI as quickly as possible. If the patient's presentation involves paradoxical worsening of a previously diagnosed OI that is already receiving treatment, OI therapy should also be continued. Disseminated MAC accounts for up to one-third of the cases of IRIS in the United States. Other important causes of IRIS are tuberculosis, CMV infection, viral hepatitis, and candida infections.

Management of HIV in Pregnancy and Women of Childbearing Potential

HIV in Pregnant Women

All pregnant women with HIV should be on ART regardless of their immunologic or virologic status in order to improve the patient's health and prevent transmission of HIV to the fetus. Increased perinatal transmission risk exists in pregnant women experiencing early HIV infection and high-level viremia. All pregnant women with newly diagnosed HIV infection should start ART as soon as possible to prevent perinatal HIV transmission. The goal of ART is to achieve and sustain viral suppression throughout the pregnancy. In a pregnant woman with newly diagnosed HIV, ART should be initiated as soon as possible. Resistance testing should be performed prior to initiating ART, but therapy may be started before receiving resistance testing results. ART regimen can be modified at a later date once resistance testing results are available.

In a patient already taking a regimen containing Efavirenz (EFV, Sustiva) who presents for prenatal care during the first trimester and has virologic suppression, EFV can be continued. The risk of fetal neural tube defects is limited to the first 5–6 weeks of pregnancy, and pregnancy is often not recognized before weeks 4–6. Unnecessary changes to a patient's ART regimen during pregnancy may result in loss of viral suppression with increased risk of perinatal transmission.

In a pregnant patient with HIV RNA viral load greater than or equal to 1000 copies/mL (or viral load is unknown) near delivery, IV infusion of zidovudine (Retrovir) during labor is recommended regardless of the patient's antepartum ART regimen or resistance

profile. Maternal ART should be continued following delivery. Following delivery, the patient should continue to follow up with their HIV care provider as recommended for non-pregnant adults.

Maternal adherence to ART reduces but does not completely eliminate the risk of transmission of HIV in breast milk. Postnatal HIV transmission can occur despite maternal ART adherence, and patients should be counseled to avoid breastfeeding. There have also been reports of mother-to-child transmission of HIV via mothers pre-masticating food and feeding it to their infants.

Pre-exposure Prophylaxis of HIV Infection

Globally, up to 2 million new HIV infections occur per year. It is estimated that up to 50,000 new HIV infections occur annually in the United States. The highest incidence of new HIV infection occurs in men who have sex with men (MSM), especially young African-American males. For uninfected patients with high risk of HIV acquisition, pre-exposure prophylaxis (PrEP) is an evidence-based method for preventing infections in those at risk. Since 2012, tenofovir disoproxil fumarate-emtricitabine (TDF-FTC, Truvada) has been approved for PrEP and is at least 90% effective in reducing risk of HIV transmission. Efficacy is dependent on medication adherence.

Daily oral PrEP is recommended as one HIV prevention option for people who are sexually active with men, adult heterosexually active men and women who are at increased risk of acquiring HIV infection, and adult injection drug users at increased risk of acquiring HIV infection (Table 5). PrEP therapy should be discussed with heterosexually active women and men with sexual partners known to have HIV infection to prevent virus transmission during conception and pregnancy.

Prior to initiating PrEP, it is important to obtain a detailed sexual and drug use history to identify patients likely to benefit from PrEP. Pertinent information includes frequency of condom use, penile–anal or penile–vaginal sex, number of sex partners, HIV serostatus of sex partner(s), drug use during sex, and history of sexually transmitted infections (STIs). It is important to determine sexual practices with a patient's main sexual partner, casual partners, and whether they have any anonymous partners. A drug history over the prior 6 months should be obtained and include injection drug use and sharing of needles. The 2014 PrEP guidelines published by the U.S. Public Health Service recommends the following questions to initiate these discussions with patients regarding their behaviors in the previous 6 months:

- Have you had sex with men, women, or both?
 - (if men or both sexes) How many men/women have you had sex with?
 - How many times did you have vaginal sex when neither you nor your partner wore a condom?
 - How many times did you have receptive anal sex (you were the bottom) with a man who was not wearing a condom?
 - How many of your male sex partners were HIV positive?
 - (if any positive) With these HIV-positive male partners, how many times did you have insertive anal sex (you were the top)/vaginal sex without wearing a condom?
 - Have you used methamphetamines (such as crystal meth or speed)?
 - Do you have a history of sexually transmitted infections (STIs)?
- Patients screened for PrEP must be screened for common bacterial STIs including serologic testing for syphilis and nucleic acid amplification tests for gonorrhea and chlamydia. This includes swabs of the oropharynx in patients who participate in oral sex and anal swabs for recipients of anal intercourse. Screening for trichomonas and bacterial vaginosis are not required prior to initiating PrEP, as they do not have a strong correlation with HIV co-infection.

Plasma HIV testing with fourth-generation antigen/antibody test should be obtained to confirm that the patient does not have undiagnosed HIV infection. Additional HIV RNA testing should be performed in patients with signs or symptoms of acute HIV infection in the last 4 weeks, those with indeterminate antigen/

TABLE 5 Preexposure Prophylaxis (PrEP)

	MEN WHO HAVE SEX WITH MEN	HETEROSEXUAL WOMEN AND MEN	INJECTION DRUG USERS
Markers of substantial risk of acquiring HIV infection	HIV-positive sexual partner Recent bacterial STI High number of sex partners History of inconsistent or no condom use Commercial sex work	HIV-positive sexual partner Recent bacterial STI High number of sex partners History of inconsistent or no condom use Commercial sex work In high-prevalence area or network	HIV-positive injection partner Sharing injection equipment Recent drug treatment (but currently injecting)
Clinical eligibility	Documented negative HIV test result before prescribing PrEP No signs/symptoms of acute HIV infection Normal renal function; no contraindicated medications Documented Hepatitis B infection and vaccination status		
Prescription recommendations	Daily, continuing, oral doses of FTC/TDF (Truvada®), ≤90 day supply		
Follow-up testing and other services	Follow-up visits at least every 3 months to assess the following: HIV test, medication adherence counseling, behavioral risk reduction support, side effect assessment, STI symptom assessment At 3 months and every 6 months thereafter, assess renal function Every 6 months, test for bacterial STIs Do oral/rectal STI testing		
	Assess pregnancy intent Pregnancy test every 3 months	Access to clean syringes/needles and drug treatment services

^bAbbreviations: STI = sexually transmitted infection.

antibody test results, and patients with high-risk HIV exposure in the preceding 4 weeks.

TDF-FTC is generally tolerated well by most patients; however, screening for those at increased risk of adverse effects should be performed prior to PrEP initiation. TDF is associated with acute and chronic kidney disease in HIV-infected patients. Its safety in patients without HIV and eGFR <60 mL/min/1.73 m² has not been documented. Serum creatinine should be measured as PrEP is not recommended for patients with estimated glomerular filtration rate <60 mL/min/1.73 m². No alternative PrEP regimens have been approved for patients with decreased kidney function at this time. In patients without reduced kidney function but have risk factors for developing renal disease, urinalysis to document baseline proteinuria can be obtained for monitoring purposes.

Screening for undiagnosed Hepatitis B infection should be performed via hepatitis B surface antigen, hepatitis B core antibody, and hepatitis B surface antibody. If the patient's serology shows non-immunity, vaccination against Hepatitis B virus should be pursued as individuals engaging in high-risk sexual and drug-use behaviors have an increased risk of HBV infection. If the patient's serology reveals chronic HBV, it must be determined whether the patient requires HBV treatment. TDF is a first-line treatment choice for chronic HBV and can be used for PrEP and treatment of chronic HBV. In those with chronic HBV who do not require HBV treatment, there is a low risk of HBV flare if TDF is discontinued.

TDF is also associated with decreased bone density, therefore patients considering PrEP should be screened for osteoporosis risk factors. The greatest amount of bone loss has been associated with the first 6 months of treatment. In patients with known osteopenia or osteoporosis, the risk of acquiring HIV versus further bone loss must be considered. If PrEP is pursued in these patients, a baseline DXA scan should be obtained prior to PrEP initiation if a recent test is not available. Repeat DXA testing on TDF therapy should be considered on a case-by-case basis as no guidelines for monitoring have been defined.

Females with childbearing potential should be screened for pregnancy. TDF and FTC are felt to be safe in pregnancy (Category B), although some concerns have been raised regarding fetal bone development with TDF use. In patients who are pregnant, the risk of acquiring HIV must be considered against the risk of using

antiretroviral medication during pregnancy. Limited data is available regarding PrEP efficacy during pregnancy.

Initiating PrEP

The combination tablet of TDF-FTC (Truvada) should be taken once daily for a duration of as long as the infection risk continues. It should be dispensed as a 90-day supply and renewed at each 3-month clinic follow-up. Condom use is encouraged while using PrEP. For patients not willing to use condoms consistently, CDC recommends condom use to prevent acquisition of HIV (and other STIs) for the first 7 days after started PrEP if engaging in receptive anal sex and 21 days if engaging in receptive vaginal sex. Common side effects of once-daily TDF-FTC include nausea and vomiting. These symptoms usually improve and resolve within the first 4 weeks of use.

Some patients who only have discrete periods of high-risk HIV exposure may not wish to take PrEP at all times. In this situation, PrEP should be initiated at least 1 week prior to high-risk sexual activity for male patients and 3 weeks for female patients. After the period of high-risk behavior ends, PrEP should be continued for at least 1 month. This information is based on pharmacokinetic data and not clinical trials.

PrEP Monitoring and Follow-Up

Patients on PrEP should have routine follow-up with their prescribing medical provider. The first follow-up should occur 1 month after initiating PrEP and every 3 months thereafter. More frequent follow-up should occur for patients with exposures or symptoms of STIs or medication side effects.

Every 3 months, patients should be screened for HIV infection with fourth-generation antigen/antibody testing, screened for symptoms of acute HIV infection, pregnancy testing, screened for STIs appropriate for recent sexual behaviors, assessed for medication adherence as well as sexual and drug use behaviors. Serum creatinine should be monitored after the first 3 months of PrEP and can be monitored at least every 3 months thereafter in patients with risk factors for kidney disease and every 6 months for patients without kidney disease. Appropriate counseling should be provided to encourage medication adherence and reduce high-risk sexual and drug use behaviors.

Post-exposure Prophylaxis of HIV Infection

The most effective means for preventing HIV infection includes preventing exposure. In the event that an isolated occupational, sexual, or injection drug–related exposure occurs, post-exposure prophylaxis can be utilized as a second line of defense against HIV acquisition.

Occupational Exposure

Health care personnel include all paid and unpaid persons working in a healthcare setting with potential for exposure to infectious materials such as bodily fluids, contaminated medical supplies, or environmental surfaces. In the occupational setting, prevention of exposures to blood and bodily fluids from infected sources is key to preventing occupationally acquired HIV infection. The overall risk of becoming infected with HIV after inadvertent exposure to body fluids from an HIV-infected patient is low. It is estimated that the average risk for HIV transmission following percutaneous exposure to HIV-infected blood is 0.3% and after mucous membrane exposure is 0.09%. The average risk of HIV transmission following non-intact skin exposure has not been defined, however, it is estimated to be lower than mucous membrane exposure. Healthcare personnel at the highest risk are those who received an accidental inoculation containing blood from a known HIV-infected source.

Initial Laboratory Evaluation

All patients initiating PEP after potential HIV exposure should be tested for HIV antigens and antibodies at baseline prior to PEP initiation. If baseline HIV testing indicates existing HIV infection, PEP should not be initiated. Repeat HIV testing should be performed at 4–6 weeks and 3 months following the exposure to determine if HIV infection has occurred. Administration of PEP should not be delayed while awaiting the results of HIV testing and can be discontinued if the source patient is found to not have HIV infection. PEP is most effective when begun as soon as possible following exposure.

Initiating PEP/Choosing Appropriate PEP Therapy

PEP is most effective when initiated as soon as possible following the exposure incident. If PEP is delayed, the effectiveness of therapy may be significantly reduced if initiated 72 hours or more following exposure. Initiating therapy after 72 hours might still be considered if the exposure is proven to be of extremely high risk of transmission.

The current recommendation for PEP therapy is FTC plus TDF (which can be dispensed as a fixed-dose combination tablet, Truvada) plus raltegravir (RAL, Isentress) for 4 weeks. Overall, this regimen has acceptable tolerability, convenient dosing, and minimal drug interactions. In patients with significant underlying renal disease, an acceptable PEP alternative is zidovudine plus lamivudine (Combivir)¹ in addition to RAL.

PEP regimens include three (occasionally more) antiretroviral medications. Due to the potential for medication-related side effects, it is important to choose a PEP regimen with a lower toxicity profile to improve patient tolerance and encourage completion of PEP therapy.

HIV PEP should be offered to pregnant or breastfeeding health care providers based on the same criteria as any other provider with a similar exposure. Risk of HIV transmission from mother to child during acute HIV infection is increased during pregnancy and breastfeeding.

TYPHOID FEVER

Method of

Tamilarasu Kadhiravan, MD

CURRENT DIAGNOSIS

- Typhoid fever typically manifests as an undifferentiated acute febrile illness.
- Soft splenomegaly, normal or low white blood cell count, and elevated liver enzymes are subtle diagnostic pointers.
- Blood culture, drawn before antibiotic administration, is the most useful investigation.
- Consider presumptive treatment in appropriate epidemiologic settings.

CURRENT THERAPY

- Decreased susceptibility to fluoroquinolones is widespread among *Salmonella enterica* serovar Typhi.
- High-dose fluoroquinolones are suboptimal for treating such infections.
- Azithromycin (Zithromax)¹ is the preferred drug for uncomplicated typhoid fever.
- Ceftriaxone (Rocephin)¹ is preferred for treating hospitalized and seriously ill patients.

¹Not FDA approved for this indication.

Typhoid fever is a bacteremic infection caused by the gram-negative bacillus *Salmonella enterica* serovar Typhi. *S enterica* Paratyphi also causes an illness clinically indistinguishable from typhoid fever. Humans are the only known host of *S enterica* Typhi, and it is transmitted by ingestion of contaminated food or water. Improvement in sanitation and hygiene led to the elimination of typhoid fever from the developed world long before the advent of antibiotics. On the other hand, in parts of the world lacking sanitation, it continues to be an important cause of febrile illness despite the availability of effective antibiotics.

Epidemiology

Typhoid fever is endemic in the developing world, especially the South and South East Asian countries of India, Nepal, Pakistan, Bangladesh, Vietnam, and Indonesia. Annual incidence in endemic settings is typically more than 100 cases per 100,000 population, and it predominantly affects children and young adults. Apart from sick persons with typhoid fever, convalescent carriers and

- Decreased susceptibility to fluoroquinolones is widespread among *Salmonella enterica* serovar Typhi.
- High-dose fluoroquinolones are suboptimal for treating such infections.
- Azithromycin (Zithromax)¹ is the preferred drug for uncomplicated typhoid fever.
- Ceftriaxone (Rocephin)¹ is preferred for treating hospitalized and seriously ill patients.

¹Not FDA approved for this indication.

Typhoid fever is a bacteremic infection caused by the gram-negative bacillus *Salmonella enterica* serovar Typhi. *S enterica* Paratyphi also causes an illness clinically indistinguishable from typhoid fever. Humans are the only known host of *S enterica* Typhi, and it is transmitted by ingestion of contaminated food or water. Improvement in sanitation and hygiene led to the elimination of typhoid fever from the developed world long before the advent of antibiotics. On the other hand, in parts of the world lacking sanitation, it continues to be an important cause of febrile illness despite the availability of effective antibiotics.

Epidemiology

Typhoid fever is endemic in the developing world, especially the South and South East Asian countries of India, Nepal, Pakistan, Bangladesh, Vietnam, and Indonesia. Annual incidence in endemic settings is typically more than 100 cases per 100,000 population, and it predominantly affects children and young adults. Apart from sick persons with typhoid fever, convalescent carriers and

asymptomatically infected food handlers (long-term carriers) are the sources of infection. Potential vehicles of infection include food or water consumed from roadside eateries, ice cubes and ice cream made from contaminated water, and raw vegetables and fruits. In contrast, most cases of typhoid fever in developed countries are imported by travel, especially to the Indian subcontinent.

Pathogenesis and Clinical Features

Following ingestion, the bacilli invade and multiply in the small-intestinal lymphoid tissue before entering the bloodstream. This primary bacteremia leads to widespread seeding of the reticuloendothelial system and intestinal lymphoid tissue, where the infection is amplified and spills over into the circulation. Onset of symptoms usually coincides with this secondary bacteremia. Interestingly, unlike other gram-negative bacteremic infections, septic shock develops relatively late in the course of illness, and the infection can be eminently cured by oral antibiotic therapy. Nonetheless, it should be emphasized that any delay in initiating antibiotic therapy increases the risk of complications (Box 1).

During the first week, temperature gradually increases in a step-ladder fashion. Localizing symptoms are usually minimal. Anorexia, lassitude, and malaise are often marked. Headache and vomiting are common; however, a supple neck helps rule out meningitis. Abdominal symptoms such as constipation, loose stools, and abdominal pain are not infrequent, but they are nonspecific and often overlooked. Soft, tender enlargement of liver or spleen is seen in about half the patients. Rose spots and relative bradycardia, though classic, are rare. When the infection goes untreated, hypertrophied lymphoid tissue of the Peyer's patches can ulcerate toward the end of the second week, resulting in torrential gastrointestinal bleeding, small intestinal perforation, and secondary bacterial peritonitis. Patients with severe illness can present with a muttering delirium described as *coma vigil*. Untreated typhoid fever often resolves spontaneously in about 4 to 6 weeks. However, the risk of death is high (>10%), and relapses are frequent. Many patients excrete *S enterica* Typhi in feces and urine during convalescence (convalescent carriers), and some of them continue to excrete beyond 1 year (long-term carriers).

Current Pattern of Antimicrobial Susceptibility

Since 1990, a sea change has occurred in the antimicrobial susceptibility of *S enterica* Typhi in endemic countries and elsewhere. Unregulated use of fluoroquinolones has resulted in emergence of *S enterica* Typhi strains with decreased susceptibility. These strains have a subthreshold increase in minimal inhibitory concentration (MIC) that is not detected by conventional disk-diffusion

testing. Hence, determination of MIC is recommended at present. Resistance to nalidixic acid (NegGram)² (a quinolone) is often used as a surrogate marker for such strains. In fact, most infections in the community are now caused by nalidixic acid-resistant *S enterica* Typhi (NARST). Not surprisingly, this change is reflected in far-away geographic locales such as the United States and the United Kingdom. Of late, sporadic instances of resistance to azithromycin and third-generation cephalosporins have been reported.

Diagnosis

Clinical features are nonspecific, and laboratory testing is essential to confirm a diagnosis of typhoid fever. A soft splenomegaly, absence of leukocytosis, mild leukopenia, and modest elevation of transaminases are subtle pointers to a diagnosis of typhoid fever. Blood culture drawn early in the illness before initiation of antibiotics is often fruitful and is the gold standard for the diagnosis of typhoid fever. The time-honored Widal test, which detects agglutinating antibodies to somatic and flagellar antigens of *S enterica* Typhi, adds little to decision making. Initial enthusiasm about rapid serologic tests such as Typhidot and Tubex TF has not been confirmed in community-based studies. None of these tests are sensitive enough to rule out typhoid. In a patient who has nonlocalizing acute febrile illness lasting more than 5 to 7 days in a suggestive epidemiologic setting (residence in or travel to endemic area; outbreaks), it is prudent to treat presumptively for typhoid fever, after reasonably ruling out competing diagnoses such as malaria, dengue, leptospirosis, and rickettsial infection.

Treatment

Fluoroquinolones (ciprofloxacin [Cipro] or ofloxacin [Floxin])¹ 7.5 mg/kg twice a day for 5–7 days are unparalleled in efficacy for treating fully susceptible *S enterica* Typhi strains. However, their use is associated with frequent treatment failures, prolonged defervescence, and higher rates of complications in NARST infections. Given the widespread emergence of NARST, fluoroquinolones are no longer considered the drug of choice. Several alternatives have been evaluated in randomized, controlled trials for treating uncomplicated typhoid fever caused by NARST (Table 1). Ease of oral administration, proven efficacy, and safety (under FDA review) make azithromycin (Zithromax)¹ a reasonable first choice for uncomplicated typhoid fever. In hospitalized seriously ill patients and treatment failures, parenteral ceftriaxone (Rocephin)¹ is preferred. Usually, it takes about 4 to 7 days for defervescence after the initiation of antibiotics. Despite in vitro susceptibility, aminoglycosides and first- and second-generation cephalosporins are not effective clinically for treating typhoid fever. Antipyretics should be used for symptom relief; ibuprofen (Motrin; 10 mg/kg every 6 hours) is superior to acetaminophen (Tylenol; 12 mg/kg every 6 hours). However, ibuprofen should be avoided when dengue fever is a possibility. A soft, low-residue diet is traditionally advised to prevent intestinal perforation. Such a practice, however, is not founded on scientific evidence. Treatment of *S enterica* Paratyphi infection is identical to that of *S enterica* Typhi infection.

Prevention

Sustained improvement in sanitation and access to safe drinking water are essential to control typhoid fever in endemic areas. Avoiding potentially contaminated food and beverages and being vaccinated before travel decrease the risk of typhoid fever among travelers (see the article on travel medicine). Recently, mass administration of the Vi polysaccharide vaccine (Typhim Vi, Typhixerix [outside United States]) has been found to confer herd immunity and is a potential tool for the control of typhoid fever in endemic settings.

BOX 1 Complications of Typhoid Fever

Abdominal

- Paralytic ileus
- Intestinal hemorrhage
- Intestinal perforation
- Secondary peritonitis
- Symptomatic liver dysfunction
- Acalculous cholecystitis

Extra abdominal

- Encephalopathy
- Cerebellar dysfunction
- Myocarditis
- Osteomyelitis and soft tissue abscesses
- Multiorgan dysfunction syndrome
- Hemophagocytic syndrome
- Hemolysis
- Glomerulonephritis

Long-term

- Gallbladder cancer

VARICELLA (CHICKENPOX)

Method of
Cassie Scripter, MD

CURRENT DIAGNOSIS

- Clinical diagnosis is marked by a characteristic pruritic rash. The rash starts with erythematous macules progressing to papules and then vesicles (“dewdrop on a rose petal” appearance) that then crust. All stages of the rash are present simultaneously.

- Polymerase chain reaction can aide in the diagnosis. Specimens are collected by unroofing a vesicle and swabbing the base or collecting the crust from a lesion.

CURRENT TREATMENT

- Supportive care is recommended for immunocompetent individuals 1 to 12 years of age.
- Aspirin should not be used because of the risk of Reye’s syndrome.
- Antiviral treatment with acyclovir (Zovirax) or valacyclovir (Valtrex) for individuals <1 year, >12 years, and immunocompromised individuals. Acyclovir is available in liquid suspension.
- Post-exposure prophylaxis with varicella immunization is recommended for children and adults without evidence of immunity.

Varicella (chickenpox) is an acute, self-limited primary infection of childhood caused by the varicella zoster virus (VZV), a herpesvirus. Transmission occurs by respiratory secretions or direct contact with skin lesions.

Epidemiology

In temperate climates varicella previously infected >90% of individuals before adolescence with epidemics every 2 to 5 years in late winter to early spring. Varicella was less common in tropical climates but more frequently affected young adults. In the early 1990s, an average of 4 million cases occurred in the United States annually, resulting in up to 150 annual deaths. A one-dose varicella immunization (Varivax) was introduced in 1995, and by 2005 the overall incidence of varicella and its associated complications had decreased by up to 90%. In the early 2000s, there were several outbreaks of mild varicella among immunized children, which led to the Centers for Disease Control and Prevention (CDC) 2006

VARICELLA (CHICKENPOX)

Method of
Cassie Scripter, MD

CURRENT DIAGNOSIS

- Clinical diagnosis is marked by a characteristic pruritic rash. The rash starts with erythematous macules progressing to papules and then vesicles (“dewdrop on a rose petal” appearance) that then crust. All stages of the rash are present simultaneously.

- Polymerase chain reaction can aide in the diagnosis. Specimens are collected by unroofing a vesicle and swabbing the base or collecting the crust from a lesion.

CURRENT TREATMENT

- Supportive care is recommended for immunocompetent individuals 1 to 12 years of age.
- Aspirin should not be used because of the risk of Reye’s syndrome.
- Antiviral treatment with acyclovir (Zovirax) or valacyclovir (Valtrex) for individuals <1 year, >12 years, and immunocompromised individuals. Acyclovir is available in liquid suspension.
- Post-exposure prophylaxis with varicella immunization is recommended for children and adults without evidence of immunity.

Varicella (chickenpox) is an acute, self-limited primary infection of childhood caused by the varicella zoster virus (VZV), a herpesvirus. Transmission occurs by respiratory secretions or direct contact with skin lesions.

Epidemiology

In temperate climates varicella previously infected >90% of individuals before adolescence with epidemics every 2 to 5 years in late winter to early spring. Varicella was less common in tropical climates but more frequently affected young adults. In the early 1990s, an average of 4 million cases occurred in the United States annually, resulting in up to 150 annual deaths. A one-dose varicella immunization (Varivax) was introduced in 1995, and by 2005 the overall incidence of varicella and its associated complications had decreased by up to 90%. In the early 2000s, there were several outbreaks of mild varicella among immunized children, which led to the Centers for Disease Control and Prevention (CDC) 2006

recommendation of a routine second dose of varicella immunization for US children. The incidence has continued to decline since, although nearly 9000 cases of varicella and 3 deaths were reported in the United States in 2016.

Risk Factors and Prevention

There are no risk factors for varicella infection other than exposure to the virus. Complications are more likely in adults, infants <1 year of age, and immunocompromised individuals.

The CDC recommends a two-dose live, attenuated varicella immunization (Varivax). The first dose is administered between 12 and 15 months of age and the second between 4 and 6 years. The second dose may be given before 4 years of age if 3 months have elapsed since the first dose. A two-dose immunization regimen is recommended for all persons 13 years and older without evidence of immunity to varicella. The two doses should be separated by at least 4 weeks. Evidence of immunity requires documentation of age-appropriate immunization, laboratory evidence of immunity or confirmation of disease, verification of history or diagnosis by a healthcare provider, or birth in the United States before 1980, although birth in the United States before 1980 is not considered a sufficient criteria for healthcare personnel or pregnant women.

Pathophysiology

VZV enters the mucosa of the nasopharynx and conjunctivae through aerosolized droplets or direct contact with lesions. The virus replicates in regional lymph nodes before disseminating and replicating in the liver and spleen. After 14 to 16 days (range 10-21 days), VZV-infected cells spread to the nasopharyngeal surface and the skin, resulting in skin lesions. During the primary infection and after immunization, VZV can infect neurons and become latent in the dorsal root and other ganglia, including those of the cranial and autonomic systems. Reactivation of latent VZV causes herpes zoster (shingles).

Clinical Manifestations

Primary infection in non-immunized individuals begins with a mild prodrome of fever, malaise, headache, pharyngitis, and anorexia followed by the development of pruritic cutaneous lesions. The 1- to 4-mm lesions present on the head, scalp, trunk, and extremities. Lesions begin as erythematous macules, progress to papules, and then become vesicles that crust after 1 to 2 days. Crusts fall off within 1 to 2 weeks. The vesicular lesions on an erythematous base are described as having a “dewdrop on a rose petal” appearance (Figure 1). New lesions develop in successive crops for 3 to 5 days (range 1-7), with lesions in various stages of development simultaneously present (Figure 2). The median number of lesions is 200 to 400 in 2 to 4 successive crops. Patients are contagious from 1 to 2 days before the onset of the rash until all lesions have crusted over. The vesicular phase is the most contagious period. Lesions can occur on mucous membranes in the oropharynx, respiratory tract, conjunctiva, cornea, and vagina.

Breakthrough varicella is defined as a VZV infection more than 42 days after immunization and is due to incomplete immunity to

Figure 2 The disease starts with lesions on the trunk and then spreads to the face and extremities.

the VZV virus. The course is mild, short-lasting, and has fewer skin lesions (<50) than primary infection. The rash is more likely to be macular than vesicular and may not follow the characteristic progression described above, making it more difficult to make a diagnosis on clinical presentation alone.

Diagnosis

Traditionally the diagnosis was based on the characteristic rash and clinical features. As more cases now occur in immunized individuals, atypical rashes present a diagnostic challenge. Infections in the immunocompromised may be severe, atypical, and difficult to diagnose based on clinical criteria. Polymerase chain reaction is recommended to confirm varicella infection if the diagnosis is unclear. Specimens are collected by unroofing a vesicle and swabbing the base of the lesion or by collecting the crust from a lesion. Specimens may be obtained from vesicular fluid or cerebrospinal fluid, blood, saliva, throat swabs, or biopsy tissue. Compared with polymerase chain reaction technology, testing for immunoglobulin M antibody using commercial kits is not recommended because of low sensitivity.

Differential Diagnosis

History and physical examination, particularly the characteristics of the rash, are key in differentiating varicella from other conditions. Smallpox was previously the most serious consideration in the differential diagnosis for varicella. Since its eradication via natural transmission, bioterrorism and laboratory exposure are the most likely sources of smallpox transmission. Smallpox has more prominent constitutional symptoms with lesions in the same stage of development. Zoster rashes appear in a dermatomal distribution. Other considerations include impetigo, diffuse herpes simplex virus, hand-foot-mouth disease, guttate psoriasis, allergic reaction (Stevens-Johnson syndrome), and viral exanthema (coxsackie virus, enterovirus).

Figure 1 A, “Dewdrop on a rose petal”; a thick-walled vesicle with clear fluid forms on a red base. B, The vesicle becomes cloudy and depressed in the center (umbilicated); the border is irregular (scalloped). C, A crust forms in the center and eventually replaces the remaining portion of the vesicle at the periphery.

Treatment

Patient age, immune status, and duration since rash eruption are key in management decisions. Symptomatic treatment is recommended in healthy children younger than 13 years because of the self-limited nature of the disease. Aspirin is not recommended because of the risk of Reye syndrome.

Oral antiviral therapy is indicated for immunocompetent individuals older than 12 years, individuals receiving long-term salicylate therapy or short, intermittent, or aerosolized courses of corticosteroids, and those with chronic dermatologic or pulmonary disease. Antivirals are most effective if administered within 48 hours of rash eruption. They decrease the duration of fever and rash, as well as the risk of severe and fatal disease. Valacyclovir (Valtrex) is preferred because of increased bioavailability. The oral dose of valacyclovir is 20 mg/kg up to 1000 mg three times daily for 5 days. Dosing for acyclovir (Zovirax) (>40 kg) is 800 mg five times daily³ for 5 days. Acyclovir is available in liquid suspension (200 mg/5 mL) and is dosed 20 mg/kg every 6 hours for 5 days in individuals older than 2 years old and less than 40 kg. The maximum daily dose is 3200 mg. Foscarnet (Foscavir)¹ is not considered first-line therapy due to potential nephrotoxicity and other adverse effects.

Infants and immunocompromised patients are treated with intravenous acyclovir at 10 to 15 mg/kg every 8 hours for 7 to 10 days. Dosing adjustment for renal impairment is recommended because intravenous antivirals can be nephrotoxic. A switch from intravenous to oral antivirals should be considered when patients have been fever free and without new lesions for 24 hours.

Pregnant women with varicella are at high risk of pulmonary complications, and antiviral treatment is recommended for any pregnant woman with pulmonary involvement. Acyclovir is a category B drug.

Post-exposure Prophylaxis

Post-exposure prophylaxis with varicella immunization¹ is effective in preventing illness or decreasing the severity of illness if administered to children up to 3 days, and possibly 5 days, after exposure. Although studies have only been conducted on children, one-dose varicella vaccination is recommended for both children and adults who have no evidence of immunity after exposure to varicella. During an outbreak, individuals who received only one dose of vaccine should receive a second dose if the appropriate time interval has lapsed. Varicella zoster immune globulin (VariZig) is available for post-exposure prophylaxis for individuals without evidence of immunity who are at greatest risk of severe disease and related complications or for those who have a contraindication to the varicella vaccine.

Complications

Varicella is typically self-limited in immunocompetent patients, but complications can occur. Secondary skin and soft tissue infections with *Staphylococcus aureus* or *Streptococcus pyogenes* are the most common complications. Other complications include pneumonia, subclinical hepatitis, encephalitis, and ataxia. Invasive infection occurs more commonly in infants younger than 1 year, adolescents, adults, immunocompromised patients, and newborns whose mothers develop a rash within 5 days before and 2 days after delivery. Congenital malformations, especially involving the central nervous system, are more likely to occur if the mother is infected during the first two trimesters. Disseminated varicella may result if infection occurs during the third trimester.

Varicella zoster virus lies dormant in the dorsal root ganglia and may activate causing herpes zoster. The incidence of shingles is approximately 10 cases per 1000 US population in those aged 60 years and older. Shingles most commonly presents as a unilateral maculopapular rash that becomes vesicular. The

characteristic dermatomal distribution of the rash and any preceding pain and paresthesia are usually diagnostic. Postherpetic neuralgia, persistent pain in the area after resolution of the rash, is the most common complication of zoster and can last a few days to years. Immunocompromised hosts are more likely to experience severe complications. Two shingles vaccines are currently available in the United States, Zostavax and Shingrix. The CDC recommends two doses of Shingrix 2 to 6 months apart for those 50 years and older, even in those who have previously received Zostavax. If patients have already received Zostavax, 2 months should be allowed before administering Shingrix. Current data show 90% effectiveness in preventing shingles and postherpetic neuralgia with two doses of Shingrix. Individuals who have had shingles should receive the Shingrix series after acute symptoms of zoster have subsided.

YELLOW FEVER

Method of

Lucius M. Lampton, MD

CURRENT DIAGNOSIS

- Yellow fever is a historically important mosquito-borne Flavivirus with high morbidity and mortality.
- Travel to yellow fever–endemic areas in Sub-Saharan Africa and tropical Central and South America is the essential risk factor.
- Symptoms may include abrupt onset of fever, relative bradycardia, headache, and, if severe, jaundice, hemorrhage, and multiorgan failure.
- Diagnosis is with viral culture and serologic tests.
- Although infectious disease experts consider it improbable that yellow fever outbreaks will return to the continental United States, this reemerging disease is threatening to become more prevalent and deadly in tropical South America and Africa. Travel-related cases should be anticipated in the United States and its territories, as well as the possibility of brief episodes of local dissemination in areas bordering the Gulf of Mexico, where the vector, the *Aedes aegypti* mosquito, can be found.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Treatment

Patient age, immune status, and duration since rash eruption are key in management decisions. Symptomatic treatment is recommended in healthy children younger than 13 years because of the self-limited nature of the disease. Aspirin is not recommended because of the risk of Reye syndrome.

Oral antiviral therapy is indicated for immunocompetent individuals older than 12 years, individuals receiving long-term salicylate therapy or short, intermittent, or aerosolized courses of corticosteroids, and those with chronic dermatologic or pulmonary disease. Antivirals are most effective if administered within 48 hours of rash eruption. They decrease the duration of fever and rash, as well as the risk of severe and fatal disease. Valacyclovir (Valtrex) is preferred because of increased bioavailability. The oral dose of valacyclovir is 20 mg/kg up to 1000 mg three times daily for 5 days. Dosing for acyclovir (Zovirax) (>40 kg) is 800 mg five times daily³ for 5 days. Acyclovir is available in liquid suspension (200 mg/5 mL) and is dosed 20 mg/kg every 6 hours for 5 days in individuals older than 2 years old and less than 40 kg. The maximum daily dose is 3200 mg. Foscarnet (Foscavir)¹ is not considered first-line therapy due to potential nephrotoxicity and other adverse effects.

Infants and immunocompromised patients are treated with intravenous acyclovir at 10 to 15 mg/kg every 8 hours for 7 to 10 days. YELLOW FEVER

Method of

Lucius M. Lampton, MD

CURRENT DIAGNOSIS

- Yellow fever is a historically important mosquito-borne Flavivirus with high morbidity and mortality.
- Travel to yellow fever–endemic areas in Sub-Saharan Africa and tropical Central and South America is the essential risk factor.
- Symptoms may include abrupt onset of fever, relative bradycardia, headache, and, if severe, jaundice, hemorrhage, and multiorgan failure.
- Diagnosis is with viral culture and serologic tests.
- Although infectious disease experts consider it improbable that yellow fever outbreaks will return to the continental United States, this reemerging disease is threatening to become more prevalent and deadly in tropical South America and Africa. Travel-related cases should be anticipated in the United States and its territories, as well as the possibility of brief episodes of local dissemination in areas bordering the Gulf of Mexico, where the vector, the *Aedes aegypti* mosquito, can be found.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

CURRENT THERAPY

- Prevention is key and accomplished by vaccination and mosquito avoidance and control.
- Supportive care is the only treatment.

Epidemiology

Yellow fever is one of the great epidemic diseases of tropical Africa and the Americas. It receives its appellation “yellow” from the symptom of jaundice, which appears in severe disease, and it is caused by an RNA virus, specifically a Flavivirus (a family name derived from yellow fever, with *flavus* Latin for yellow), that is held in natural reservoirs by forest monkeys and spread to people via mosquitoes. The disease, termed an acute hemorrhagic fever, infects humans, all species of monkeys, and certain other small mammals and is transmitted among its hosts by several species of mosquitoes.

There are three types of yellow fever infection: urban, jungle, and intermediate. In urban or classical yellow fever, human-to-human spread occurs by the bite of the *A. aegypti* mosquito, which breeds in urban unpolluted water and bites principally in the daytime. Reinvasion of this mosquito in Central and South America has occurred beginning in the 1970s owing to increases in breeding sites resulting from urbanization and the collapse of vector control efforts. In jungle or sylvatic yellow fever, which was first recognized in 1933, the disease is perpetuated by enzootic infection of mammals, usually monkeys, disseminated by several different mosquitoes: in South America via the *Haemagogus* and *Sabethes* spp.; in East Africa via *Ae. africanus*; and in West Africa via a variety of species of *Aedes*. Human infection arises by jungle exposure to these mosquitoes. In intermediate or savannah yellow fever, which commonly occurs in Africa, the virus disseminates from mosquitoes to humans residing or working in areas bordering jungles. This cycle also involves spread of the virus from monkey to human or from human to human via the bite of a mosquito.

Yellow fever, also termed Yellow Jack, the Saffron Scourge, fievre jaune, Bronze John, and Black Vomit (the Spanish name is *vómito negro*), is the deadliest arthropod virus ever to emerge in the Americas. Both the molecular taxonomic research of viral strains and the annals of history reveal an African origin. Most authorities assert it was introduced to the new world by *A. aegypti*-infested slave ships voyaging from West Africa, with its first recognition in the Americas occurring in Yucatan, Mexico, in 1648 (although research suggests the disease was present in the Americas as early as 1498). Over the next two and a half centuries, yellow fever erupted with regularity in American and European port cities, with hundreds of thousands of deaths, earning the virus deserved recognition as one of the worst plagues the world had ever seen. Two of the most significant North American epidemics occurred in Philadelphia in 1793 and in the Mississippi Valley in 1878. American epidemics were the result of the introduction of the mosquito vector and infected humans along routes of trade, especially sea and river ports and rail lines, with particular virulence associated with the Gulf region where *A. aegypti* resided. Early attempts at control focused on quarantine and sanitary measures. The devastation associated with American epidemics was an important impetus in the nation's early public health and sanitation movements for the creation of city, state, and national boards of health.

Although two 19th-century physicians, Josiah Nott and Carlos Juan Finlay, suggested the mosquito was the infectious agent for yellow fever, it was not until 1900 that the work of the US Army Commission in Cuba under Major Walter Reed established that the vector of the urban form of this disease was the *A. aegypti* mosquito, with its viral cause not established until after 1928. Max Theiler developed an attenuated vaccine strain in 1937, which was recognized with a Nobel Prize. In what is acknowledged as

one of the most successful campaigns in history against infectious disease, mosquito eradication and control efforts and this vaccine effectively controlled and eliminated urban yellow fever in the Americas and the West Indies, with the last large outbreak occurring in the continental United States in New Orleans in 1905. However, the disease persisted in its jungle form in forest areas in Africa and South America. Vaccine administration remains incomplete in endemic areas, and outbreaks periodically recur. As well, mosquito eradication efforts in both the Americas and Africa have recently slackened, with the resulting resurgence of *A. aegypti* into nearly all of the tropical American countries, placing this region at extraordinary risk for urban outbreaks. Also, while only travel-related cases have been documented in Asia, theoretic anthroponotic dissemination could also take place there in the many areas where the urban vector resides.

Official statistics suggest the incidence of yellow fever fluctuates, with 90% of the 200,000 annual cases reported in Africa. However, authorities warn that these statistics considerably underestimate (owing to underreporting) the true magnitude of epidemics, which field studies estimate as 50 times greater. A frightening prospect associated with failing mosquito control in urban habitats is the potential reemergence of yellow fever similar to the recent rapid resurgence of dengue, which is also transmitted by the vector *A. aegypti*. Experts contend that one of the most profound mysteries of tropical medicine is that this dangerous virus has not emerged more frequently where a susceptible, unimmunized human population and the vector density coexist. However, since the 1980s, a resurgence of yellow fever has been seen across South America and Africa, which augurs potential risk for the United States. While yellow fever outbreaks remain unlikely in the United States, travel-related cases should be expected, as well as the possibility of brief urban cycle transmission in the American Southeast.

The 2015–2018 outbreaks in Brazil and Africa portend ominously that yellow fever appears to be moving from its typical rural setting toward urban areas. A large urban outbreak in Angola, which began in December 2015 and subsequently spread to the Democratic Republic of the Congo, resulted in 962 confirmed cases and 393 deaths and included multiple travel-related cases appearing in nonendemic areas internationally such as China. The outbreak in Brazil was first recognized in December 2016, with more than 1828 confirmed cases and 560 deaths noted as of April 24, 2018, including two dozen travel-related cases. This upsurge of human cases, which is the highest observed in the Americas for decades, reflects the spread into densely populated metropolitan areas, such as Rio de Janeiro and Sao Paulo, which in the past were not considered at risk for transmission. This outbreak has impacted not only Brazil but six other American countries: Bolivia, Colombia, Ecuador, French Guiana, Peru, and Suriname. In the current outbreak, all human cases have been linked only to *Haemagogus* and *Sabethes* mosquitoes.

In response to yellow fever's reemergence in Africa, the World Health Organization (WHO) launched the Yellow Fever Initiative in 2006, vaccinating in mass campaigns more than 105 million people in West Africa and attempting to secure a global vaccine supply. In March 2018, Brazil's health minister announced that all of the country's 78 million people will be targeted in a large-scale vaccination campaign by April 2019.

Yellow fever remains the most dangerous arbovirus ever to inhabit the Western Hemisphere. Despite ongoing vaccination and mosquito control efforts in endemic areas, sylvatic and intermediate transmission cycles persist and appear to be expanding toward urban spread. Public health leaders encourage clinicians to utilize heightened suspicion and awareness for the virus, especially among travelers to tropical areas. Recent yellow fever outbreaks underscore boldly the potential threat this disease poses for the international community.

Risk Factors

Travel to yellow fever-endemic areas in Sub-Saharan Africa and tropical Central and South America, between the 15th parallel north and the 15th parallel south, is the essential risk factor.

Pathophysiology

Yellow fever virus has three types or cycles of transmission: urban, jungle (sylvatic), and intermediate (savannah). In urban yellow fever, the virus is spread by the bite of an *A. aegypti* mosquito infected about 2 weeks previously by feeding on a person with viremia. In jungle (sylvatic) yellow fever, the virus is transmitted by various forest canopy mosquitoes that acquire it from wild primates and then disseminate it to humans who are visiting or working in the jungle. Incidence of the disease is highest during months of peak temperature, rainfall, and humidity in South America and during the late rainy and early dry seasons in Africa. In the intermediate (savannah) cycle, which is most common in Africa, transmission of the virus to humans results from humans living or working in jungle border areas, with the virus spread from monkey to human or from human to human by mosquitoes. Humans infected with the virus are infectious to mosquitoes (what is termed being “viremic”) shortly before the onset of illness and up to 5 days after onset. Yellow fever is not transmissible by contact, only via a vector’s bite.

Prevention

Yellow fever is a mosquito-borne infection that can be prevented by mosquito avoidance and vaccination. Recovery from yellow fever imparts lifelong immunity against the virus.

Mosquito control is an essential component of any strategy to prevent the spread of yellow fever. Before the development of the vaccine and after the mosquito was proven as the vector, eliminating mosquito-breeding sites and decreasing exposure to *A. aegypti* mosquitoes proved successful in ending yellow fever outbreaks in North America and also in the building of the Panama Canal. Today, it remains critical not only to reduce the number of mosquitoes through larvicides and insecticides but also to limit mosquito bites through the use of house screening, mosquito netting, the wearing of protective attire, and the use of insect repellants such as diethyltoluamide (DEET). During jungle outbreaks, mosquito elimination is impractical and evacuation is essential until individuals are immunized and mosquitoes controlled. To prevent further mosquito transmission during outbreaks, infected patients should be isolated in well-screened rooms sprayed with insecticides.

Immunization is the most effective and reliable way to prevent yellow fever in areas in which it is endemic. Live attenuated yellow fever virus vaccine (17D strain) (YF-VAX) should be given (0.5 mL subcutaneously every 10 years) at least 10 days before travel to endemic areas in Africa and Central and South America. A single dose of vaccine gives greater than or equal to 99% protection and confers lifelong immunity. (Although required by some countries, a booster dose of the vaccine is not medically needed.) Although infection is uncommon in most of the endemic areas, vaccination is legally required for entry into many of these countries. The typically well-tolerated vaccine is contraindicated in pregnant women, in individuals with concurrent febrile illness or compromised immunity, and in infants younger than 6 months. If infants aged 6 to 8 months cannot avoid travel to a high-risk location, parents should discuss immunization with their physician, since the vaccine is usually not offered until the age of 9 months. In the United States, the vaccine is given only at US Public Health Service-authorized Yellow Fever Vaccination Centers. The International Certificate of Vaccination is valid for 10 years from 10 days after immunization or immediately after reimmunization.

After the 2016 outbreaks depleted global vaccine supplies, experts suggested as a dose-sparing strategy the utilization of a fractional dose of the vaccine among children 2 years of age or older and among nonpregnant adults.³ In an observational study, a one-fifth dose of the vaccine induced seroconversion in 98% of recipients. In the 2018 outbreaks, mass vaccination campaigns have utilized primarily fractional dosing.

Clinical Manifestations

Yellow fever is characterized by the swift onset of fever, rigors, myalgias, headache, nausea, and vomiting. With an incubation period lasting 3 to 6 days, the illness is typically biphasic, with a two-stage course during which the pulse slows and kidney involvement occurs along with bleeding disorders. Between 5% and 50% of the cases are so mild they are inapparent. In those cases recognized, the pulse is usually rapid initially but by the second day becomes slow for the degree of fever (Faget sign). A tendency to bleed may be seen early in the disease. Often, the face is flushed, with facial edema and conjunctival injection. Restlessness, irritability, and leukopenia are also common. In most cases, this initial period of mild infection resolves after 1 to 3 days, occasionally longer, and the illness concludes with rapid recovery and no sequelae. However, approximately 15% of those infected progress further into the moderate to severe phases. In these cases, the falling fever and remission of symptoms 2 to 5 days after onset are only transitory, and a deadly phase soon begins with renewal of malignant symptoms. This stage of the illness, called intoxication, is marked by the fever returning, and although the pulse remains slow, the blood pressure drops, with resultant renal failure. The flushed face is replaced by a dusky pallor, with swollen, bleeding gums and a pronounced hemorrhagic tendency with telltale black vomit (one of the disease’s monikers and classic symptoms) and melena. The skin and eyes may appear yellow (jaundice), the symptom that gave rise to the disease’s popular name. (However, this jaundice is generally a symptom of convalescence more than acute disease.) Liver and renal failure (which may progress to acute tubular necrosis) and epigastric tenderness with hematemesis and gastrointestinal hemorrhage often occur. There may be oliguria, albuminuria, disseminated intravascular coagulopathy, backache, dizziness, ecchymoses, myocarditis, agitated delirium, intractable hiccups, seizures, coma, and multiple organ failure. During recovery, bacterial superinfections, particularly pneumonia, may occur.

In terminal cases, death usually transpires within 7 days of onset and is rare beyond 10 days of illness. In patients with intoxication (malignant yellow fever), a 20% to 60% mortality may be seen, with survival depending on the quality of supportive management. At autopsy, the kidneys, liver, heart, and spleen appear to be the organs most impacted by the disease.

Diagnosis

Yellow fever is suspected in patients in endemic areas or returning from them if they develop classic clinical features such as sudden fever with relative bradycardia and jaundice. Mild infection often escapes recognition by the patient or clinician. Complete blood count, urinalysis, liver function tests, coagulation studies, viral blood cultures, and serologic tests should be done. Leukopenia with relative neutropenia is common, as are thrombocytopenia, prolonged clotting, and increased prothrombin time. Bilirubin and aminotransferase levels may be elevated acutely and for several months. Albuminuria, which occurs in 90% of patients, may reach 20 g/L. This finding helps differentiate yellow fever from viral hepatitis. In malignant yellow fever, hypoglycemia and hyperkalemia may occur terminally.

Diagnosis is confirmed by viral culture, serology, the identification of viral antigens and virus-specific immunoglobulin M (IgM) and neutralizing antibodies in serum by several rapid diagnostic methods, or detecting characteristic midzonal hepatocyte necrosis at autopsy. Suspected or confirmed cases must be quarantined and health departments notified. Needle biopsy of the liver during illness is contraindicated because of high risk of hemorrhage.

Differential Diagnosis

Mild yellow fever appears clinically like a broad expanse of other infections presenting with similar symptoms, including dengue, viral hepatitis, malaria, typhus, Q fever, typhoid, Rift Valley fever,

³Exceeds dosage recommended by the manufacturer.

leptospirosis, drug-induced syndromes, and toxic causes. Yellow fever may be distinguished from malaria by the findings of conjunctival suffusion or relative bradycardia. The other viral hemorrhagic fevers, which include dengue, Lassa fever, Marburg disease, Ebola, Crimean-Congo hemorrhagic fever, and Bolivian and Argentine hemorrhagic fevers, usually present without jaundice. As well, albuminuria is a reliable hallmark of yellow fever that allows its differentiation from other causes of viral hepatitis.

Treatment

Since no antiviral therapy is currently available, treatment is supportive, focused on aggressive symptom management designed to correct the acid-base imbalance and electrolyte abnormalities caused by emesis, heart failure, and renal derangements. Placement in an intensive care unit is recommended. Transfusions of blood, fresh-frozen plasma, and vitamin K¹ may be utilized with hemorrhagic symptoms. As well, a proton pump inhibitor, H₂ blocker, and sucralfate (Carafate)¹ can be helpful as prophylaxis for gastrointestinal bleeding and should be considered in all hospitalized patients. Antipyretics, oxygen, vasopressors, and IV hydration may also be helpful. Avoidance of sedatives and drugs metabolized hepatically is prudent, and medication dosing should be adjusted in the face of declining renal function. Antibiotic therapy for secondary bacterial sepsis is often necessary during the recovery period. Owing to the increased risk of bleeding, avoidance of aspirin and other nonsteroidal antiinflammatory drugs, such as naproxen and ibuprofen, is recommended.

Complications

The majority of those infected with yellow fever will be asymptomatic or experience only mild disease with total recovery. The mortality rates in tropical America range from 45% to 75%, compared with less than 30% in Africa. This difference suggests genetic factors play a role in the course of the illness, as well as the viral strain. The convalescence of a yellow fever patient is usually prolonged and varies from patient to patient. Although uncommon, late death (weeks after the acute illness) can occur as a result of cardiac complications or renal failure. Profound asthenia and fatigue usually last for 1 to 2 weeks, but in some cases can last many months. Jaundice and the elevation of liver enzymes have been known to last an extended period (several months) during convalescence. Survival of an attack imparts lifelong immunity against subsequent infection.

WHOOPING COUGH (PERTUSSIS)

Method of

Deon Regis, MD

CURRENT DIAGNOSIS

- Primarily a toxin-mediated disease
- Incubation period 7 to 10 days (range 4 to 21 days)
- Insidious onset, similar to the common cold with nonspecific cough
- Catarrhal stage: 1 to 2 weeks
- Paroxysmal cough stage: 1 to 6 weeks
- Convalescence: weeks to months
- Nasopharyngeal culture—gold standard

CURRENT TREATMENT

- Vaccination is key for prevention.
- Early treatment eradicates the organism from secretions, decreasing transmission, and may shorten the course of the illness.
- Macrolides are the treatment of choice, specifically azithromycin (Zithromax).¹

¹Not FDA approved for this indication.

Pertussis, or whooping cough, is an acute infectious disease caused by the bacterium *Bordetella pertussis*. Outbreaks of pertussis were first described in the 16th century, and the organism was first isolated in 1906.

In the 20th century, pertussis was one of the most common childhood diseases and a major cause of childhood mortality in the United States. In 1932, an outbreak of whooping cough hit Atlanta, Georgia, and a pediatrician by the name of Leila Denmark began her study of the disease. In partnership with Emory University and Eli Lilly & Company, she developed the first pertussis vaccine. Before the availability of the pertussis vaccine in the 1940s, more than 200,000 cases of pertussis were reported annually. Since widespread use of the vaccine began, incidence has decreased more than 80% compared with the prevaccine era.

Epidemiology

Worldwide, it is estimated that there are about 16 million pertussis (whooping cough) cases and about 195,000 pertussis deaths in children per year. Despite generally high coverage with childhood pertussis vaccines, pertussis is one of the leading causes of vaccine-preventable deaths worldwide. Most deaths occur in infants who are either unvaccinated or incompletely vaccinated. The World Health Organization (WHO) estimates that in 2008, global vaccination against pertussis prevented approximately 687,000 deaths. The year 2012 was the peak year in which there were more than 48,000 reported cases in the United States, which drew the attention of the public health community.

Transmission

Pertussis is a human disease. There is no animal, insect source, or vector. Adolescents and adults are an important reservoir for *B. pertussis* and are often the source of infection for infants.

Transmission most commonly occurs by the respiratory route through aerosolized respiratory droplets or by direct contact with airborne droplets of respiratory secretions. Transmission occurs less frequently by contact with freshly contaminated articles of an infected person as the bacteria cannot survive long outside of the reservoir. Pertussis is highly communicable. Persons with

leptospirosis, drug-induced syndromes, and toxic causes. Yellow fever may be distinguished from malaria by the findings of conjunctival suffusion or relative bradycardia. The other viral hemorrhagic fevers, which include dengue, Lassa fever, Marburg disease, Ebola, Crimean-Congo hemorrhagic fever, and Bolivian and Argentine hemorrhagic fevers, usually present without jaundice. As well, albuminuria is a reliable hallmark of yellow fever that allows its differentiation from other causes of viral hepatitis.

Treatment

Since no antiviral therapy is currently available, treatment is supportive, focused on aggressive symptom management designed to correct the acid-base imbalance and electrolyte abnormalities caused by emesis, heart failure, and renal derangements. Pertussis, or whooping cough, is an acute infectious disease caused by the bacterium *Bordetella pertussis*. Outbreaks of pertussis were first described in the 16th century, and the organism was first isolated in 1906.

In the 20th century, pertussis was one of the most common childhood diseases and a major cause of childhood mortality in the United States. In 1932, an outbreak of whooping cough hit Atlanta, Georgia, and a pediatrician by the name of Leila Denmark began her study of the disease. In partnership with Emory University and Eli Lilly & Company, she developed the first pertussis vaccine. Before the availability of the pertussis vaccine in the 1940s, more than 200,000 cases of pertussis were reported annually. Since widespread use of the vaccine began, incidence has decreased more than 80% compared with the prevaccine era.

Epidemiology

Worldwide, it is estimated that there are about 16 million pertussis (whooping cough) cases and about 195,000 pertussis deaths in children per year. Despite generally high coverage with childhood pertussis vaccines, pertussis is one of the leading causes of vaccine-preventable deaths worldwide. Most deaths occur in infants who are either unvaccinated or incompletely vaccinated. The World Health Organization (WHO) estimates that in 2008, global vaccination against pertussis prevented approximately 687,000 deaths. The year 2012 was the peak year in which there were more than 48,000 reported cases in the United States, which drew the attention of the public health community.

Transmission

Pertussis is a human disease. There is no animal, insect source, or vector. Adolescents and adults are an important reservoir for *B. pertussis* and are often the source of infection for infants.

Transmission most commonly occurs by the respiratory route through aerosolized respiratory droplets or by direct contact with airborne droplets of respiratory secretions. Transmission occurs less frequently by contact with freshly contaminated articles of an infected person as the bacteria cannot survive long outside of the reservoir. Pertussis is highly communicable. Persons with

pertussis are most infectious during the catarrhal period and the first 2 weeks after cough onset.

Microbiology

B. pertussis is a small, aerobic, gram-negative rod. *B. pertussis* produces multiple antigenic and biologically active products, including pertussis toxin (PT), filamentous hemagglutinin (FHA), agglutinogens, adenylate cyclase, pertactin, and tracheal cytotoxin. These products are responsible for the clinical features of pertussis disease, and an immune response to one or more produces immunity following infection.

Pathogenesis

Pertussis is primarily a toxin-mediated disease. The bacteria attach to the cilia of the respiratory epithelial cells, causing inflammation, and produce toxins that paralyze the cilia, which interferes with the clearing of pulmonary secretions.

The steps in pathogenesis are:

- Exposure/inoculation
- Tissue tropism/attachment
- Proliferation and production of virulence factors
- Evasion/modulation of host defenses
- Local and systemic cell and tissue dysfunction/damage
- Clearance and resolution of symptoms or chronic infection or death

Pertussis Toxin*

PT is important as its effects include induction of lymphocytosis, alteration in insulin secretion, and enhancement of sensitivity to histamine and other mediators.

Filamentous Hemagglutinin*

This large surface protein can participate in the interaction of *B. pertussis* with host cells and exerts immunomodulatory effects; thus it is appropriately classified as an adhesion.

Pertactin*

Pertactin (PRN) can contribute to bacterium–host cell interaction as an adhesion and was found to have a role in host defense against neutrophils.

Fimbriae*

These surface appendages, similar to those in other bacteria, function as adhesins and make up several of the agglutinogens, which are used for *Bordetella* serotyping.

Adenylate Cyclase Toxin

This toxin increases cyclic adenosine monophosphate (cAMP) levels, resulting in inhibition of phagocyte function and activation of apoptosis in some cell types. Adenylate cyclase toxin is a critical virulence factor.

Tracheal Cytotoxin

The cytotoxin kills respiratory epithelial cells by a mechanism involving intracellular interleukin-1 and nitric oxide.

Clinical Features

The whole clinical course of the illness can typically last from 30 to 90 days and is divided into three stages. The incubation period of pertussis is commonly 7 to 10 days but can range anywhere from 4 to 21 days.

The first stage, the catarrhal stage, is similar to the symptoms of the common cold, which makes early diagnosis difficult. It is characterized by sneezing, low-grade fever, rhinitis, and a mild, occasional cough. This cough gradually becomes more severe over 1 to 2 weeks, which transitions to the second, or paroxysmal, stage.

It is during the paroxysmal stage that the diagnosis of pertussis is usually suspected. Typically the patient has severe paroxysms. Due to the length and force of the paroxysm, a long deep inspiratory effort is usually accompanied by a distinguishing high-pitched “whoop.” Children and young infants usually appear very ill

and distressed during these occurrences. Post-tussive vomiting and exhaustion commonly follow the episode. There have also been reported rib fractures due to the force of the cough. Between attacks, the patient may not appear ill.

During the first 1 or 2 weeks of this stage, the attacks increase in frequency and severity, remain at the same level for 2 to 3 weeks, and then gradually decrease. The paroxysmal stage usually lasts 1 to 6 weeks but may persist for up to 10 weeks.

In the convalescent stage, recovery is gradual. The cough becomes less paroxysmal and disappears in 2 to 3 weeks. However, paroxysms often recur with subsequent respiratory infections for many months.

Complications

The most common complication and the cause of most pertussis-related deaths is secondary bacterial pneumonia. Young infants are at highest risk for acquiring pertussis-associated complications. Neurologic complications such as seizures and encephalopathy may occur as a result of hypoxia or possibly from the toxin itself. Neurologic complications of pertussis are more common among infants. Other less serious complications of pertussis include otitis media, anorexia, and dehydration. Complications resulting from pressure effects of severe paroxysms include pneumothorax, epistaxis, subdural hematomas, hernias, and rectal prolapse.

In 2008 through 2011, a total of 72 deaths from pertussis were reported to the Centers for Disease Control and Prevention (CDC). Children 3 months of age or younger accounted for 60 (83%) of these deaths.

Prognosis

Most healthy older children and adults fully recover, but those with comorbid conditions have a higher risk of morbidity and mortality.

Infection in newborns is particularly severe. Pertussis is fatal in an estimated 1.6% of hospitalized U.S. infants younger than 1 year of age. First-year infants are also more likely to develop complications, such as pneumonia (20%), encephalopathy (0.3%), seizures (1%), failure to thrive, and death (1%).

Diagnosis

The diagnosis of pertussis is based on a characteristic clinical history (cough for more than 2 weeks with whoop, paroxysms, or posttussive vomiting), as well as a variety of laboratory tests (culture, polymerase chain reaction [PCR], and serology).

An elevated white blood cell count with a lymphocytosis is usually present in classical disease of infants. However, lymphocytosis is not absolute. Chest radiographs may show peribronchial consolidation, interstitial edema, or variable atelectasis, all of which are non-specific.

Culture is considered the gold standard laboratory test and is the most specific of the laboratory tests for pertussis. However, *B. pertussis* is difficult to culture. As with any sample, the yield of culture can be affected by specimen collection, transportation, and isolation techniques. Specimens should be obtained from the posterior nasopharynx, not the throat. Successful culture rates are highest during the first 2 weeks of illness (catarrhal and early paroxysmal stages). Since adolescents and adults have often been coughing for several weeks before they seek medical attention, it is often too late for culture to be useful.

PCR is a rapid test and has excellent sensitivity. PCR tests vary in specificity, so obtaining culture confirmation of pertussis for at least one suspicious case is recommended any time there is suspicion of a pertussis outbreak. Results should be interpreted along with the clinical symptoms and epidemiologic information.

All positive test results should be reported to the local health department.

Treatment

Early treatment of pertussis is very important. The earlier a person, especially an infant, starts treatment the better. If treatment for pertussis is started early in the course of illness, during the first 1 to 2 weeks before coughing paroxysms occur, symptoms may be

lessened. Clinicians should strongly consider treating prior to receiving test results if clinical history is strongly suggestive or the patient is at risk for severe or complicated disease (e.g., infants).

If the patient is diagnosed late, antibiotics will likely not alter the course of the illness, but they will help to eradicate the organism from secretions, thereby decreasing communicability. Recommended first-line antibiotics are macrolides. Options are as follows:

- Azithromycin (Zithromax)¹
- Erythromycin (Ery-Tab)
- Fluoroquinolones¹
- Trimethoprim-sulfamethoxazole (least effective)¹

Postexposure Antimicrobial Prophylaxis

The CDC supports targeting postexposure antibiotic use to persons at high risk of developing severe pertussis and to persons who will have close contact with those at high risk of developing severe pertussis.

Prevention

The primary method of prevention for pertussis is vaccination. Refer to the CDC recommended immunization schedule for details. There is insufficient evidence to determine the effectiveness of antibiotics in those who have been exposed but are without symptoms. Preventive antibiotics, however, are still frequently used in those who have been exposed and are at high risk of severe disease (such as infants).

¹Not FDA approved for this indication.

ZIKA VIRUS DISEASE

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

Zika virus is a mosquito-borne flavivirus. In 1947, researchers at the East African Research Institute in Entebbe, Uganda, were studying yellow fever and placed a caged rhesus macaque in the nearby Zika Forest. The monkey developed a fever and from its serum was isolated a transmissible agent that was first described as Zika virus in 1952. Initially, Zika virus, borne by arboreal mosquitoes such as *Aedes africanus*, infected wild primates and rarely infected humans, even in highly enzootic areas. From its discovery until 2007, there were only 14 confirmed human cases of Zika virus infection, the vertebrate life cycle primarily involving monkey-mosquito-monkey, with rare spread to humans. The Zika virus appears to have mutated in character while expanding its geographical range, transforming from a localized endemic, mosquito-borne infection producing only a mild illness to a disease causing explosive outbreaks linked with neurological disorders including Guillain-Barré syndrome and microcephaly. Estimates are that, between October 2015 and January 2016, approximately 1.5 million Brazilians were infected by Zika with 3,500 cases of microcephaly reported and with the three poorest states of Paraíba, Pernambuco, and Bahia having the highest incidence. The strain of Zika virus most closely related to the one that emerged in Brazil was originally isolated from patient samples in French Polynesia. In all probability, Zika virus arrived in Brazil in 2014 during the Confederation Cup, when Tahiti's soccer team and its supporters visited a variety of Brazilian venues.

In November 2016, the World Health Organization declared that “The Zika virus and associated consequences remain a significant enduring public health challenge requiring intense action but no longer represent a public health emergency of international concern.”

Zika virus cases in the Americas have dramatically decreased since August 2017.

Epidemiology

Zika virus is transmitted by the daytime-active *Aedes* mosquitoes, such as *A. aegypti* and *A. albopictus*. With the exception of West Nile virus, which is predominantly spread by culex-species mosquitoes, the arboviruses reaching the Western Hemisphere have all been transmitted by *Aedes* mosquitoes. Millennia ago, North African villagers began storing water in their dwellings, giving arboreal *A. aegypti* a new medium for depositing their eggs—domestic water-containing vessels. The hatched mosquitoes then fed on humans, evolving into an entirely new maintenance cycle of human–*A. aegypti*–human transmission. Now, thousands of years later, the worst effects of this evolutionary cascade are being seen in the repeated emergence of arboviruses in human ecosystems.

The distribution of *A. aegypti* is now the most extensive ever recorded, extending across all continents including North America.

Another significant Zika virus vector is *Aedes albopictus*, commonly known as the Asian tiger mosquito, named for its white striped legs. *A. albopictus* is of medical importance due to its aggressive daytime human-biting behavior and ability to vector many viruses, including dengue, La Crosse, and West Nile. Figure 1 shows the estimated range of the *Aedes aegypti* and *Aedes albopictus* mosquitoes in the United States (Table 1).

Most significantly, pregnant mothers may vertically transmit the virus to the developing fetus, potentially resulting in microcephaly. Zika virus has been isolated in semen and vaginal secretions. Male to female as well as female to male sexual transmission of the Zika virus has been reported. Blood transfusions have been a source of

lessened. Clinicians should strongly consider treating prior to receiving test results if clinical history is strongly suggestive or the patient is at risk for severe or complicated disease (e.g., infants).

If the patient is diagnosed late, antibiotics will likely not alter the course of the illness, but they will help to eradicate the organism from secretions, thereby decreasing communicability. Recommended first-line antibiotics are macrolides. Options are as follows:

- Azithromycin (Zithromax)¹
- Erythromycin (Ery-Tab)
- Fluoroquinolones¹
- Trimethoprim-sulfamethoxazole (least effective)¹

Postexposure Antimicrobial Prophylaxis

The CDC supports targeting postexposure antibiotic use to persons at high risk of developing severe pertussis and to persons who will have close contact with those at high risk of developing severe pertussis.

Prevention

The primary method of prevention for pertussis is vaccination. Refer to the CDC recommended immunization schedule for details. There is insufficient evidence to determine the effectiveness of antibiotics in those who have been exposed but are without symptoms. Preventive antibiotics, however, are still frequently used in those who have been exposed and are at high risk of severe disease (such as infants).

ZIKA VIRUS DISEASE

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

Zika virus is a mosquito-borne flavivirus. In 1947, researchers at the East African Research Institute in Entebbe, Uganda, were studying yellow fever and placed a caged rhesus macaque in the nearby Zika Forest. The monkey developed a fever and from its serum was isolated a transmissible agent that was first described as Zika virus in 1952. Initially, Zika virus, borne by arboreal mosquitoes such as *Aedes africanus*, infected wild primates and rarely infected humans, even in highly enzootic areas. From its discovery until 2007, there were only 14 confirmed human cases of Zika virus infection, the vertebrate life cycle primarily involving monkey-mosquito-monkey, with rare spread to humans. The Zika virus appears to have mutated in character while expanding its geographical range, transforming from a localized endemic, mosquito-borne infection producing only a mild illness to a disease causing explosive outbreaks linked with neurological disorders including Guillain-Barré syndrome and microcephaly. Estimates are that, between October 2015 and January 2016, approximately 1.5 million Brazilians were infected by Zika with 3,500 cases of microcephaly reported and with the three poorest states of Paraíba, Pernambuco, and Bahia having the highest incidence. The strain of Zika virus most closely related to the one that emerged in Brazil was originally isolated from patient samples in French Polynesia. In all probability, Zika virus arrived in Brazil in 2014 during the Confederation Cup, when Tahiti's soccer team and its supporters visited a variety of Brazilian venues.

In November 2016, the World Health Organization declared that “The Zika virus and associated consequences remain a significant enduring public health challenge requiring intense action but no longer represent a public health emergency of international concern.”

Zika virus cases in the Americas have dramatically decreased since August 2017.

Epidemiology

Zika virus is transmitted by the daytime-active *Aedes* mosquitoes, such as *A. aegypti* and *A. albopictus*. With the exception of West Nile virus, which is predominantly spread by culex-species mosquitoes, the arboviruses reaching the Western Hemisphere have all been transmitted by *Aedes* mosquitoes. Millennia ago, North African villagers began storing water in their dwellings, giving arboreal *A. aegypti* a new medium for depositing their eggs—domestic water-containing vessels. The hatched mosquitoes then fed on humans, evolving into an entirely new maintenance cycle of human–*A. aegypti*–human transmission. Now, thousands of years later, the worst effects of this evolutionary cascade are being seen in the repeated emergence of arboviruses in human ecosystems.

The distribution of *A. aegypti* is now the most extensive ever recorded, extending across all continents including North America.

Another significant Zika virus vector is *Aedes albopictus*, commonly known as the Asian tiger mosquito, named for its white striped legs. *A. albopictus* is of medical importance due to its aggressive daytime human-biting behavior and ability to vector many viruses, including dengue, La Crosse, and West Nile. Figure 1 shows the estimated range of the *Aedes aegypti* and *Aedes albopictus* mosquitoes in the United States (Table 1).

Most significantly, pregnant mothers may vertically transmit the virus to the developing fetus, potentially resulting in microcephaly. Zika virus has been isolated in semen and vaginal secretions. Male to female as well as female to male sexual transmission of the Zika virus has been reported. Blood transfusions have been a source of

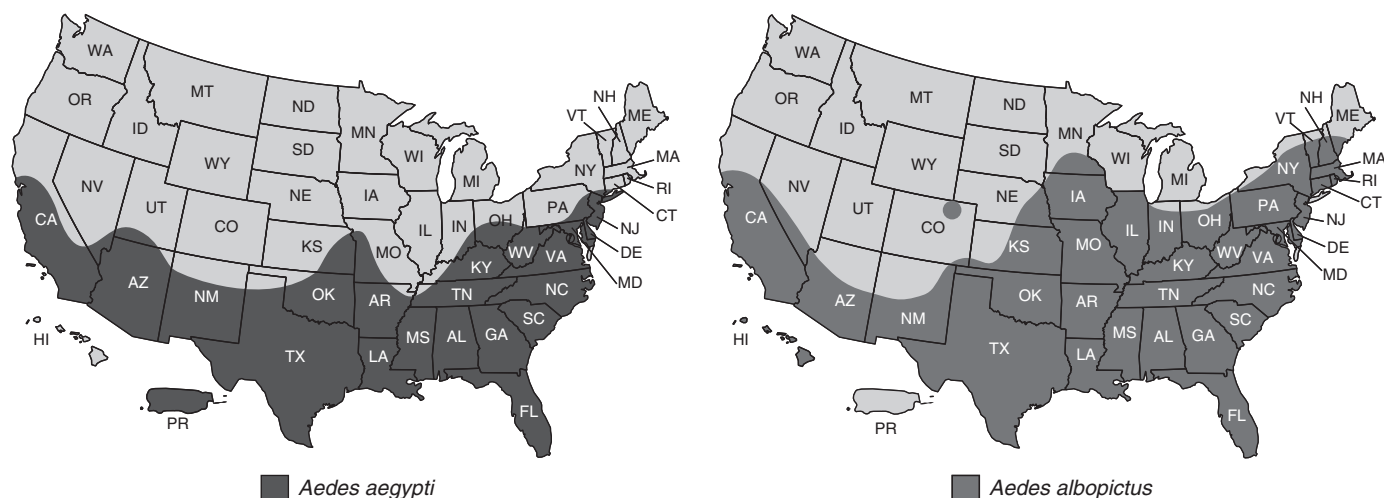

Figure 1 Range of Zika-transmitting mosquitoes in the United States. (Source: <https://www.cdc.gov/zika/vector/range.html>).

TABLE 1 Prevention of Mosquito Bites

- Remove yard debris (e.g., old tires) and containers that collect water and may provide mosquito breeding sites.
- Wear long-sleeved shirts, long pants, and socks. Tuck pants into socks.
- Apply permethrin to outer clothing.
- Use window screens.
- Use mosquito netting at night if sleeping quarters are not screened.
- Use mosquito netting when children less than 2 months of age—before they can use mosquito repellants—must go outside.
- Apply mosquito repellents directly to exposed skin. When applying mosquito repellents to the face, spray it on the hands, then rub it in. Avoid the eyes and mouth.
- Do not allow young children to apply mosquito repellents themselves. Children who rub mosquito repellent into their own skin are prone to putting their hands into their mouths or touching their eyes.
- Adults should apply mosquito repellent on children by putting the repellent on their own hands and rubbing it into the child's skin.
- To limit the total amount of mosquito repellent that might be absorbed, do not apply to skin under clothing or on skin that is broken (i.e., cuts, rashes).
- Do not use mosquito repellents near food. Wash hands before eating or drinking.
- Wash off mosquito repellent from the skin when it is no longer needed.
- At the end of the day, wash treated skin with soap and water.

transmission outside of the United States. The blood supply in the United States is tested for Zika virus. Although Zika virus has been detected in breast milk, there are no reports of infants being infected with Zika virus through breastfeeding.

Zika has followed a pattern of dispersion analogous to chikungunya, spreading pandemically from west to east. Both viruses now encircle the globe. It appears that both viruses migrated from East Africa to Asia evolving into unique genotypes. There is a similar striking movement of Zika and chikungunya from Asia into the Pacific Islands and then to the Americas. Perhaps analogous ecological factors might be responsible for their similar spread and may be a key to understanding effective prevention strategies.

Risk Factors

The risk of Zika virus infection for pregnant women is more pronounced because of the potential link to microcephaly of the infant. In Zika confirmed infections in pregnancy, the incidence of birth defects in the offspring was 7% in one study. The risk was greatest if the infection was obtained early in pregnancy. There is no evidence that pregnant women are more susceptible to Zika virus

infection or that the disease is more severe during pregnancy. While the virus generally clears from the blood in 7 days, it has been detected in the blood of pregnant women for at least 70 days. Based on what is known about similar arbovirus infections, once a person has been infected and developed antibodies to Zika virus, he or she is likely to be protected from a future Zika infection. Based on currently available evidence, once the virus has cleared from the blood of a Zika-infected woman, she is not felt to be at future risk for having a child with a Zika-related birth defect.

Pathophysiology

The Zika virus is a member of the Flaviviridae virus family, which includes dengue, yellow fever, West Nile, and Japanese encephalitis viruses. Zika is a single-stranded, positive-sense RNA virus that has been fully sequenced. It is one of many arthropod-borne arboviruses. Monkeys are the common vertebrate host of the virus. Arboviruses oftentimes have complex natural transmission cycles involving mammals, birds, and blood-feeding arthropod vectors.

Until recently, only a few arboviruses have caused clinically significant human diseases. These include mosquito-borne alphaviruses such as chikungunya and flaviviruses such as dengue and West Nile. The most historically important of these is the yellow-fever virus, the first recognized viral cause of deadly epidemic hemorrhagic fever.

Prevention

Population-based mosquito control measures are recommended to prevent the spread of Zika virus. Although yellow fever has historically been prevented entirely by aggressive mosquito control, in the modern era vector control has been problematic because of the expense, logistics, public resistance, the development of resistance to the pesticides used and their collateral adverse effects on humans. Although a chemical war against the vector can have short-term effects, programs for improving urban infrastructure and environmental sanitation with a stable supply of potable water would offer more durable results. Among the best preventive measures against Zika virus are house screens, air conditioning, and removal of yard and household debris and containers that provide mosquito-breeding sites, luxuries often unavailable to impoverished residents of crowded urban locales where such epidemics take their greatest toll. Releasing mosquitoes that are sterile or genetically modified to die before they can reproduce is being investigated. Researchers funded by the Bill and Melinda Gates Foundation have proposed infecting mosquitoes with the *Wolbachia* bacteria, which seem to inhibit the transmission of dengue and other viruses by the mosquito.

Because of the association between Zika virus infection and microcephaly in fetuses, the United States Centers for Disease

Control and Prevention (CDC) issued travel guidance on affected countries, including the use of enhanced precautions and guidelines for pregnant women including considering postponing travel. Pregnant women and those considering pregnancy should reference the CDC website at <https://wwwnc.cdc.gov/travel/page/zika-information>. Women who are considering becoming pregnant should consult with their physicians for preconception counseling.

The CDC recommends that women who have had Zika virus exposure through travel or sexual contact and do not have ongoing risks for exposure should wait at least 8 weeks from date of diagnosis, symptom onset (if symptomatic), or last possible exposure before attempting to conceive. During this waiting period, either abstinence should be practiced or barrier contraception with condoms should be used. The 8-week waiting period may decrease the risk of maternal-fetal transmission of the Zika virus.

Zika virus typically remains in the semen for longer periods of time than other body fluids. Accordingly, the CDC recommends waiting at least 6 months from date of diagnosis, symptom onset (if symptomatic), or after the last possible exposure before attempting conception with their partner. During this waiting period, either abstinence should be practiced or barrier contraception with condoms should be used. The recommendation to wait at least 6 months for asymptomatic men is based on the length of time the Zika virus RNA has been detected in semen, although 95% of men clear Zika virus from their semen by 81 days. There is lack of evidence that the risk of sexual transmission differs in symptomatic and asymptomatic men.

Pregnant women and men and women who are considering parenthood and who have visited or are considering traveling to areas at risk should consult their physician and reference the CDC website for travel alerts and pregnancy counseling recommendations.

Avoiding mosquito bites is important for disease control. There are hundreds of insect repellants sold in the United States. These insect repellants have different ingredients, different concentrations of ingredients, and different combinations of ingredients. Furthermore, different species of mosquitoes may be differentially repelled by different repellants. Though research is limited, the *Aedes aegypti* and *Aedes albopictus* mosquitoes seem to be most effectively repelled by products that contain at least 25% DEET (N,N-diethyl-m-toluamide), 30% Oil of Lemon Eucalyptus, or 20% picaridin. When applied appropriately, these ingredients may repel mosquitoes for approximately 7 hours and seem to be safe when used during pregnancy. Products with lower concentrations of DEET, Oil of Lemon Eucalyptus, and picaridin are much less effective. Products containing IR3535, 2-undecanone, and products made from natural plant oils such as citronella, lemon-grass oil, cedar oil, rosemary oil, cinnamon oil, and geraniol seem to be ineffective against Zika-transmitting mosquitoes. Insect repellents can be used with sunscreen, but the sunscreen should be applied first.

Additional protection from mosquito bites can be achieved by treating outer clothing with permethrin. Permethrin, a derivative of *Chrysanthemum cinerariifolium*, is an insect repellent and insecticide. Though it is poorly absorbed and rapidly inactivated permethrin should not be applied directly to the skin and it should not be used on underclothing. The Environmental Protection Agency (EPA) recommends that clothes treated with permethrin should be washed separately from clothes that are not treated. If washed together, underclothing may absorb permethrin into the fabric which may increase the risk of absorption. Permethrin-treated clothing will retain repellent activity through multiple washes. The EPA indicates there is no evidence that exposure to permethrin results in adverse effects for pregnant or nursing mothers or adverse developmental effects in their children. Permethrin is listed as pregnancy category B. It can be used on the outer clothing of children older than 2 months of age.

At present no Zika vaccines are available, however there is encouraging data from phase I studies.

Clinical Manifestations

The incubation period for Zika virus is estimated to be 3 to 12 days. Serosurvey results from the Yap Islands indicate that only 19% of persons who were infected had symptoms that were attributable to Zika virus. Common symptoms were macular or papular rash (90% of patients), fever (65%), arthritis or arthralgia (65%), non-purulent conjunctivitis (55%), myalgia (48%), headache (45%), retro-orbital pain (39%), edema (19%), and vomiting (10%). The rash is generally maculopapular and pruritic, and fever, when present, is generally short-term and low-grade. In more than 60 years of observation, severe disease requiring hospitalization is uncommon and case fatality is low. Rarely, immune thrombocytopenia purpura has been linked to Zika.

Diagnosis

In a “pure” Zika epidemic, a diagnosis can be ascertained on clinical grounds. However, dengue and chikungunya have similar clinical presentations and have been epidemic in the Americas, confounding a clinical diagnosis.

The CDC website should be consulted for Zika virus testing of women who are symptomatic or asymptomatic during pregnancy. Instructions for testing can be found at <https://www.cdc.gov/zika/hc-providers/types-of-tests.html>.

Cross-reaction with related flaviviruses (e.g., dengue and yellow-fever viruses) is common, complicating the immunologic interpretation of infection. Physicians who deliver an infant suspected of suffering the effects of maternal Zika virus infection should consult the CDC to discuss blood, placental, and umbilical cord sampling. Zika virus infection is a nationally notifiable disease.

Differential Diagnosis

Differential diagnosis encompasses a wide variety of other viral diseases such as dengue, chikungunya, Mayaro virus disease, Ross River fever, Barmah Forest disease, o'nyong-nyong disease, and Sindbis fever. In addition, the CDC lists group A streptococcus, leptospirosis, malaria, rickettsia, rubella, measles, parvovirus, enterovirus, and adenovirus in the differential diagnosis.

Treatment

At present, there is no treatment or vaccine for Zika virus disease. Because symptoms are usually absent or mild, most acutely infected patients do not access the medical system and treat themselves symptomatically. Antiviral medication is ineffective. The mainstays of management are bed rest and supportive care. When multiple arboviruses are co-circulating, testing for a specific viral diagnosis, if available, can be important in anticipating, preventing, and managing complications.

Although the Zika virus has not been associated with hemorrhagic fever, it is probably best to avoid aspirin and nonsteroidal antiinflammatory medications due to their association with hemorrhagic fever syndromes and death when taken for the treatment of similar viruses. The use of aspirin should be avoided in children due to the risk of Reye syndrome. Guidelines for pregnant women during a Zika virus outbreak can be accessed at the CDC website: <https://www.cdc.gov/pregnancy/zika/women-and-their-partners.html>.

Because of the rapidly evolving knowledge about the Zika virus, clinicians are encouraged to freely consult the CDC and WHO websites for clinical guidance.

Monitoring

Pregnant women should be asked about their travel history. Currently the WHO recommends anomaly ultrasound investigations at 18 to 20 weeks' gestation to identify, monitor, or exclude fetal brain abnormalities, particularly microcephaly, for all pregnant women living in areas with ongoing Zika virus transmission.

International monitoring of Zika virus infection is important. Each year, nearly 10 million international travelers depart from Brazilian airports favorable to year-round transmission of the Zika virus, and over one-quarter of these travelers are headed to the United States. In the United States, during 2017, 424 symptomatic

Zika virus disease cases were reported, 414 occurred in travelers returning from affected areas, 4 cases presumed were contracted through local mosquito-borne transmission (Florida-2, Texas-2) and 6 cases acquired through sexual transmission.

Complications

The major complication of Zika virus disease is the potential risk of microcephaly as a result of vertical transmission. Amniocentesis has been used to detect the presence of Zika virus in amniotic fluid of women who had ultrasound confirmation of microcephalic fetuses. The virus has been isolated in the brains of newborns and miscarried fetuses. It is unclear whether there may be contributory factors to the development of microcephaly such as nutritional and environmental factors or concomitant infection with other micro-organisms. Other fetal findings have included intracranial calcifications, orbital calcifications, and microphthalmia.

The gestational age of pregnancy when Zika virus infection may affect fetal development is uncertain. The proportion of fetuses who develop microcephaly after their mothers' contract Zika virus infection during pregnancy is currently unknown although a systematic review of the literature and meta-analysis indicates the incidence at 2.7%. The microcephaly may be subtle. Children may have a general appearance of craniofacial disproportion and abnormal cranial shape. The fontanelles may be closed or very small and the sutures may be uneven or overlapping. In addition to microcephaly, a phenotypic spectrum has been identified in congenital Zika syndrome. Neurologically, there may be changes in motor activity, severe muscle hypertonia, feeding difficulties, and excessive and inconsolable crying. Musculoskeletal problems include joint immobility, hand and finger contractures, feet contractures and malposition, deep and multiple dimples over joints, abnormal palmar creases and generalized arthrogryposis. Skin on the scalp and other areas of the body may be redundant. Brain imaging may show calcifications, abnormal gyral patterns, enlarged ventricles, and marked decreases in the volume of gray and white matter. The corpus callosum may be thin or absent. The brainstem and cerebellum may be underdeveloped. Seizures, especially in infants between 3 and 6 months of age, may develop and children may exhibit visual problems, hearing loss, and impaired growth. The viruses' strong affinity for neural cells may cause neurologic damage that only becomes apparent as children age. It is unclear whether infants and children who contract Zika in infancy or early childhood may develop neurologic complications.

Retrospective data from the French Polynesia Zika virus outbreak from October 2013 to April 2014 indicate a close association with Guillain-Barré syndrome. Of the 42 patients diagnosed with Guillain-Barré syndrome, 41 (98%) had anti-Zika virus IgM or

IgG, and all (100%) had neutralizing antibodies against Zika virus compared with 54 (56%) of 98 in the control group.

Zika virus is a pandemic in progress and uncertainty remains regarding its teratogenicity and long-term complications. A larger issue still to be elucidated in the emergence of Zika and other novel infectious diseases is the role played by urban crowding, ease of international travel, and human encroachments into complex ecosystems.

ACUTE FACIAL PARALYSIS

Method of

Steven L. Meyers, MD

CURRENT DIAGNOSIS

- Typical cases of acute facial paralysis are diagnosed based on examination and do not require additional evaluation.
- All patients with acute facial paralysis should have a complete neurologic and head and neck examinations.
- The presence of atypical features such as a slowly progressive course, failure to improve, recurrent attacks, or other neurologic findings should prompt additional evaluation with computed tomography (CT) or magnetic resonance imaging (MRI) of the head and a specialist consultation.

CURRENT THERAPY

- Steroid therapy, such as prednisone¹ 60–80 mg daily for 7 days, initiated within 3 days of onset of the facial paralysis, increases the chances of recovery
- The use of antiviral therapy remains controversial without strong evidence of benefit, but valacyclovir (Valtrex)¹ 1000 mg three times daily for 7 days may be beneficial in patients with severe paralysis.
- Eye care with artificial tears, ophthalmic ointments at night, and eye protection should be used in patients with severe facial paralysis.

¹Not FDA approved for this indication.

Acute facial nerve paralysis, or Bell's palsy, is a common disorder manifesting with the acute to subacute onset of unilateral paralysis of the muscles of facial expression. The Scottish physician Sir Charles Bell described cases of facial paralysis due to trauma in the 1800s, and the idiopathic condition carries his name today. However, there are many possible causes of facial paralysis, and each patient requires a careful history and complete neurologic examination to exclude these possibilities.

Epidemiology and Risk Factors

The annual incidence rate is between 13 and 34 cases per 100,000 population. All age ranges can be affected, but persons between the ages of 15 and 40 years are most commonly affected. Diabetics, pregnant women in the third trimester, and women in the immediate postpartum period are at increased risk. There is no gender, race, or geographic predilection.

Pathophysiology

The seventh cranial, or facial, nerve arises from the pontomedullary junction and runs in close proximity to the eighth cranial nerve to the internal auditory meatus. The nerve then runs through the

bony fallopian canal before exiting the skull at the stylomastoid foramen. The labyrinthine portion of the fallopian canal is very narrow, and it is postulated that swelling of the nerve results in compression in this region.

Three branches arise from the facial nerve within the fallopian canal. The greater petrosal nerve arises from the geniculate ganglion, passes to the pterygopalatine ganglion, and eventually supplies innervation to the lacrimal and palatine glands. The second branch is the nerve to the stapedius muscle in the middle ear. The final branch is the chorda tympani, which supplies taste sensation from the anterior two thirds of the tongue.

The pathophysiology of Bell's palsy is uncertain, but a viral cause is the most commonly accepted hypothesis. Many different viruses have been associated with facial paralysis, with herpes simplex virus (HSV) having the strongest evidence. HSV-1 DNA has been detected by polymerase chain reaction assay in endoneural fluid in patients with Bell's palsy undergoing facial nerve decompression.

Herpes zoster is another virus associated with facial nerve paralysis. Herpes zoster oticus (Ramsey Hunt syndrome) is diagnosed when vesicles are seen in the external auditory canal or on the auricle. Other viruses implicated include cytomegalovirus, Epstein-Barr virus, adenovirus, rubella, mumps, influenza B, and coxsackievirus.

The histopathology of the facial nerve supports an inflammatory etiology with findings similar to those seen in herpes zoster infection. The perineurium is edematous, with diffuse infiltration of inflammatory cells between nerve bundles and surrounding the intraneural vessels.

Clinical Manifestations

The clinical presentation of Bell's palsy is typically dramatic and very stereotypical. Pain behind the ear in the region of the mastoid can precede the onset of weakness by hours to days. Weakness of the muscles of facial expression on one side progresses over a period up to 48 hours. Progression over more prolonged periods raises the possibility of a neoplasm affecting the nerve. The degree of weakness can range from quite subtle to complete paralysis of all muscles of facial expression. Typical features include inability to close the eye, sagging of the eyelid, loss of the nasolabial fold, and inability to wrinkle the forehead muscles. Sparing of the forehead muscles suggests a central or upper motor neuron lesion because these muscles receive bilateral innervation. Additional symptoms that may be reported include hyperacusis caused by paralysis of the stapedius muscle, loss of taste in the anterior tongue due to involvement of the chorda tympani, and decreased tearing due to dysfunction of the parasympathetic innervation of the lacrimal gland. However, most patients actually report increased tearing from the affected eye owing to diminished blinking.

Diagnosis and Differential Diagnosis

There is no specific diagnostic test for Bell's palsy. The diagnosis is based on a typical history and examination. Atypical features mandate a search for other causes. A slowly progressive course, parotid gland mass, or involvement in selected branches of the facial nerve can suggest neoplastic compression. Vesicles over the ear or internal auditory canal suggests herpes zoster infection. Patients should be asked about preceding fevers, rashes, and arthralgias, which can

Sjögren syndrome

prompt evaluation for Lyme disease. However, in the absence of these features, routine serologic testing is not recommended. Sarcoid is a rare cause of usually bilateral facial paralysis. The onset of facial paralysis in the setting of head injury, particularly in the presence of ipsilateral hearing loss, should prompt imaging of the skull base to rule out a temporal bone fracture (Box 1).

Treatment

Treatment of Bell's palsy can be divided into three categories: general medical therapy, specific medical therapy, and surgical therapy. General medical care includes proper eye care. Reduced blinking and inability to completely close the eye increases the risk of corneal abrasion and ulceration. Artificial tears and ophthalmic ointments can prevent these complications. Patients should be instructed to use proper eye protection to prevent injuries. Facial muscle massage and facial nerve stimulation have no evidence to support their use.

Medical Therapy

Specific medical therapy includes glucocorticoid and antiviral medications. Glucocorticoid therapy has been demonstrated to be effective in both meta-analyses and randomized trials. The two largest trials of glucocorticoid and antiviral therapy demonstrated benefit for steroids but no benefit for antiviral therapy when used either alone or in combination with steroids. Treatment in these trials was begun within 72 hours of onset of paralysis and consisted of relatively high-dose prednisolone (Millipred)¹ 50 to 60 mg daily for 10 days. Antiviral therapy evaluated included acyclovir (Zovirax)¹

400 mg five times daily for 10 days and valacyclovir (Valtrex)¹ 1000 mg three times daily for 7 days, neither of which showed benefit.

Smaller, lower-quality studies have suggested a benefit of combining antiviral therapy with glucocorticoids, particularly in patients with more severe baseline dysfunction.

Surgical Therapy

Surgical decompression of the facial nerve is not recommended. A 2011 Cochrane review and a 2001 review by the American Academy of Neurology both found no good evidence supporting this treatment modality. Only two small randomized studies showed no differences in outcome between surgical and medical therapy.

Monitoring and Complications

The overall prognosis of Bell's palsy is favorable. In one study of untreated patients, 85% showed signs of recovery within 3 weeks. Ultimately, 71% experienced complete recovery and an additional 13% were felt to have only slight residual weakness. The degree of weakness at onset is an important prognostic indicator: 94% of patients with incomplete paralysis experienced complete recovery. The absence of any improvement, no matter how small, at 3 to 4 months should raise concern regarding the diagnosis and lead to a search for alternative etiologies.

Motor nerve conduction studies, or electroneurography, can be used to help predict prognosis in selected patients. Patients with incomplete lesions that have an excellent prognosis do not require further evaluation. Motor nerve conduction studies involve stimulating the facial nerve electrically and recording muscle responses with surface electrodes over appropriate muscles. The amplitude of the evoked muscle response on the affected side at 10 days can be compared with the unaffected side, giving an estimate of the degree of axonal loss. A 90% drop in amplitude predicts less than complete recovery, and loss greater than 98% predicts significant residual weakness and synkinesis.

In severe cases of facial paralysis, attention to good eye care as previously discussed is important to prevent eye damage and vision loss.

During recovery from severe nerve injury, axonal regrowth may be misdirected, resulting in synkinesis. Voluntary activation of one muscle group can cause activation of other muscles. Attempts at blinking can result in twitching of the mouth, or smiling can cause involuntary blinking. Misdirection of autonomic fibers can result in the syndrome of "crocodile tears," involuntary lacrimation while eating.

Recurrent attacks of facial paralysis on the ipsilateral or contralateral side occur in up to 15% of patients even after many years. Additional recurrences are quite rare, being reported at a rate between 1% and 3%.

ALZHEIMER'S DISEASE

Method of

Philip D. Sloane, MD, MPH; and Daniel I. Kaufer, MD

CURRENT DIAGNOSIS

- Routine screening for cognitive impairment is controversial but may be beneficial for early diagnosis and identifying treatable causes.
- Combining the Mini-Cog screening test with screening questions on the informant-based AD8 provides a rapid, sensitive, validated screening assessment.
- A comprehensive dementia evaluation includes a battery of cognitive tests, a laboratory panel for treatable causes, a neurologic examination, a brain MRI, and other testing (e.g., depression screen), as indicated.
- The diagnosis of Alzheimer's disease (AD) continues to rest on having a presentation and course of dementia that is consistent with the disease, and ruling out other identifiable etiologies.
- AD often coexists with cerebrovascular disease; atypical and non-AD dementias generally merit a consultation with a neurology or geriatric specialist.

CURRENT THERAPY

- Patient and family education and support are the cornerstones of effective care.
- Preventive measures with the strongest supporting evidence include hypertension control; head injury prevention; physical, cognitive, and social activity; and a Mediterranean diet.
- "Review medications and reduce anticholinergic burden to the extent feasible".
- Cholinesterase inhibitors and memantine (Namenda) alone or jointly have a modest effect on improving or slowing cognitive decline.
- The primary approach to managing behavioral symptoms is person-centered care using dementia-focused communication skills.
- First-line drug agents that may help control behavioral symptoms include cholinesterase inhibitors and mood stabilizers; anticonvulsants and antipsychotics may be helpful for moderate to severe agitation.

Alzheimer's disease (AD) and related disorders of cognitive function are a common and growing issue for all clinicians who provide care to older adults. In discussing this condition, several related but distinctly different terms are used:

- *Cognitive impairment* refers to the presence of one or more measurable deficits in cerebral function when compared with normal persons of the same age.
- *Neurocognitive disorder* generally refers to a clinical syndrome involving cognitive decline from a previous level of functioning, most commonly associated with Alzheimer's disease. Each neurocognitive disorder is divided into mild and major forms, with the latter distinguished by clinically significant functional disability due to compromise in multiple domains. Within this new DSM-V framework, mild cognitive impairment is now referred to as mild neurocognitive disorder, and dementia is now referred to as major neurocognitive disorder.
- AD is the most common cause of dementia; it has a characteristic pathophysiology and clinical presentation.

Lack of a simple, reliable diagnostic test makes it difficult to know with certainty how many persons in the United States currently have AD, but estimates place the number between 5 million and 8 million. Onset can occur when people are in their 40s or 50s,

but it is largely a disease of older persons, with the prevalence approximately doubling every 5 years after age 65. By age 85 to 90, up to 50% of individuals will meet criteria for dementia, often with mixed features of AD and cerebrovascular disease.

Risk Factors

Numerous risk factors have been associated with AD (Table 1); however, the strongest ones—age and a positive family history—cannot be modified. Of the modifiable risk factors, current emphasis is being placed on reduction of risk factors for atherosclerotic disease (especially hypertension) and traumatic brain injury, particularly sports-related concussions.

AD is associated with the pathological hallmarks of extracellular amyloid plaques and intracellular neurofibrillary tangles that are composed of hyper-phosphorylated tau protein. How these two protein markers of AD lead to the gradual loss of neuronal cell connections and eventually cell death remains poorly understood. New brain-imaging techniques have shown that amyloid deposits may begin decades before the onset of clinical signs, whereas the presence of neurofibrillary tangles composed of abnormal tau protein is much more strongly correlated with disease severity. Genetic mutations that cause AD and the strongest known AD genetic risk factor, the epsilon 4 allele of the apolipoprotein E locus, have led to a primary focus on abnormal amyloid protein processing, but amyloid-based therapeutics to date have been ineffective.

Despite intensive research efforts, the precise mechanisms and interrelationships between extracellular amyloid plaque and intracellular neurofibrillary tangle deposition remains elusive.

Prevention

With the disappointing lack of progress in developing safe, effective new medications to treat AD, increased emphasis is being placed on prevention through (a) modification of vascular risk factors, prevention of neural injury, and buildup of neuronal reserves (see Table 1). Among the preventive measures that can be recommended to persons with a family history of AD or other risk factors for the disease include:

- Control of hypertension, with the goal of a blood pressure of 130 to 140 or 80 to 90. Lower blood pressures are not generally advocated, especially in older persons, because of concern that more aggressive blood pressure reduction in persons with existing vascular disease may reduce cerebral perfusion, leading to ischemic damage.
- Reduction in other cardiovascular risk factors by not smoking and by treating hyperlipidemia and diabetes.
- Avoidance of and/or treatment of anything else that causes injury to brain cells, including head trauma, alcoholism, and obstructive sleep apnea.
- Maintenance of good general health by engaging in regular physical activity, being socially active, and adhering to healthy dietary principles, such as the Mediterranean diet.
- Avoidance when possible of medications that have anticholinergic side effects, depleting acetylcholine and increasing the risk of memory loss.
- Promotion of brain use and activity through such activities as learning a language and doing puzzles.
- Failure to treat mid-life hearing loss and depression are other factors that have recently been identified as being associated with a greater relative risk of dementia.

Clinical Features

Diagnostic criteria for *dementia* include a chronic, progressive disease characterized by (a) memory impairment; (b) impairment of one or more other aspects of neurologic function, such as executive function, visuospatial function, aphasia, apraxia, and/or agnosia; and (c) significant reduction in social or occupational function from the person's previous level of performance, which is not explained by another psychiatric or neurologic disorder. Diagnostic criteria for AD include meeting all criteria for dementia and ruling out delirium and the other dementias (see next section). Over

TABLE 1 Major Risk Factors for Alzheimer's Disease and Evidence of Ability to Modify Risk

RISK FACTOR	DIRECTION OF EFFECT	MODIFIABLE?/ STRATEGY	EVIDENCE OF RISK REDUCTION*
Older age	↑	No	—
Family history of Alzheimer's	↑	No	—
Head injury history	↑	Yes/head protection in sports	B
Hypertension	↑	Yes/treat to $\leq 140/90$	A
Other cardiovascular risk factors	↑	Yes/risk factor reduction	C
Apolipoprotein E4 allele	↑	No	—
Physical activity	↓	Yes/aerobic and strength training	B
Mediterranean diet	↓	Yes/diet modification	B
Diabetes	↑	Yes/treatment to reduce HbA1c	C
Moderate alcohol use	↓	Yes/encourage limited use	C
Heavy alcohol use	↑	Yes/successful alcoholism treatment	C
Cognitive and social activity	↓	Yes/brain health activities	B

*A = consistent, good-quality patient-oriented evidence; B = inconsistent or limited-quality patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion. For information about the SORT evidence rating system, see <http://www.aafp.org/afpsort.xml>.

time, these criteria may change: In 2011 the Alzheimer's Association and the National Institute on Aging defined AD to include a preclinical stage and mild cognitive impairment (MCI); however, at present, these definitions are for research purposes only.

The cardinal feature of AD is short-term memory loss or difficulty learning new information, which is often accompanied by a lack of awareness or concern of the memory problem. Word-finding difficulties, loss of time orientation, getting lost or misplacing things, and impaired judgment and planning are other common features. On average, the person with AD lives 6 to 10 years after the diagnosis and progresses through several stages. Over time, progressive cognitive disturbances become more pervasive, leading to impairment in instrumental activities of daily living (IADLs) and later even basic activities of daily living (ADLs). Ultimately, if the person does not die from some other cause, they will progress to being unable to express themselves verbally and will be relatively immobile, with contractures, swallowing problems, cachexia, weight loss, and eventually death.

Differential Diagnosis

The most important considerations in the differential diagnosis of AD are the following:

- Vascular dementia (VaD). There are two general types: (a) cortical—resulting from multiple infarcts in the cerebral cortex; and (b) subcortical—resulting from small-vessel disease with multiple lacunar infarcts. Presentation is highly variable; however, memory deficits are typically less prominent than in AD.
- Frontotemporal dementia (FTD). This diagnosis is relatively uncommon but accounts for up to half of all cases before age 65. The clinical presentation is highly variable, depending on the lateral distribution of pathological changes. Language disturbances involving expression or comprehension or prominent changes in behavior and personality (e.g., apathy, disinhibition, repetitive motor behaviors, loss of empathy) are the two main clinical subtypes (left and right side predominant, respectively). Clinical diagnosis can be aided by MRI brain imaging showing severe focal atrophy in the frontal and/or temporal lobes, which may not always be appreciated on radiology reports.
- Lewy body dementia (LBD) is an umbrella term for dementia with Lewy bodies (DLB) and Parkinson's disease dementia (PDD). DLB is used to describe the syndrome when cognitive symptoms predominate in conjunction with parkinsonian motor signs (bradykinesia, rigidity, and tremor), prominent visual

hallucinations, and sleep-wake disturbances (e.g., fluctuating arousal, daytime somnolence, acting out dreams). PDD refers to late-occurring dementia in a patient with Parkinson's disease, often with other clinical features associated with DLB, though lacking formal diagnostic criteria.

- Rare but distinctive forms of dementia. These include progressive supranuclear palsy, corticobasal degeneration, normal-pressure hydrocephalus, Creutzfeldt-Jakob disease, post-anoxic dementia, post-traumatic brain injury, chronic subdural hematoma(s), and Huntington's disease.
- MCI. This is a condition in which the person is able to carry out his or her normal activities but has deficits in certain areas of higher function such as short-term memory, judgment, and planning. There are two kinds of MCI: *amnesic*, which is characterized by isolated short-term memory loss; and *non-amnesic*, in which one or more other cognitive domains are affected. Amnesic MCI is particularly likely to progress to AD and in such cases reflects a prodromal stage of the disease.
- Delirium. In contrast to the dementias, delirium tends to be subacute or acute in onset and to be completely or partially reversible. Key characteristics include fluctuating consciousness, confusion, and hallucinations or delusions. The cause is usually identifiable and is most often because of medication, stress (such as infection or surgery), or a metabolic disturbance. Delirium often occurs in patients with dementia, reflecting increased vulnerability of a compromised brain to toxic, metabolic, or infectious insults.
- Depression. Decades ago, depression was at times mistaken for dementia and termed "pseudo-dementia," because people with depression often say "I don't know" in response to cognitive status questions. Improved interviewing techniques and routine use of depression screening tests as part of a dementia evaluation have largely eliminated this confusion. However, depression remains an important consideration in the dementia evaluation because it frequently coexists with dementia, particularly in early stages of the illness.

Screening for Cognitive Impairment

Whether to screen for AD is highly controversial. Advantages of early diagnosis include offering earlier treatment and research participation, allowing the person an opportunity to make life-planning decisions at a point where his or her residual cognitive function is at its best, helping family understand what is happening

and learn how best to provide support, providing guidance to patient and family about managing finances wisely and avoiding scams, and providing time for decision making about such things as durable power of attorney and advance-care planning. Medicare currently requires cognitive screening as part of the annual Medicare wellness visit; in addition, we recommend screening anyone age 75 and older and anyone for whom a memory lapse or vagueness noted in an interview or an error in judgment (e.g., causing an auto accident) raises suspicion of cognitive impairment.

Primary care physicians can conduct expedient, reliable screening for dementia by employing the Mini-Cog (patient) and the AD8 (informant). Each can be administered simultaneously by a nurse or medical assistant in about 3 minutes.

- The *Mini-Cog* consists of asking the person to remember three items; to draw a clock face, putting in the numbers and placing the hands at “10 after 11”; and then to recall the three items. A positive screen occurs if the person cannot recall any of the items (regardless of the clock drawing), or if they recall one to two items and the clock is drawn incorrectly.
- The *AD8* requires the person being screened to be accompanied by a spouse, child, or other person who knows him or her well. It inquires about whether the person has had a change over the past several years in eight areas: judgment, interest in hobbies/activities, repeating things, learning, orientation, financial management, remembering appointments, and other memory. A change in two or more items is a positive screen.

Downloadable, printable copies of both instruments with instructions are available at <https://carolinamemorycarenet.com/>.

Diagnostic Evaluation

There are five general steps in a diagnostic evaluation for AD: (1) history; (2) cognitive assessment; (3) physical examination, with a focus on the neurologic evaluation; (4) laboratory testing; and (5) establishment of a working diagnosis (including consideration of and attempts to rule out other depression, delirium, and non-Alzheimer's dementias). Each of these is discussed below.

History

Patients suspected of having AD typically present either because a family member reports changes in their behavior and function or because of a positive screening evaluation. Judgment and decision-making can be impaired early in the disease, which may lead to an incident that draws attention to the problem. Examples include auto accidents, uncharacteristic purchases or donations, problems managing a household budget, or being victimized by a scam. Increased awareness of early warning signs and following the Medicare requirement for cognitive screening should help identify a higher proportion of patients with mild, as opposed to major, neurocognitive disorder.

An individual who presents with memory or other cognitive difficulties may not be able to provide a reliable history. The primary or at least collateral source of historical information about functional change needs to be a family member close to the individual. Such a history typically includes gradual functional decline in multiple domains including short-term memory (repeating oneself), getting lost while driving, having trouble managing a checkbook, saying things that the person normally wouldn't have said, and difficulty making decisions.

An important element of the history should be questions aimed at identifying other potential causes of cognitive impairment, such as alcoholism, illicit drug use, and prescription medications.

In addition, inquiry about a person's psychiatric history should be undertaken as well as screening for anxiety and depression. A formal screening tool, such as the Geriatric Depression Scale or the Patient Health Questionnaire nine-item depression screen (PHQ-9), is recommended.

Cognitive Status Examination

The cognitive status examination should include a standardized cognitive test, both for comparison with other patients and to provide a numerical result that can be followed over time. We

recommend either the St. Louis University Mental Status Examination (SLUMS) or the Montreal Cognitive Assessment examination (MoCA), both of which cover a wide range of cognitive domains, are more sensitive to detecting cognitive impairment compared to older tests (e.g., Mini-Mental State Examination), have been validated in many populations, and are freely available in the public domain (i.e., available for download from the Internet).

The standardized examination should be supplemented by several other components to help round out the evaluation, identify behavioral issues, and screen for non-Alzheimer's dementias. Supplementary examination components that are useful include

- Verbal fluency testing—naming as many objects, such as animals, as they can in 1 minute (category fluency) and as many words beginning with a single letter such as “F” as they can in 1 minute (letter fluency). These not only tap into early loss cognitive areas but also help differentiate between AD (where category fluency tends to be more impaired) and other dementias, where impairment is similar (e.g., VaD) or letter fluency tends to be more impaired (e.g., FTD and LBD).
- Trail-Making Test B:—this is a timed paper-and-pencil test; it is a particularly sensitive test for early cognitive changes in non-memory domains (visuospatial and executive).
- Psychological and behavioral symptom evaluation—this is best obtained from a family member using a questionnaire tool such as the Neuropsychiatric Inventory (NPI).

Physical Examination

After evaluating cardiovascular and pulmonary status, the physical examination should focus on neurologic function, looking for signs that suggest a diagnosis other than AD. In particular, the examination should look for asymmetry in strength and/or motor function (suggesting one or more prior strokes), tremor and bradykinesia (suggesting parkinsonism), abnormalities of eye movement, especially inability to gaze downward (suggesting progressive supranuclear palsy), and peripheral neuropathy (suggesting the possibility of vitamin B12 deficiency, hypothyroidism, alcoholism, or neurosyphilis [although diabetes is more often the cause]).

Laboratory Testing and Neuroimaging

If the cognitive status examination confirms dysfunction, then a laboratory battery should be conducted largely to help identify remediable causes of cognitive impairment. Basic testing should include a complete blood count, blood glucose, electrolytes, renal function (BUN/creatinine), thyroid function, liver function tests, vitamin B12 level, and, if appropriate, a serologic test for syphilis.

Although research advances in brain imaging offer promise for more early and definitive diagnosis, a routine brain MRI remains the standard of clinical practice. It can identify cerebrovascular disease as discrete old infarcts (usually cortical) or as greater-than-normal deep white-matter changes (leukoariosis, suggesting subcortical vascular disease). The MRI is also useful in ruling out tumor or normal pressure hydrocephalus and in identifying focal cortical atrophy consistent with FTD.

Recently, positive emission tomography (PET) scanning for brain amyloid (florbetapir F 18 or Amyvid) has become commercially available, but is currently reimbursed by Medicare only if done as part of a research protocol. A large multicenter study is currently underway to evaluate the potential impact of amyloid brain PET imaging on clinical care for AD patients. Future therapeutic advances in MCI and early AD will likely usher in the selective, if not routine use of amyloid brain imaging in clinical care. At present, however, the only clinical indication for routine metabolic brain PET reimbursed by Medicare is to distinguish FTD from AD.

Establishment of a Working Diagnosis

Because no gold-standard clinical test exists for diagnosing AD, the evaluation usually results in a working diagnosis. If the evaluation raises suspicions that a non-AD dementia may be involved (Table 2), then consultation with a specialist in neurology or geriatric medicine is advised. General principles of management apply

TABLE 2 Differential Diagnosis of Alzheimer's Disease

DIAGNOSIS	TYPICAL PRESENTING HISTORY	KEY EXAMINATION FINDINGS	BRAIN IMAGING/LAB FINDINGS
Alzheimer's disease (AD)	Progressive, gradual onset; behavioral symptoms variable		
Mild	Short-term memory loss; IADL and judgment problems	Mild praxis or gait difficulty may be present	Normal CT or medial temporal atrophy; + amyloid brain PET scan
Moderate	ADL impairment; prominent memory deficits and confusion	May have frontal release signs	Medial temporal and parietal lobe atrophy; + amyloid PET scan
Mild cognitive impairment (MCI)	Impaired short-term memory without functional impairment	Mild praxis or gait difficulty may be present	Variable medial temporal atrophy (nonspecific)
Vascular dementia (VaD)	Stepwise progression; stroke history and/or vascular risk factors; gait problems early	Abnormal neurologic examination with lateralizing findings (may be subtle)	MRI shows cortical and/or subcortical infarcts, leukoariosis
Frontotemporal dementia (FTD)	Behavioral, personality, language changes; apathy	Variable, gait apraxia, frontal release signs	Marked atrophy in frontal and/or temporal lobes
Lewy body dementia (LBD)	Fluctuating attention, visual hallucinations, gait/motor/sleep disturbance (act out dreams)	Limb rigidity, bradykinesia, may see intention tremor and gait disturbance	MRI nondiagnostic
Parkinson's dementia	History of Parkinson's disease, later-onset cognitive dysfunction	Limb rigidity, bradykinesia, resting tremor, gait disturbance	MRI nondiagnostic
Delirium	Acute onset; identifiable pharmacologic, metabolic, toxic, or infectious cause	Fluctuating attention, fidgety, agitated, tremulous, or apathetic; may be obtundant	Diffuse EEG slowing, evidence of drug or metabolic toxicity, infection

to all dementias; however, different dementias respond differently to certain medications discussed later in this chapter, and so consultation may help direct appropriate therapeutic interventions in addition to clarifying the diagnosis.

Treatment

In managing AD, the physician needs to treat at least two individuals: the person with the disease and the person (or persons) who serves as the primary caregiver. A common thread in this dualistic approach is to promote safety and quality of life for all involved. While cognitive function is the key to diagnosis, behavioral symptoms are often the most important to address in the context of management and burden of care. [Table 3](#) reviews the main therapeutic targets and interventions.

Counseling and Caregiver Support

The patient and caregiver should be counseled about the disease course, about increased safety risks from such things as operating machinery and driving a motor vehicle, about the desirability of establishing a durable power of attorney for health care decisions, and about the value of having conversations early on about desires for end-of-life care, including completion of advance directives. As the disease progresses, regular meetings with the patient and family are important so as to anticipate and address key decision points.

AD leads to progressive dependency; maintaining the health and well-being of the caregiver(s) is a critical component of care. Make sure the caregiver has a physician and is under treatment for any medical problems he or she may have. In addition, the caregiver should be advised about community resources that can provide

TABLE 3 Alzheimer's Disease Management Strategies

OUTCOME TO BE AFFECTED	INTERVENTION	COMMENTS	LEVEL OF EVIDENCE*
Cognitive symptoms (memory, judgment, etc.)	Cholinesterase inhibitors (donepezil [Aricept], rivastigmine [Exelon], galantamine [Razadyne], memantine [Namenda])	Effective for mild, moderate, and severe dementia. Effect equal to slowing decline by 6 months	A
		Modest benefits in apo E4 negative subjects only	B/C
		Improved ability specific to the abilities trained	B
	Medical food: Caprylidene (Axona) Cognitive training Physical activity and adequate rest	Improved alertness and physical function; reduced depression	B
Behavioral symptoms (agitation, resistance to care, physical violence)	Mediterranean or modified Mediterranean (MIND) diet	Reduced risk of onset of Alzheimer's disease	B
	Individualized, person-centered ADL care	Reduced agitation; improved quality of life	A
	Cognitive enhancers (e.g., donepezil, memantine)	Effects modest but fewer adverse effects than other medications	A
	Antipsychotic drugs	Only a minority of patients clearly benefit; high adverse effect profile; "black box" warning on atypical antipsychotics for increasing cardiovascular disease but typical antipsychotics also have adverse effects	B
	Anticonvulsants	Carbamazepine (Tegretol) ¹ reduces agitation, anxiety, and restlessness; ataxia and hematologic toxicity occur

TABLE 3 Alzheimer's Disease Management Strategies—cont'd

OUTCOME TO BE AFFECTED	INTERVENTION	COMMENTS	LEVEL OF EVIDENCE
Caregiver stress, burden, and depression	Education, group programs, respite services	Early disease—education and group activities for caregiver and person with dementia; respite Moderate/advanced disease—caregiver support group; respite	A
Depression in persons with dementia	Selective serotonin reuptake inhibitors (SSRIs) (sertraline [Zoloft], citalopram [Celexa]) Physical activity/exercise	Mild to moderate effects on mood; no effect on agitation, aggression Formal program of caregiver education and exercise for the person with dementia; improved depression	A B
Quality of life; well-being	Pleasant sensory stimulation		A

*A = consistent, good-quality patient-oriented evidence; B = inconsistent or limited-quality patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion. For information about the SORT evidence rating system, see <http://www.aafp.org/aafpsort.xml>.

¹Not FDA approved for this indication.

assistance, such as the local chapter of the Alzheimer's Association, programs for persons with early-stage dementia, support programs for caregivers, local adult day care centers, and respite programs. In addition, because the majority of persons with AD spend their final days in a nursing home or assisted living community, health care providers should be prepared to provide support for that decision when appropriate.

Management of Cognitive Symptoms

The lack of novel therapeutic approaches during the past 10 years, in spite of very active research, has been a major disappointment. The cholinesterase inhibitors and memantine (Namenda) remain mainstays of treatment. Key points in using these drugs include the following (see Table 4):

- There is no demonstrated value to withholding drugs for later, when the patient gets worse.
- The overall benefit of treatment may be difficult to assess clinically; “real-world” changes noted by caregivers may be more important than cognitive test scores.
- Side effects are largely gastrointestinal (pain, bloating, nausea). Treatment should involve reducing the dose or switching to another agent. Donepezil (Aricept), while generally given at bedtime, may cause leg cramps, insomnia, or vivid bizarre dreams that often abate by switching to morning dosing.
- Studies indicate that combining a cholinesterase inhibitor with memantine (Namenda) produces a modest additive benefit.
- Long-term treatment effects involve symptom reduction and are not cumulative; if the efficacy of one or more drug treatments is

in question, it is reasonable to pursue a sequential trial taper and withdrawal (resuming the previous dose or medication if acute decline is noted by informants).

- Ensuring adequate sleep, activity, and nutrition is important for optimizing the patient's functional abilities.

Management of Behavioral Symptoms

A wide variety of behavioral symptoms can develop. Among the more common are (a) early in the disease—repetitive questions, wandering, and refusing assistance; (b) in the mid-stage of the disease—resistance to care, agitation or pacing, verbal and physical agitation and aggression, and antisocial behaviors such as inappropriate sexual remarks; (c) late in the disease—resistance to care and repetitive vocalizations such as moaning and screaming.

The key to managing most behavioral symptoms rests on non-pharmacologic approaches involving good adaptive dementia communication skills. Key elements include making eye contact before speaking; using simple language; speaking slowly, clearly, and in a low-pitched voice; communicating empathy through such actions as smiling and giving a hug; asking only one question at a time and allowing the patient adequate time to respond; breaking instructions down into small steps and presenting one at a time; and backing off and trying later if the person becomes agitated or refuses. If the person doesn't seem to understand a statement, repeat the statement using the same wording; if this does not work, rephrase and allow time for processing. When a specific problem develops, such as resistance to care or unwanted exiting, caregivers should use a structured problem-solving approach that defines the

TABLE 4 Drug Therapy for Cognitive Symptoms in Alzheimer's Disease

symptom, tries to identify reasons (including emotions and delusions) behind the symptom, and develops a management strategy to try and evaluate, using a quality improvement approach.

At times, however, families or facility caregivers report aggressive, frightening, or socially unacceptable behaviors that do not remit even in spite of excellent personalized psychosocial care. In these situations, medical providers are often asked for a prescription. Sometimes all that is needed is time, as aberrant behaviors tend to moderate over time. If a medication is needed, the first step should be a cholinesterase inhibitor, which has been shown to have potential benefits on apathy, delusions, and purposeless motor behaviors. If that is unsuccessful, then an antipsychotic or anticonvulsant should be considered, starting at a low dose and increasing until improvement is seen or intolerable side effects occur. Patients who demonstrate, or later develop, prominent behavioral features (e.g., visual hallucinations, disinhibition) should be referred to an appropriate specialist in neurology, geriatrics, or psychiatry. Caution is particularly warranted in managing psychotic symptoms in patients with Lewy body dementias, including Parkinson's disease with dementia. Eliminating anticholinergic or reducing dopaminergic medications should be the first line of treatment.

Monitoring

Patients and caregivers should be reevaluated every 3 to 6 months. If the person with AD resists going to the doctor (a common feature early in the disease), then some of these check-in evaluations can be handled by telephone. Indeed, telephone consultation is highly valued by caregivers, for whom a trip to the doctor can be costly and disruptive. To help provide readily available consultation, primary care practices are encouraged to designate a nurse, nurse practitioner, or physician assistant to focus on dementia treatment and care. This focus would include coordinating dementia screening in the practice, knowing each of the patients and families with dementia, coordinating a support group (if the practice chooses to have one), and responding to questions from caregivers.

BRAIN TUMORS

Method of

Ryan Merrell, MD

CURRENT DIAGNOSIS

- Subacute to chronic onset of generalized or focal neurologic symptoms should alert the physician to order neuroimaging to investigate the possibility of a brain tumor.
- Magnetic resonance imaging (MRI) is preferable to computed tomography (CT) for imaging tumors.
- A biopsy or resection is necessary to diagnose a primary brain tumor or a metastatic tumor of unknown primary origin. The diagnostic yield is increased with a resection.
- Neuroimaging suggestive of meningioma does not require a tissue diagnosis and in many cases can be followed closely with serial neuroimaging.

- If a primary central nervous system (CNS) lymphoma is suspected, corticosteroids should not be given unless absolutely necessary to avoid confounding the biopsy diagnosis.

CURRENT THERAPY

- Surgical resection is preferred for patients with most types of brain tumors as long as the resection does not leave the patient with permanent neurologic deficits.
- Whole-brain radiotherapy and stereotactic radiosurgery are the primary treatment modalities for patients with metastatic brain tumors.
- Surgical resection is preferred for patients with large or symptomatic meningiomas that are surgically accessible and in patients who can tolerate surgery.
- Patients with gliomas are treated with fractionated radiotherapy alone or in combination with chemotherapy.
- Patients with primary CNS lymphoma are treated with high-dose methotrexate¹ alone or in combination with other chemotherapy drugs.

¹Not FDA approved for this indication.

Brain tumors are categorized as metastatic or primary. The incidence and prevalence of metastatic tumors outweigh those of primary tumors up to 10:1. Lung and breast carcinoma make up the majority of metastatic tumors, largely because of their increased prevalence in the population compared with other tumors. Melanoma is a less-prevalent malignancy but has a high propensity to metastasize to the brain. Meningioma is usually a benign tumor that is found most often in the fourth through sixth decade, with a female-to-male ratio of 2:1. Gliomas are primary brain tumors that are categorized as high-grade gliomas or low-grade gliomas. High-grade gliomas usually affect patients in the fifth and sixth decades and older, whereas low-grade gliomas usually affect patients in the third and fourth decades. Primary central nervous system (CNS) lymphoma is a rare tumor that usually affects patients in the sixth decade and older.

There are very few identifiable risk factors for brain tumors. The histology of the primary neoplasm confers the risk of brain metastases because lung cancer, breast cancer, and melanoma are more likely to metastasize to the brain, whereas colorectal, ovarian, and prostate cancers are less likely to metastasize to the brain. Past exposure to ionizing radiation and a family history of a genetic cancer syndrome are the only known risk factors for primary tumors. Despite much press, cell phone use has not been irrefutably shown to be a risk factor for brain tumors. Immunocompromise such as HIV infection is a well-known risk factor for primary CNS lymphoma.

Brain tumors manifest with the subacute or chronic onset of generalized symptoms such as confusion, headaches, seizures, and nausea or focal symptoms and signs such as visual field deficit, loss of language, unilateral weakness, sensory neglect, or difficulty walking. There are no symptoms or signs specific to any brain tumor because the anatomic location of the tumor in the brain dictates the presentation. These symptoms and signs should prompt neuroimaging with MRI. MRI has largely replaced CT for evaluating brain tumors, although CT serves as a quick screening modality and must be used in patients who have contraindications to MRI. Radiographic features on MRI can predict the type of tumor but cannot accurately confirm the pathology. A tissue diagnosis through a biopsy or surgical resection is necessary to confirm the pathology, except in patients with metastatic tumors with a known primary tumor. The differential diagnosis of mass lesions in the brain includes abscess, demyelinating lesion, inflammatory disease, and other infections such as toxoplasmosis and cysticercosis.

symptom, tries to identify reasons (including emotions and delusions) behind the symptom, and develops a management strategy to try and evaluate, using a quality improvement approach.

At times, however, families or facility caregivers report aggressive, frightening, or socially unacceptable behaviors that do not remit even in spite of excellent personalized psychosocial care. ¹Not FDA approved for this indication.

Brain tumors are categorized as metastatic or primary. The incidence and prevalence of metastatic tumors outweigh those of primary tumors up to 10:1. Lung and breast carcinoma make up the majority of metastatic tumors, largely because of their increased prevalence in the population compared with other tumors. Melanoma is a less-prevalent malignancy but has a high propensity to metastasize to the brain. Meningioma is usually a benign tumor that is found most often in the fourth through sixth decade, with a female-to-male ratio of 2:1. Gliomas are primary brain tumors that are categorized as high-grade gliomas or low-grade gliomas. High-grade gliomas usually affect patients in the fifth and sixth decades and older, whereas low-grade gliomas usually affect patients in the third and fourth decades. Primary central nervous system (CNS) lymphoma is a rare tumor that usually affects patients in the sixth decade and older.

There are very few identifiable risk factors for brain tumors. The histology of the primary neoplasm confers the risk of brain metastases because lung cancer, breast cancer, and melanoma are more likely to metastasize to the brain, whereas colorectal, ovarian, and prostate cancers are less likely to metastasize to the brain. Past exposure to ionizing radiation and a family history of a genetic cancer syndrome are the only known risk factors for primary tumors. Despite much press, cell phone use has not been irrefutably shown to be a risk factor for brain tumors. Immunocompromise such as HIV infection is a well-known risk factor for primary CNS lymphoma.

Brain tumors manifest with the subacute or chronic onset of generalized symptoms such as confusion, headaches, seizures, and nausea or focal symptoms and signs such as visual field deficit, loss of language, unilateral weakness, sensory neglect, or difficulty walking. There are no symptoms or signs specific to any brain tumor because the anatomic location of the tumor in the brain dictates the presentation. These symptoms and signs should prompt neuroimaging with MRI. MRI has largely replaced CT for evaluating brain tumors, although CT serves as a quick screening modality and must be used in patients who have contraindications to MRI. Radiographic features on MRI can predict the type of tumor but cannot accurately confirm the pathology. A tissue diagnosis through a biopsy or surgical resection is necessary to confirm the pathology, except in patients with metastatic tumors with a known primary tumor. The differential diagnosis of mass lesions in the brain includes abscess, demyelinating lesion, inflammatory disease, and other infections such as toxoplasmosis and cysticercosis.

A biopsy or surgical resection provides the definitive diagnosis of the tumor. For most tumors, a resection is preferred when safely possible, because the greater amount of tissue obtained avoids the sampling error that can occur with a biopsy. The goal of surgery for all brain tumors is to provide a maximal resection while leaving the patient free of permanent neurologic deficits. Metastatic brain tumors are classified according to the cell of origin. Primary brain tumors are classified according to the World Health Organization (WHO) classification system. Additional molecular classification that can provide prognostic and therapeutic information is often obtained on select primary brain tumors. Oligodendroglioma is a primary brain tumor that has well-characterized chromosomal deletions on the short arm of chromosome 1 and the long arm of chromosome 19 (1p/19q co-deletion) that have been shown to predict improved survival and increased sensitivity to treatment. Similarly, O-6-methylguanine-DNA-methyltransferase (MGMT) promoter methylation is a marker that predicts improved survival and may predict improved response to treatment in high-grade glioma.

A major challenge to treating brain tumor is to find drugs that cross the blood–brain barrier. Many chemotherapy drugs used to treat systemic tumors are too large or hydrophilic to cross the blood–brain barrier. Treatments designed to circumvent the blood–brain barrier have only been modestly successful to date.

Metastatic Tumors

Metastatic brain tumors are the most common brain tumors, with as many as 170,000 new cases diagnosed in the United States each year. Metastatic tumors can occur with or without evidence of a primary neoplasm. Findings on brain MRI suspicious for a metastatic tumor should prompt an investigation for a primary malignancy with body imaging (Figure 1). The discovery of a systemic mass that can be biopsied might avoid a brain biopsy or resection in select patients. Occasionally, after an extensive evaluation, no evidence of a primary tumor is found. About 50% of patients have a single metastasis, and the rest have multiple tumors. In general, prognosis is poor, but some patients with less-aggressive primary tumors (breast, non-small cell lung carcinoma) can achieve long-term survival.

Figure 1 Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass with surrounding edema at the gray–white junction, suggesting a metastatic tumor.

Tumors can metastasize to the nervous system through infiltration of the cerebrospinal fluid (CSF), a process termed *leptomeningeal carcinomatosis* or *carcinomatous meningitis*. Symptoms suggesting leptomeningeal carcinomatosis include altered mental status, headaches, loss of vision, double vision, slurred speech, difficulty swallowing, and lower extremity pain and weakness. Brain MRI can show enhancement of the meninges, and CSF from lumbar puncture shows low glucose and elevated protein with malignant cells. A lumbar puncture is not necessary to confirm the diagnosis in a patient with a known primary malignancy and characteristic clinical presentation and MRI findings. The prognosis is poor, on the order of several months. Patients with lymphoma and breast cancer might realize longer survival.

Several factors determine the approach to treatment of metastatic tumors. The age, comorbidities, functional status, degree of neurologic impairment, and extent of the systemic disease determine whether surgery is indicated. Solitary metastases and large symptomatic tumors in patients with multiple tumors are generally resected in patients who are good surgical candidates. Whether a patient undergoes surgical resection or not, radiotherapy is the mainstay of treatment for metastatic tumors.

The two approaches to radiotherapy are whole-brain radiotherapy and stereotactic radiosurgery. In whole-brain radiotherapy, a dose of radiation is fractionated into several treatment sessions and given to the entire brain. In stereotactic radiosurgery, a high dose of radiation is given only to areas of brain involved with tumor and often in one treatment session. The effectiveness of whole-brain radiotherapy versus stereotactic radiosurgery has not been established in large randomized trials. Whole-brain radiotherapy is more suited for patients with multiple metastases or large tumors (>3 cm diameter). Stereotactic radiosurgery is indicated for patients with fewer than four metastases, for smaller-volume tumors (less than 3 cm diameter), and for radioresistant tumors such as melanoma. Whole-brain radiotherapy has the advantage of treating the visible and undetectable tumors, but it carries a risk of delayed neurotoxicity that often manifests as cognitive impairment. Stereotactic radiosurgery has the advantage of local control by treating the visible tumors and carries less risk of delayed neurotoxicity. Stereotactic radiosurgery can be repeated if new tumors develop in areas of brain not previously radiated. The disadvantage of stereotactic radiosurgery is the potential for new tumors to develop in areas of brain not treated.

There is an increasing role for select chemotherapy drugs in metastatic tumors, as some drugs can cross the blood brain barrier. This is especially true for newer targeted agents in NSCLC and melanoma. However, these drugs have not supplanted radiotherapy as the standard of care.

Treatment of leptomeningeal carcinomatosis involves chemotherapy or radiotherapy. Chemotherapy is often administered directly into the spinal fluid (intrathecal), usually through a ventricular (Omay) reservoir. Alternatively, chemotherapy can be given systemically. Common chemotherapeutic agents include methotrexate (Methotrexate PF),¹ cytarabine (Cytarabine PF)¹, and thiotepa.¹ Radiotherapy is usually only used as a salvage treatment after chemotherapy failure.

Meningiomas

Meningiomas are the most common primary brain tumor, accounting for more than 32% of all tumors. Meningiomas arise from the arachnoid cap cells. They are often discovered incidentally when a patient undergoes neuroimaging for symptoms that are unrelated to the meningioma. The radiographic appearance of meningiomas is one of the most specific of all brain tumors and allows a confident diagnosis without the need for a confirmatory biopsy (Figure 2). The most common radiographic mimic is a metastatic tumor to the meninges, but usually a patient in this circumstance has a known history of malignancy. Small meningiomas may be monitored with serial imaging. Meningiomas that correlate with

¹Not FDA approved for this indication.

Figure 2 Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass arising from the dura, with the typical appearance of a meningioma.

neurologic deficits or tumors that have grown significantly over time should be treated.

Surgical resection is the preferred treatment if it can be safely accomplished, but it should be avoided in the elderly. Meningiomas are graded WHO I to III; 90% are grade I (benign), and grade III (anaplastic) are the most aggressive and likely to recur. Complete resection is curative in most cases, but some meningiomas recur. If recurrent tumors are large or symptomatic, surgery is the preferred treatment if possible. Radiotherapy, either fractionated or stereotactic radiosurgery, can be used after surgery to treat residual tumor or to treat tumors that cannot be resected. Meningiomas have an intermediate response to radiotherapy, and grade III tumors often show minimal response.

There is no defined chemotherapy for meningiomas, although several drugs are being actively investigated.

Gliomas

Gliomas consist of astrocytomas, oligodendrogliomas, and ependymomas, in decreasing order of prevalence. It was once thought that these tumors derived from mutations of normal glial cells, but it is increasingly recognized that gliomas derive from brain tumor progenitor cells. Glioblastoma is the most malignant glioma and accounts for 60% to 70% of all gliomas. Gliomas are classified by the glial cells from which they originate and the histologic features that give them a grade according to the WHO classification (Table 1). Grade III and IV tumors are high-grade gliomas, and grade II tumors are low-grade gliomas. Grade I glioma (pilocytic astrocytoma) is rarely seen in adults. A maximal surgical resection that leaves the patient with minimal neurologic deficits is the preferred initial treatment for all grades of gliomas.

High-Grade Gliomas

Most high-grade gliomas are glioblastoma or anaplastic astrocytoma (WHO grade III); anaplastic oligodendroglioma and anaplastic ependymoma are less common. The brain MRI often shows a ring-enhancing mass centered in the white matter surrounded by edema and causing mass effect (Figure 3). A maximal surgical

TABLE 1

World Health Organization Classification of Common Gliomas in Adults

SUBTYPE	WORLD HEALTH ORGANIZATION GRADE
Low-Grade Gliomas	
Astrocytoma	II
Oligodendroglioma	II
Oligoastrocytoma	II
High-Grade Gliomas

Glioblastoma	IV

Figure 3 Contrast-enhanced magnetic resonance image shows a ring-enhancing mass with surrounding edema with the typical appearance of glioblastoma.

resection that leaves the patient without permanent neurologic deficits is the goal in high-grade glioma. A maximal resection, younger age, and good performance status are favorable prognostic factors. Methylation of the MGMT promoter correlates with improved survival. High-grade gliomas are aggressive, incurable tumors; the median survival for glioblastoma is 14 to 18 months and for anaplastic astrocytoma is 2 to 2.5 years. The isocitrate dehydrogenase I (IDH 1) mutation is less commonly seen in high-grade gliomas and correlates with improved survival.

TABLE 2 Common Chemotherapy for Gliomas

GENERIC NAME	TRADE NAME	DOSE
Temozolomide	Temodar	75 mg/m ² daily during radiotherapy, 150–200 mg/m ² after radiotherapy on 5 d per 28 d schedule 50 mg/m ² daily or 75 mg/m ² 3 wk on, 1 wk off, for recurrent high-grade glioma
Bevacizumab	Avastin	10 mg/kg every 2 wk

Treatment of high-grade glioma is based on the histology of the tumor. The standard treatment of glioblastoma consists of fractionated radiotherapy given over 6 weeks with temozolomide (Temodar), an oral chemotherapeutic drug. Temozolomide is given 1 month after the completion of radiotherapy until tumor progression, which occurs on average around 7 months after the original diagnosis for glioblastoma (Table 2). Patients with anaplastic astrocytoma are treated with six weeks of radiotherapy alone followed by adjuvant temozolomide. Patients with glioblastoma and anaplastic astrocytoma are usually treated with 6 months of temozolomide, although some practitioners will treat glioblastoma patients with up to 12 months of temozolomide. Tumor treating fields (TTF) is a cap-like device worn on a shaved scalp. TTF delivers radiofrequency pulses to the tumor. Based on the results of a large randomized clinical trial, TTF were approved to add on to the standard therapy of radiation with temozolomide for newly diagnosed glioblastoma.

Careful consideration should be given to neuroimaging findings suggesting tumor progression within the first 6 months after radiotherapy because these changes can reflect radiation necrosis (pseudoprogression) rather than true tumor progression.

In the setting of tumor progression, salvage chemotherapy is the mainstay of treatment. Bevacizumab (Avastin), a drug that inhibits blood vessel formation around tumors, is the most common drug that is given at tumor recurrence. Temozolomide given in low dose daily is another approach for recurrent high-grade glioma. TTF can also be used in the recurrent setting if not used at initial diagnosis. Experimental chemotherapy through a clinical trial is a common option used in recurrent high-grade glioma. Occasionally, surgical resection is indicated to improve symptoms, but it has not been shown to improve survival. Likewise, focused radiation such as stereotactic radiosurgery has not been shown to affect survival.

Anaplastic oligodendroglioma treated with radiation followed by chemotherapy, either PCV (procarbazine [Matulane]¹, CCNU [Lomustine], vincristine¹) or temozolomide while anaplastic ependymoma is usually treated with radiotherapy alone. Anaplastic oligodendrogliomas with chromosomal 1p/19q co-deletions carry better prognosis and response to treatment.

Low-Grade Gliomas

Despite being lower-grade tumors, low-grade gliomas are not benign. The natural history is that patients with low-grade gliomas ultimately progress to high-grade glioma. Low-grade gliomas account for about 15% of all primary brain tumors. Low-grade gliomas are more likely to manifest with seizures than high-grade gliomas. The brain MRI often shows a non-enhancing mass with involvement of white matter and sometimes abutting the cerebral cortex (Figure 4). As in high gliomas, a maximal surgical resection confers a survival advantage in low grade gliomas. Prognosis varies considerably by tumor histology: Patients with astrocytoma live 5 to 10 years after diagnosis, whereas patients with oligodendroglioma live 10 to 15 years after diagnosis. The isocitrate dehydrogenase I (IDH 1) mutation correlates with improved survival. This mutation is seen in the majority of patients with low-grade glioma.

Figure 4 Fluid-attenuated inversion recovery (FLAIR) magnetic resonance image shows a nonenhancing tumor abutting the cerebral cortex with the typical appearance of a low-grade glioma. The tumor proved to be a grade II oligodendroglioma.

The results of a recent randomized clinical trial revealed superior progression-free survival and overall survival in patients with low grade gliomas treated with radiation followed by adjuvant PCV.

In the absence of a head to head clinical trial of PCV with temozolomide, many clinicians would use temozolomide in place of PCV since temozolomide is better tolerated. Therefore radiation followed by PCV or temozolomide has become the new standard of care for all patients with low-grade gliomas. It is still common practice to take a watch and wait approach in select patients with newly diagnosed low grade glioma who have had a gross total resection. When patients with low-grade gliomas have findings on neuroimaging that suggest progressive tumor, a surgical resection or biopsy is often conducted to alleviate symptoms and to establish the grade of the tumor. Patients with low-grade gliomas that progress to high-grade glioma are treated similarly to patients with de novo high-grade glioma but with consideration to previous treatments.

Primary Central Nervous System Lymphoma

Primary CNS lymphoma is a rare non-Hodgkin lymphoma that affects the brain, eyes, meninges, and spinal cord and accounts for about 5% of all brain tumors. This tumor is associated with the immunocompromised state, but it has a significant incidence in the immunocompetent. The characteristic radiographic appearance suggests but does not confirm the diagnosis (Figure 5). If primary CNS lymphoma is suspected, corticosteroids should not be given unless they are necessary to reduce increased intracranial pressure. This is because corticosteroids are directly cytotoxic to lymphoma cells, which can confound the tissue diagnosis. Occasionally, the diagnosis can be obtained through CSF testing, but a brain biopsy is often necessary.

Surgical resection has no role in treating this tumor because lymphoma is sensitive to chemotherapy and radiotherapy. The exception is in large tumors causing significant mass effect. Staging tests are necessary to rule out a systemic lymphoma that has metastasized to the CNS. Despite being incurable, primary CNS lymphoma is a more treatable tumor, and many patients live 5 years or longer after diagnosis.

¹Not FDA approved for this indication.

Figure 5 Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass near the surface of the ventricle, suggesting primary central nervous system lymphoma.

Primary CNS lymphoma is treated with intravenous or intrathecal chemotherapy with or without radiotherapy. Methotrexate¹ is the principal drug used either alone or in combination with other chemotherapy drugs. High doses of methotrexate ($3.5\text{--}8\text{ g/m}^2$)³ must be used to overcome the blood–brain barrier. Owing to the potential for renal toxicity, high-dose methotrexate must be given in a setting where kidney function can be carefully monitored (usually the inpatient setting).

Radiotherapy was previously used as an initial treatment, but it is associated with profound cognitive impairment, especially in patients older than 60 years. However, more recent approaches have used lower doses of radiotherapy combined with chemotherapy with less neurotoxicity reported. Opinion is divided about the use of radiotherapy. Chemotherapy can also be used as a salvage treatment. Besides methotrexate, other commonly used chemotherapy drugs include cytarabine,¹ etoposide (Toposar),¹ rituximab (Rituxan),¹ procarbazine (Matulane),¹ and temozolomide (Temodar).¹ In younger patients, an increasingly used treatment at the time of relapse is high-dose chemotherapy with autologous stem cell transplantation. This approach is increasingly being investigated in the newly diagnosed setting.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

GILLES DE LA TOURETTE SYNDROME

Method of

Steve W. Wu, MD; and Donald L. Gilbert, MD, MS

CURRENT DIAGNOSIS

- Multiple motor and one or more vocal tics have been present for some time during the illness, although not necessarily concurrently.
- The tics may wax and wane in frequency but have persisted for more than 1 year since first tic onset.
- Onset occurs before age 18 years.
- The disturbance is not caused by the direct physiologic effects of a substance or a general medical condition.

Gilles de la Tourette syndrome, or Tourette syndrome, was named after French neurologist Georges Gilles de la Tourette, who in 1885 described a series of nine patients with chronic tics. Tourette syndrome is a neuropsychiatric illness that begins in childhood. It is characterized by multiple motor and vocal tics that last for longer than 1 year (see Current Diagnosis box). The prevalence of Tourette syndrome varies greatly among epidemiologic studies, ranging from 0.1% to 3.8%. The prevalence of tic disorders is even higher, especially in children requiring special education.

Simple motor tics are sudden, brief, patterned movements such as eye blinking, facial grimace, head jerk, or shoulder shrug. Complex motor tics can involve a series of simple tics or a seemingly purposeful action, such as jumping, touching, or copropraxia (i.e., performing obscene gestures). Simple vocal tics consist of sounds such as throat clearing, sniffing, and coughing. Patients with complex vocal tics may exhibit echolalia (i.e., repeating others' words), palilalia (i.e., repeating their own words), or coprolalia (i.e., utterance of foul language).

Older children and adolescents often describe a premonitory urge before their tics. Tics can usually be transiently suppressed and are often diminished during focused mental or physical activities. Unlike myoclonus or chorea, tics usually do not affect activities of daily living or occupational or recreational activities. After the brief suppression, the release of the tic often brings relief to the patient. Tic severity commonly worsens during times of emotional stress. Fatigue or illness may also increase tics. Parents often notice more tics when the child is bored or unoccupied with an activity. Tics can occur during light sleep and rapid eye movement (REM) sleep.

Clinical Course

The onset of tics can occur after children are 3 years old, but they usually begin in children 6 to 7 years old. Children often present with motor tics first, followed by the development of vocal tics. Tics often wax and wane in the course of Tourette syndrome. During the early school years, tics often can go unnoticed or be mislabeled as a habit. If tics are noticed by fellow students, bullying is typically not an issue at this age. However, when parents notice the tics, they are often distressed and frequently tell their children to stop the movements.

Tic severity usually increases in the later elementary school years and into adolescence. This is the time when social interference such as bullying begins to occur. By late adolescence and early adulthood, most patients with Tourette syndrome have minimal tics, and some may “outgrow” tics. Because of this pattern, most individuals presenting for medical attention for tics are children.

Patients with Tourette syndrome frequently present with comorbid attention-deficit/hyperactivity disorder (ADHD) and obsessive-compulsive disorder (OCD). They also tend to have more sleep problems, anxiety, and mood disorders.

Figure 5 Contrast-enhanced magnetic resonance image shows a homogeneously enhancing mass near the surface of the ventricle, suggesting primary central nervous system lymphoma.

Primary CNS lymphoma is treated with intravenous or intrathecal chemotherapy with or without radiotherapy. Gilles de la Tourette syndrome, or Tourette syndrome, was named after French neurologist Georges Gilles de la Tourette, who in 1885 described a series of nine patients with chronic tics. Tourette syndrome is a neuropsychiatric illness that begins in childhood. It is characterized by multiple motor and vocal tics that last for longer than 1 year (see Current Diagnosis box). The prevalence of Tourette syndrome varies greatly among epidemiologic studies, ranging from 0.1% to 3.8%. The prevalence of tic disorders is even higher, especially in children requiring special education.

Simple motor tics are sudden, brief, patterned movements such as eye blinking, facial grimace, head jerk, or shoulder shrug. Complex motor tics can involve a series of simple tics or a seemingly purposeful action, such as jumping, touching, or copropraxia (i.e., performing obscene gestures). Simple vocal tics consist of sounds such as throat clearing, sniffing, and coughing. Patients with complex vocal tics may exhibit echolalia (i.e., repeating others' words), palilalia (i.e., repeating their own words), or coprolalia (i.e., utterance of foul language).

Older children and adolescents often describe a premonitory urge before their tics. Tics can usually be transiently suppressed and are often diminished during focused mental or physical activities. Unlike myoclonus or chorea, tics usually do not affect activities of daily living or occupational or recreational activities. After the brief suppression, the release of the tic often brings relief to the patient. Tic severity commonly worsens during times of emotional stress. Fatigue or illness may also increase tics. Parents often notice more tics when the child is bored or unoccupied with an activity. Tics can occur during light sleep and rapid eye movement (REM) sleep.

Clinical Course

The onset of tics can occur after children are 3 years old, but they usually begin in children 6 to 7 years old. Children often present with motor tics first, followed by the development of vocal tics. Tics often wax and wane in the course of Tourette syndrome. During the early school years, tics often can go unnoticed or be mislabeled as a habit. If tics are noticed by fellow students, bullying is typically not an issue at this age. However, when parents notice the tics, they are often distressed and frequently tell their children to stop the movements.

Tic severity usually increases in the later elementary school years and into adolescence. This is the time when social interference such as bullying begins to occur. By late adolescence and early adulthood, most patients with Tourette syndrome have minimal tics, and some may “outgrow” tics. Because of this pattern, most individuals presenting for medical attention for tics are children.

Patients with Tourette syndrome frequently present with comorbid attention-deficit/hyperactivity disorder (ADHD) and obsessive-compulsive disorder (OCD). They also tend to have more sleep problems, anxiety, and mood disorders.

Diagnosis and Differential Diagnosis

Diagnosis of tic disorders depends on correctly recognizing that the abnormal movements are tics by means of a careful history and thorough physical examination. Laboratory and imaging studies are rarely needed.

Tics may resemble other abnormal movements, such as stereotypy, chorea, ballism, dystonia, and myoclonus. *Stereotypies* are repetitive, simple movements that are suppressible and that usually occur when a child is excited. Stereotypies usually start when the child is younger than 3 years. *Chorea* consists of a sequence of random, continual, involuntary, nonpurposeful, nonrhythmic movements. Choreic movements often flow from one body part to another. *Ballism* is a large-amplitude choreic movement affecting the proximal limb. *Myoclonus* is an involuntary, sudden, shocklike movement. Chorea, ballism, and myoclonus cannot be volitionally suppressed. *Dystonia* is produced by co-contraction of agonist and antagonist muscles, leading to abnormal postures, and its twisting movements typically are slower than tics.

Vocal tics may sometimes lead to the misdiagnosis of asthma, chronic cough, or allergic rhinitis. Other primary tic disorders include Provisional Tic Disorder, Persistent (Chronic) Motor or Vocal Tic Disorder, Other Specified Tic Disorder and Unspecified Tic Disorder (DSM-5).

Tics are nonspecific and may occur in drug-induced movement disorders, after head trauma, and in a variety of neurodevelopmental and neurodegenerative disorders. Complex or atypical cases with multiple comorbidities or multiple abnormalities identified on a general or neurologic examination should be referred for specialist consultation.

A controversial diagnosis in which tics or OCD may occur is called pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). Criteria for this diagnosis classically include abrupt appearance in prepubertal children of tics or OCD on two or more occasions after documented group A β -hemolytic streptococcal (GABHS) infections. The paradigm for this diagnosis is rheumatic (Sydenham's) chorea; however, PANDAS has no arthritis, carditis, or nephritis and is not thought to be a rheumatic disease. As a result of recent epidemiological studies, tics are no longer considered a primary symptom of PANDAS. The following interventions are not routinely recommended: diagnostic throat cultures and antistreptococcal antibody tests; therapeutic or preventive antibiotics; and immune-modulating therapies such as steroids, intravenous immunoglobulins, or plasmapheresis. Specialty consultation should be considered.

Treatment

There are many factors to consider when treating a patient with Tourette syndrome, including the presence of common symptoms such as inattentiveness, hyperactivity, obsessive or compulsive behaviors, depression, and anxiety (Box 1). When deciding to treat the patient, it is important to prioritize all the neuropsychiatric symptoms and provide accurate educational information. Tics may not always need to be treated medically, and if treatment is needed, tics may not be the first symptom to manage. Daily tic-suppressing medication is considered when there is functional interference, social interference, pain, or classroom or occupational disruption.

The first step in treating Tourette syndrome is educating the patient, parents, and other adult caregivers. Parents, teachers, and other adult caregivers are discouraged from telling the child to stop ticcing because this produces emotional anxiety that may worsen the tics. Educational materials for teachers often promote a conducive environment for the child at school. The patient is encouraged to openly talk about his or her disorder to classmates to promote understanding and minimize bullying. Newer cognitive-behavioral treatments for tic suppression appear to be helpful for children and adolescents, and they should be considered.

Clinical trials enrolling patients with Tourette syndrome are usually small and show small effect sizes. Most commonly used tic-suppressing medications belong to two classes: α_2 -adrenergic agonists and dopamine receptor blocking agents (Table 1). Other

BOX 1 Therapeutic Approach for Tourette Syndrome

- Educate the patient and family about tics and how tics often diminish spontaneously. Long-term reductions in tics may occur in the late teens, irrespective of pharmacologic therapy.
- Rank the tics, attention-deficit/hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), anxiety, mood problems, learning problems, and behavior problems in order of the patient's or the family's perception of severity.
- Consider nonpharmacologic and pharmacologic treatment for each symptom in the order of perceived severity or impairment.
- Provide information to educate teachers and classmates to reduce social impairment.
- If the patient has learning problems, encourage formal assessment through the school or a psychologist. These children may qualify for modified educational methods.
- If ADHD is the most concerning problem, consider treating with clonidine (Kapvay), guanfacine (Intuniv), atomoxetine (Strattera), or methylphenidate (Ritalin). Stimulants are *not* absolutely contraindicated in patients with Tourette syndrome. However, if symptoms of OCD, anxiety, or pervasive developmental disorder are present, ticcing or compulsions may escalate on stimulants. If a patient has done well for months to years on stimulants for ADHD before an exacerbation of tics, it usually is not necessary to discontinue stimulants.
- If behavior problems are the most concerning problem or if a first-degree family member has a bipolar or psychotic disorder, refer the patient to a psychologist or psychiatrist.
- Anxious parents often worsen tic severity. If the family's anxiety is excessive, refer family members to a psychologist.
- If OCD or generalized anxiety disorder is the most severe problem, treatment with a selective serotonin reuptake inhibitor may be considered.
- Do not begin treatment with more than one central nervous system drug simultaneously. Start one, wait 2 to 4 weeks, and then reassess all symptoms before starting the next medication.
- Monitor the benefits and side effects at regular intervals.
- Maintain stable dosing during the school year; consider tapering medications in the summer.
- Consider weaning tic-suppressing medications in the middle to late teen years if tics wane.

agents may show modest benefit. Because Tourette syndrome is a chronic, nonfatal disorder, it is prudent to start treatment with medications that carry the least side effects. For this reason, α_2 -adrenergic agonists are usually the first-line treatment. Although it is unclear what the second-line agents should be, it is reasonable in many cases to restrict dopamine receptor blocking agents to the most severe cases.

α_2 -Adrenergic Agonists

Clonidine (Catapres)¹ and guanfacine (Tenex)¹ are α_2 -adrenergic agonists often used to treat tics. Several randomized trials have shown that these agents reduce tic and ADHD symptoms. The main side effects are sedation and lightheadedness due to mild hypotension. Sedation is more common with clonidine. The clonidine patch (Catapres-TTS)¹ may produce less peak sedation, but it commonly produces local skin irritation.

Dopamine Receptor Blocking Agents

Typical and atypical neuroleptics are dopamine receptor blocking agents that can be used to treat tics. Neuroleptics such as pimozide (Orap) and haloperidol (Haldol) can be very effective in tic

¹Not FDA approved for this indication.

*The system areas are 3.5 cm² (Catapres TTS-1), 7.0 cm² (Catapres TTS-2), and 10.5 cm² (Catapres TTS-3), and the amount of drug released is directly proportional to the area.

suppression, but they can cause acute akathisia, dystonic reactions, cognitive blunting, acute anxiety with somatizations and school refusal, sedation, weight gain, metabolic syndrome, and QT prolongation. Monitoring for tardive dyskinesia is also important. Some experts recommend baseline electrocardiograms, particularly for individuals with personal or family history of cardiac arrhythmias. Weight gain and metabolic syndrome should be considered when starting neuroleptics, particularly risperidone (Risperdal)¹ and aripiprazole (Abilify).¹ Some experts recommend obtaining baseline values for weight, blood pressure, fasting glucose, and lipid profile, with follow-up monitoring every 3 months to detect drug-induced metabolic syndrome. Diet modification, routine exercise, or medical therapy may be needed.

Other Tic-Suppressing Medications

Several small, controlled studies show benefit for topiramate (Topamax),¹ dopamine agonists,¹ baclofen (Lioresal)¹, benzodiazepines,¹ and botulinum toxin type A (Botox)¹ injections for focal, strong tics. Tetrabenazine (Xenazine)¹ has been reported to reduce tics.

Behavioral Therapy

Recent clinical trials show that Comprehensive Behavioral Intervention for Tics, in which the patient learns to increase self-awareness of tics and premonitory urges and to perform antagonistic movements, reduces tics.

Treatment of Comorbid Conditions

ADHD and OCD are common comorbid conditions in Tourette syndrome. These comorbid symptoms are often more debilitating than the tics. Concern about stimulant therapy worsening tics was addressed by the Tourette Syndrome Study Group in the landmark Treatment of ADHD in Children with Tics (TACT) study. In this study, children treated with methylphenidate (Ritalin) had, on average, reduced tic severity, contrary to the widely held belief that stimulants exacerbate tics.

Medical treatment options for ADHD include psychostimulants, α_2 -adrenergic agonists guanfacine (Intuniv) and clonidine (Kapvay), and the selective norepinephrine reuptake inhibitor atomoxetine (Strattera). OCD management includes cognitive-behavioral

therapy, clomipramine (Anafranil), and any of the selective serotonin reuptake inhibitors.

Summary

Tourette syndrome is a complex neuropsychiatric illness with many potential symptoms that may need medical and nonmedical therapies. Cooperation among the primary care physician, neurologist, psychiatrist, and psychologist is imperative for the comprehensive care of severely affected patients. If a patient has mild tics and few or no comorbid symptoms, medical therapy may not be needed. However, if the tics are severe in the presence of many neuropsychiatric symptoms, it is reasonable to refer patients to specialists.

INTRACEREBRAL HEMORRHAGE

Method of

Joshua N. Goldstein, MD, PhD

CURRENT DIAGNOSIS

- Obtain a thorough history, including time of symptom onset
- Imaging of the cerebral vessels should be performed in patients younger than 55 years and should be strongly considered in all patients in whom underlying aneurysm or arteriovenous malformation is suspected.
- Obtain contrast-enhanced neuroimaging if underlying cerebral mass or tumor is suspected.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

*The system areas are 3.5 cm² (Catapres TTS-1), 7.0 cm² (Catapres TTS-2), and 10.5 cm² (Catapres TTS-3), and the amount of drug released is directly proportional to the area.

suppression, but they can cause acute akathisia, dystonic reactions, cognitive blunting, acute anxiety with somatizations and school refusal, sedation, weight gain, metabolic syndrome, and QT prolongation. Monitoring for tardive dyskinesia is also important. Some experts recommend baseline electrocardiograms, particularly for individuals with personal or family history of cardiac arrhythmias. Weight gain and metabolic syndrome should be considered when starting neuroleptics, particularly risperidone (Risperdal)¹ and aripiprazole (Abilify).¹ Some experts recommend obtaining baseline values for weight, blood pressure, fasting glucose, and lipid profile, with follow-up monitoring every 3 months to detect drug-induced metabolic syndrome. Diet modification, routine exercise, or medical therapy may be needed.

Other Tic-Suppressing Medications

Several small, controlled studies show benefit for topiramate (Topamax),¹ dopamine agonists,¹ baclofen (Lioresal)¹, benzodiazepines,¹ and botulinum toxin type A (Botox)¹ injections for focal, strong tics. Tetrabenazine (Xenazine)¹ has been reported to reduce tics.

Behavioral Therapy

Recent clinical trials show that Comprehensive Behavioral Intervention for Tics, in which the patient learns to increase self-awareness of tics and premonitory urges and to perform antagonistic movements, reduces tics.

Treatment of Comorbid Conditions

ADHD and OCD are common comorbid conditions in Tourette syndrome. These comorbid symptoms are often more debilitating than the tics. Concern about stimulant therapy worsening tics was addressed by the Tourette Syndrome Study Group in the landmark Treatment of ADHD in Children with Tics (TACT) study. In this study, children treated with methylphenidate (Ritalin) had, on average, reduced tic severity, contrary to the widely held belief that stimulants exacerbate tics.

Medical treatment options for ADHD include psychostimulants, α_2 -adrenergic agonists guanfacine (Intuniv) and clonidine (Kapvay), and the selective norepinephrine reuptake inhibitor atomoxetine (Strattera). OCD management includes cognitive-behavioral

therapy, clomipramine (Anafranil), and any of the selective serotonin reuptake inhibitors.

Summary

Tourette syndrome is a complex neuropsychiatric illness with many potential symptoms that may need medical and nonmedical therapies. Cooperation among the primary care physician, neurologist, psychiatrist, and psychologist is imperative for the comprehensive care of severely affected patients. If a patient has mild tics and few or no comorbid symptoms, medical therapy may not be needed. However, if the tics are severe in the presence of many neuropsychiatric symptoms, it is reasonable to refer patients to specialists.

INTRACEREBRAL HEMORRHAGE

Method of

Joshua N. Goldstein, MD, PhD

CURRENT DIAGNOSIS

- Obtain a thorough history, including time of symptom onset
- Imaging of the cerebral vessels should be performed in patients younger than 55 years and should be strongly considered in all patients in whom underlying aneurysm or arteriovenous malformation is suspected.
- Obtain contrast-enhanced neuroimaging if underlying cerebral mass or tumor is suspected.

¹Not FDA approved for this indication.

CURRENT THERAPY

- Maintain airway, breathing, and circulation; stabilize the neck if fracture is considered.
- Detect and emergently correct coagulopathy.
- Arrange emergent neurosurgical consultation for cerebellar hemorrhage and intraventricular hemorrhage.

Epidemiology

Intracerebral hemorrhage (ICH) is most often the acute manifestation of a chronic, progressive disorder of the blood vessels of the brain. With an estimated incidence rate of between 35 and 45 cases per 100,000 population in Europe and North America, ICH generally accounts for between 10% and 15% of acute strokes on those continents. The incidence is higher in East Asia, with estimates that ICH accounts for as many as 30% to 40% of acute stroke cases in those countries. Hospital-based series consistently suggest that mortality from ICH ranges between 35% and 65% and substantial permanent disability occurs in at least 50% of survivors.

Risk Factors

Risk factors for primary ICH include chronic conditions, chronic exposures, and acute physiologic derangements. Secondary ICH refers to hemorrhage that develops in the setting of vascular malformations, including saccular aneurysms, brain tumor, cerebral venous thrombosis, or hemorrhagic conversion of an ischemic infarct. Among patients older than 55 years, who account for the majority of cases, chronic hypertension, cerebral amyloid angiopathy, and chronic use of antithrombotic medication are the leading risk factors for primary ICH. History of a prior stroke, chronic alcohol use, and family history of ICH also contribute, and patients with severe coagulopathy, cocaine abuse, and liver disease are also at higher risk for ICH. Accumulating data suggest that aggressive lowering of serum cholesterol or chronic use of statin therapy can increase risk for ICH in the elderly. Although chronic hypertension has long been identified as contributing to the largest proportion of ICH cases, recent population-based studies demonstrate a substantial fall in hypertension-associated ICH. In parallel, however, the aging of the population has led to the broader use of antithrombotic medications as well as increases in the prevalence of amyloid angiopathy. The result is that ICH incidence rates overall have not fallen.

Pathophysiology

ICH arises when a blood vessel within the brain ruptures and blood leaks out to form a hematoma. Because the skull is fixed in volume and is completely filled by brain, blood, and CSF, any accumulation of blood within the brain must necessarily compress, distort, and disrupt surrounding brain structures. The result is that the damage caused by ICH is due to mass effect of the hematoma as well as the toxic effects of the blood itself. The volume of blood that leaks out is thus the most potent predictor of outcome from ICH. In addition, extravasated blood can enter the CSF drainage system, leading to hydrocephalus, another predictor of poor outcome.

Bleeding in ICH often occurs over hours, a phenomenon that can be documented with serial head computed tomography (CT) scans. The volume of ICH can be compared between a CT scan obtained at the time of presentation to the emergency department and one obtained several hours later. The shorter the time interval between symptom onset and presentation to the emergency department, the more likely the patient is to have ongoing bleeding and hematoma expansion after the initial CT scan.

Location of the ICH within the brain can be a clue to the underlying vessel abnormality responsible for the rupture. Among patients 55 years and older, hemorrhage in lobar locations, the junction of the cortical gray matter and underlying white matter,

is most commonly a manifestation of underlying cerebral amyloid angiopathy, although other underlying conditions such as chronic hypertension and an underlying vascular malformation may instead be responsible. By contrast, hemorrhages centered in the deep gray structures of the basal ganglia, thalamus, and the brain stem arise most often as a complication of chronic hypertension, with amyloid angiopathy playing no role. Hemorrhages in the cerebellum can arise from any of these conditions.

ICH in the setting of chronic antithrombotic therapy is increasing in incidence as use of anticoagulants becomes increasingly widespread. Although it is likely that excessive doses of antithrombotic medication can cause ICH, the majority of cases in patients receiving antithrombotic medication occur in the absence of an overdose. This suggests that the majority of cases of antithrombotic-associated ICH arise in patients with an underlying disorder of the cerebral vessels such as cerebral amyloid angiopathy or hypertensive vasculopathy.

Recurrent ICH is common among survivors of ICH. In particular, patients 55 years and older who survive a lobar hemorrhage have a risk of recurrent lobar ICH in the range of 10% per year. The explanation for this is likely the inexorable progression of the underlying blood vessel disease, amyloid angiopathy. On the other hand, whereas survivors of ICH in the nonlobar regions are also at high risk for recurrent ICH, adequate control of hypertension following the initial ICH appears to substantially reduce that risk, suggesting that hypertension-related disease of the cerebral blood vessels can be arrested.

Prevention

Adequate control of chronic hypertension reduces the incidence of ICH in addition to reducing the incidence of a broad range of other cardiovascular conditions. Although no specific therapies have been shown to be effective in preventing ICH in patients with cerebral amyloid angiopathy, recognition of this condition might become useful in selecting patients for long-term antithrombotic use. Chronic statin therapy can increase risk of ICH, but more studies are required to inform the decision to withhold statins from patients at high risk for ICH.

Clinical Manifestations

Symptomatic ICH manifests with an acute stroke syndrome such as the sudden development of impaired consciousness, language difficulty, disorientation, or weakness. Nausea and vomiting can be prominent, particularly in patients with cerebellar hemorrhages as well as those who rapidly develop substantial mass effect or hydrocephalus. Headache and seizure at the onset of symptoms are more common in ICH than in ischemic stroke.

Small asymptomatic ICH also occurs in the setting of diseases like chronic hypertension and cerebral amyloid angiopathy. These hemorrhages, usually only detectable on magnetic resonance imaging (MRI) of the brain that includes susceptibility-weighted sequences sensitive to the permanent hemosiderin deposits left by all hemorrhages, are increasingly recognized as contributing to age-related deterioration in cognition, memory, and gait.

Diagnosis

ICH is a medical emergency. Rapid diagnosis and urgent critical care management (airway, breathing, circulation) are essential, particularly because ICH patients can deteriorate rapidly within hours of presentation. Noncontrast CT scan of the brain is the gold standard for confirming acute ICH, and all patients with suspected acute stroke or ICH should undergo an emergent noncontrast CT scan. In centers where emergent MRI is available, it can be substituted for noncontrast CT only if susceptibility-weighted sequences are performed. Angiographic imaging in the form of traditional catheter-based angiography or CT angiography should be performed in any patient younger than 55 years or in patients in whom underlying vascular malformation or ruptured saccular aneurysm is suspected. The history and laboratory evaluation, summarized in [Box 1](#), should be focused on identifying possible contributing causes as well as targets for treatment.

BOX 1 Focused Evaluation of Intracerebral Hemorrhage

Assess airway, breathing, circulation

History

Time of symptom onset (or when last seen well)
Recent trauma or surgery
Headache
Seizures
Alcohol or drug abuse
History of hypertension
Prior stroke
Liver disease
Cancer
Coagulopathy
Medications, including antithrombotics

Physical Examination

General physical examination
Glasgow Coma Scale
NIH stroke scale

Neuroimaging

Computed tomography, magnetic resonance imaging
CT angiography for patients younger than 55 years or in whom an underlying vascular lesion is suspected
Venography if venous sinus thrombosis is suspected
Cervical spine imaging if trauma is suspected

Laboratory

Electrolytes
Complete blood count
Coagulation panel
Toxicology screen
Electrocardiogram

Abbreviation: NIH = National Institutes of Health.

BOX 3 Targeted Therapy to Prevent Deterioration in Acute Intracerebral Hemorrhage

Neck stabilization in any patient at risk for cervical spine injury
Anticoagulant-associated ICH: Correct prothrombin time as rapidly as possible using intravenous vitamin K and prothrombin complex concentrate; dabigatran (Pradaxa) can be reversed with idarucizumab (Proxbind). Some clinicians use prothrombin complex concentrate to reverse Factor Xa inhibitors.

Severe thrombocytopenia or coagulation factor deficiency: Platelet and/or factor replacement. Platelet transfusion should not be given simply to treat those taking oral antiplatelet agents, as it worsens outcomes.

Blood pressure: Reduce systolic BP to less than 180 mm Hg for patients whose systolic BP is >220 mm Hg.

Avoid hypoglycemia.

Maintain euthermia.

Anticonvulsant medication: Only in patients who have had a seizure.

External ventricular drainage catheters: Consider for any patient with hydrocephalus or intraventricular hemorrhage.

Emergent surgical clot removal: Indicated for cerebellar hemorrhage with brain stem compression or neurologic deterioration.

Prevention of deep venous thrombosis: Intermittent pneumatic compression device and elastic stockings. Low-dose heparin should be started once serial CT scans confirm that bleeding has stopped and there is no longer any ICH expansion occurring.

Rehabilitation: Multidisciplinary rehabilitation should be offered to all ICH patients.

Abbreviations: BP = blood pressure; CT = computed tomography; ICH = intracerebral hemorrhage.

Differential Diagnosis

Emergent neuroimaging can confirm the presence of ICH (Box 2). For patients in whom the history is not obtainable, or who have associated trauma, it is sometimes difficult to distinguish traumatic from nontraumatic ICH. It is therefore essential to examine head imaging for skull fractures and the presence of subdural or subarachnoid hemorrhage, which might be traumatic in origin.

Treatment

After the focused evaluation (see Box 1) is completed, emergency care is devoted to preventing neurologic deterioration (Box 3). Blood pressure elevation is common in ICH; clinical trials suggest

that reducing systolic blood pressure below 140 is safe but does not clearly improve outcomes. Many clinicians lower systolic blood pressure below 160.

Because ICH is a devastating condition that most commonly affects the elderly, physicians and families are often confronted with the question of whether their patient or loved one would choose to survive the event. Accurate prediction of prognosis is essential to guide such decision-making. The most commonly used tool to risk stratify patients for mortality is the ICH score (Table 1). A tool to predict the likelihood of functional recovery among survivors is the FUNC score (Table 2). Tools such as the **FUNC score calculator** (<http://www.massgeneral.org/stopstroke/funcCalculator.aspx>) can be useful in guiding decisions about aggressiveness of care, but their precision remains to be proved. Clinicians are advised to provide care according to the principles outlined in this chapter for all patients at the outset, and to defer decisions to limit aggressiveness of care for the first 24 hours.

BOX 2 Differential Diagnosis of Intracerebral Hemorrhage**Primary Intracerebral Hemorrhage**

Cerebral small-vessel disease
Cerebral amyloid angiopathy
Hypertensive vasculopathy

Secondary Intracerebral Hemorrhage

Vascular malformations
Cerebral venous thrombosis
Hemorrhagic conversion of an ischemic infarct
Moya moya disease
Cerebral vasculitis
Bacterial endocarditis
Brain tumor
Trauma

Monitoring

Initial monitoring of the ICH patient is best provided by an intensive care unit with neurointensive care specialists available. Because subclinical seizures are common in ICH patients, EEG monitoring should be considered in any patient who has had a seizure or whose level of consciousness is altered. Invasive monitoring of intracranial pressure should be considered in patients with evidence of shift of the intracranial contents on neuroimaging.

Complications

Prevention of ICH, particularly recurrent ICH, is increasingly recognized as a priority in making decisions about whether or not to offer chronic anticoagulation to elderly patients with atrial fibrillation, prosthetic heart valves, and other conditions accompanied by high risk of thromboembolic ischemic stroke. Given the established

ISCHEMIC CEREBROVASCULAR DISEASE

Method of

Alvaro Cervera, MD; and Geoffrey A. Donnan, MD

Treatment of ischemic stroke has improved significantly in the past few years, and mortality and disability rates owing to this condition have decreased. The management of patients in stroke units and the demonstration of the efficacy of thrombolysis and thrombectomy have been crucial in this achievement. Control of vascular risk factors has decreased the number and severity of events. Improved management has included high-quality rehabilitation, which is started as soon as possible to improve the recovery (i.e., functional independence) of stroke survivors.

The multidisciplinary management of stroke can be improved with specific educational programs aimed at increasing awareness of stroke in the general population and among professionals. The concept of *time is brain* has great value in emphasizing that stroke is an emergency. Because the window for the available time-dependent treatments is very narrow, avoiding delay is the major goal in the prehospital phase of acute stroke care. All stroke patients must be transported as soon as possible to the closest hospital with a stroke unit. In rural or remote areas with no stroke unit facilities, telemedicine has proved to be a valid alternative.

Prevention

Lifestyle modification can be a major contributor to reducing the risk of ischemic stroke. Strategies to achieve this protection include avoiding smoking and excessive alcohol consumption, keeping a low-normal body mass index, practicing regular exercise, and having a diet low in salt and saturated fat, high in fruits and vegetables, and rich in fiber. There is no need to add vitamin supplements to the diet because they have not been found to affect stroke prevention.

Regular assessment of vascular risk factors (e.g., hypertension, diabetes, hypercholesterolemia) is important because their control can reduce significantly the incidence of vascular events. Blood pressure should be managed with diet and pharmacologic therapy, aiming at normal levels of 120/80 mm Hg. After an ischemic stroke, blood pressure should be lowered even in patients with normal blood pressure. Diabetes should be managed with lifestyle modification and pharmacologic therapy as required, and blood pressure needs to be more tightly controlled in these patients (<130/80 mm Hg). The best antihypertensive treatments for diabetic patients are angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor antagonists. Hypercholesterolemia should be managed with lifestyle modification and a statin. After a noncardioembolic ischemic stroke, statins are beneficial in all patients for secondary prevention.

ISCHEMIC CEREBROVASCULAR DISEASE

Method of

Alvaro Cervera, MD; and Geoffrey A. Donnan, MD

Treatment of ischemic stroke has improved significantly in the past few years, and mortality and disability rates owing to this condition have decreased. The management of patients in stroke units and the demonstration of the efficacy of thrombolysis and thrombectomy have been crucial in this achievement. Control of vascular risk factors has decreased the number and severity of events. Improved management has included high-quality rehabilitation, which is started as soon as possible to improve the recovery (i.e., functional independence) of stroke survivors.

The multidisciplinary management of stroke can be improved with specific educational programs aimed at increasing awareness of stroke in the general population and among professionals. The concept of *time is brain* has great value in emphasizing that stroke is an emergency. Because the window for the available time-dependent treatments is very narrow, avoiding delay is the major goal in the prehospital phase of acute stroke care. All stroke patients must be transported as soon as possible to the closest hospital with a stroke unit. In rural or remote areas with no stroke unit facilities, telemedicine has proved to be a valid alternative.

Prevention

Lifestyle modification can be a major contributor to reducing the risk of ischemic stroke. Strategies to achieve this protection include avoiding smoking and excessive alcohol consumption, keeping a low-normal body mass index, practicing regular exercise, and having a diet low in salt and saturated fat, high in fruits and vegetables, and rich in fiber. There is no need to add vitamin supplements to the diet because they have not been found to affect stroke prevention.

Regular assessment of vascular risk factors (e.g., hypertension, diabetes, hypercholesterolemia) is important because their control can reduce significantly the incidence of vascular events. Blood pressure should be managed with diet and pharmacologic therapy, aiming at normal levels of 120/80 mm Hg. After an ischemic stroke, blood pressure should be lowered even in patients with normal blood pressure. Diabetes should be managed with lifestyle modification and pharmacologic therapy as required, and blood pressure needs to be more tightly controlled in these patients (<130/80 mm Hg). The best antihypertensive treatments for diabetic patients are angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor antagonists. Hypercholesterolemia should be managed with lifestyle modification and a statin. After a noncardioembolic ischemic stroke, statins are beneficial in all patients for secondary prevention.

Postmenopausal hormone replacement therapy should be avoided for the primary or secondary prevention of stroke because it can increase the risk of new vascular events. Other strategies to prevent stroke include the treatment of obstructive sleep apnea with continuous positive airway pressure (CPAP) breathing.

Antithrombotic Therapy

Low-dose aspirin can be used for the primary prevention of stroke in women or of myocardial infarction in men. Nevertheless, its effect is very small, and it cannot be recommended on a population-wide basis. Aspirin is beneficial for the prevention of stroke in patients with asymptomatic carotid stenosis.

In patients with atrial fibrillation, the CHA₂DS₂-VASc scale (Table 1) is used to decide whether to use anticoagulation. If the score is 2 or more, treatment with oral anticoagulants is indicated. With a score of 1, the decision should be made according to the presence of risk factors, risk of bleeding, and patient choice. There is no need to start antithrombotic treatment, either antiplatelets or anticoagulants, if the score is 0. All patients with stroke or transient ischemic attack (TIA) should be given anticoagulants, unless strictly contraindicated. Patients with valvular atrial fibrillation require anticoagulation with warfarin, aiming at an international normalized ratio (INR) of 2.0 to 3.0. Patients with prosthetic heart valves should also receive warfarin, and the target INR depends on the prosthesis type. In nonvalvular atrial fibrillation the treatment options include warfarin (INR 2.0–3.0) or one of the new direct oral anticoagulants (dabigatran [Pradaxa], apixaban [Eliquis], rivaroxaban [Xarelto], edoxaban [Savaysa]). The newer agents are associated with a decreased risk of intracranial hemorrhage. Dabigatran (150 mg bid) and apixaban (5 mg bid) have shown to be superior to warfarin in stroke prevention. The dose of the direct oral anticoagulants needs to be adjusted depending on age, renal function, or weight.

After ischemic stroke, all patients should receive antithrombotic therapy. Antiplatelet agents are the first choice unless anticoagulation is required. The most effective regimen is clopidogrel (Plavix) or aspirin plus dipyridamole (Aggrenox). However, low-dose aspirin is a reasonable alternative. During the first 3 weeks after a minor stroke or TIA, the combination of aspirin plus clopidogrel can be more effective in reducing ischemic events than clopidogrel alone, although the evidence is scarce. However, this dual antiplatelet treatment is not recommended in the long term, unless there is an association with unstable angina or non-Q-wave myocardial infarction or there has been a recent stenting.

Anticoagulation is usually indicated for secondary prevention if the stroke cause is cardioembolic and in specific situations such as aortic arch atheroma, fusiform aneurysms of the basilar artery, or patent foramen ovale in the presence of proven deep venous thrombosis. However, level 1 evidence is lacking for these approaches.

TABLE 1 Prevention of Stroke in Patients With Atrial Fibrillation

Congestive heart failure	1
Hypertension	1
Age ≥75	2
Age 65–74	1
Diabetes mellitus	1
Stroke or transient ischemic attack	2
Vascular disease	1
Female sex	1

Management of Carotid Stenosis

In patients with asymptomatic carotid stenosis (≥60%), surgery is indicated only if the risk of stroke is high. Endarterectomy is the treatment of choice if the stenosis is symptomatic (i.e., has been associated with an ipsilateral stroke or TIA) and severe (70%–99%). Surgery should be performed in centers with a perioperative complication rate of less than 6% and as soon as possible after the last ischemic event.

Endarterectomy may be indicated for certain patients with moderate stenosis (50%–69%), although it should be performed only in centers with a perioperative complication rate of less than 3% to be effective. In cases of symptomatic carotid lesions, angioplasty plus stenting is a reasonable alternative, mainly in patients younger than 70 years old. If stenting is performed, a combination of clopidogrel and aspirin is required immediately before the procedure and for at least 1 month to prevent stent thrombosis.

In patients with intracranial atheromatosis and stroke recurrences, intensive medical treatment is the preferred option. Angioplasty and stenting are not recommended.

Management of Acute Ischemic Stroke

All stroke patients should be treated in a stroke unit, because this is associated with a reduction of death, dependency, and the need for institutional care. This effect is seen for all types of patients, irrespective of gender, age, stroke subtype, and stroke severity. Patients with stroke should have a careful clinical assessment, including a neurologic examination. The use of a stroke rating scale, such as the National Institutes of Health Stroke Scale (NIHSS), provides important information about the severity of stroke.

Urgent cranial computed tomography (CT) is mandatory after an ischemic stroke before starting any therapy. Alternatively, magnetic resonance imaging (MRI) or CT perfusion (CTP) can be performed and can provide additional information about the selection of patients for thrombolytic therapy beyond 4.5 hours, or when the time of onset is unknown. However, there is not enough evidence to recommend its routine use in the acute stroke setting.

For the detection and early management of the medical complications of stroke, neurologic status, pulse, blood pressure, temperature, and oxygen saturation should be monitored. Similarly, serum glucose levels need to be monitored and hyperglycemia treated with insulin accordingly. Normal saline is recommended for fluid replacement during the first 24 hours after stroke. If the patient has a fever, treatment with paracetamol (acetaminophen) may be used while sources of infection are being sought. Reducing blood pressure is recommended only in patients with extremely high blood pressure or when indicated by other medical conditions. Blood pressure should be lowered gradually, avoiding abrupt changes.

Thrombolysis

All patients with an ischemic stroke within 4.5 hours of onset should receive thrombolytic treatment with intravenous tissue plasminogen activator (tPA [Activase]) unless contraindicated, because it is effective in improving stroke outcome (Box 1). There is also evidence from phase II trials (e.g., EPITHET) that selecting patients with MRI to assess the penumbra can be an appropriate tool to extend the time window of this treatment, because tPA was associated with increased reperfusion in these patients and a trend toward better outcomes. Nevertheless, increasing the time window does not mean that treatment can be delayed. As evidenced by pooled analysis, earlier treatment results in a better outcome. There is enough evidence indicating that thrombolysis is still effective in the very elderly, even with significant comorbidities.

Endovascular Thrombectomy

Mechanical thrombectomy using stent retrievers in addition to thrombolysis is more effective in improving outcome than thrombolysis alone in anterior circulation strokes and a large artery occlusion, with a time window of up to 6 hours. This treatment is also effective when thrombolysis cannot be administered. In a recent meta-analysis of five major trials (MR CLEAN, ESCAPE,

BOX 1**Treatment of Acute Ischemic Stroke: Intravenous Administration of Tissue Plasminogen Activator**

- Infuse 0.9 mg/kg (maximum dose 90 mg) of tissue plasminogen activator (tPA [Activase]) over 60 minutes, with 10% of the dose given as a bolus over 1 minute.
- Admit the patient to a stroke unit for monitoring. Perform neurologic assessment and blood pressure measurement every 15 minutes during the infusion, every 30 minutes thereafter for the next 6 hours, and then hourly until 24 hours after treatment. Administer antihypertensive medications to maintain systolic blood pressure ≤ 180 and diastolic ≤ 105 .
- If intracranial hemorrhage is suspected, discontinue the infusion and obtain an emergency computed tomography scan.
- Obtain a follow-up computed tomography scan at 24 hours before starting anticoagulants or antiplatelet agents.

REVASCAT, SWIFT PRIME, and EXTEND IA), endovascular thrombectomy led to significantly reduced disability at 90 days compared with control (odds ratio 2.49), with a number needed to treat of 2.6. This effect was seen in all subgroups of patients. Therefore health authorities have to implement access to thrombectomy within a reasonable time range in a network including stroke centers.

Antithrombotic Drugs

All patients should receive a low dose of aspirin daily, and this should be started within 48 hours after stroke onset. The use of other antiplatelet agents during the acute phase of stroke cannot be recommended based on available evidence. Similarly, early administration of unfractionated heparin, low-molecular-weight heparin, or heparinoids is not indicated in patients with acute ischemic stroke.

Treatment of Stroke Complications

Brain edema develops between the second and fifth day after stroke onset and is the cause of early deterioration and death. In the case of a malignant infarction of the middle cerebral artery, the mortality rate is 80%. In patients younger than 60 years with this pattern of cerebral infarction, hemicraniectomy has been effective in reducing mortality and severe disability, as shown in the pooled analysis of the DECIMAL, DESTINY, and HAMLET trials. Decompressive hemicraniectomy is also effective in reducing mortality in patients older than 60 years, although the rates of severe disability are very high. Surgery needs to be performed within 48 hours after symptom onset. Surgical decompression is also indicated in the case of large cerebellar infarctions that compress the brainstem.

Stroke-associated infections require appropriate antibiotics, but prophylactic administration is discouraged. Venous thromboembolism is a frequent complication after stroke, but its incidence can be reduced with appropriate hydration and graded compression stockings. If the risk of deep venous thrombosis or pulmonary embolism is high, the use of subcutaneous heparin or low-molecular-weight heparin is beneficial. Early mobilization is an effective way of preventing complications such as aspiration pneumonia or pressure ulcers. Anticonvulsants are administered only to prevent recurrent seizures but are not used prophylactically.

In case of urinary incontinence, specialist assessment and management are recommended. Dysphagia is common after stroke and is associated with a higher incidence of medical complications and increased mortality. Malnutrition also predicts a poor functional outcome and increased mortality, and it is important to assess the swallowing capacity and the nutritional status of the patient.

Rehabilitation should be started after admission to the stroke unit. The optimal timing of first mobilization is unclear, but mobilization within the first few days appears to be well tolerated. However, very early mobilization can be associated with a worse outcome, as shown in the AVERT trial. An early, lower-dose out-of-bed activity regimen is preferable to very early, frequent,

higher-dose intervention. It is important to assess cognitive deficits and depression during the patient's hospital stay, because this may require specific intervention, although evidence about the type is lacking.

Definition

Migraines are episodic headaches accompanied by nausea and/or photophobia plus phonophobia. The headache must last 4 to 72 hours and have at least two defining features (it is unilateral, pulsating, moderate-to-severe intensity, and/or aggravated by movement). Five attacks and the exclusion of other conditions

are required for diagnosis. Patients with migraine may also suffer from other types of headaches (e.g., tension).

Epidemiology

About 45 million U.S. adults (18–23% of women, 6–9% of men) report migraine. Onset is usually between ages 12 and 30. Prevalence peaks in young adults. Migraine is diagnosed in about 30% of family medicine headache patients. A positive migraine diagnosis by a family physician is over 95% accurate, but cases may be misdiagnosed, especially as a tension or sinus headache.

Risk Factors

Besides age and female sex, the biggest risk factor is family history.

Pathophysiology

Migraine results from complex interactions among multiple genetic and environmental factors. The primary neuronal process may be a depolarizing wave (Leão's cortical spreading depression) activating the trigeminal nerve afferents and causing vasoactive neuropeptide release, local inflammation, vascular instability, and blood-brain barrier changes. The type and location of symptoms depend on which parts of the complex trigeminovascular system are activated. This system innervates pain-sensitive blood vessels and meninges and connects with various areas of the brain, including the thalamus and sensory cortex. Biochemically, serotonin, calcitonin gene-related peptide (CGRP), and other substances are implicated in migraine.

The suspected role of right-left cardiac shunts, especially patent foramen ovale, has not been validated.

Prevention

The vulnerability to migraine cannot be eliminated, but patients can be assisted to reduce the number of attacks and minimize the negative impact of migraine through a consideration of triggers and use of prophylaxis.

Triggers

Some migraineurs have specific precipitants for an attack. The strongest evidence is for stress, menstruation, missed meals, weather changes, and sleep disturbances. Migraines may be associated with stress or its relief (weekend migraine). Avoiding or minimizing triggers may reduce the likelihood of a migraine.

Prophylactic Medications

The U.S. Headache Consortium (USHC) and other guidelines recommend discussing prophylaxis with patients who meet the following criteria:

- They have severe and/or frequent symptoms that disrupt daily activities despite adequate treatment.
- They have a poor efficacy or inability to use standard treatments for acute attacks (e.g., because of adverse effects, contraindications, cost).
- They have specific rare migraine syndromes associated with dangerous neurologic complications (basilar migraine, prolonged aura, hemiplegic migraine).

Successful prophylaxis depends on balancing potential benefit against adverse effects and the demands of adherence to long-term medications. Selection of a prophylactic medication depends on patient factors (personal preferences, comorbidities such as hypertension and depression) and medication concerns (including efficacy, cost, pharmacokinetics, adverse effects, and medication interactions).

Prophylactic medication should be started at a low dose and gradually increased until benefit is demonstrated or adverse effects outweigh benefits. Individual patients show enormous variation in the effective dose of prophylactic medication. An adequate trial of prophylaxis requires several months. A patient may have poor outcomes from one agent but good response to an agent from a different class. A headache diary is useful to monitor symptoms and

adverse effects. Therapy should be reevaluated every 3 to 6 months.

The USHC evidence-based recommendations for migraine prophylaxis based on efficacy and potential adverse effects have been updated by the American Academy of Neurology (AAN) (Table 1). The AAN (2012) and European (2009) guidelines confirm the use of certain beta-blockers and antiepileptic medications and also for the first time rate herbal and complementary treatments. Level A evidence was established for petasites (butterbur extract)⁷ 50 to 75 mg twice daily. Magnesium (400–600 mg),¹ feverfew⁷ (as MIG-99 extract, 6.25 mg three times daily), and riboflavin⁷ (400 mg) were classified as level B. Coenzyme Q10⁷ (100 mg tid) was classified as level C and omega-3⁷ (3 g twice daily) as level U.

Nonpharmacologic Therapies

Nondrug therapies to prevent attacks may be preferred by some patients, including those who have had limited success with medications. The four main types of nonpharmacologic therapies are relaxation training, biofeedback therapy, cognitive-behavioral training (stress-management training), and physical treatments (acupuncture, cervical manipulation, and mobilization therapy). Each may be used alone or in combination with other therapies, including medications.

Research evidence is lacking or controversial for many of these therapies. The USHC concluded that relaxation training, thermal biofeedback combined with relaxation training, and cognitive-behavioral therapy are all modestly effective in preventing migraine (Grade A); behavioral therapy (relaxation, biofeedback) combined with preventive drug therapy (propranolol [Inderal], amitriptyline [Elavil]¹) may provide additional clinical improvement (Grade B); but no recommendations could be made for hypnosis, acupuncture, transcutaneous electric neuromuscular stimulation, cervical manipulation, occlusal adjustment, and hyperbaric oxygen as preventive or acute therapy for migraine.

Clinical Manifestations

Prodrome: About 60% of migraineurs experience 1 to 2 days of symptoms such as yawning, intense hunger, mild euphoria, or depression/irritability before an attack.

Aura

About 25% of migraineurs report consistent, specific neurologic changes about 5 to 60 minutes before the onset of headache. Common aura symptoms include visual (flashing lights, zigzag lines, scotoma), sensory (paresthesia, numbness), or speech disturbances.

Symptoms

Migraine combines a specific type of headache (unilateral, throbbing, moderate-to-severe, worse with activity) with other diagnostic symptoms (nausea/vomiting and/or photophobia/phonophobia). Many patients also experience vertigo, allodynia, and fatigue. Additional symptoms may be prominent in migraine subtypes such as basilar or ophthalmoplegic migraine. Patients vary enormously in the symptom pattern as well as in the frequency, intensity, and impact of attacks. Some have infrequent episodes with mild symptoms, whereas others are incapacitated by recurrent, severe attacks.

Duration and Complications

Classically, migraine patients lie still in a dark room until sleep resolves symptoms. Afterward, some patients feel refreshed, others are tired, and others experience localized skull tenderness or headache on movement.

Status migrainosus is debilitating migraine lasting more than 72 hours. The patient may be dehydrated, exhausted, and/or suffering adverse medication effects. Very rarely, migraine subtypes

(basilar, ophthalmoplegic, hemiplegic) are complicated by seizure or cerebral infarction. Chronic migraine (defined as symptoms on more than 15 days per month) requires investigation, especially for medication-rebound headache. With inappropriate therapy, migraine can transform into chronic daily headache.

Diagnosis

Migraine diagnosis depends on history. Identifying classic symptoms has a high probability of accurate diagnosis (Table 2). The headache pattern should distinguish migraine from other primary headaches (e.g., tension, cluster). The clinical history and

TABLE 2 Diagnostic Probability of Symptoms for Migraine (POUND Mnemonic)

From Gilmore and Michael (2011).

examination target identifying conditions that could cause secondary headache. Neurologic examination must be documented, because change over time is crucial in detecting the rare cases of intracranial pathology that present with migraine-type symptoms.

Diagnostic imaging is not indicated in migraine patients with normal neurologic examination. Guidelines recommended imaging only for atypical symptoms or “red flag” indications of serious pathology but recognize that some patients may require testing for excessive anxiety (Table 3). Other testing (e.g., complete blood count, sedimentation rate, analysis of cerebrospinal fluid) are selected to identify specific potential causes of symptoms in individual patients. Guidelines stress that testing should be done only if results are likely to change management.

Differential Diagnosis

Other recurrent headaches, especially tension or cluster, can usually be distinguished by the combination of features (unilaterality, nausea, photo/phonophobia) and pattern (frequency of occurrence and duration).

Intracranial pathology (including acute or chronic bleeding, infection, or space-occupying lesions) can cause headache resembling migraine. This can also occur with head and neck conditions such as temporal arteritis, sinusitis, temporomandibular joint syndrome, and various neuralgias as well as systemic conditions including carbon monoxide poisoning, sudden rise in blood pressure, or medication adverse effect. Diagnosis depends on recognizing that the clinical picture is not completely congruent with migraine, and also on identifying risk factors, symptoms, and signs, along with positive targeted testing for the underlying condition.

Treatment

Treatment goals for acute migraine are rapid symptom control, minimizing adverse effects, preventing recurrence, and optimizing function. Self-management and efficient use of resources are priorities. The USHC guidelines (2000) and more recent European guidelines (2009) are based on research evidence. Individual patients vary enormously in response to specific medications and in the effective dose. Patients who do not respond to an appropriate dose of one medication may have good outcomes from another agent in the same class or one from a different class. Medications should be taken in adequate dosage as early as possible during a migraine attack. Nonoral formats or adjunct medications may

TABLE 3 “Red Flag” Findings Associated with Increased Risk of Underlying Pathology in Headache

Acute onset
Occipitocuchal location
Age greater than 55 years
Associated symptoms (fever, neurologic symptoms, mental status changes)
Abnormal neurologic examination

Adapted from Silberstein (2000).

Notes: Headache type, severity, characteristics, or duration were not risk factors; increasing frequency and headache awakening from sleep were positively associated. In the ER setting, patients over 50 years of age with acute onset and neurologic signs had 98.6% specificity for serious intracranial pathology.

be necessary because of vomiting or poor absorption resulting from gastric stasis.

Many medications have antimigraine activity (Table 4). Considerations in selecting an agent include patient comorbidities (e.g., hypertension) and the medication's potential adverse effects. Cost may be a significant concern.

Of first-line therapies, NSAIDs or combination analgesics with caffeine are recommended for mild-to-moderate attacks or more severe attacks that have previously responded to these agents. Evidence also supports intramuscular ketorolac (Toradol)¹ as a useful strategy for vomiting patients.

Triptans are recommended for moderate-to-severe migraine and for mild-to-severe attacks that have not responded adequately to other first-line therapies. Individual triptans have comparable efficacy and tolerability but differ in speed of onset and duration of action. This allows for the selection of an agent with pharmacokinetics that correspond to the patient's migraine symptom pattern. The most effective agent and dose for each patient can only be established by experience. Triptans may be combined synergistically with NSAIDs. Potential triptan adverse effects include vasoconstriction and serotonin syndrome.

Ergotamines are effective in migraine but limited by adverse effects, especially vasoconstriction. They are less effective than triptans but may have good results in some patients. Nasal spray is useful if the patient cannot take oral medications. In emergency

¹Not FDA approved for this indication.

room studies, parenteral dihydroergotamine (D.H.E. 45) combined with antiemetics has been as effective as opiates. Opiates are rarely appropriate for migraine. Studies show that other agents are more effective with fewer adverse effects and no risk of addiction or exploitation.

Chronic Migraine

An estimated 3% of migraine sufferers progress to develop chronic migraine each year. Chronic migraine is defined as at least three months of headache on 15 or more days per month with headaches fulfilling criteria for migraine on at least eight days per month. Other causes of symptoms, including medication overuse, must be excluded for diagnosis of chronic migraine. Persistent changes in brain structure and function occur in chronic migraine resulting in central sensitization, intractable symptoms and vulnerability to psychiatric comorbidities. Treatment requires lifestyle modification, consideration of non-pharmacological therapies (biofeedback, cognitive behavioral therapy, physical therapy, relaxation therapy or acupuncture), management of symptoms, and prophylactic therapy. The only currently approved prophylactic treatments specifically for chronic migraine are onabotulinumtoxin A (Botox) and topiramate (Topamax)¹ but other prophylactic therapies may reduce the frequency and impact of recurrent migraine headaches in patients with chronic migraine.

Monitoring

Regular monitoring can allow for the adjustment of medication for maximum efficacy and minimal adverse effects, promote healthy lifestyles, and aid in screening for migraine comorbidities, especially depression. Conversion to chronic daily headache by overuse of medications is a major concern.

MULTIPLE SCLEROSIS

Method of

B. Mark Keegan, MD

CURRENT DIAGNOSIS

- Multiple sclerosis (MS) is an autoimmune demyelinating disease of the central nervous system (CNS).
- Diagnosis is secured from having repeated CNS demyelinating attacks or new CNS demyelinating lesions on magnetic

resonance imaging (MRI) or progressive neurologic dysfunction consistent with MS with no better alternative explanation.

- Presence of cerebrospinal fluid (CSF)–specific oligoclonal bands, characteristic of MS, aids diagnosis.

CURRENT THERAPY

- Acute attacks of multiple sclerosis (MS) are treated with high-dose corticosteroids and, in severe cases, plasma exchange.
- Therapy is directed at relapsing–remitting disease with one of the following type 1 interferon β medications: glatiramer acetate, fingolimod (Gilenya), teriflunomide (Aubagio), dimethyl fumarate (Tecfidera), and natalizumab (Tysabri). Therapy for primary progressive MS (progressive disease from onset without prior relapse) is ocrelizumab (Ocrevus).
- Novel MS medications, including further oral medications, and infusion-based monoclonal antibodies are currently under scientific evaluation.

Multiple sclerosis (MS) is an autoimmune inflammatory demyelinating disease of the central nervous system (CNS) that affects approximately 400,000 people in the United States alone.

Risk Factors

Women are at least twice as likely to have development of MS as are men. Other known risk factors for development of MS include ethnicity, genetic background, and socioeconomic and environmental exposures. Persons of European ethnicity, particularly those born and reared in extreme northern or southern latitudes, are particularly susceptible to MS. African Americans are less likely to be diagnosed with MS than European Americans, but they have a more severe clinical course. Genetic susceptibility is associated with the major histocompatibility allele HLA-DRB1, as well as interleukin-2 and interleukin-7 receptors. Low serum vitamin D levels are associated with an increased risk of development of MS and may influence the severity of its clinical course. There are intriguing but as yet unproven associations with infection with Epstein-Barr virus (infectious mononucleosis), particularly if this is contracted later in adolescence. Exposure to Epstein-Barr virus may be necessary but insufficient for developing MS. Comorbid chronic vascular diseases and mood disorders complicate and worsen MS disease course. Cigarette smoking is associated with an increased risk for development of MS and likely is associated with an increased severity and clinical course of MS, including that of cognitive impairment.

Pathophysiology

The etiology and pathophysiology of MS as a whole remains uncertain. However, most evidence supports an inflammatory demyelinating disease induced by uncertain environmental factors in a genetically susceptible host. Animal studies including experimental allergic encephalomyelitis and Theiler's murine encephalomyelitis virus also point to an autoimmune inflammatory demyelinating etiology, possibly associated with viral infection. Studies that suggest chronic cerebrospinal vascular insufficiency has an important association with MS remain unconfirmed.

Pathophysiology likely varies among individual patients with MS. Four distinct pathologies in active demyelinating MS lesions have been described. Pattern 1 displays marked macrophage infiltration without humoral abnormalities. Pattern 2 shows distinct humoral abnormalities with complement activation and immunoglobulin (Ig) deposition. Pattern 3 involves primary oligodendrocyte degeneration and early loss of myelin-associated glycoprotein. Pattern 4 reveals oligodendrocyte dystrophy in periplaque white matter. Early studies suggest there could be a therapeutic advantage with different therapies for different types of demyelinating disease.

room studies, parenteral dihydroergotamine (D.H.E. 45) combined with antiemetics has been as effective as opiates. Opiates are rarely appropriate for migraine. Studies show that other agents are more effective with fewer adverse effects and no risk of addiction or exploitation.

Chronic Migraine

An estimated 3% of migraine sufferers progress to develop chronic migraine each year. Chronic migraine is defined as at least three months of headache on 15 or more days per month with headaches fulfilling criteria for migraine on at least eight days per month. Other causes of symptoms, including medication overuse, must be excluded for diagnosis of chronic migraine. Persistent changes in brain structure and function occur in chronic migraine resulting in central sensitization, intractable symptoms and vulnerability to psychiatric comorbidities. Treatment requires lifestyle modification, consideration of non-pharmacological therapies (biofeedback, cognitive behavioral therapy, physical therapy, relaxation therapy or acupuncture), management of symptoms, and prophylactic therapy. The only currently approved prophylactic treatments specifically for chronic migraine are onabotulinumtoxin A (Botox) and topiramate (Topamax)¹ but other prophylactic therapies may reduce the frequency and impact of recurrent migraine headaches in patients with chronic migraine.

Monitoring

Regular monitoring can allow for the adjustment of medication for maximum efficacy and minimal adverse effects, promote healthy lifestyles, and aid in screening for migraine comorbidities, especially depression. Conversion to chronic daily headache by overuse of medications is a major concern.

¹Not FDA approved for this indication.

MULTIPLE SCLEROSIS

Method of

B. Mark Keegan, MD

CURRENT DIAGNOSIS

- Multiple sclerosis (MS) is an autoimmune demyelinating disease of the central nervous system (CNS).
- Diagnosis is secured from having repeated CNS demyelinating attacks or new CNS demyelinating lesions on magnetic

resonance imaging (MRI) or progressive neurologic dysfunction consistent with MS with no better alternative explanation.

- Presence of cerebrospinal fluid (CSF)–specific oligoclonal bands, characteristic of MS, aids diagnosis.

CURRENT THERAPY

- Acute attacks of multiple sclerosis (MS) are treated with high-dose corticosteroids and, in severe cases, plasma exchange.
- Therapy is directed at relapsing–remitting disease with one of the following type 1 interferon β medications: glatiramer acetate, fingolimod (Gilenya), teriflunomide (Aubagio), dimethyl fumarate (Tecfidera), and natalizumab (Tysabri). Therapy for primary progressive MS (progressive disease from onset without prior relapse) is ocrelizumab (Ocrevus).
- Novel MS medications, including further oral medications, and infusion-based monoclonal antibodies are currently under scientific evaluation.

Multiple sclerosis (MS) is an autoimmune inflammatory demyelinating disease of the central nervous system (CNS) that affects approximately 400,000 people in the United States alone.

Risk Factors

Women are at least twice as likely to have development of MS as are men. Other known risk factors for development of MS include ethnicity, genetic background, and socioeconomic and environmental exposures. Persons of European ethnicity, particularly those born and reared in extreme northern or southern latitudes, are particularly susceptible to MS. African Americans are less likely to be diagnosed with MS than European Americans, but they have a more severe clinical course. Genetic susceptibility is associated with the major histocompatibility allele HLA-DRB1, as well as interleukin-2 and interleukin-7 receptors. Low serum vitamin D levels are associated with an increased risk of development of MS and may influence the severity of its clinical course. There are intriguing but as yet unproven associations with infection with Epstein-Barr virus (infectious mononucleosis), particularly if this is contracted later in adolescence. Exposure to Epstein-Barr virus may be necessary but insufficient for developing MS. Comorbid chronic vascular diseases and mood disorders complicate and worsen MS disease course. Cigarette smoking is associated with an increased risk for development of MS and likely is associated with an increased severity and clinical course of MS, including that of cognitive impairment.

Pathophysiology

The etiology and pathophysiology of MS as a whole remains uncertain. However, most evidence supports an inflammatory demyelinating disease induced by uncertain environmental factors in a genetically susceptible host. Animal studies including experimental allergic encephalomyelitis and Theiler's murine encephalomyelitis virus also point to an autoimmune inflammatory demyelinating etiology, possibly associated with viral infection. Studies that suggest chronic cerebrospinal vascular insufficiency has an important association with MS remain unconfirmed.

Pathophysiology likely varies among individual patients with MS. Four distinct pathologies in active demyelinating MS lesions have been described. Pattern 1 displays marked macrophage infiltration without humoral abnormalities. Pattern 2 shows distinct humoral abnormalities with complement activation and immunoglobulin (Ig) deposition. Pattern 3 involves primary oligodendrocyte degeneration and early loss of myelin-associated glycoprotein. Pattern 4 reveals oligodendrocyte dystrophy in periplaque white matter. Early studies suggest there could be a therapeutic advantage with different therapies for different types of demyelinating disease.

Prevention

Currently, there is no known way to prevent the development of MS. Patients with a single clinical attack of demyelination and abnormal magnetic resonance imaging (MRI) ("high-risk" clinically isolated syndrome) have a delayed onset to MS diagnosis with immunomodulatory therapy; however, there is no evidence to support that this prevents the eventual development of MS.

Clinical Manifestations

The clinical course of MS is varied. Approximately 85% of patients present with a relapsing–remitting course. This entails an acute impairment within the CNS, depending on the area of inflammation. A demyelinating cause of a focal neurologic symptom is suggested by an onset over hours to days, with a plateau of impairment over a few weeks. Symptoms then improve either spontaneously or with the use of corticosteroids over a number of days to weeks or longer. Following this, however, symptoms might not completely resolve. Inflammation within the optic nerve (optic neuritis) is heralded by painful, unilateral, central monocular visual deficit (central scotoma). Symptoms of brain stem dysfunction include binocular diplopia, sensory deficits unilaterally on the face and contralaterally on the arm and leg, significant dysarthria, and vertigo. Cerebellar dysfunction is seen with pure ataxia that is typically unilateral. Spinal cord inflammation is indicated by a distinctive, usually gradually rising sensory level of deficit that commonly is accompanied by bowel and bladder impairment and paraparesis or quadriparesis, depending on a thoracic versus cervical level of the lesion.

Progressive forms of MS include secondary progressive MS and primary progressive MS. These are heralded by a slow (months to years) but steady and insidious, progressive neurologic deficit, usually a progressive myelopathy of upper motor neuron gait disorder with spasticity, neurogenic bladder and bowel impairment, and progressive weakness. Occasionally, patients with progressive MS have insidious cerebellar ataxia or dementia in isolation or in association with the myelopathy. Secondary progressive MS is diagnosed when a patient has had a prior history of at least one clinical attack (relapse) with improvement in the past. Primary progressive MS is diagnosed with progressive CNS disease consistent with MS and typical MRI brain or spinal lesions from onset without any prior relapse, often with cerebrospinal fluid (CSF) or visual evoked potential abnormalities that support the diagnosis.

Diagnosis

The diagnosis of MS is formalized by the continually revised McDonald criteria. This entails having two or more clinical attacks (relapses) in the accompaniment of two or more objective lesions seen on clinical examination or with evidence for dissemination in space and time diagnosed by further development of new MRI lesions. Additionally, patients with a single clinical attack who have both the presence of MRI gadolinium enhancing lesions (indicative of acute MS lesions) and nongadolinium enhancing lesions (indicative of prior MS lesions) are diagnosed with relapsing remitting MS. Progressive MS is diagnosed when there is progressive CNS disease characteristic of MS for at least 1 year and abnormal brain or spinal cord MRI scan with or without CSF-specific oligoclonal bands (Figure 1). Occasionally, visual-evoked potentials and somatosensory-evoked potentials are used to further document dissemination of MS within the CNS. Serologic investigations are done primarily to rule out MS mimickers depending on and directed by any accompanying systemic symptoms and the clinical setting in individual patients. These may include antinuclear antibodies (ANA for lupus), erythrocyte sedimentation rate, anticardiolipin antibodies, vitamin B₁₂, Lyme serology, and chest imaging for CNS sarcoidosis.

Differential Diagnosis

Other CNS demyelinating diseases can mimic relapsing or progressive MS. Acute disseminated encephalomyelitis (ADEM) is an acute, typically monophasic, and postinfectious CNS inflammatory demyelinating disease. It may be severe; however, if recurrent episodes occur separated by at least 3 months, a diagnosis of relapsing–remitting MS is by far more likely.

Neuromyelitis optica is an autoimmune disease with severe acute attacks but is relatively restricted to the optic nerves and spinal cord. Other brainstem and deep cerebral structures, such as the area postrema, cerebral white matter, and hypothalamus, can also be affected by neuromyelitis optica. Brain MRI scan is usually not consistent with MS, at least early on in the disease, and a specific autoantibody (neuromyelitis optica IgG) directed against the aquaporin 4 water channel is found in most cases.

Clinical syndromes of CNS demyelination with inflammatory myelopathies, inflammatory optic neuritis and ADEM with serological presence of antibodies to myelin oligodendroglial protein (MOG-Ab) are increasingly recognized.

Figure 1 Magnetic resonance image showing brain T₁ gadolinium-enhancing lesions (A) and T₂ thoracic spine (B) typical of multiple sclerosis.

Optic neuritis may further be mimicked by acute ischemic optic neuropathy. This condition is typically painless, occurs suddenly, and occurs in patients with advanced age and preexisting vascular risk factors.

Progressive myelopathies that mimic primary progressive MS or secondary progressive MS include a compressive myelopathy from cervical spondylosis, disk disease, or neoplastic infiltration; nutritional deficiencies (such as vitamin B₁₂ or copper deficiencies); paraneoplastic disease (e.g., CRMP-5 auto-antibodies); or a vascular progressive cause due to dural arteriovenous fistula.

Treatment

Acute demyelinating MS attacks (relapses) may be treated with high doses of corticosteroids. These may be given orally or intravenously; however, high doses of corticosteroids are necessary and are superior to low doses. For example, a typical regimen is intravenous methylprednisolone (Solu-Medrol) 1000 mg once daily for 3 to 5 days without oral corticosteroid tapering doses. The oral equivalent to this intravenous regimen is prednisone 1000 to 1250 mg orally once daily for 5 days with no oral corticosteroid taper afterward. Gastrointestinal intolerance occurs in some patients, and concomitant use of stomach-protecting agents such as proton pump inhibitors may be recommended. Typical acute corticosteroid side effects include insomnia, irritability, and increased appetite as well as an extremely rare association with avascular hip necrosis. Chronic corticosteroid side effects such as diabetes mellitus, cataracts, and weight gain and cushingoid habitus are more associated with chronic corticosteroid use and not short courses of steroids.

Generally, only MS attacks that are associated with functional impairment (vision loss, diplopia, motor weakness, ataxia) are treated because clinical recovery is hastened but final clinical recovery is not found to be altered by this therapy. Rarely, patients have very severe acute attacks of MS or other demyelinating disease that does not improve with use of high-dose corticosteroids. In these rare patients, the use of plasma exchange (seven exchanges over approximately 14 days) is recommended. Approximately 45% of patients experience functional recovery within 1 month following plasma exchange. Side effects of plasma exchange therapy include paresthesias related to hypocalcemia, anemia, thrombocytopenia, or complications of central venous access that is required for many patients. Intravenous immunoglobulin (Gammagard)¹ has not yet been shown to improve severe clinical attacks of demyelinating disease.

Chronic therapy for relapsing–remitting MS includes the use of type 1 β interferons (IFN- β 1), glatiramer acetate (Copaxone), natalizumab (Tysabri), alemtuzumab (Lemtrada), or ocrelizumab (Ocrevus) (Table 1). Ocrelizumab is approved for treatment of primary progressive MS course as well. Patients with relapsing–remitting MS may be treated with traditional injectable therapies with preparations of IFN- β 1, or glatiramer acetate. Alternatively, oral therapies with fingolimod (Gilenya), teriflunomide (Aubagio), and dimethyl fumarate (Tecfidera) are increasingly used as first-line therapies. The side-effect profile is well known for traditional injectable agents such as interferons and glatiramer acetate (see Table 1), and they have been safely used for many years. The safety profile for oral therapies seems satisfactory, but their long-term side-effect profile is still being assessed. For fingolimod, first dose monitoring for 6 hours is required to assess heart rate and rhythm and occasional patients have developed progressive multifocal leukoencephalopathy (PML). Teriflunomide may be associated with liver disease and teratogenicity. Dimethyl fumarate is associated with flushing, gastrointestinal discomfort, and rare patients have developed PML on dimethyl fumarate. Highly active MS therapy may be indicated with natalizumab, alemtuzumab, or ocrelizumab if first-line medications are intolerable, if therapeutic response is suboptimal (continued MS attacks or marked ongoing and new

inflammatory disease on MRI despite therapy), or when a concerning clinical onset (severe attack with multiple lesions and incomplete recovery) occurs. The goal of chronic immunomodulatory therapy for MS is a reduction in clinical attacks of MS (somewhere between 30% and 60%, depending on the agent) and reduction in new inflammatory MRI lesions (somewhere between 40% and 90%, depending on the agent). Patients and health care professionals should realize that the medications are not a cure or for symptomatic benefit (making people feel better) but specifically for reduction in relapse-related disease.

Natalizumab is clearly associated with the development of PML (progressive multifocal leukoencephalopathy), a severely impairing, and often fatal, opportunistic brain infection caused by reactivation of dormant JC virus. In North America, natalizumab is only available through the TOUCH (Tysabri outreach: unified commitment to health) prescribing program. Risk factors for PML in natalizumab-treated patients include the presence and index value of JC virus serum antibody (JCV-AbAB), duration of therapy of at least 2 years, and history of prior immunosuppressive medication therapy (e.g., methotrexate, azathioprine). Seropositivity of MS patients for JC virus antibody is over 55%. Seroconversion rate from JC virus Ab negativity to positivity is approximately 2–5% per year, and false-negative results are rare (less than 3%). Currently, no cases of PML have been found in patients persistently seronegative for JCV antibodies. Risk prevalence estimation after 2 years of treatment in JCV Ab–positive patients range from 1:250 for those without history of immunosuppression to 1:90 in those with history of prior immunosuppressive therapy. Mitoxantrone is a chemotherapy agent that is approved for secondary progressive MS, but given its severe side effect profile (acute and delayed cardiotoxicity, cases of acute myelogenous leukemia), it is rarely used today.

Alemtuzumab (Lemtrada) is a monoclonal antibody (anti-CD52; T and B cells) for relapsing remitting MS with major safety precautions that include development of: autoimmune thyroid disease, immune thrombocytopenia and rarely anti-glomerular basement membrane disease. Daclizumab (Zinbryta) (anti-CD25, IL2 receptor) was withdrawn voluntarily because of case reports of an association with presumably immune-mediated encephalitis. Ocrelizumab (anti-CD20 B cells; humanized form) is approved for both relapsing remitting MS and is the only therapy approved for primary progressive MS.

Autologous bone marrow transplantation with stem cell delivery for recovery is under evaluation to determine which cases may respond favorably to it and whether it is equivalent or not to highly active MS therapies.

Monitoring

Most, if not all, MS patients should be followed by a neurologist at least occasionally. Recommendations for clinical assessment range from 6 to 18 months, depending on clinical activity of relapses and disability. The ideal scheduling of repeat brain MRI scans is controversial and varies depending on MS clinical activity, but general recommendations are every 1 to 2 years.

Complications

MS is one of the main causes for impairment at a young age and trails only acute trauma. Often patients need gait assistance when impairment becomes more severe. This includes the use of a single gait aid, such as a cane or walking stick, or an ankle-foot orthosis for symptomatic foot drop.

Patients often experience symptoms of neurogenic bladder dysfunction. This includes symptoms of urgency and urge-related incontinence. Bladder stimulants such as caffeine need to be avoided. Patients with this symptom should be investigated for completeness of bladder emptying. If there is severe impairment in bladder emptying, urinary catheterization often is recommended. If bladder emptying is complete or only mildly impaired (<100 mL postvoid residual), use of medications such as oxybutynin (Ditropan) or tolterodine (Detrol) may be recommended for urge-related symptoms; however, ongoing monitoring of bladder

¹Not FDA approved for this indication.

TABLE 1 Approved Immunomodulatory Therapy for Relapsing-Remitting Multiple Sclerosis

MEDICATION	DOSING	SIDE EFFECTS	MONITORING	ADDITIONAL INFORMATION
Interferon β 1a (Avonex)	30 μ g IM injection 1 \times /wk	Flulike symptoms (fever, chills, arthralgias, myalgias, and headaches), elevated liver function tests, anemia, leukopenia, thrombocytopenia, depression Localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level every 3 mo while on therapy Thyroid function cascade upon initiation of therapy	Premedication with acetaminophen can ameliorate any postinjection flulike symptoms Ibuprofen and naproxen Pregnancy category C medication
Interferon β 1a (Rebif)	22 μ g or 44 μ g SC injection 3 \times /wk	Flulike symptoms (fever, chills, arthralgias, myalgias, and headaches), elevated liver function tests, anemia, leukopenia, thrombocytopenia, depression Localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level every 3 mo while on therapy Thyroid function cascade on initiation of therapy	Premedication with acetaminophen can ameliorate any postinjection flulike symptoms Ibuprofen and naproxen Pregnancy category C medication
Peginterferon β 1a (Plegridy)	125 μ g SC every 14 d	Flulike symptoms (fever, chills, arthralgias, myalgias, and headaches), elevated liver function tests, anemia, leukopenia, thrombocytopenia, and depression. Localized injection-site rejections	CBC with differential, AST, ALT, alkaline phosphatase, and total bilirubin level. Every 3 months while on therapy. Thyroid function cascade upon initiation of therapy.	Premedication with acetaminophen may ameliorate any postinjection flulike symptoms. Ibuprofen and naproxen. Pregnancy category C medication.
Interferon β 1b (Betaseron, Extavia)	250 μ g SC injection every other day	Flulike symptoms (fever, chills, arthralgias, myalgias, and headaches), elevated liver function tests, anemia, leukopenia, thrombocytopenia, depression Localized injection-site rejections	CBC with differential, AST, ALT, ALP, and total bilirubin level every 3 mo while on therapy. Thyroid function cascade on initiation of therapy.	Premedication with acetaminophen can ameliorate any postinjection flulike symptoms. Ibuprofen and naproxen Pregnancy category C medication
Glatiramer acetate (Copaxone)	20 mg SC injection daily or 40 mg SC injection 3 \times /wk	Injection-site reactions (erythema, edema, pruritus, pain), transient chest pain, palpitations, facial flushing, anxiety, shortness of breath	None	Pregnancy category B medication
Fingolimod hydrochloride (Gilenya)	0.5 mg by mouth once daily	Headache, flu, diarrhea, back pain, liver enzyme elevations, and cough New FDA labeling required; investigating unexplained deaths occurring during treatment with fingolimod	Ophthalmologist review before therapy and in 3-4 mo for macular edema, repeated annually in those with diabetes mellitus or uveitis. Serology for VZV-IgG to determine immunity CBC with differential, AST, ALT, alkaline phosphatase, and total bilirubin level, ECG ECG before first dose and after 6-hour monitoring; first dose must be monitored for 6 hours for heart-rate reduction and blood-pressure changes; 6-hour monitoring following oral dose must be repeated for patients who discontinue therapy for 14 or more consecutive days. For VZV nonimmune patients, vaccination (2 doses at least 1 month apart) before starting treatment is needed, and treatment may commence 1 month after the second VZV vaccination.	Should not be used in patients with recent MI, unstable angina, stroke, TIA, 2nd- or 3rd-degree AV block, CHF, SSS without cardiac pacing, or QTc >500 ms, or with Class Ia or III antiarrhythmic drugs. Overnight continuous ECG monitoring recommended for those with: preexisting cardiac or cerebrovascular disease; recurrent syncope; severe, untreated obstructive sleep apnea; use of β -blockers; or prolonged QTc. Occasional PML Pregnancy category C medication.
Teriflunomide (Aubagio)	7 mg or 14 mg PO once daily	Diarrhea, abnormal liver tests, nausea, influenza, alopecia, potential for hepatotoxicity, may cause significant birth defects if used during pregnancy (pregnancy category X), peripheral neuropathy, transient acute renal failure, and hyperkalemia	CBC monthly for the first 6 mo Liver enzymes Tuberculin skin test Pregnancy test (women of childbearing potential)	Prolonged half-life; recommend removal by activated charcoal or cholestyramine when required. Pregnancy category X medication

Continued

TABLE 1 Approved Immunomodulatory Therapy for Relapsing-Remitting Multiple Sclerosis—cont'd

MEDICATION	DOSING	SIDE EFFECTS	MONITORING	ADDITIONAL INFORMATION
Dimethyl fumarate (Tecfidera)	120 mg PO twice daily for 7 days, then 240 mg PO twice daily	Flushing, abdominal pain, nausea, diarrhea	CBC Consider serum JCV Ab serology	CBC annually PML rare
Ocrelizumab (Ocrevus)	600 mg ³ IV X2 q 2 wks then 600 mg IV q 24 wks	Infusion reactions (~34%) Infections respiratory tract, herpes infections Possible increased risk of cancer including breast cancer	CBC, Rule out hepatitis B virus before first dose	Approved for RRMS and PPMS PMS Do not administer if signs of infection delay until infection resolves. Administer vaccines >6 wks before ocrelizumab infusions Live and live-attenuated vaccines not recommended until B-cell counts recover after discontinuation.
Natalizumab (Tysabri)	300 mg IV once every 28 d	Urticaria and anaphylaxis, headache, arthralgias, nausea, fatigue, depression, infections (urinary tract, pneumonia, herpes simplex or reactivation)	Before treatment: JCV Ab serologic study, head MRI with or without gadolinium, CBC with differential, AST, ALT, alkaline phosphatase, and total bilirubin and pregnancy test if applicable. Every 6 months: JCV Ab serology if seronegative (no need to repeat if JCV Ab is seropositive); head MRI with and without gadolinium every 6 months while on therapy; if PML is suspected, discontinue therapy immediately, PLEX to remove drug, MRI head with and without gadolinium with diffusion-weighted imaging; CSF for JCV PCR	Monotherapy approved Risk of PML may be greater in patients with prolonged therapy and those previously treated with immunosuppressive medications. Prescribing professional requires TOUCH enrollment Pregnancy category C medication
Alemtuzumab (Lemtrada)	IV infusion over 4 h × 2 treatment course. First Course: 12 mg/day on 5 consecutive days. Second course: 12 mg/day on 3 consecutive days 12 months after the first treatment course	Infusion reactions with anaphylaxis. Autoimmune thyroid disorders, immune thrombocytopenia, antglomerular basement membrane disease. Malignancies including thyroid cancer, melanoma and lymphoproliferative disorders	CBC with differential, monthly for 48 months after last dose. Creatinine, urinalysis with urine cell counts periodically for 48 months after last dose. Baseline and yearly skin examinations	Premedicate with high dose corticosteroids, check VZV status and vaccinate those VZV antibody negative

Abbreviations: Ab = antibody; ALP = alkaline phosphatase; ALT = alanine aminotransferase; AST = aspartate aminotransferase; AV = atrioventricular; BUN = blood urea nitrogen; CBC = complete blood count; CHF = congestive heart failure; CSF = cerebrospinal fluid; ECG = electrocardiogram; FDA = U.S. Food and Drug Administration; JCV = JC virus; MI = myocardial infarction; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; PLEX = plasma exchange; PML = progressive multifocal leukoencephalopathy; PPD = purified protein derivative; SPMS = secondary progressive multiple sclerosis; SSS = sick sinus syndrome; TIA = transient ischemic attack; TOUCH = Tysabri Outreach: Unified Commitment to Health; VZV-IgG = varicella zoster virus immunoglobulin G.

emptying is recommended. Some patients require formal urodynamic evaluation for complex bladder symptoms.

Fatigue is a common MS-related symptom. A complete sleep history to ensure appropriate sleep hygiene is imperative. This includes initiating sleep promptly, maintaining sleep throughout the night, and awakening feeling refreshed. Encouragement of a formal exercise program to facilitate restful sleep and daytime vigor is important. Obstructive sleep apnea, restless legs syndrome, and other parasomnias need to be ruled out as additional contributing factors to fatigue. If sleep hygiene is entirely normal and late afternoon fatigue remains a problem, pharmacologic therapy for MS-related fatigue can proceed. Pharmacologic recommendations are limited but include amantadine hydrochloride (Symmetrel)¹ 100 mg by mouth twice daily. Modafinil (Provigil)¹ has been

shown in some studies to have an effect on MS-related fatigue at a dose of 200 mg by mouth once daily.

Spasticity associated with upper motor neuron weakness in the lower extremities may be treated with an active daily exercise program directed by physical therapists and physiatrists. Judicious use of baclofen (Lioresal) is helpful (starting at 10 mg once to three times by mouth daily no more than a maximum of 80 mg per day). Baclofen side effects include drowsiness and liver enzyme elevations. Some patients with significant lower extremity weakness are assisted in their gait by the leg support provided by spasticity, and if spasticity is reduced pharmacologically, this can in fact worsen their gait. Alternatives to baclofen include tizanidine (Zanaflex) and clonidine (Catapres).¹

¹Not FDA approved for this indication.

MS is a common CNS inflammatory demyelinating disease with heterogeneous presentation and prognosis. Relapsing–remitting or attack-related MS is treated with corticosteroids to hasten resolution of acute relapses and chronic immunomodulatory medications such as IFN- β , glatiramer acetate, fingolimod, teriflunomide, dimethyl fumarate, alemtuzumab, and natalizumab to reduce the number of future clinical attacks and new MRI lesions. Ocrelizumab is the only medication approved for primary progressive MS. Symptomatic care is important in those patients, including the treatment of gait disorder, spasticity, neurogenic bladder dysfunction, and fatigue.

MYASTHENIA GRAVIS

Method of

Taylor B. Harrison, MD; and William P. Roche, MD

CURRENT DIAGNOSIS

- Myasthenia gravis (MG) is an autoimmune disorder that affects the neuromuscular junction, resulting in fatigable skeletal muscle weakness.
- Diagnosis may be based on clinical history and exam in combination with identification of autoantibodies (Ach-R Abs) or abnormalities on electrodiagnostic testing.
- Myasthenic crisis, defined by respiratory failure, can stem from respiratory or oropharyngeal weakness. It may develop abruptly and typically occurs in the setting of illness, change in medications, or early in the disease course.

CURRENT THERAPY

- Mild symptoms can respond well to anticholinesterase inhibitors such as pyridostigmine (Mestinon).
- A wide range of medications may be used to treat MG, including steroids, nonsteroidal immunosuppressants, as well as intravenous immunoglobulin¹ and plasmapheresis. Thymectomy may be considered in patients with acetylcholine receptor antibodies.
- It is important to recognize that certain medications may worsen MG.
- Myasthenic crisis is a medical emergency, and patients should be treated in the intensive care unit with close respiratory monitoring and possibly intubation. Intravenous immunoglobulin¹ and plasmapheresis are treatment options for myasthenic crisis.

¹Not FDA approved for this indication.

Epidemiology

Myasthenia gravis (MG) is the most common acquired disorder of neuromuscular transmission, with an incidence of 8 to 10 per million annually. The prevalence is 150 to 250 per million, reflecting the disease's low mortality rate. An estimated 700,000 people are living with MG worldwide, with between 36,000 to 60,000 living in the United States.

There exists a bimodal age distribution with two peaks of incidence: the first peak in the second to third decades of life, and a second peak in the seventh to eighth decades. Women predominate in early-onset MG (defined by onset <50 years of age) whereas men predominate with late-onset disease (>50 years of age).

Risk Factors

MG is associated with thymoma: approximately one-third of patients with thymoma will develop myasthenia, and 10% of myasthenic patients have a thymoma. Certain HLA subtypes, which are known to predispose to autoimmune disorders in general, also increase the risk of MG. Other autoimmune disorders are present in about 15% of myasthenic patients, most commonly thyroiditis, followed by systemic lupus erythematosus and rheumatoid arthritis. A small percentage of patients may have a myasthenia-myositis overlap syndrome (Tables 1 and 2).

Pathophysiology

To understand the pathophysiology, a review of normal physiology is needed. In normal muscle contraction, an action potential (AP) travels down a motor nerve to the presynaptic axon terminal. At the axon terminal, the AP triggers voltage-gated calcium channels to open, causing calcium influx. Calcium influx causes synaptic vesicles containing acetylcholine to fuse with the cell membrane, resulting in exocytosis of acetylcholine into the synaptic cleft. Acetylcholine diffuses across the synaptic cleft and binds with nicotinic acetylcholine receptors (AChRs) on the cell membrane of the muscle fiber. The AChRs are ligand-gated ion channels that, once opened, allow cation influx, generating an end plate potential (EPP). When the EPP reaches a threshold value, it triggers voltage-gated sodium channels in the postsynaptic membrane to open, resulting in further

MS is a common CNS inflammatory demyelinating disease with heterogeneous presentation and prognosis. Relapsing–remitting or attack-related MS is treated with corticosteroids to hasten resolution of acute relapses and chronic immunomodulatory medications such as IFN- β , glatiramer acetate, fingolimod, teriflunomide, dimethyl fumarate, alemtuzumab, and natalizumab to reduce the number of future clinical attacks and new MRI lesions. Ocrelizumab is the only medication approved for primary progressive MS. Symptomatic care is important in those patients, including the treatment of gait disorder, spasticity, neurogenic bladder dysfunction, and fatigue.

TABLE 2 Suggested Medication Monitoring

MEDICATION	SUGGESTED MONITORING
Azathioprine (Imuran)	CBC, LFTs weekly for the first month then monthly to every 3 months
Cyclosporine (Sandimmune)	Monthly CBC, LFTs, renal function monthly for 3 months then quarterly Periodic trough level Blood pressure checks
Cyclophosphamide (Cytoxan)	CBC (attention to neutrophil count), electrolytes and renal function, LFTs, UA every 2–4 weeks
Eculizumab (Soliris)	CBC, renal function, LFTs
IVIG (Gammagard)	Renal function monthly, with repeated dosing maybe every 3 months
Methotrexate (Trexall)	CBC, LFTs monthly initially, then at stable dose at least every 3 months
Mycophenolate mofetil	CBC every 2 weeks for first month, then monthly to quarterly
Plasma exchange	Blood pressure and serum calcium
Prednisone	Weight and blood pressure Periodic potassium and HgbA1c Bone density test Periodic eye exam
Rituximab (Rituxan)	CD 20 counts may be considered but varies among providers

CBC, Complete blood count.

cation influx and membrane depolarization, resulting in a muscle fiber AP and muscle fiber contraction. Excess acetylcholine is then broken down by the enzyme acetylcholinesterase (AChE) in the synaptic cleft.

The safety factor is an important concept in understanding the muscle fatigability of MG. The safety factor is the ratio of postsynaptic EPP generated by a quantity of acetylcholine to the threshold required to generate an all-or-none muscle fiber AP and thus muscle fiber contraction. In the healthy state, more acetylcholine is released than is needed to generate a muscle fiber AP. In myasthenia the safety factor is lower, and sufficient acetylcholine may not be released to generate successive APs with repeated contractions. Exercise will result in insufficient neuromuscular transmission over time because of this reduction in safety factor, and as muscle fibers fail to reach threshold to generate an AP, fatigable weakness ensues.

MG is caused by antibodies targeting antigens of the postsynaptic membrane of the neuromuscular junction. In myasthenia gravis, the normal action of acetylcholine at the postsynaptic muscle cell membrane is disrupted by one of several antibody-mediated mechanisms. Most commonly, antibodies are formed against the AChR itself. These AChR antibodies interrupt normal transmission by cross-linking the receptors causing increased turnover or complement-mediated degradation or by inducing conformational changes in the channel, keeping acetylcholine from activating the channel. Other antibodies have been found to cause MG, including antibodies against muscle-specific kinase (MUSK), lipoprotein-related protein 4 (LRP4), or agrin. The postsynaptic cell membrane is folded into secondary synaptic folds, increasing the surface area of the cell membrane, and AChRs are organized in clusters at the peaks of these folds (adjacent to the nerve axon terminal). MUSK, LRP4, and agrin are proteins that participate in AChR clustering on these peaks. Antibody-mediated disruption of the function of these proteins causes reduced AChR concentration on the postsynaptic membrane with reduced safety factor, resulting in a myasthenia phenotype.

Some patients do not have antibodies that are detectable by current serologic testing. These patients are presumed to have antibodies against components of the postsynaptic membrane that have not yet been identified.

Prevention

Although there is no recognized prevention for developing myasthenia, exacerbations (myasthenic crises) are preventable by avoiding certain drugs. In particular, beta blockers, some antibiotics (aminoglycosides, fluoroquinolones, and macrolides), and chelating agents (penicillamine [Cuprimine]) should be avoided in myasthenic patients (see Box 1). Statins should be used cautiously and only at the lowest effective dose.

Clinical Manifestations

Patients with MG will present with weakness of the extraocular, bulbar, axial, or limb muscles. The most characteristic feature of the weakness seen in myasthenia is fatigability; that is, the tendency of a muscle to get weaker with repeated use. Thus, when thinking about weakness from MG, it is important to get a sense of whether the patient's symptoms are exacerbated by exercise, or demonstrate a diurnal fluctuation (with the most typical pattern being weakness that is worse at the end of the day).

Ocular symptoms (ptosis and diplopia) are the first symptoms of myasthenia in approximately 60% of patients, and in 15% to 20% of all myasthenic patients, weakness remains limited to the eye muscles (so-called "ocular myasthenia"). Patients will complain of a drooping eyelid or binocular double vision (that improves with closing one eye) that frequently fluctuates throughout the day or with activity. On physical examination, these patients have ptosis or limitations in extraocular movements that are triggered or exaggerated by sustained upgaze for 60 seconds (so-called "upgaze paresis"). The extraocular manifestations are rarely symmetric, and the ptosis is very often more significant on one side.

Weakness of the limbs tends to be symmetric and usually affects proximal more than distal muscles. Patients will frequently complain of reduced ability to perform repetitive actions of the proximal muscles, such as lifting an arm to comb hair or climbing stairs. On physical examination, fatigability can be demonstrated by having the patient activate the deltoids (arm abduction) or iliopsoas (hip flexion) either against gravity for 2 minutes or against examiner resistance for 5 repetitions of 5 seconds each. Typically, myasthenic patients with weakness of these muscle groups will have a significant decrement in strength between the first repetition and the last. Similar maneuvers can be performed using whichever muscle groups are affected, according to the patient's complaints.

Bulbar weakness manifests as difficulty with speech (dysarthria) or swallowing (dysphagia). These symptoms may also be fatigable; for example, patients may notice more difficulty enunciating toward the end of the day or at the end of a speech, or more trouble swallowing toward the end of a meal or when eating chewy foods such as steak. If shortness of breath is present, it typically improves moving from a supine to sitting position, which helps with diaphragm excursion. Strength of sniff and cough can be easily assessed at the bedside, and weakness of neck flexion may indicate risk for diaphragmatic weakness.

Sensation is not affected in MG. If a patient has sensory loss, static weakness that does not fluctuate with exercise, or other neurologic symptoms aside from weakness, this should prompt the examiner to consider an alternate diagnosis. Deep tendon reflexes are normal in myasthenia gravis.

Diagnosis

It is important to understand the proper diagnostic algorithm for MG, which is based on the combination of clinical history, examination findings, presence of autoantibodies, and results of electrodiagnostic testing. In the setting of a good clinical history and positive examination findings, the presence of pathologic autoantibodies is likely sufficient to confirm the diagnosis. When the clinical history or examination is suggestive but autoantibodies are not present, electrodiagnostic testing is important to confirm a suspected diagnosis, particularly if immunosuppressive or interventional therapies are considered.

Bedside tests to support a diagnosis include the ice pack test and edrophonium. Placement of ice over a ptotic eyelid may lead to clinical improvement, as cool temperature slows down the breakdown

of Ach in the synapse due to slowed action of AchE. Edrophonium (Enlon, previously marketed as Tensilon) is a short-acting AchE inhibitor may be used to help confirm a clinical diagnosis. It is best used if the patient has ptosis or extraocular paresis because there is less subjectivity in assessing improvement. Edrophonium is given intravenously (IV) with 0.1 mL of a 10 mg/mL solution administered initially as a test to assess tolerance, and if no unwanted effects are noted, the remainder of the drug is injected and the patient is observed for a clinical response. If a cholinergic reaction occurs, which may include bradycardia or hypotension, then administer 0.5 mg atropine IV.

Laboratory evolution of autoantibodies is standard of care in patients with suspected MG. In generalized MG, Ach-R Abs are generally present in up to 85% of affected individuals with generalized MG. Ach-R Abs may include blocking, binding, as well as modulating antibodies. Of those patients with generalized MG who are seronegative for Ach-R Ab, approximately 30% to 40% are seropositive for MUSK antibodies. In ocular MG, where symptoms are limited to ptosis or binocular diplopia, only about 15% are seropositive for autoantibodies, and if present, those autoantibodies are Ach-R ab. The vast majority are seronegative and require further evaluation for confirmation of the diagnosis.

Electrodiagnostic testing for a disorder of neuromuscular transmission includes slow repetitive nerve stimulation (RNS). A stimulator is used to depolarize a motor nerve (resulting in an all-or-none nerve AP) and generate a muscle twitch recorded as a compound motor action potential (CMAP). A train of stimuli (between 4 to 6) are performed at a rate of 3 to 5 per second. In MG the dysfunction at the postsynaptic muscle membrane results in some muscle fibers not achieving depolarization sufficient to cause an all-or-none muscle fiber AP, and the size of the overall CMAP (from multiple muscle fibers) is reduced. The threshold for abnormality is a CMAP decrement of >10%, generally between the first and fourth stimuli. If a baseline study at rest is normal, the patient is asked to exercise the muscle for 1 minute, and the study is repeated at 1-minute intervals to assess for the development of decrement. It should be noted that the sensitivity of RNS is increased with the presence of fatigable weakness on examination, because the clinical correlate of a decrement is weakness. Aside from distal hand muscles, trapezius or facial muscles such as nasalis can be studied.

Single fiber electromyography looks for “jitter” or loss of synchronization of individual muscle fibers innervated by a single anterior horn cell in the spinal cord. This is the most sensitive electrodiagnostic test for MG.

Differential Diagnosis

The differential diagnosis for diplopia and ptosis includes cranial nerve palsies: oculomotor (cranial nerve III), trochlear (cranial nerve IV), and abducens (cranial nerve VI). Horner's syndrome may also cause ptosis due to weakness in Mueller's muscle, although other signs such as anisocoria (unequal pupils) that is worsened in the dark is present. Thyroid eye disease may cause any of these symptoms as well. The differential diagnosis for appendicular weakness without sensory loss includes myopathy, pure motor neuropathy, anterior horn cell disease, or a central nervous system pathology involving the motor pathways. These causes of weakness result in static rather than fluctuating weakness.

The main differential diagnosis for fatigable weakness as seen in MG is the Lambert-Eaton myasthenic syndrome (LEMS). LEMS is caused by antibodies against voltage-gated calcium channels on the presynaptic neuromuscular junction and may be paraneoplastic (small cell carcinoma of the lung) or autoimmune. MG and LEMS can be differentiated by the presence of postexercise facilitation of reflexes (after 10 seconds of sustained exercise), as well as antibody and electrodiagnostic testing.

Therapy

Overall, the treatment goal is to achieve freedom from symptoms or functional limitations, recognizing that patients may still have some weakness of some muscles (this is known as minimal manifestation status). Mainstays of treatment include anticholinesterase inhibitors,

as well as oral steroids, and a variety of immunosuppressants, as well as intravenous immunoglobulin (IVIG),¹ and plasmapheresis may be used. Broadly, medical therapy can be classified as symptomatic or disease-modifying, the latter with an immunomodulatory effect targeting the underlying disease pathophysiology.

It should be noted that there exists wide variation in therapeutic approaches, and there are limited head-to-head data comparing individual medications. Current treatments, as well as advances in clinical care, have significantly improved the mortality rate of MG and outcomes of myasthenic crisis.

Symptomatic Therapy

Pyridostigmine (Mestinon) is an AchE inhibitor that increases the amount of acetylcholine in the synaptic cleft by slowing its breakdown by AchE and should be considered as initial therapy. Onset of action is typically within 30 minutes, with benefit generally lasting 3 to 4 hours. As such it is initially dosed 60 mg 3 times daily by mouth and may be increased to 120 mg every 3 to 4 hours while awake, with the total dose typically not exceeding 480 mg/d. It does not penetrate the central nervous system, and most side effects are gastrointestinal. Side effects may include nausea, vomiting, abdominal cramping, diarrhea, sweating, blurred vision, or muscle twitching and cramps. Anticholinergic agents such as glycopyrrolate (Robinul)¹ 1 mg or hyoscyamine sulfate (Levsin)¹ 0.125 mg with each pyridostigmine dose can usually treat these muscarinic side effects effectively. Data suggest that MUSK Ab-positive patients may have a lesser response to acetylcholinesterase therapy when compared with Ach-R-seropositive patients. In the setting of ocular myasthenia, there appears to be more of response in ptosis when compared with diplopia.

Corticosteroids

Corticosteroids, typically prednisone,¹ are a mainstay of immunotherapy and used when pyridostigmine alone does not achieve an adequate treatment response. Two general approaches exist, using either a low-dose or high-dose regimen. Decisions may be dictated by the severity of weakness, presence of significant bulbar dysfunction, or comorbid conditions (such as diabetes). A “low-dose” approach is used with milder disease and includes initiation of 10 to 20 mg daily, and increasing by 5 mg orally weekly to a lower target dose (generally 40–60 mg/d). Oral high-dose (1 mg/kg/d) steroid therapy may be used with moderate-severe weakness and generally has a latency of 2 to 4 weeks before onset of benefit with maximal benefit in 5 to 6 months. It is important to recognize that early clinical deterioration is possible (reported up to 50%) approximately 7 to 10 days after treatment initiation, generally when steroids are dosed at 1 mg/kg/d or higher. In those patients for whom high-dose therapy is introduced, concomitant treatment with either IVIG or plasma exchange (PLEX), discussed herein, may provide protection against early clinical deterioration.

For a patient who has achieved the treatment goal of minimal manifestation on a particular dose of steroids, it is important to consider weaning the dose to reduce side effects. A common approach is a slow taper decreasing 5 mg/d per month on alternate days, with a slower taper once a total dose of 10 mg daily is achieved. Many patients can be maintained on low doses of steroids.

Some patients have an inadequate response to steroids or intolerable side effects or are unable to taper because of recurrence of symptoms. These patients are typically treated with alternative, steroid-sparing, immunomodulatory therapies. Some patients with comorbidities that limit steroid dosing are started on steroids and nonsteroidal immunosuppressant medications concurrently.

Thymectomy

Thymectomy is considered standard of care for those with thymoma, which is present in approximately 15% of patients with generalized MG. A recent study supports thymectomy in Ach-R Ab-positive patients with at least moderately severe disease. Thymectomy patients demonstrated improved outcomes compared with placebo, required less steroids, fewer required steroid-sparing

¹Not FDA approved for this indication.

immunosuppressants, and experienced fewer hospitalizations. Thymectomy is controversial for mild symptoms, purely ocular disease, older age (>60 years), and there exist various surgical approaches. It is considered standard of care to pretreat with IVIG or PLEX before surgery if patients are symptomatic.

Other Immunomodulatory Therapies

Azathioprine (Imuran)¹ is a purine analogue that inhibits nucleic acid synthesis, as well as T- and B-cell proliferation. It is a commonly used steroid-sparing immunosuppressant that is considered first-line and has shown efficacy in a randomized clinical trial. Azathioprine allows reduced steroid dose, reduces relapse rate, and prolongs duration of remission. Treatment is generally started at 50 mg daily, increasing by 50 mg every 1 to 2 weeks to approximately 150 to 200 daily (2–3 mg/kg/d), generally in split doses. Onset of action is estimated at 4 to 8 months, and therapy requires regular blood count and liver function monitoring. Side effects include a flulike illness at initiation (reported in up to 10% to 20%, requires cessation), leukopenia, and transaminitis. Thiopurine methyltransferase enzyme testing can be performed, if available, before starting to identify patients at high risk of bone marrow suppression (although monitoring of blood counts is favored by many practitioners).

Intravenous immunoglobulin (IVIG, Gammagard)¹ has been shown to improve weakness in MG. Its mechanism of action is unclear although presumed to stem from neutralizing circulating pathogenic autoantibodies. A dose of 2 g/kg spread over 5 days is a common algorithm for initial treatment, although in patients who previously tolerated it, IVIG could be given as 1 g/kg/d over 2 days. Onset of action is typically within the first week, and benefit may be sustained for 3 to 4 weeks after treatment. Side effects include headache (sometimes severe and related to aseptic meningitis), thrombosis because of increased serum viscosity, and renal failure. Avoidance of sucrose-containing products may decrease risk of renal failure. Slowed infusion rates may help avoid decompensation of heart failure. Patients on maintenance dosing may receive IVIG 1 g/kg every 3 to 4 weeks.

Mycophenolate mofetil (Cellcept)¹ inhibits guanosine nucleotide synthesis that is needed for B and T lymphocytes. Although there have been two negative randomized clinical trials, there are several retrospective reports supporting efficacy and consensus expert opinion is that it remains a treatment option. It is started at 500 mg twice daily and titrated to 1000 to 1500 mg twice daily. Side effects include nausea, vomiting, diarrhea, and leukopenia. It has teratogenic potential and should not be used in pregnancy.

Cyclosporine (Sandimmune)¹ is a calcineurin inhibitor that has suppressed inflammatory cytokines and has multiple effects on T-cell function. It is initiated at approximately 3 mg/kg daily as a twice-daily split dose and may be titrated up to 5 mg/kg/d with a target trough level <300 ng/mL. Onset of action is approximately 2 to 3 months. Side effects include hirsutism, hypertension, clinically significant nephrotoxicity, and increased cancer risk (including dermatologic cancers). Cyclosporine level may be affected by multiple drug interactions, and concomitant medications should be reviewed.

Methotrexate (Trexall)¹ is a folate antimetabolite that may be dosed orally or subcutaneously. A typical oral dose is initiated at 10 mg weekly and titrated to 15 to 25 mg orally once a week. It is recommended that the patient take folate¹ supplementation of approximately at least 1 mg daily. Side effects include stomatitis (folate supplementation may help prevent this), bone marrow suppression, as well as interstitial lung disease (rare). It is important to note that methotrexate is a known teratogen and should be avoided in women of childbearing potential.

Plasmapheresis or PLEX removes plasma from the circulation and replaces it, typically with albumin, with the net effect of removing pathologic autoantibodies and inflammatory cytokines. Typically five exchanges are performed over a period of 1 to 2 weeks, and benefit is typically observed by the third exchange. PLEX requires placement of a vascath or (if to be used as a maintenance

therapy) a permacath. When used as a maintenance therapy, 1 to 2 exchanges are typically performed, at variable intervals, as frequently as weekly. There is a risk of deep venous thrombosis or line infection. Hypotension may occur because of citrate-induced hypovolemia, and it may be associated with hypocalcemia. ACE inhibitors need to be held 24 hours because of bradykinin-related vasodilation.

Rituximab (Rituxan)¹ is a CD20 antibody that has been evaluated in a randomized controlled trial, the results of which are pending. There exists retrospective data to support efficacy, particularly in MUSK Ab patients who have failed initial therapy. It is dosed 325 mg/m² weekly for 4 weeks, although it can also be dosed 1 g/m² with a second dose 2 weeks later. Dosing may be repeated at 6-month intervals. Side effects include infusion-related symptoms including pruritis, headache, hypotension, nausea, and chills. Rituximab may additionally result in leukopenia, anemia, or thrombocytopenia. Infusion-related symptoms can be pretreated with acetaminophen and diphenhydramine.

Eculizumab (Soliris) is a complement inhibitor that was recently FDA approved for AchR Ab generalized myasthenia gravis. It is dosed at 900 mg weekly for 4 weeks, followed by 1200 mg for the fifth week and thereafter 1200 mg every 2 weeks. Generally only mild infusion reactions are reported, typically managed by pretreatment acetaminophen and diphenhydramine, although there is risk for severe meningococcal infection. Meningococcal immunization is recommended before treatment initiation.

Cyclophosphamide (Cytosan)¹ is typically reserved for treatment-refractory patients. It may be administered orally with a daily dose ranging from 1.5 to 5 mg daily. Potential side effects of oral cyclophosphamide include cystitis as well as bladder cancer, leading many treating physicians to use IV pulse dosing. A common approach for pulse dosing is 1 gm/m² monthly for 6 months (less toxic). Onset of action with pulse dosing is relatively quick, generally about 1 month.

Treatment Considerations in Pregnancy

Pregnancy and postpartum status have been reported to be triggers for worsening of myasthenia. Ideally, prepregnancy planning allows for optimization of clinical status to improve pregnancy outcomes. These patients require expert multidisciplinary care through the postpartum period. In pregnancy the treatment of choice is pyridostigmine, with steroids being the immunosuppressant of choice. Azathioprine¹ and cyclosporine¹ are relatively safe in expectant mothers who are not satisfactorily controlled or cannot tolerate corticosteroids. IVIG¹ and PLEX may also be treatment options.

Transient neonatal myasthenia may affect the newborn infant. This is difficult to predict and requires close attention for signs after delivery. Neonatal critical care support should be readily available for these infants.

Monitoring

After a diagnosis of MG is confirmed, additional testing or monitoring is indicated. The frequency of clinical assessment should be dictated by the severity and nature of the patient's symptoms, as well as the impact of the disease on function. Patients with MG should be managed in concert with a neurologist. Refractory MG is defined by symptoms that affect function and are unchanged or worse after corticosteroids and at least two other immunosuppressive agents used in adequate doses for adequate duration. Patients meeting criteria for refractory MG should be referred to a physician or medical center with expertise in MG.

Computed tomography of the chest should be performed to screen for thymoma. Assessment of thyroid function is important. If immunomodulatory medications are used for disease control, TB screening should be performed.

Pulmonary and swallowing dysfunction may be encountered. Pulmonary function testing should be performed for patients with symptomatic generalized MG, particularly if there are complaints of dyspnea. Speech therapy referral for a swallow evaluation should be performed if there is concern for dysphagia.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Periodic laboratory monitoring is required with use of immunomodulatory medications, which may vary depending on the specific medication used. Suggested tests and monitoring algorithms are detailed in Box 2.

Complications

The most severe complication of MG is myasthenic crisis, which is defined by worsening of weakness requiring intubation or noninvasive ventilation. Myasthenic crisis may be seen in up to 20% of patients at some point in disease course. Myasthenic crisis is most commonly encountered in the setting of concomitant illness, change in medications, or early in the disease course because maximum weakness occurs in the first year of the disease in 66% of patients. Respiratory failure can result from respiratory muscle weakness, oropharyngeal weakness, or a combination of both. It is important to recognize that new respiratory or swallowing complaints can quickly escalate, and patients with these complaints should be quickly assessed. One can assess diaphragm strength by the force of a strong sniff or cough; patients should be able to count to 20 after a deep breath. Staccato speech or dyspnea that precludes speaking in full sentences is of high concern for myasthenic crisis. Spirometry with forced vital capacity <2 L or negative inspiratory force of <40 cm H₂O should be sent to the hospital for further evaluation. Assessment of swallowing function by speech therapy and possible modified barium swallow should be considered in the context of dysphagia for solids and liquids.

IVIG and PLEX have comparable outcomes for the treatment of patients with moderate-to-severe weakness. The response to PLEX may be more predictable than IVIG in severe MG exacerbations, and retrospective data suggests PLEX may be more effective than IVIG in myasthenic crisis. PLEX, however, may be associated with more complications, as well as longer hospital stay and associated hospital costs.

- Avoid low-dose oral steroid monotherapy, as this is associated with a higher relapse rate.
- If brain MRI or blood testing suggest a high-risk, clinically isolated syndrome, consider disease-modifying therapy to delay progression to Multiple Sclerosis (MS) or Neuro-myelitis optica (NMO).
- If the clinical features suggest NMO spectrum optic neuritis, consider IV methylprednisolone and plasma exchange therapy.
- If the patient's history and testing suggest MS or NMO, consider treatment for these conditions.

Epidemiology

The incidence of optic neuritis is approximately 1 to 5 in 100,000. Though it typically affects women in their fourth decade of life, 1 in 4 patients are male, and patients have been reported ranging from the first to seventh decades of life. Optic neuritis occurs worldwide in persons of various ethnicities.

Optic neuritis can be classified as a clinically isolated syndrome or in association with a disease such as multiple sclerosis (MS) or neuromyelitis optica (NMO). NMO is clinically distinguished by more frequent involvement of the optic nerves and spinal cord and less involvement of the brain than MS and by distinct pathophysiology. A recently identified distinct classification is anti-myelin oligodendrocyte glycoprotein (MOG) associated optic neuritis. Approximately half of patients with optic neuritis as a clinically isolated syndrome develop MS. A small percentage develop NMO.

Risk Factors

A diagnosis of a disease associated with optic neuritis, such as MS or NMO, increases the risk of developing optic neuritis. In one study, more than 70% of patients with MS and 100% of patients with NMO had unilateral optic neuritis at some point.

Pathophysiology

Most optic neuritis occurs as a result of inflammation causing demyelination of the ganglion cell axons that compose the optic nerve. This is thought to be an immune-mediated process.

Prevention

Disease-modifying therapies have been shown to reduce risk of neurologic relapses in patients with MS or NMO. These therapies presumably also decrease the risk of MS- or NMO-associated optic neuritis because optic neuritis is a common relapse syndrome in these conditions.

Clinical Manifestations

A typical optic neuritis patient experiences acute or subacute loss of vision characterized by decreased visual acuity, visual field loss, and/or color vision loss, accompanied or preceded by pain in the affected eye that is worse with eye movements. However, 8% of patients do not have pain. Other symptoms include positive visual phenomena in 30% of patients. Other signs include a relative afferent papillary defect in cases where one eye is affected and a mildly swollen optic nerve head in approximately one-third of patients. Optic neuritis in NMO is more likely to have bilateral involvement and severe visual impairment. The spectrum of anti-MOG associated optic neuritis is being defined with initial case series describing a higher prevalence of optic nerve head swelling than MS or NMO associated optic neuritis.

The natural history of clinically isolated optic neuritis includes resolution of pain 3 to 5 days after onset and nadir of vision 7 to 14 days after onset. Spontaneous improvement in vision is typically evident within 3 weeks, and almost 70% of affected patients recover 20/20 visual acuity even in the absence of treatment. Optic neuritis associated with NMO tends to have less spontaneous recovery of vision and early recognition is important due to benefits of early treatment.

OPTIC NEURITIS

Method of

Heather E. Moss, MD, PhD

CURRENT DIAGNOSIS

- Vision is impaired, including visual acuity, visual field, and/or color perception.
- Patients typically have eye pain that is worse with eye movement.
- There is a relative afferent papillary defect if only one eye is affected.
- The anterior optic nerve has a normal appearance in two-thirds of affected patients.

CURRENT THERAPY

- Consider IV methylprednisolone (Solu-Medrol, 1 g/day IV for 3 days) followed by oral steroids (1 mg/kg per day for 11 days).

Periodic laboratory monitoring is required with use of immunomodulatory medications, which may vary depending on the specific medication used. Suggested tests and monitoring algorithms are detailed in Box 2.

Complications

The most severe complication of MG is myasthenic crisis, which is defined by worsening of weakness requiring intubation or noninvasive ventilation. Myasthenic crisis may be seen in up to 20% of patients at some point in disease course. Myasthenic crisis is most commonly encountered in the setting of concomitant illness, change in medications, or early in the disease course because maximum weakness occurs in the first year of the disease in 66% of patients. Respiratory failure can result from respiratory muscle weakness, oropharyngeal weakness, or a combination of both. It is important to recognize that new respiratory or swallowing complaints can quickly escalate, and patients with these complaints should be quickly assessed. One can assess diaphragm strength by the force of a strong sniff or cough; patients should be able to count to 20 after a deep breath. Staccato speech or dyspnea that precludes speaking in full sentences is of high concern for myasthenic crisis. Spirometry with forced vital capacity <2 L or negative inspiratory force of <40 cm H₂O should be sent to the hospital for further evaluation. Assessment of swallowing function by speech therapy and possible modified barium swallow should be considered in the context of dysphagia for solids and liquids.

IVIG and PLEX have comparable outcomes for the treatment of patients with moderate-to-severe weakness. The response to PLEX may be more predictable than IVIG in severe MG exacerbations, and retrospective data suggests PLEX may be more effective than IVIG in myasthenic crisis. PLEX, however, may be associated with more complications, as well as longer hospital stay and associated hospital costs.

Optic neuritis associated with NMO tends to have less spontaneous recovery of vision and early recognition is important due to benefits of early treatment.

OPTIC NEURITIS

Method of

Heather E. Moss, MD, PhD

CURRENT DIAGNOSIS

- Vision is impaired, including visual acuity, visual field, and/or color perception.
- Patients typically have eye pain that is worse with eye movement.
- There is a relative afferent papillary defect if only one eye is affected.
- The anterior optic nerve has a normal appearance in two-thirds of affected patients.

CURRENT THERAPY

- Consider IV methylprednisolone (Solu-Medrol, 1 g/day IV for 3 days) followed by oral steroids (1 mg/kg per day for 11 days).

Diagnosis

The diagnosis is based on the clinical presentation. Where there is uncertainty, magnetic resonance imaging (MRI) of the orbits, including fat-saturated sequences (T2 and T1 with and without gadolinium contrast), can help visualize inflammation in the retrobulbar optic nerve. Changes on MRI involving the chiasm or more than 50% of the optic nerve are suggestive of NMO spectrum optic neuritis. Anti-MOG optic neuritis may have distinct imaging features.

Optic neuritis is often associated with other demyelinating syndromes, most commonly MS. Therefore it is important to screen for historical and current neurologic impairment through history and examination. MRI and/or cerebrospinal fluid analysis documenting evidence of dissemination in time and space is diagnostic of MS in patients with clinically isolated optic neuritis. In addition, for patients not meeting criteria for MS at time of presentation with clinically isolated optic neuritis, MRI of the brain has been shown to be an important prognostic indicator for development of MS. MRI of the brain showing 0, 1, or more than 3 lesions typical for MS is associated, respectively, with a 25%, 60%, and 78% risk of progression to clinically definite MS.

Less commonly, optic neuritis is associated with other demyelinating syndromes such as NMO. This should be considered in patients with severe vision loss, bilateral involvement, or history of prior optic neuritis or transverse myelitis. A serum antibody (anti-aquaporin 4 or NMO antibody) has been identified as a pathologic agent in this disorder. Testing for this is commercially available with a published sensitivity and specificity of 63% and 99%, respectively. Positive testing for anti-AQP4-IgG in a patient with optic neuritis is diagnostic of NMO per published consensus criteria. A serum antibody (MOG-IgG) is commercially available and aids in the identification of Anti-MOG associated optic neuritis.

Differential Diagnosis

Other diagnostic considerations in a patient with unilateral painful vision loss without explanatory pathology evident on ophthalmic examination include other optic neuropathies such as those due to sarcoidosis, lupus, vasculitis, neoplastic, vascular, and infectious causes. Atypical features for optic neuritis such as systemic symptoms, history of cancer, pain that persists beyond 2 weeks, progressive vision loss beyond 14 days, no spontaneous improvement in vision, retinal hemorrhages, cotton-wool spots, or macular exudates should prompt diagnostic evaluation for etiologies other than optic neuritis.

Treatment and Monitoring

The Optic Neuritis Treatment Trial (ONTT) was a randomized trial comparing placebo, oral prednisone, and IV methylprednisolone (1 g/day IV for 3 days) followed by oral prednisone (1 mg/kg per day for 11 days) for acute optic neuritis. IV steroids hastened recovery of vision without affecting final visual outcome compared with placebo treatment. Treatment with low-dose oral prednisone alone (1 mg/kg/day for 14 days) was associated with an increased risk of relapse compared with placebo treatment. The 15-year follow-up results, published in 2008, demonstrated persistence of visual recovery. Studies have demonstrated non-inferiority of high-dose oral steroids (1250 mg prednisone/day for 3 days) to IV methylprednisolone with regards to vision recover following acute optic neuritis.

Many clinicians offer IV or high-dose oral steroid treatment to hasten visual recovery. Monotherapy with low-dose oral prednisone should be avoided. Regardless of the decision to treat or not with steroids, all patients should be monitored closely. Continued progression of vision loss, failure to spontaneously recover vision, or persistent pain should prompt additional diagnostic workup as well as consideration for additional IV steroid therapy for atypical optic neuritis. If this is not effective, plasma exchange has been reported as an effective acute therapy for atypical optic neuritis including NMO-spectrum optic neuritis.

In patients with acute optic neuritis and NMO or acute optic neuritis on the NMO-spectrum, treatment with plasma exchange

or rituximab (Rituxan)¹ should be considered to improve functional visual outcome.

In patients with a clinically isolated syndrome, consideration should be given to institution of disease-modifying therapy for MS based on the type and number of lesions on brain MRI and oligoclonal bands in cerebrospinal fluid. Several clinical trials have shown an association between early treatment with MS therapies and decreased incidence of progression to clinically definite MS in patients with a recent clinically isolated syndrome and clinically silent lesions on brain MRI.

In patients who meet diagnostic criteria for either MS or NMO, consideration should be given to treating the underlying disease.

Complications

Though more than 70% of patients with optic neuritis recover objectively normal visual acuity, many have residual subjective visual disturbances. These often worsen or recur in heat, which is known as Uhthoff's phenomenon.

Complications of steroid therapy include insomnia, agitation, and stomach irritation. Long-term side effects of steroid treatment for this condition are rare owing to the brief period of treatment. Complications of disease-modifying therapies for MS and NMO are reviewed elsewhere.

¹Not FDA approved for this indication.

PARKINSON'S DISEASE

Method of

Jessica Tate, MD

CURRENT DIAGNOSIS

- Clinical diagnosis based on 4 cardinal features
 - Bradykinesia
 - Rigidity
 - Resting tremor
 - Postural instability

- Supportive features: asymmetric onset, response to dopaminergic medication, presence of non-motor features such as REM behavior disorder and anosmia.
- Single photon emission tomography or olfactory testing may aid diagnosis in specific circumstances.

CURRENT THERAPY

- Initial symptomatic treatment with monoamine oxidase-B (MAO-B) inhibitor, dopamine agonist, or carbidopa/levodopa
- Carbidopa/levodopa (Sinemet) first-line for patients >70; should be initiated in younger patients when severity of motor symptoms warrants it, rather than strict levodopa-sparing approach.
- Anticholinergic can be used as first-line treatment in younger patients with predominant tremor.
- MAO-B inhibitor, dopamine agonist, or catechol-O-methyltransferase (COMT) inhibitor can be added to levodopa to reduce on-off fluctuations.
- Amantadine (Symmetrel) can reduce levodopa-induced dyskinesias.
- Deep brain stimulation (DBS) is effective for patients with medication-refractory tremor.
- DBS or carbidopa/levodopa intestinal gel (Duodopa)² is more effective than oral medication alone for patients with severe motor fluctuations.
- Exercise is crucial at all stages and may have neuroprotective benefits.

²Not available in the United States.

Epidemiology

Parkinson's disease (PD) affects roughly 1% of the population over the age of 60 years and is projected to affect approximately 1 million people in the United States by the year 2020. Updated epidemiologic studies are currently under way. PD is more common in men than women and is suggested to be more common in whites than other racial groups, although this may relate to disparities in health care. The average age of onset is in the seventh decade of life, but onset is before age 40 in 3% to 5% of cases. Ninety percent of cases are considered to be sporadic or idiopathic, whereas approximately 10% are inherited.

Risk Factors

Age is the most significant risk factor. Other proposed risk factors include exposure to pesticides, herbicides, solvents, and well water. Cigarette smoking, coffee consumption, regular exercise, and elevated uric acid levels may be protective. Risk of PD is doubled in first-degree relatives of those affected.

Pathophysiology

The formation of Lewy bodies, intracellular accumulations of the protein α -synuclein, is central to the pathogenesis of PD. This leads to degeneration of dopamine-producing neurons in the substantia nigra pars compacta, setting off a chain of altered signaling in the basal ganglia and ultimately reduced activation of the motor cortex. However, Lewy body deposition and neurodegeneration also occurs in other brain regions, perhaps well before the degeneration of the substantia nigra. This may explain the myriad non-motor manifestations of PD, such as early loss of smell and REM behavior disorder, which are under consideration as prodromal symptoms of PD.

Unfortunately, the pathophysiological process that leads to Lewy body formation is not well understood at this time, and several different mechanisms have been proposed. PD is likely caused by a combination of genetic predisposition and environmental

factors, which may differ from one individual to another depending on the specific gene or genes responsible. Early disease-modifying interventions, when they become available, are likely to target specific genetic subtypes, and thus genetic testing will likely play a more crucial role in the future diagnosis and treatment of PD.

Clinical Manifestations

The hallmark signs and symptoms of PD are bradykinesia (slow, small-amplitude movement or lack of movement), muscle rigidity (increased resistance to passive movement of the joints that is not velocity-dependent), and resting tremor. Although tremor is a common presenting symptom in PD, some patients with PD *never* develop tremor. The other hallmark symptoms of gait dysfunction and postural instability (loss of postural reflexes crucial to maintaining balance) are uncommon in the early stages of PD but occur later in the disease course.

Loss of dexterity with fine motor tasks, micrographia (small handwriting), hypophonia (soft speech), masked facies (diminished facial expression and reduced blinking), shortened strides, and decreased arm swing while walking are all potential manifestations of bradykinesia.

Rigidity can lead to complaints of stiffness, aching, or cramping. This symptom can lead a patient to explore musculoskeletal causes, such as seeking out a specialist in sports medicine, before realizing it has a neurologic basis. Many physicians believe "cogwheeling" to be specific to a diagnosis of PD. However, cogwheeling typically will not be evident in PD patients without tremor. In addition, patients with essential tremor can exhibit cogwheeling without underlying rigidity.

Parkinsonian tremor most classically starts in one hand, although it can be seen in the jaw and lower extremity as well. It has a slow frequency (4–6 Hz) and is visualized with the affected body part at rest. It is often enhanced by distraction (conversation, having the patient perform calculations or name the months backward) and can be temporarily alleviated by concentration or repositioning. When a patient with PD tremor extends an affected upper extremity, the tremor may reappear after a delay. This is referred to as "reemergent rest tremor" and differs from essential tremor, which is typically present immediately on extending the arms.

Early gait changes can include bent posture and shuffling or dragging of the feet, often initially on one side of the body. Later gait changes can include freezing (hesitancy and difficulty initiating a stride with a sensation of feeling stuck to the floor) and festination (a series of small, rapid steps with a sensation of being propelled forward and unable to stop). Postural instability is assessed with the "pull test," in which the examiner stands behind the patient and tugs back firmly on his or her shoulders. An abnormal response is defined by taking two or more steps backward or, in severe cases, by complete lack of response, leading to the examiner catching the patient as he or she falls back.

Diagnosis

The diagnosis of PD is still made clinically in most cases, with a detailed history and neurologic examination. Often, the United Kingdom Parkinson's Disease Society Brain Bank Criteria is used, which requires the presence of bradykinesia along with at least one other cardinal feature as described above. When patients are seen by a movement disorders specialist (a neurologist with additional subspecialty training in PD and related conditions), these clinical features are often objectively scored and tracked over time using a validated measure such as the Unified Parkinson's Disease Rating Scale. Additional supportive diagnostic criteria are also required, which can include unilateral onset, persistent asymmetry, progression with time, and response to levodopa. Patients also should be questioned about the presence of specific nonmotor symptoms suggestive of PD. These can include loss of smell or presence of REM sleep behavior disorder, which can precede onset of motor symptoms by years or even decades, and autonomic symptoms such as constipation, urinary frequency and urgency, sexual dysfunction, or drooling. These are discussed further in [Table 1](#).

TABLE 1 Recognition and Management of Common Nonmotor Symptoms in Parkinson's Disease

SYMPTOMS	MANAGEMENT SUGGESTIONS	CONSIDERATIONS
Mood disorders Depression Anxiety disorders	If periodic, optimize PD treatment to minimize on-off fluctuations If more static, typical individualized treatment options including SSRIs, SNRIs, TCAs, counseling, psychotherapy, transcranial magnetic stimulation, etc.	Multiple antidepressants shown to be safe in combination with MAO-B inhibitors, but be aware of rare risk of serotonin syndrome
Sleep disturbances REM sleep behavior disorder (REM-BD) Insomnia Restless leg syndrome (RLS)	For REM-BD, melatonin ⁷ or clonazepam (Klonopin) ¹ at bedtime For insomnia, sleep hygiene counseling, screening for sleep apnea with referral for sleep study if warranted, management of nocturia, treatment of nocturnal stiffness or cramping, etc. For RLS, iron supplementation if ferritin <75, dopamine agonists, gabapentin (Neurontin) ¹	Avoidance of sedative hypnotics due to high risk of adverse effects
Psychosis Illusions Hallucinations Delusions	Lower PD medication dosages <i>if possible</i> ; discontinuation of other potential offending medications Acetylcholinesterase inhibitors, quetiapine (Seroquel) ¹ or clozapine (Clozaril) ¹ , pimavanserin (Nuplazid)	If acute, requires full medical/neurological evaluation for infection and other possible causes
Constipation	Hydration, exercise, removal of offending medications if possible PEG 3350 (Miralax)	
Urinary dysfunction	Mirabegron (Myrbetriq) may be helpful for patients without BPH	Urodynamic testing recommended, since multiple factors may be at play (such as BPH) Caution regarding anticholinergics; possible delirium
Orthostatic hypotension	Abdominal binder or compression stockings Midodrine (Proamatine) fludrocortisone (Florinef) ¹ , or droxidopa (norepinephrine precursor) (Northera)	Extra caution in the hour following levodopa doses Must balance with supine hypertension, which may improve by raising head of bed 30 degrees or a nighttime antihypertensive
Fatigue	Exercise, treatment of depression or sleep disorders if present Avoiding under-medication of PD symptoms Selegiline (Eldepryl), amantadine (Symmetrel) Stimulants such as methylphenidate (Ritalin) ¹ (rarely, in extreme cases)	
Drooling	Hard candy or gum Rimabotulinum toxin B (Myobloc) ¹ injections in salivary glands Sublingual atropine ¹	
Weight loss	Monitoring, nutritional supplementation, referral to nutritionist	Associated with negative outcomes in PD including dementia and earlier death; unclear if causal ⁹

Abbreviations: MAO-B = monoamine oxidase type B; PD = Parkinson's disease.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

Differential Diagnosis

The differential diagnosis for PD varies somewhat depending on age of onset. In young patients, secondary Parkinsonism should be excluded with testing for Wilson's disease. Dopa-responsive dystonia (DRD) can also mimic PD in younger patients. Drug-induced Parkinsonism, usually secondary to dopamine-blocking agents such as atypical antipsychotics or antiemetics, can occur at any age. In older patients, vascular Parkinsonism can resemble idiopathic PD but is secondary to accumulation of significant chronic microvascular ischemic changes, often in the periventricular brain regions, or an accumulation of acute cerebral infarcts over time. These findings can be easily visualized on a noncontrast magnetic resonance imaging (MRI) scan of the brain. An MRI scan can also reveal disproportionate enlargement of the ventricles that may raise suspicion for normal pressure hydrocephalus, a poorly understood and somewhat controversial condition that can lead to a shuffling gait or freezing of gait resembling PD. Atypical Parkinsonism syndromes include progressive supranuclear palsy (PSP), multiple systems atrophy cerebellar and Parkinsonian types, corticobasal degeneration, and Lewy body dementia. These conditions can be very difficult to differentiate from idiopathic PD early in their course. Red flags include symmetric onset, lack of response (distinguished from intolerance) to an appropriate dose of levodopa, and early onset of symptoms typically seen in advanced stages of PD such as gait freezing, postural instability, severe

autonomic dysfunction such as symptomatic orthostatic hypotension, or hallucinations.

In specific situations, particularly those in which DRD, vascular Parkinsonism, or drug-induced Parkinsonism are suspected, a [¹²³I] FP-CIT single photon emission tomography scan—known as a DaTscan—can be used to provide supportive information. This scan is designed to detect reduced presynaptic dopamine activity in the caudate and putamen. Uptake is expected to be normal in essential tremor, DRD, drug-induced Parkinsonism, and most cases of vascular Parkinsonism, whereas it is reduced in neurodegenerative Parkinsonism. A major limitation of the DaTscan is its inability to differentiate between PD and atypical Parkinsonism such as PSP.

Treatment

Exercise is believed to have neuroprotective benefits and should be strongly encouraged in all stages of PD. Most emphasis has been on cardiovascular forms of exercise, but strength and balance training are likely to be beneficial in this population as well. There are multiple Parkinson's-specific exercise programs appearing nationwide, including stationary cycling, noncombat boxing, and dance.

Symptomatic medication is often initiated either when tremor becomes bothersome, or when motor disability is affecting day-to-day activities. A sizable minority of patients with PD may have

medication-refractory tremor, an important point to keep in mind because a patient with isolated tremor and lack of improvement with dopaminergics should not necessarily be considered a nonresponder. Dopaminergics may still be useful to those patients in the future for symptoms such as bradykinesia and rigidity.

For early-stage PD, there are three classes of drugs that are frequently used: monoamine oxidase (MAO)-B inhibitors, dopamine agonists, and levodopa. Levodopa may be chosen as initial therapy in a patient 70 years of age or older because of the lower potential for side effects. In younger patients, it is common to start with an MAO-B inhibitor or dopamine agonist and escalate to levodopa if either of those are poorly tolerated or ineffective. Although a levodopa-sparing strategy has been commonly adopted by clinicians, evidence suggests that earlier initiation of levodopa is associated with better long-term outcomes for patients. Regardless of the patient's age, levodopa should be started when the patient is experiencing disabling symptoms that have not responded to other medication choices. Especially for patients on levodopa, it is best practice to treat with the lowest effective dose to help reduce the risk of dyskinesias. This symptom will be discussed in further detail in the next section. Typical dosages and side effects to consider can be found in Table 2.

Patients with moderate to advanced PD have typically reached a degree of symptom severity that necessitates levodopa. Eventually, they will begin to develop medication fluctuations. These include wearing-off of symptomatic benefits before the next dose, erratic failures of dosages to take effect, and dyskinesias. Dyskinesias are rocking, writhing, or twisting movements that can affect any region of the body. They most commonly occur at the peak of a levodopa dose but, for some patients, can occur at the end of a dose or in a diphasic manner. The pathophysiology behind dyskinesias is not fully understood, but they are believed to be a function of both disease stage and dosage of levodopa. If dyskinesias are not

bothersome to the patient, they do not require treatment. If they are bothersome, dosage reduction can be considered but is not always possible due to worsening of motor symptoms. The addition of amantadine (Symmetrel) can be helpful. For early wearing-off, dosing—particularly frequency—of levodopa can be modified, or adjunctive medication can be used such as an MAO-B inhibitor, a dopamine agonist, or entacapone (Comtan). Patients should also be counseled about the potential effect of protein on levodopa absorption and encouraged to space their doses 30 to 60 minutes from meals. For dose failures or abrupt wearing-off, apomorphine (Apokyn) injections can be used to provide rapid onset of symptom relief. Typical dosages and side effects of drugs used for advanced PD are summarized in Table 3. When medication fluctuations are severe, the patient may be considered for an advanced treatment option such as DBS or carbidopa-levodopa intestinal gel (Duodopa).² The ideal candidate for DBS has idiopathic PD, does not have dementia, and is typically receiving less-than-ideal benefit from medications for one of two reasons. In the first circumstance, levodopa is providing definite symptom reduction, but medication fluctuations have become a significant problem. In the second circumstance, the patient has medication-refractory tremor with or without additional troublesome motor symptoms.

Monitoring

Swallowing function should be monitored periodically, typically with a modified barium swallow, and modifications in diet and swallowing technique may reduce aspiration risk. A cognitive screening tool such as the Montreal Cognitive Assessment should be administered yearly. Supportive treatment strategies should be

²Not available in the United States.

TABLE 2 Medication Choices in Early Parkinson's Disease

DRUG CLASS	MEDICATION NAMES	TYPICAL DOSE RANGE	SIDE EFFECTS TO CONSIDER	COMMENTS
MAO-B inhibitors	Selegiline (Eldepryl)	5 mg daily–5 mg BID	Insomnia, confusion, hallucinations	Controversy re: neuroprotective benefits Potential medication interactions (serotonin syndrome)
	Rasagiline (Azilect)	0.5 mg–1 mg daily		
Anticholinergics	Benztrapine (Cogentin)	0.5 mg daily–1 mg TID	Dry mouth, cognitive impairment, hallucinations, urinary retention, blurred vision	Useful for tremor, high risk in elderly
	Trihexyphenidyl (Artane)	1 mg daily–3 mg BID		
Dopamine agonists	Pramipexole (Mirapex)	IR 0.125 mg–1.5 mg TID ER: 0.375 mg–4.5 mg daily	Nausea, leg edema, weight gain, daytime sleepiness, impulse control disorders, hallucinations Patch: skin irritation	Less favorable side effect: efficacy profile than levodopa
	Ropinirole (Requip)	IR 0.25 mg–8 mg TID XL: 2 mg–24 mg daily		
	Rotigotine (Neupro)	Transdermal 2 mg–8 mg/24 hours		
Levodopa preparations	Carbidopa/levodopa (Sinemet) C/L controlled release (Sinemet CR)	25/100 mg BID–TID– 50/200 mg BID–TID	Nausea, daytime sleepiness, orthostatic hypotension, hallucinations	Dyskinesias are a long-term complication of therapy

Abbreviations: BID = two times daily; C/L = Carbidopa/levodopa; MAO-B = monoamine oxidase type B; PD = Parkinson's disease; TID = three times daily.

TABLE 3 Medication Choices in Advanced Parkinson's Disease

DRUG CLASS	MEDICATION NAMES	TYPICAL DOSE RANGE	SIDE EFFECTS TO CONSIDER	COMMENTS
MAO-B inhibitors	Selegiline (Eldepryl)	5 mg daily–5 mg BID	Insomnia, confusion, hallucinations	Adjunct to levodopa
	Rasagiline (Azilect)	0.5 mg–1 mg daily		
	Safinamide (Xadago)	50 mg–100 mg daily		
Dopamine agonists	Pramipexole (Mirapex)	IR 0.125 mg–1.5 mg TID ER: 0.375 mg–4.5 mg daily	Nausea, leg edema, weight gain, daytime sleepiness, impulse control disorders, hallucinations	Adjunct to levodopa
	Ropinirole (Requip)	IR 0.25 mg–8 mg TID XL: 2 mg–24 mg daily		
	Rotigotine (Neupro)	Transdermal 2 mg–8 mg/24 hours	Skin irritation	Rapid onset within 10 minutes, used as rescue medication
	Apomorphine (Apokyn)	Subcutaneous 0.2 mL (2 mg)–0.6 mL (6 mg)	Orthostatic hypotension	
COMT inhibitor	Entacapone (Comtan)	200 mg with each dose of levodopa	Orange urine, diarrhea	Used to prolong levodopa effects Can worsen dyskinesias
Levodopa preparations	C/L (Sinemet) C/L controlled release (Sinemet CR)	Variable—total of 1200–2500 mg levodopa/day	Nausea, daytime sleepiness, orthostatic hypotension, hallucinations	Escalating dosage and frequency in advanced PD to combat wearing-off, must be balanced with side effects
	C/L ER capsules (Rytary)	23.75 mg/95 mg TID - variable		
	C/L entacapone (Stalevo)	25/100/200 mg TID–50/200/200 mg 8 times/day	Orange urine, diarrhea	
NMDA antagonist	Amantadine (Symmetrel)	50 mg daily–100 mg TID	Livedo reticularis, leg edema, insomnia, dry mouth, confusion, hallucinations, myoclonus	Reduces dyskinesias Can also be used for mild, early PD symptoms but now less commonly
	Amantadine ER (Gocovri)	137 mg–274 mg QHS		

Abbreviations: C/L = carbidopa/levodopa; COMT = catechol-O-methyltransferase; ER = extended release; MAO-B = monoamine oxidase type B; PD = Parkinson's disease; TID = three times daily.

used on an ongoing basis, including speech/swallow therapy, physical therapy, and occupational therapy. Therapists with specific training in neurologic disorders should be used when possible. PD-specific programs such as the Lee Silverman Voice Therapy Loud (speech therapy) and Big (physical therapy) programs are particularly helpful.

Complications and Nonmotor Symptoms

Non-motor symptoms of PD can be more disabling in some cases than the more well-known motor symptoms. These are summarized in Table 1. Depression and anxiety, in particular, affect high numbers of patients with PD. Psychosis is not an inevitable occurrence but affects approximately 50% of patients, usually in more advanced stages of the disease. When PD psychosis is causing fear or agitation, it should be treated with an escalating strategy. Typically, acetylcholinesterase inhibitors will be introduced first,

followed by either low-dose quetiapine (Seroquel)¹ or pimavanserin (Nuplazid) if symptoms are not stabilized. Pimavanserin is the only drug approved by the Food and Drug Administration for Parkinson's psychosis. Atypical antipsychotics have been associated with an increased risk of death in the elderly, and deaths have also been reported in patients receiving pimavanserin, although causality is not necessarily clear. Risks and benefits must be carefully weighed, but currently these medications may be the only option for a patient experiencing severe psychosis.

The gradual progression of PD is inevitable but highly variable in speed and severity from one individual to another. This is likely dependent on age of onset, other comorbid health conditions, access to expert care, and level of physical activity among other

¹Not FDA approved for this indication.

factors. Abrupt worsening of any symptoms of PD should prompt a workup for provoking medical conditions, such as occult urinary tract infection. PD does not directly lead to death, but death can occur in the setting of dysphagia leading to failure to thrive or aspiration pneumonia, or from serious injuries incurred from falls.

REHABILITATION OF THE STROKE PATIENT

Method of

Marlís González-Fernández, MD, PhD; and Dorianne Feldman, MD

CURRENT THERAPY

- Stroke rehabilitation improves functional outcomes.
- A comprehensive rehabilitation team composed of physicians, nurses, therapists, and community reintegration professionals can achieve the best outcomes.
- Early evaluation of family support and the home environment is critical to prevent unnecessary institutionalization.
- Evaluation and management of modifiable stroke risk factors, such as smoking, hypertension, and diabetes, are imperative during stroke rehabilitation to prevent stroke recurrence.
- Rehabilitation of the stroke patient can be hindered by conditions such as pneumonia (usually caused by aspiration), deep venous thrombosis, urinary tract infections, shoulder pain, depression, and spasticity. Early identification and treatment of these conditions are necessary to maximize functional outcomes.

According to the National Center for Health Statistics, 5.6 million Americans live with the disability caused by a previous stroke. Stroke is the leading cause of permanent disability in adults. Conservative estimates suggest that about 45% of stroke patients have moderate to severe disabilities requiring rehabilitation.

The goals of stroke rehabilitation are to maintain and optimize medical management, to maximize functional recovery, to minimize disability, and to improve quality of life and participation in society. The rehabilitative approach endeavors to provide patient-centered care that is organized, comprehensive, and specific to the needs of the stroke patient. The concerted efforts of the patient, family, and rehabilitation team are essential for achieving these goals. Recovery after stroke can be a long and challenging process for the patient and the family. Although functional gains occur most rapidly in the first year after a stroke, additional motor

recovery is possible beyond 1 year when patients are involved in targeted rehabilitation programs.

The rehabilitation team is composed of rehabilitation physicians (physiatrists), other physicians such as neurologists and neurosurgeons, rehabilitation nurses, occupational therapists, physical therapists, speech and language pathologists, rehabilitation neuropsychologists, social workers, case managers, nutritionists, vocational counselors, and pharmacists. A goal of the acute inpatient rehabilitation team is discharging the patient to the least restrictive environment, ideally home. To accomplish this goal, it is critical to evaluate family support and the home environment.

Rehabilitation should start as part of the acute stroke inpatient stay. The decision-making process to determine the appropriate rehabilitation setting after discharge is described in [Figure 1](#). Speech-language pathologists, physical therapists, and occupational therapists evaluate deficits in cognition, communication, deglutition, mobility, and activities of daily living. The severity of deficits in these major areas and the ability of the patient to tolerate therapy determine the appropriate rehabilitation setting.

Stroke patients with mild deficits are able to return home with home or outpatient therapy services. Patients with moderate to severe strokes benefit from more intensive therapy in an institutional setting. Comprehensive inpatient rehabilitation is suitable for patients with moderate to severe deficits who can tolerate intensive rehabilitation (3 h/day for 5 days each week or 15 hours of therapy over a 7 day period). If the severity of deficits or medical comorbidities limits the ability of the patient to participate in intensive therapy, alternate settings can be considered.

During the inpatient rehabilitation stage, medical management focuses on secondary stroke prevention: diet; exercise; smoking cessation; and reducing complications, including optimizing blood pressure control while maintaining cerebral perfusion, preventing and treating lipid disorders, and managing post-stroke pain, depression, and abnormal muscle tone. During this stage, much of the rehabilitation effort is directed toward educating stroke survivors about complications and the importance of adherence to medical recommendations.

Medical complications, such as deep venous thrombosis and related thromboembolism, pneumonia (usually related to aspiration), skin breakdown, and urinary infections, can hinder a patient's recovery. Early identification of these complications is necessary to maintain progress in the rehabilitation effort. Other complications, such as seizures and cardiac decompensation, are possible and should be monitored.

Stroke often causes significant impairment and activity limitations. Deficits in strength, swallowing, vision, balance, muscle tone, communication, comprehension, cognition, attention, sensory perception, and bladder function are common and can cause difficulty completing activities of daily living, walking, transferring to and from different surfaces, and getting in and out of the bed. Post-stroke depression, fatigue, and pain are common and should be addressed to maximize participation in rehabilitative efforts.

Transition to the chronic phase begins after the patient is medically stable and inpatient therapy goals are met. Outpatient therapy services are initiated in conjunction with physiatric, primary care, and neurologic follow-up.

Hemiparesis

Hemiparesis, or one-sided weakness, is one of the most frequent complications after stroke. Recovery of motor function varies. Often, it is limited by muscle atrophy, co-contraction of agonists and antagonists, and abnormal tone. Usually, motor recovery is preceded by the development of patterned muscle movements, or synergies. Synergies occur when select muscles contract in a predictable manner. In the paretic upper extremity, a flexion synergy pattern (i.e., humeral adduction, internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion) is common. In the lower extremity, extension synergies (i.e., hip internal rotation, adduction, extension, knee extension, and ankle extension and inversion) predominate. These patterns can be regarded as functional and nonfunctional. For instance, extension synergy patterns

factors. Abrupt worsening of any symptoms of PD should prompt a workup for provoking medical conditions, such as occult urinary tract infection. PD does not directly lead to death, but death can occur in the setting of dysphagia leading to failure to thrive or aspiration pneumonia, or from serious injuries incurred from falls.

During the inpatient rehabilitation stage, medical management focuses on secondary stroke prevention: diet; exercise; smoking cessation; and reducing complications, including optimizing blood pressure control while maintaining cerebral perfusion, preventing and treating lipid disorders, and managing post-stroke pain, depression, and abnormal muscle tone. During this stage, much of the rehabilitation effort is directed toward educating stroke survivors about complications and the importance of adherence to medical recommendations.

Medical complications, such as deep venous thrombosis and related thromboembolism, pneumonia (usually related to aspiration), skin breakdown, and urinary infections, can hinder a patient's recovery. Early identification of these complications is necessary to maintain progress in the rehabilitation effort. Other complications, such as seizures and cardiac decompensation, are possible and should be monitored.

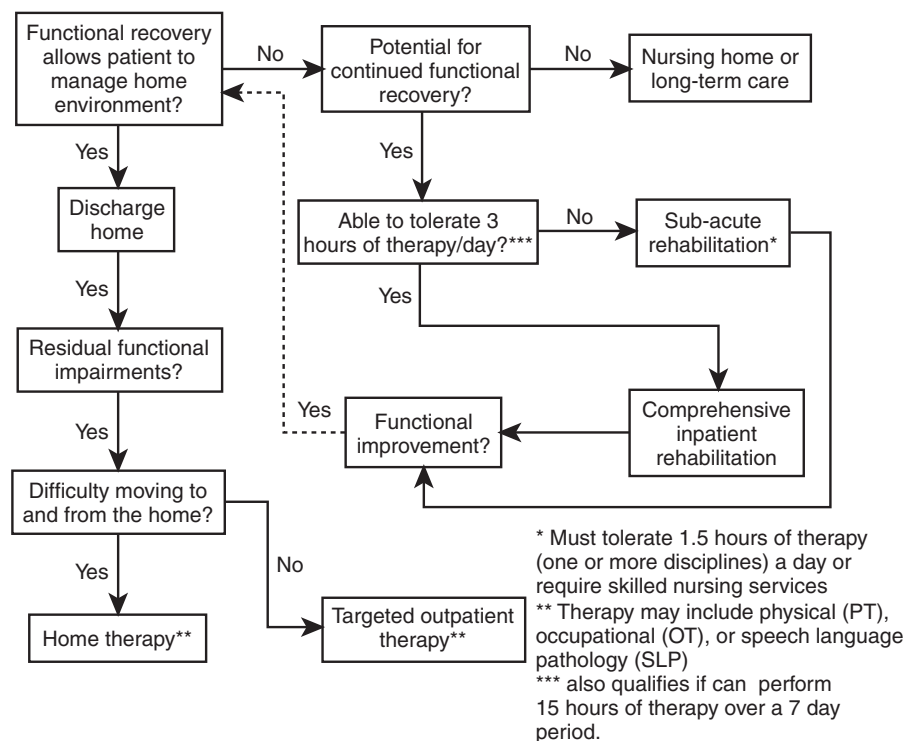

Stroke often causes significant impairment and activity limitations. Deficits in strength, swallowing, vision, balance, muscle tone, communication, comprehension, cognition, attention, sensory perception, and bladder function are common and can cause difficulty completing activities of daily living, walking, transferring to and from different surfaces, and getting in and out of the bed. Post-stroke depression, fatigue, and pain are common and should be addressed to maximize participation in rehabilitative efforts.

Transition to the chronic phase begins after the patient is medically stable and inpatient therapy goals are met. Outpatient therapy services are initiated in conjunction with physiatric, primary care, and neurologic follow-up.

Hemiparesis

Hemiparesis, or one-sided weakness, is one of the most frequent complications after stroke. Recovery of motor function varies. Often, it is limited by muscle atrophy, co-contraction of agonists and antagonists, and abnormal tone. Usually, motor recovery is preceded by the development of patterned muscle movements, or synergies. Synergies occur when select muscles contract in a predictable manner. In the paretic upper extremity, a flexion synergy pattern (i.e., humeral adduction, internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion) is common. In the lower extremity, extension synergies (i.e., hip internal rotation, adduction, extension, knee extension, and ankle extension and inversion) predominate. These patterns can be regarded as functional and nonfunctional. For instance, extension synergy patterns

Figure 1 Determination of rehabilitation needs of patients being discharged after an acute stroke.

of the lower limb can augment rehabilitation because this position fosters early ambulatory therapy. Conversely, flexion synergy patterns in the upper extremity can significantly impair arm function.

Rehabilitation of the patient with hemiparesis should concentrate on maintaining range of motion and improving strength and posturing. Exercise programs should incorporate functional use of the hemiparetic limb and weight bearing to promote limb recognition, better alignment, muscle elongation, and muscle tone reduction.

Hemiparesis can lead to contracture, particularly when profound weakness is present, and contracture occurs most commonly in the wrist and ankle. Resting hand splints and solid ankle-foot orthoses can be used to maintain the limb in a neutral position. These devices can be used to prevent loss of motion, control muscle tone, and aid in positioning, particularly when wheelchairs are necessary.

Functional electrical stimulation (FES) has gained increasing interest as a means of enhancing functional movement and strength. Muscle contraction is induced with electrical stimulation. Many products on the market incorporate FES technology for the treatment of footdrop and hand weakness.

Preservation of scapulohumeral positioning is a critical component of rehabilitation. With shoulder weakness, the scapula becomes downwardly rotated, causing the glenoid fossa to move vertically and resulting in humeral subluxation. Traditionally, shoulder slings have been prescribed for the hemiplegic shoulder, but their effectiveness in preventing subluxation is questionable.

FES has been used to augment motor return in the hemiplegic shoulder and prevent subluxation. Despite advances in the treatment of the hemiplegic shoulder, it is still unclear which therapeutic interventions should constitute the standard of care.

Constraint-induced therapy (CIT), a therapeutic approach in which the nonparetic limb is restrained, can improve functional movement of the paretic upper extremity in patients with residual hand and wrist movement, even in patients more than 1 year after a stroke. More recently, CIT concepts have been applied to the treatment of aphasia. By limiting the use of nonverbal communication and stimulating verbal output, participants were able to improve language performance and communication.

Weight-supported treadmill training has been proposed to enhance gait training after a stroke. Although a recent clinical trial

showed no clear benefit from weight-supported treadmill training on improving gait speed, walking ability, or balance, some advocate for continued research on the effects of this training on overall health, including maintaining bone mass and decreasing insulin resistance.

Dysphagia

Dysphagia after stroke occurs acutely in approximately 50% of stroke patients. Identifying dysphagia in this population is essential for preventing associated morbidity and mortality. Stroke patients with dysphagia are at risk for dehydration, malnutrition, and aspiration pneumonia. As allowed by their overall clinical status and consciousness level, stroke patients should be evaluated as early as possible during their acute hospital stay. Trained clinicians (most commonly speech-language pathologists) should evaluate the patient to make recommendations regarding further dysphagia evaluation or testing and the need for diet modifications or dysphagia rehabilitation.

Hemiplegic Shoulder Pain

Stroke survivors with residual hemiparesis or weakness are at risk for pain syndromes (particularly in the upper extremity), which can significantly limit rehabilitation efforts. These pain syndromes are usually multifactorial. In the rehabilitation setting, prevention of shoulder pain is key, and interventions should focus on proper positioning, handling, and transfer techniques.

In severe cases, shoulder pain can be accompanied by hand swelling, tenderness, skin changes, erythema, hyperhidrosis, and allodynia. When this occurs, it is referred to as *shoulder-hand syndrome*, a subtype of complex regional pain syndrome (CRPS). Although the mechanism and cause are unclear, it has been suggested that this process is the result of an overreaction to a neurologic insult and may be inflammatory in nature. In some cases, the pain is severe, resulting in decreased and guarded movements of the limb that limit functional use. Shoulder pathology such as rotator cuff strains or tears, bicipital tendonitis, subacromial and subdeltoid bursitis, and glenohumeral subluxation or dislocation contribute to poststroke shoulder pain and should be treated.

Nonpharmacologic treatment focuses on desensitization techniques, gentle range-of-motion exercises, and physical modalities

(e.g., heat, cold, transcutaneous electrical nerve stimulation [TENS], FES). Pharmacologic management includes medications typically used for neuropathic pain syndromes, such as anticonvulsants, tricyclic antidepressants (TCAs), nonsteroidal anti-inflammatory drugs, topical agents (e.g., lidocaine [Xylocaine],¹ clonidine [Catapres-TTS],¹ capsaicin [Zostrix]¹), and injections of steroid or local anesthetics. Antispasmodic medications have been used. When pain relief is not achieved with conservative treatment, sympathetic blocks can be considered. Sympathectomies and spinal cord stimulators can be considered as last resorts.

Spasticity

Spasticity after stroke can significantly impact rehabilitation. The classic upper extremity flexor synergy pattern (i.e., adducted shoulder with flexed elbow, wrist, and fingers) can markedly interfere with the function of the affected arm. Conversely, the classic lower extremity extensor synergy pattern (i.e., extended hip and knee and ankle plantar flexion) can be advantageous for ambulation if plantar flexion can be controlled by physical or pharmacologic agents. If untreated, these patterns can lead to abnormal positioning and contracture.

Treatment of spasticity after stroke should address positioning and exacerbating factors. Splinting or bracing, appropriate wheelchair sitting position, and physical therapy techniques are important to prevent contracture and promote motor recovery. Painful or noxious stimuli can exacerbate spasticity. Shoulder pain, pressure sores, deep venous thrombosis, bladder distention, and constipation are examples of stimuli that can exacerbate spasticity. Pharmacologic treatment should take into account the presence of these triggers because spasticity is likely to improve after the stimuli are resolved or relieved.

Pharmacologic treatment of post-stroke spasticity presents some challenges. Effective antispasmodic agents such as baclofen (Lioresal) or tizanidine (Zanaflex) can cause somnolence or weaken unaffected muscles, which can significantly affect rehabilitation. Localized treatments such as botulinum toxins (Botox, Dysport, Myobloc, Xeomin)¹ injections or phenol blocks¹ can be useful, because treatment can be directed toward muscles that are affecting functional use of the limbs. Surgical interventions can be used for patients with severe spasticity limiting functional positioning or for those with the potential for functional grip if tendon lengthening or transfer can be considered.

Cognitive Dysfunction

Stroke patients can experience many cognitive deficits, including visuospatial neglect, cognitive-linguistic deficits, apraxia, memory

loss, and attention deficits. Cognitive rehabilitation should concentrate on treatment of the specific deficits of the patient. Visuospatial rehabilitation (including scanning training) is recommended for deficits associated with visual neglect after right stroke. Cognitive-linguistic therapies are recommended for left hemispheric stroke patients with language deficits. Treatment of apraxia should include specific gestural and strategy training.

The use of medications that may impair cognitive function should be limited. Medications that are commonly considered during a stay in a rehabilitative facility that may have a significant impact on cognition and rehabilitation are highlighted in Table 1.

Depression and Neuropharmacology

Depression can be seen in up to one half of all stroke patients. It has been associated with poor functional outcomes and more severe impairments. Vegetative symptoms can have a significant impact on rehabilitative efforts because participation in therapy is critical.

Psychoactive drugs can be beneficial and should be considered. Selective serotonin reuptake inhibitors (SSRIs) are recommended in this population because of a better side effect profile and because of the undesirable anticholinergic side effects of TCAs. In cases unresponsive to treatment with SSRIs, nortriptyline (Pamelor) may be helpful. In the rehabilitation setting when rapid short-term improvement in symptoms is necessary to increase participation in therapy, the use of psychostimulants (e.g., methylphenidate [Ritalin]¹) may be indicated. Table 1 shows the neuropharmacologic agents commonly used during stroke rehabilitation. Psychotherapy has been associated with modest improvement in post-stroke depression and is considered to be part of a multidisciplinary approach. Research has demonstrated the benefit of the antidepressant fluoxetine (Prozac)¹ on motor recovery; administration of the drug for 3 months as an adjunct to physical therapy improved motor functioning in poststroke patients.

Bladder Dysfunction

Bladder dysfunction after stroke depends on the stroke's location. During the rehabilitation phase, the most common problem is urinary incontinence and urgency associated with uninhibited bladder contraction. Ultrasound bladder scans (usually every 4 hours and after voiding) should be ordered to detect bladder distention and urinary retention. It is standard practice to intervene when bladder volumes are greater than 500 mL. If volumes exceed this cutoff point, intermittent catheterization should be started. Intermittent catheterization is preferable to indwelling catheters because the risk of urinary tract infection is higher with the latter. Bladder scans are

TABLE 1 Neuropharmacologic Agents Commonly Used During Stroke Rehabilitation

DRUG CLASS	DRUG NAME	INDICATION	POTENTIAL PROBLEMS
Benzodiazepines	Diazepam (Valium) Lorazepam (Ativan)	Agitation, ¹ spasticity Agitation, ¹ seizures	Sedation, confusion, sundowning Sedation, paradoxical reactions, confusion, sundowning
Tricyclic antidepressants (TCAs)	Nortriptyline (Pamelor) Amitriptyline (Elavil)	Depression, neuropathic pain, ¹ central pain ¹	Anticholinergic effects, sedation
Selective serotonin reuptake inhibitors (SSRIs)	Sertraline (Zoloft) Escitalopram (Lexapro) Citalopram (Celexa) Fluoxetine (Prozac)	Depression, stimulation ¹ Depression motor recovery ¹	Long titration period, suicidal ideations, serotonin syndrome, syndrome of inappropriate antidiuretic hormone (SIADH), somnolence, seizures As above for other SSRIs
Stimulants	Modafinil (Provigil) Methylphenidate (Ritalin)	Drowsiness, ¹ decreased alertness, ¹ impaired concentration, ¹ diminished attention ¹	Arrhythmia, seizures, hepatotoxicity, blood pressure changes

¹Not FDA approved for this indication.

usually discontinued when post-voiding residual volumes at 3- to 4-hour intervals are low (<150 mL) for a period of 24 to 48 hours.

Mobility and Use of Adaptive Equipment

Activity limitations vary among stroke survivors and can include difficulties with bed mobility, wheelchair propulsion, transfers, gait, stairs, and the basic activities of daily living. The goal of physical therapy and occupational therapy is to maximize functional independence. Addressing mobility limitations is fundamental in stroke rehabilitation because it is related to long-term care needs and independence.

Transfer training comprises learning how to maneuver from one surface or height to another. Ideally, patients should learn to roll and transfer toward the involved and uninvolved sides; however, early mobility efforts are directed to the uninvolved side to minimize the risk of injury.

Gait deviations are common after stroke and interfere with safety and efficiency of locomotion. If an assistive device is needed, the goal of physical therapy is to progress to the least restrictive device possible. Hemiwalkers and wide-based quad canes provide the most stability. An ankle-foot orthosis may be indicated for patients with decreased ankle control and footdrop. Instruction in ascending or descending stairs depends on assistive device requirements. With weakness, stairs are ascended by initiating movement with the uninvolved or stronger lower extremity. This process is reversed when descending.

For some stroke survivors, functional ambulation is not a realistic goal. In these cases, the wheelchair becomes the primary means of locomotion. Wheelchair prescription requires considerable skill and training and must take into account posturing, body habitus, cognition, physical fitness level, and the home environment. An appropriate wheelchair prescription is required to maximize mobility and prevent complications such as shoulder pain. Physical and occupational therapists should evaluate the patient before providing wheelchair recommendations to vendors. Hemi wheelchairs (i.e., wheelchairs situated closer to the ground) and one-arm drive wheelchairs allow hemiplegic patients to use the uninvolved side for wheelchair propulsion. Lap boards with arm supports can be added to improve hemiparetic arm posturing and sitting symmetry.

For some stroke survivors, the ability to return to driving is considered one of the most important long-term rehabilitation goals. Formal driving rehabilitation programs are available to evaluate and improve driver safety. Driver rehabilitation specialists perform vision, cognitive, and perceptual examinations. Perception tests assess reaction times to visual and auditory stimuli. Values for

vision and reaction times are standardized and state-dependent. Specialists should also perform a behind-the-wheel assessment, beginning in a parking lot and progressing to the negotiation of more complex traffic situations. Many modifications can increase independence and assist with a return to driving, including a spinner knob, which can be attached to the steering wheel to allow one-arm control; hand controls for acceleration and braking; left foot pedals to compensate for right foot impairment; and wheelchair lifts.

Adaptive equipment, including bracing, shoe modification, and other tools, increases independence through completion of activities of daily living (e.g., long-handled sponge, reacher, shoe horn, mirror, sock aids) and is extremely beneficial for those with moderate to severe strokes, particularly if hemiparesis is dense (Figure 2). Silverware, pens, and other utensils can be modified for easier maneuverability. Multipodous boots can be used to prevent plantar flexion contracture development in the hemiparetic limb.

Falls

Falls are common after moderate to severe strokes. In rehabilitation settings, fall prevention usually requires a multimodal approach. Strategies include use of bed-chair alarms, placing those at risk close to the nursing station, wearing skid socks, limiting or refraining from polypharmacy, eliminating slick or irregular floors, and in some cases, providing a sitter for closer monitoring. Physical and occupational therapists must include general safety and fall recovery as part of the treatment plan.

Visual Impairment

Depending on the location of the stroke, the visual system may be involved. One of the most debilitating visual impairments is visuospatial neglect, a complication of right hemisphere strokes. Left-sided stimuli are not attended to or recognized, and affected individuals must learn to deal with this deficit. Other complications include gaze weakness or paralysis, diplopia, visual field loss, ptosis, tracking disorders, decreased visual acuity, and cortical blindness.

Screening for primary visual skills, including visual acuity, visual fields, and visual tracking, should be done by psychiatrists, neurologists, and occupational therapists. If problems are identified, patients should be referred to neuro-ophthalmologists and low-vision rehabilitation programs. Visual acuity problems often can be addressed by incorporating the use of glasses into the therapy session or by changing the prescription. Eye movement disorders and visual field deficits usually lessen as time elapses and may

Figure 2 Adaptive equipment commonly used during stroke rehabilitation. The tapered front scoop dish (A) has nonskid feet to keep the plate from sliding. The curved edge simplifies scooping food. The dish is especially suited for individuals who have limited flexibility, have decreased motor coordination, or feed using one hand, such as a hemiparetic stroke patient. The reacher (B) is used to get items from the floor. The long-handled dressing aid (C) is used to reach clothes on the floor or to bring clothes up the paretic side. The long-handled shoe horn (D) aids with slipping into shoes. The long-handle sponge (E) is used for reaching the involved side while bathing or when the shoulder range of motion does not allow reaching. The leg lifter (F) and the sound upper limb can be used to assist in moving the paretic lower limb. Adapted feeding utensils (G) are used for patients with grip weakness or difficulties with upper limb range of motion; *left to right*: bent-handle spoon, no-grip fork, rocker bottom knife, and thick-handle spoon. No-tie laces (H) are elastic shoelaces that do not require tying. When using the sock-donning aid (I), the sock slides onto the plastic portion of the device, and the strap is used to pull the sock with the device on the foot.

respond to treatment with prisms, head positioning, and unilateral eye occlusion with tape or a patch technique. Prism therapy has also shown promise in treating hemispatial neglect. Those with continued visual field impairment should be taught eye movement techniques to expand the visual area.

Brain-Based Therapies: Noninvasive Brain Stimulation

Repetitive transcranial magnetic stimulation (rTMS) applies a brief magnetic field to the scalp with enough intensity to penetrate the skull and induce neuronal activation. Some promising results have been seen when rTMS is used after stroke. A second modality, transcranial direct current stimulation (tDCS), applies low-voltage electrical current to stimulate or modify neuronal activity in the brain cortex. The stimulation is applied to discrete areas of the head to target affected areas. Although the side-effect profile of these techniques is positive, more research is necessary to determine best candidates for treatment and optimal treatment protocols.

Robotics

The aim of robotic technology is to use an adjustable, programmable device to augment mobility in a task-specific manner. Robots can serve in an assistive (perform desired function) or therapeutic capacity (enhance gait or upper extremity function) and are suitable for this purpose as they not only enable more intensive therapy than conventional modes but also incorporate a greater degree of activity repetition. Present recommendations are for use as an adjunct to traditional rehabilitation interventions.

Conclusions

Stroke rehabilitation requires the concerted efforts of the patient, family, and medical professionals. A multidisciplinary team with training to address the particular impairments and functional limitations of the stroke patient is critical. The physician's efforts should focus on preventing complications and treating stroke sequelae with the primary goal of improving overall function and participation in society.

SEIZURES AND EPILEPSY IN ADOLESCENTS AND ADULTS

Method of

Jose A. Padin-Rosado, MD

CURRENT DIAGNOSIS

- Obtain a thorough clinical history, including a detailed description of the paroxysmal events from the patient and from witness accounts.
- Perform a thorough physical and neurologic examination.
- Perform laboratory tests including electrolytes, blood glucose, liver function, and toxicology.
- Obtain a lumbar puncture if signs of infection are present.
- Neuroimaging is strongly recommended. Magnetic resonance imaging (MRI) is the preferred test due to higher resolution. Head computed tomography (CT) is acceptable in the acute setting to rule out hemorrhage.
- Routine electroencephalography (EEG) with sleep deprivation and activation procedures should be performed as close to the time of occurrence of the paroxysmal event to increase the diagnostic yield.

CURRENT THERAPY

- Choose the right medication for the type of epilepsy and epilepsy syndrome.
- Consider the side-effect profile, cost, and drug dosing schedule, and adapt to the unique patient characteristics, taking into consideration the patient comorbidities.
- Aim for monotherapy whenever possible.
- Start low and increase slowly when initiating antiepileptic drug (AED) therapy to minimize side effects and increase compliance.
- An adequate AED trial with titration of the medication until clinical effectiveness or side effects occur is recommended.
- When switching from one drug to another, consider overlapping medications to provide with protection until the first drug is discontinued.
- If the two antiepileptic drugs fail, the patient should be referred to an epilepsy center for evaluation.
- If the patient is seizure free after 2 years of treatment, consider withdrawing AEDs for epilepsies of unknown etiology or epilepsy syndromes known to resolve.

Epilepsy is a disease characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. Epilepsy is commonly defined as having two or more unprovoked seizures greater than 24 hours apart. However, as per the new classification proposed by the International League Against Epilepsy (ILAE), a single seizure can be classified as epilepsy if risk of seizure recurrence is high (see classification section).

A seizure is defined as transient signs or symptoms caused by abnormal excessive synchronous activity of brain neurons. Seizures can be classified as either acute symptomatic (provoked) or unprovoked. Acute symptomatic seizures are associated with a transient systemic or brain insult and will usually not require treatment with antiepileptic drugs because of the transient nature of the precipitant

respond to treatment with prisms, head positioning, and unilateral eye occlusion with tape or a patch technique. Prism therapy has also shown promise in treating hemispatial neglect. Those with continued visual field impairment should be taught eye movement techniques to expand the visual area.

- If the patient is seizure free after 2 years of treatment, consider withdrawing AEDs for epilepsies of unknown etiology or epilepsy syndromes known to resolve.

Epilepsy is a disease characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. Epilepsy is commonly defined as having two or more unprovoked seizures greater than 24 hours apart. However, as per the new classification proposed by the International League Against Epilepsy (ILAE), a single seizure can be classified as epilepsy if risk of seizure recurrence is high (see classification section).

A seizure is defined as transient signs or symptoms caused by abnormal excessive synchronous activity of brain neurons. Seizures can be classified as either acute symptomatic (provoked) or unprovoked. Acute symptomatic seizures are associated with a transient systemic or brain insult and will usually not require treatment with antiepileptic drugs because of the transient nature of the precipitant

and the associated low risk for development of epilepsy. Unprovoked seizures, on the other hand, may represent the beginning of epilepsy.

Epidemiology

Epilepsy is one of the most common neurologic conditions, affecting more than 50 million people worldwide. The prevalence of epilepsy (number of people with active epilepsy) is approximately 1% in the United States, with 3.4 million people (3 million adults and 470,000 children) suffering from the disease. The incidence of epilepsy (number of new cases of epilepsy) is around 150,000 each year or 55 per 100,000 population. The incidence is higher in infants younger than age year and in people older than age 65. Men have a slightly higher risk of developing epilepsy than women. African-Americans and disadvantaged populations are affected at a higher rate than Caucasians. The lifetime risk of developing a seizure is around 9% to 10%.

Classification

Definition of Epilepsy

In 2014, the ILAE published a practical definition of epilepsy. The new definition classifies epilepsy as a disease of the brain characterized by any of the following criteria: at least two unprovoked or reflex seizures occurring 24 hours apart, one unprovoked or reflex seizure and a probability of recurrent seizures similar to the general recurrence risk (60%) after two unprovoked seizures, occurring over the next 10 years or a diagnosis of an epilepsy syndrome.

In 2017, the ILAE released a major revision of both the classification of the epilepsies and epilepsy syndromes and the classification of seizure types. The classification of the epilepsies and epilepsy syndromes has three levels: (1) classification of the seizure type, (2) classification of the epilepsy type, and (3) diagnosis of an epilepsy syndrome whenever possible. The cause and associated comorbidities are considered at each diagnostic step because these carry treatment implications.

The first step is to classify the type of seizure (Figure 1 and Box 1). It assumes that the patient has been diagnosed with an epileptic seizure and then organizes the seizures by where they originate in the brain into either focal onset seizures, formerly known as partial-onset seizure (emanating from networks in one lobe or hemisphere), generalized-onset seizure (seizures engaging bilateral

BOX 1

Changes in Seizure Type Classification from 1981 to 2017

- Change of “partial” to “focal”
- Certain seizure types can be either of focal, generalized, or unknown onset.
- Seizures of unknown onset may have features that can still be classified.
- Awareness is used as a classifier of focal onset seizures.
- The terms *dyscognitive*, *simple partial*, *complex partial*, *psychic*, and *secondary generalized* were eliminated.
- New focal seizure types include automatisms, autonomic, behavioral arrest, cognitive, emotional, hyperkinetic, sensory, and focal to bilateral-tonic-clonic seizures. Atonic, clonic, epileptic spasms, myoclonic, and tonic seizures can be either focal or generalized.
- New generalized seizure types include absence with eyelid myoclonia, myoclonic absence, myoclonic-tonic-clonic, myoclonic atonic, and epileptic spasms.

Fisher et al: Classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia* 58:522–530, 2017.

neural networks), and unknown-onset seizures. The term *secondary generalized seizure* is replaced by focal to bilateral tonic-clonic seizure, and it is placed in a special category. Then focal-onset seizures can be optionally classified into seizures with preserved awareness as focal aware seizures (formerly known as simple partial seizures) and seizures with impaired awareness as focal impaired awareness seizures (formerly known as complex partial seizures). Focal-onset seizures, generalized-onset seizures, and unknown-onset seizures can be optionally and further subdivided into whether they have associated motor symptoms or other non-motor symptoms. In some settings classification into seizure type will be the only attainable level possible for diagnosis because there may be no access to EEG, video, and imaging studies or

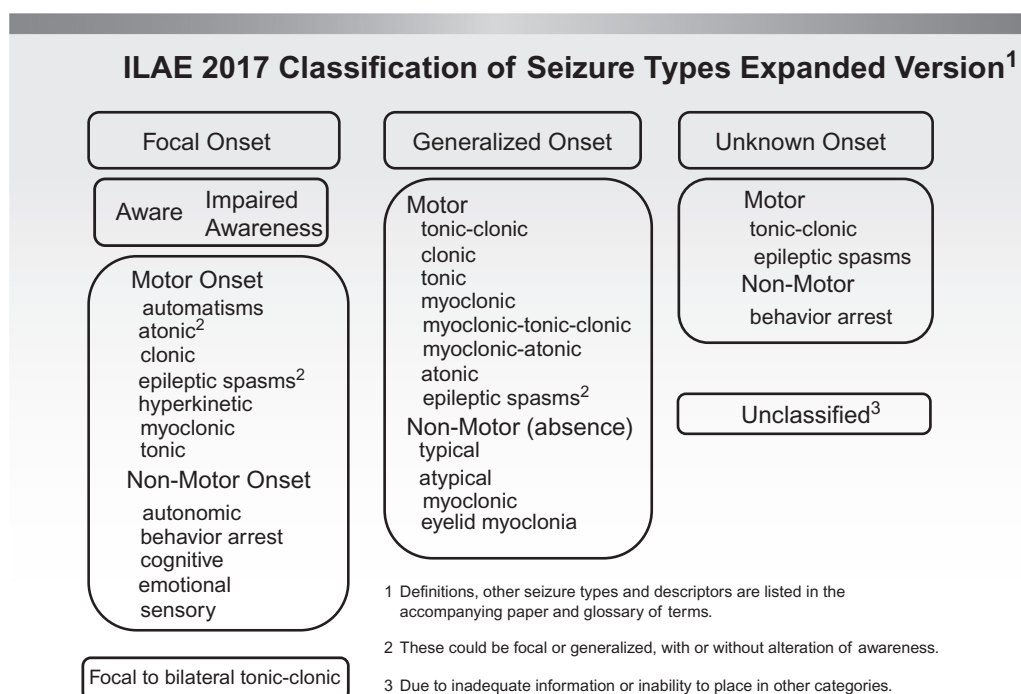

Figure 1 Classification of seizure types. (From operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and terminology: Fisher RS, et al. *Epilepsia*, 58:522–530, 2017 Wylie Journal: page 525 figure 2.)

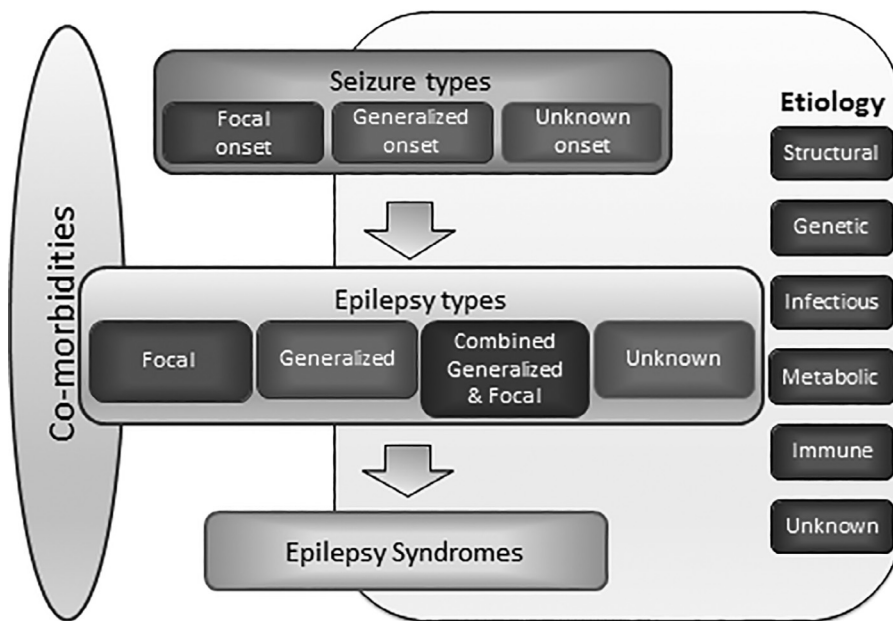

Figure 2 Classification of the Epilepsies. (From ILAE Classification of the Epilepsies: Position paper of the ILAE Commission for Classification and Terminology: Scheffer IE, et al: *Epilepsia* 58:512–521, 2017. Wiley Journal: [Figure 1](#) page 515.)

too little information available to make a higher level of diagnosis.

The second step is to classify the type of epilepsy ([Figure 2](#)). This step in the classification assumes that the patient fulfills the diagnosis of epilepsy (ILAE 2014 definition of epilepsy—see above) and classifies the epilepsies into focal (focal clinical features and EEG with focal epileptiform abnormalities), generalized (bilateral clinical features and EEG with generalized epileptiform abnormalities), combined generalized and focal (features of both on clinical evaluation and on EEG), and unknown type (either no clinical information available and normal or no EEG available).

The third step is the diagnosis of an epilepsy syndrome whenever possible. A syndrome refers to a cluster of features such as seizure type, EEG findings, and imaging features that tend to occur together and may give information regarding treatment implications and prognosis. Within the generalized epilepsies, a well-known subgroup, known as the idiopathic primary generalized epilepsies, exists and includes four distinct syndromes: childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, and generalized-tonic-clonic seizures.

From the moment the patient is diagnosed with having an epileptic seizure, a cause should be sought. Etiologies include structural etiology (structural abnormality seen on brain MRI that is strongly associated with the development of seizures), for example, temporal lobe seizures from mesiotemporal sclerosis; genetic etiology (epilepsies with a presumed genetic mutation), for example, benign familial neonatal epilepsy with mutation in *KNCQ2* or *KNCQ3* (potassium channels); infectious etiology, for example neurocysticercosis; metabolic etiology, for example, porphyria and pyridoxine-dependent seizures; immune etiology, for example, anti-NMDA receptor encephalitis and anti-LG1 encephalitis and unknown etiology.

Comorbidities should be considered for every patient with epilepsy at each stage of classification just like etiology. Comorbidities include learning, psychological, and behavioral problems. The term *benign* is replaced by self-limiting (likely spontaneous resolution of a syndrome) and pharmacoresponsive (the epilepsy syndrome will be controlled with appropriate AED treatment). This new classification is aimed at providing tools for improved diagnosis and understanding of etiology and targeted therapies to the patient's disease.

Diagnosis

The diagnosis of a seizure and epilepsy is largely a clinical one and is highly dependent on the history and physical examination. The

clinical history should be obtained from the patient and from a witness. After the aforementioned is obtained, the information is analyzed to determine whether indeed the paroxysmal event in question represents a true seizure or a seizure mimicker. If the event of concern represents a seizure, then it is further classified into focal or generalized and into acute symptomatic, a transient phenomena with lower seizure recurrence or unprovoked, which confers a higher risk for seizure recurrence and development of epilepsy.

The clinical history is aimed at obtaining a clear description of the prodromal or premonitory state, the pre-ictal state, the ictal state, and the post-ictal state. The prodromal state occurs hours to days prior to the ictus and is most commonly seen in generalized seizures but may also occur in focal onset seizures and consists of behavioral changes, mood swings, fatigue, and changes in sleep patterns. Regarding the pre-ictal period, the patient should be questioned about the presence of warning signs immediately before the seizure onset, also known as auras. An aura is a simple partial seizure or seizure without impaired awareness. An aura points to a focal seizure onset and according to the description of the aura we can potentially determine the lobe of onset. For example, a rising gastric sensation and a sensation of déjà vu points to seizure onset in the temporal lobe and visual hallucinations point to the occipital lobe.

Then ask what happened during the event (ictal period). Issues to consider include the level of awareness, the presence of ability to speak, the presence of automatisms (lip-smacking, ipsilateral hand automatisms, and contralateral dystonia points to ipsilateral temporal lobe seizures), other behavior, and the duration of the event (true seizures usually last less than 2 minutes whereas nonepileptic events are usually of longer duration).

Next focus on what happened after the event (post-ictal period): whether there is any confusion or fatigue, how long it takes the patient to come back to baseline, presence of tongue bites and muscle aches, and urinary incontinence (commonly seen with true seizures). Also ask for triggers including sleep deprivation, stress, drug intake, and alcohol withdrawal.

Other information to obtain include the presence of diurnal variations, for example frontal lobe seizures usually occur at nighttime, and generalized tonic-clonic and myoclonic seizures occur mostly during the morning. If more than one seizure occurs, then ask for maximum seizure-free period, seizure frequency to assess for severity of disease and response to treatment, number of visits to the hospital or the emergency department to assess for seizure severity, as well as the presence of falls or injuries during seizures to assess for risks and degree of seizure control.

Medical history should include questions on patient's prenatal history and development to assess for remote symptomatic causes of seizures, history of febrile seizures, history of central nervous system (CNS) lesions (tumors, stroke) and infections, history of brain trauma specifically with associated penetrating injuries with intraparenchymal blood, skull fractures, and prolonged loss of consciousness, and family history of epilepsy.

Social history should include questions on level of education and employment. Patients with a higher level of education usually will have a better understanding of their diagnosis and prognosis. Employment is important, because patients at higher risk for development of subsequent seizures after a first seizure have a higher risk of injury if they work in a high-risk job (e.g., in construction handling heavy machinery). Patients with altered awareness during a seizure should not be driving. Clinicians should be familiar with the specific state laws regarding driving in patients with seizures and epilepsy. Use of drugs and alcohol are risk factors for the development of a first provoked seizure, and some illegal drugs may exacerbate or cause seizures. Patients should be discouraged from using illegal drugs and from the excessive intake of alcohol. Review of current medications or newly started medications should be performed to determine whether any can precipitate seizures (e.g., tramadol, bupropion).

After the medical history is obtained, a thorough physical and neurologic examination should be performed. The clinician should look for skin abnormalities such as neurocutaneous manifestations of diseases (tuberous sclerosis and neurofibromatosis). Test for muscle strength to rule out subtle weakness or post-ictal Todd's paralysis; look for lateral tongue/cheek bites, which are commonly seen in true epileptic seizures; also look for bruises, scrapes from falls, burns, and muscle and back pain commonly seen in compression fractures caused by convulsive seizures.

The evaluation of a new-onset seizure should be aimed at determining whether the seizure represents an acute symptomatic seizure, usually a transient phenomenon or an unprovoked seizure.

If the history and examination points to a probable acute symptomatic seizure, then life-threatening conditions should be ruled out (hemorrhage, CNS infection, neoplasms) as soon as possible. Basic laboratory tests should be ordered including complete blood count, electrolytes (sodium), blood glucose, liver function tests, and toxicology to rule out drug use. If signs of CNS infection are present (fever, nuchal rigidity), consider performing a lumbar puncture. Emergency neuroimaging (usually HCT in acute setting) should also be performed. If the patient continues to be altered or confused or to have focal deficits not explained by neuroimaging or is not at baseline 30 to 60 minutes after a seizure, emergency EEG or continuous video EEG monitoring should be performed to look for subclinical seizures. If there is evidence of provoking factors (sleep deprivation, alcohol or drug use), normal neuroimaging and the patient is back to baseline, then the EEG can be delayed and performed in the outpatient setting. The EEG is important, because some patients with symptomatic seizures can also have epileptiform abnormalities perhaps requiring AED treatment (alcohol withdrawal seizure with focal IEDs coming from area of encephalomalacia due to falls).

Unprovoked seizures are classified into seizures of unknown etiology and seizures with a preexistent brain lesion (remote symptomatic). If the initial workup points to a probable unprovoked seizure, an MRI with epilepsy protocol (3 Tesla MRI with 1- to 3-mm slices and coronal fluid-attenuated inversion recovery sequences) interpreted by a neuroradiologist should be performed to rule out subtle lesions such as cortical dysplasias and mesiotemporal sclerosis, which confer higher risk of development of epilepsy. Also the EEG is of paramount importance to stratify patients at risk for recurrent seizures. The EEG should be performed with sleep deprivation and with activating procedures and as close as possible to the seizure (within 24 hours) to increase the yield of detecting interictal epileptiform abnormalities. There is a 51% chance of recording epileptiform abnormalities if EEG performed 24 hours after a seizure.

Differential Diagnosis

The diagnosis of a seizure or epilepsy can be challenging. There are many paroxysmal conditions, both psychiatric and organic, that may mimic seizures. Of all the seizure mimickers, psychogenic nonepileptic attacks also known as psychogenic nonepileptic seizures are the condition most commonly misdiagnosed as epilepsy. The estimated prevalence of psychogenic nonepileptic attacks is 2 to 33 per 100,000 and most patients are younger females. The clinical history and physical examination usually points to the diagnosis of psychogenic nonepileptic attacks. Red flags include poor control on multiple AEDs with a series of normal EEGs, psychiatric history, unusual triggers such as pain and getting upset, diagnosis of chronic pain syndrome and fibromyalgia, seizures in the outpatient clinics or at doctors visit (presence of an audience), and a never-ending list of symptoms on review of systems. Some of these patients also have history of sexual, emotional, or physical abuse. The physical examination may reveal give-way weakness and histrionic behavior. The "gold standard" for the diagnosis of psychogenic nonepileptic events is continuous video EEG monitoring. The combination of atypical semiology and lack of EEG findings during the paroxysm allows for a definitive diagnosis. Common behaviors seen during a nonepileptic paroxysmal event include position of convenience, ictal eye closure, retained awareness with bilateral motor features resembling a convulsive event, opisthotonic posturing (arched back), pelvic thrusting, crying/weeping, ictal stuttering, baby talk, side-to-side head movements, pseudo-sleep, irregular out-of-phase motor activity (like a fish out of water), gradual onset and termination, prolonged attacks, and stop-and-go phenomena.

Syncopal events are the second most common paroxysmal event misdiagnosed as seizures. Syncope represents a transient lack of blood flow to the brain. Some features are helpful in differentiating syncope from true seizures, and these include prodromal symptoms of general malaise, sweating, dizziness, nausea, palpitations and chest pain, and loss of consciousness with rapid recovery after hitting the ground due to rapid brain reperfusion. The challenging part is the fact that many syncopal events show "convulsive-like" behavior such as clonic phenomena, making the diagnosis more challenging. Syncopal attacks are usually shorter than typical convulsive seizures and recovery is faster with no post-ictal state and usually no tongue-bites or urinary incontinence a feature commonly seen in true convulsive seizures. The most common type of syncope is vasovagal and is precipitated by some situations such as pain and sight of blood. The other type is reflex syncope due to micturition, cough, Valsalva maneuver, and defecation. The EEG shows a typical progression of generalized slowing followed by suppression without any associated ictal features. Cardiac mechanisms should be explored because some could be life-threatening (e.g., Brugada syndrome or other arrhythmias) and requires immediate intervention.

Migraines, especially complicated migraines, and migraine auras cause positive focal symptoms such as visual auras, sensorimotor phenomena and weakness, which could potentially mimic partial seizures. The course, however, for migraines is in the range of minutes and of seizures in the range of seconds. A complicated migraine may be misdiagnosed as Todd's paralysis. Patients with migraines do have history of headaches and retained awareness during the attack; these two features favor the diagnosis of migraines headaches.

Transient ischemic attacks or TIAs should not be misdiagnosed as seizures because this entity has marked focal negative phenomena (weakness, numbness, aphasia), whereas seizures present mostly positive phenomena (movement, automatisms, jerking). Positive symptoms rarely occur during TIAs (limb-shaking TIA).

Other conditions that may mimic seizures include hypoglycemia, panic attacks, paroxysmal movement disorders, nonepileptic myoclonus, sleep disorders, parasomnias, cataplexia, hypnic jerks. It is important therefore to obtain a detailed history, followed by continuous video-EEG monitoring to try to capture these events for final diagnostic purposes, because it is not uncommon to misdiagnose and mislabel these conditions as epilepsy.

Treatment

Treatment should be initiated only if the potential benefit from treatment exceeds the potential for harm. In general, if the patient has an acute symptomatic seizure, treatment with antiepileptic drugs is usually not necessary because these seizures are caused by a transient and reversible precipitating factor. In these cases it is best to treat the provoking factor (discontinue an offending drug or treating electrolyte abnormality) or allow sufficient time for the acute provoking etiology to resolve.

If an acute symptomatic cause cannot be found, then it is possible that the patient's seizure represents the first unprovoked seizure of an underlying epileptic disorder. About 150,000 adults will have an unprovoked first seizure. Unprovoked seizures are classified into remote symptomatic seizures (preexistent brain lesion) or seizures of unknown etiology. The rate of seizure recurrence after an unprovoked single seizure ranges from 31% to 56% over 2 to 5 years, and most patients will experience a recurrence in the first year. Seizure recurrence rates are significantly higher if there is a prior brain insult (twofold increase), if the EEG shows epileptiform abnormalities, if there is an abnormality on neuroimaging, and if the seizure occurs out of sleep (nocturnal seizure). If any of the aforementioned factors are present, then AED treatment may be warranted. If AED treatment is recommended, then patients should be advised that the risk of side effects will range between 7% to 31%, and these are mild and reversible. Patients should be informed that immediate AED therapy will reduce the risk of seizure recurrence in the first 2 years after the seizure but will not improve the long-term (>3 years) chance of attaining seizure remission. Also a single seizure can potentially be treated if the consequences of a recurrent seizure will significantly impact quality of life such as driving, work, or general safety. If two or more unprovoked seizures separated by 24 hours occur or if seizure recurrence risk is equal to 60% or more after a single event, then epilepsy is diagnosed, and AED treatment is strongly recommended.

The goal of therapy is complete seizure freedom with no side effects. Around 50% to 60% of patients become seizure free on a single drug. Unfortunately this is not possible in 30% to 40% of patients, necessitating referral to epilepsy centers for evaluation to rule out seizure imitators, evaluate for the presence of possible surgically remediable syndromes, and to try other options including diets and or devices (vagal nerve stimulator, responsive nerve stimulator).

When starting AED treatment always choose the medication that is effective for the seizure type or epilepsy syndrome. Of all the available AEDs, there are five that have a "broad spectrum" of action (work for both focal and generalized seizures): valproate (Depakote), lamotrigine (Lamictal), levetiracetam (Keppra), topiramate (Topamax), and zonisamide (Zonegran).¹ Consider a broad-spectrum AED if the type of seizure is unknown. All of the available AEDs are effective against focal seizures except ethosuximide (Zarontin); this medication is only effective in the treatment of typical absence epilepsy.

Next, consider the side effect profile, cost, and drug dosing schedule, and adapt to the unique patient characteristics, taking into consideration the patient comorbidities (Table 1 and 2). For example, drugs with a once-a-day schedule are optimal for patients with history of prior poor compliance and for the elderly; in patients taking multiple drugs for other comorbidities, administration of liver enzyme inducers (phenytoin) should be avoided. If the patient suffers from obesity, topiramate should be considered. In patients with migraine, either valproate or topiramate should be considered because these drugs are also effective for migraine prophylaxis.

Aim for monotherapy whenever possible to decrease side effects and drug interactions. Begin titration with a low dose and increase slowly to maximize compliance and decrease side effects. If mild side effects occur, reassure the patient, because most are usually transient.

Increase AED dose until seizure freedom is achieved or until side effects occur. If side effects occur, decrease dose to the maximum tolerated dose. When switching from one AED to another, always overlap the medications. For example, if a new medication is added, consider titrating to effective dose before decreasing the failed medication. This approach provides with some protection against breakthrough seizures during medication transitions.

If polytherapy is needed, consider AEDs with different mechanism of actions (rational polytherapy); for example, a sodium channel blocker with a GABA enhancer or synergistic mechanisms (e.g., valproate and lamotrigine). Consider medications with parenteral formulations and a rapid time to therapeutic onset for rapid control of seizures if you want to discharge the patient from the ED with an adequate therapeutic dose. Drug levels should be obtained when compliance is an issue. Medications drug levels are a guide and not a goal. Always follow the patient's clinical response to AEDs.

In general it is reasonable to consider AED discontinuation in patients who have been seizure free for 2 years. The reported relapse rates after stopping AEDs is around 41% or less. Factors associated with higher relapse include symptomatic epilepsy, age of onset between 10 to 12 years, cognitive delay, abnormal neurologic examination, juvenile myoclonic epilepsy, symptomatic partial epilepsy, abnormal EEG, family history of seizures or epilepsy, poor initial response to drug and more than 1 drug before discontinuation. If epileptiform abnormalities are seen and there is worsening of the EEG (increased EEG abnormalities) during discontinuation, then relapse rates are higher. Therefore consider performing EEG before and after AED discontinuation.

Characteristics of Specific Antiepileptic Drugs

Phenytoin

Phenytoin (Dilantin) is one of the most used antiepileptic medications. It is effective in the treatment of focal seizures and generalized seizures, prophylaxis after neurosurgical procedures, and status epilepticus that do not respond to benzodiazepines. It can exacerbate absence seizures and myoclonus. Phenytoin exerts its antiepileptic effect by blocking sodium channels, thereby preventing post-tetanic potentiation. It is metabolized by the cytochrome P-450 enzyme in the liver and follows 0 order or nonlinear kinetics, and therefore very steep elevations in blood levels can occur with minimal drug increases when the blood level is close to 20 µg/mL. Idiosyncratic reactions include blood dyscrasias and hepatitis, but these are rare. Common cumulative side effects include gum hyperplasia, coarsening of facial features, hirsutism, ataxia caused by cerebellar degeneration, nystagmus, drowsiness, lethargy, rash, headaches, nausea, vomiting, bone marrow hypoplasia, vitamin K and folate deficiency, and osteoporosis. Phenytoin is a strong inducer of hepatic enzymes, and it alters the metabolism of other drugs.

Fosphenytoin sodium (Cerebyx) is a prodrug, with phenytoin as its active metabolite. This medication is intended for parenteral administration; it is better tolerated than parenteral phenytoin because it is an aqueous solution with neutral a pH and can be administered three times as fast as phenytoin (150 mg/min vs. 50 mg/min). It has fewer cardiovascular side effects, including less hypotension, because, unlike phenytoin, it is not mixed with polyethylene glycol and it won't cause vein irritation or purple glove syndrome because of its neutral pH.

Carbamazepine

Carbamazepine (Tegretol) is one of the most used AEDs in the world. It has been used in the United States since 1974 for the treatment of focal epilepsies and generalized tonic-clonic seizures. It is highly effective and usually well tolerated. Carbamazepine, like phenytoin, blocks sodium channels. This medication is metabolized in the liver, and the major metabolic pathway is epoxidation to CBZ 10-11-epoxide. This epoxide confers most of the toxicity associated to this drug. It undergoes autoinduction and therefore induces its own metabolism in the first 3 to 5 weeks, and it takes longer to reach steady-state blood levels. Usually the extended-

¹Not FDA approved for this indication.

TABLE 1 Dosage and Side Effect Profile of Commonly Prescribed Antiepileptic Drugs

DRUG	HALF-LIFE	INITIAL DOSAGE	MAINTENANCE DOSAGE	INCREMENT	DOSING SCHEDULE	ADVERSE EFFECTS
Carbamazepine (Tegretol)	12–17 h	200 mg BID	600–1800 ³ mg	200 mg q wk	TID–QID	Hyponatremia, leukopenia, rare aplastic anemia and hepatitis
Gabapentin (Neurontin)	5–7 h	300 mg QD	1200–3600 mg	300 mg q3–7 d	TID	60% removed by hemodialysis, prolonged half-life to 51 h with hemodialysis Dosed 300 mg after hemodialysis
Lacosamide (Vimpat)	13 h	50 mg QD	300–600 mg ³	100 mg q wk	BID	Extra 50% of dose after each hemodialysis Can prolong PR interval at high doses
Lamotrigine (Lamictal)	25 h alone; 60 h with VPA	6.25–12.5 mg QD to QOD	400 mg alone 100 mg with VPA	12.5–25 mg	BID q2 wk	Life-threatening rash, especially with rapid titration and VPA Titration and maintenance doses vary based on other AEDs
Levetiracetam (Keppra)	7 h	500 mg QD	2000–4000 ³ mg	500 mg q wk	BID	Decrease dose in chronic renal insufficiency, severe hepatic disease
Oxcarbazepine (Trileptal)	9–11 h	300 mg QD	900–2400 mg	300 mg q wk	BID	Hyponatremia Fewer side effects than carbamazepine
Phenobarbital	80–100 h	30–60 mg QD	60–120 mg	30 mg q1–2 wk	QD–BID	Sedation, Dupuytren's contractures, rebound seizures with rapid tapering
Phenytoin (Dilantin)	22 h	200 mg QD	200–300 mg	100 mg q wk	QD–BID	Gum hypertrophy, hirsutism, cerebellar ataxia or atrophy, peripheral neuropathy, rare hypersensitivity, hepatitis
Pregabalin (Lyrica)	6 h	50 mg QD	150–600 mg	50 mg q3–7d	BID–TID	Weight gain
Topiramate (Topamax)	21 h	25 mg QD	200–400 mg	25 mg q1–2 wk	BID	Cognitive impairment at > 400 mg/day, rare kidney stones, glaucoma, oligohidrosis
Valproic acid (Depakene)	9–16 h	250 mg QD	750–3000 mg	250 mg q3–7 d	TID–QID	Tremor, weight gain, alopecia, thrombocytopenia Rare hepatitis and pancreatitis Risk of teratogenesis and neural tube defects
Zonisamide (Zonegran)	63 h	100 mg QD	200–400 mg	100 mg q2 wk	BID	Kidney stones, oligohidrosis, rare blood dyscrasias

³Exceeds dosage recommended by the manufacturer.

Abbreviations: AED = antiepileptic drug; BID = 2 times daily; q = every; QD = every day; QID = 4 times daily; QOD = every other day; TID = 3 times daily; VPA = valproic acid.

release formulations (Carbatrol and Tegretol XR) are better tolerated than the immediate-release formulations. Idiosyncratic side effects are rare and include aplastic anemia, agranulocytosis, hyponatremia, thrombocytopenia, hepatitis, and Stevens-Johnson syndrome. White blood cell counts may drop mildly and do not require intervention unless the level drops below 3000 per mm³. Dose-related side effects include diplopia, dizziness, nausea, and ataxia.

Phenobarbital

Phenobarbital (Luminal) is the most commonly used AED of the twentieth century. It is inexpensive and long acting, but due to the poor side effect profile, it has fallen out of favor for newer AEDs. It is used for the treatment of focal-onset, generalized seizures and neonatal seizures.¹ It is a barbiturate and acts on the GABA-A barbiturate binding site and therefore prolongs the

duration of calcium channel opening stabilizing neuronal membranes. It has a very long half-life (70–120 hours) in adults and therefore is suitable for once-a-day administration. It is a powerful inducer of microsomal liver enzymes. Side effects include cognitive problems, sedation, psychomotor slowing, depression, coarsening of facial features, osteopenia, folic acid deficiency, Dupuytren's contractures, megaloblastic anemia, and hepatitis (autoimmune reaction). Withdrawal of this medication should be performed very slowly because of the high risk of withdrawal seizures.

Primidone (Mysoline) is metabolized to phenobarbital (main active metabolite) and phenylethylmalonamide. It is a second-line agent used for the treatment of focal seizures and secondary generalized seizures, and the side-effect profile is similar to phenobarbital.

Valproic Acid

Valproic acid (Depakene) and its sodium salt divalproex (Depakote) are “broad-spectrum” medications and the drugs of choice for the treatment of primary generalized epilepsies such as juvenile

¹Not FDA approved for this indication.

TABLE 2 Choice of Antiepileptic Drug in Special Situations

SPECIAL SITUATION	DRUG OF CHOICE	COMMENTS
Partial seizures	Carbamazepine, lamotrigine, levetiracetam, oxcarbazepine, topiramate, gabapentin	
Refractory partial seizures	Lacosamide, pregabalin, zonisamide	Second-line treatment
Generalized epilepsies	Lamotrigine, topiramate, valproic acid, ¹ zonisamide ¹	Avoid valproic acid in women
Absence seizures	Ethosuximide, lamotrigine, ¹ valproic acid, topiramate ¹	Ethosuximide is the choice for only pure absence seizures and is insufficient in other associated generalized tonic-clonic or myoclonic seizures
Juvenile myoclonic epilepsy	Valproic acid, ¹ topiramate, ¹ lamotrigine, ¹ zonisamide, ¹ levetiracetam	Avoid valproic acid in women
Myoclonic seizures	Clonazepam, valproic acid, ¹ levetiracetam	Lamotrigine occasionally exacerbates myoclonic seizures
Women of childbearing potential	Lamotrigine, topiramate, levetiracetam, oxcarbazepine	Avoid enzyme-inducing agents that alter steroid hormones and OCP levels; use OCPs with ≥ 50 μ g of estrogen; OCPs increase the elimination of lamotrigine Significant increased risk of teratogenicity with valproic acid
Elderly patients	Lamotrigine, gabapentin, levetiracetam, topiramate	Avoid polypharmacy and highly protein-bound AEDs and AEDs with high drug-drug interactions
Depression	Lamotrigine, ¹ topiramate ¹	
Bipolar disorder	Valproic acid, ¹ carbamazepine, lamotrigine, topiramate ¹	
Migraine	Valproic acid, topiramate	Consider the choice according to sex, side effect profile, and seizure type
Chronic pain	Pregabalin, ¹ gabapentin ¹	
Neuropathic pain	Carbamazepine, ¹ gabapentin, ¹ pregabalin	

¹Not FDA approved for this indication.

Abbreviations: AED = antiepileptic drug; OCP = oral contraceptive pill.

myoclonic epilepsy,¹ absence epilepsy, photosensitive epilepsy, Lennox-Gastaut Syndrome (LGS),¹ and second-line in epileptic spasms; it is also approved for the treatment of focal-onset epilepsies, although higher doses are needed to treat focal epilepsy. A parenteral form (Depacon) is available for the treatment of status epilepticus.¹ It works by enhancing GABA function; it may increase GABA by stimulation of glutamate decarboxylase (GAD) and by selective modulation of voltage-gated sodium channels. Divalproex sodium (Depakote) is a powerful inhibitor of both oxidation and glucuronidation. Common side effects include dyspepsia, thinning and curling of hair, weight gain, tremor, rashes, bone marrow suppression, polycystic ovarian syndrome, amenorrhea with anovulatory cycles, thrombocytopenia, hepatitis and pancreatitis which could be life threatening, hyperammonemia, and sedation. Valproic acid should not be given to women of childbearing potential because of the high risk of fetal defects (10%), specifically neural tube defects. Decreased IQ scores have been noted in children whose mothers were treated with valproate during pregnancy.

Ethosuximide

The ethosuximide (Zarontin) mechanism of action is blockade of T-type calcium channels, and it is indicated in the treatment of typical absence epilepsy. This medication will not work to control any other seizure types. Common side effects are minimal and include dyspepsia, nausea, loss of appetite, and tiredness.

Felbamate

Felbamate (Felbatol) is effective in the treatment of multiple seizure types, but because of the occurrence of aplastic anemia and hepatic failure, it was briefly withdrawn from the US market in 1994. It is now available only for patients with intractable seizures in whom other medications have failed and when benefits outweigh the risks. Its mechanism of action is blockade of NMDA receptors, modulation of sodium channels, and blockade of calcium channels. The risk for hepatic failure is 14 of 110,000 patients and increases with polytherapy.

Gabapentin

Gabapentin (Neurontin) is similar to the structure of GABA but has no effect on the GABA receptor. It enhances GAD, thereby increasing levels of GABA. This medication has no drug interactions. It is excreted entirely unchanged in kidneys. Gabapentin is used for the treatment of focal seizures with or without secondary generalization. It is ineffective in myoclonus and primary generalized seizures, and it is ineffective at lower doses. Dose should be adjusted in patients with renal disease according to creatinine clearance.

Pregabalin

Pregabalin (Lyrica) is an analogue of GABA but, like gabapentin (Neurontin), has no effect on the GABA receptor. It has no drug interactions, and it is usually well tolerated. It has to be dose-adjusted in patients with renal failure, and it is 50% removed after hemodialysis. It is used as an adjunct in adult patients with focal epilepsies. Common side effects include dizziness, drowsiness, weight gain, dry mouth, and edema.

¹Not FDA approved for this indication.

Lamotrigine

Lamotrigine (Lamictal) works by sodium channel blockade and inhibits release of glutamate. It is “broad spectrum,” and it is used for adjunctive treatment of focal-onset seizures with or without secondary generalization, crossover to monotherapy, and in Lennox-Gastaut syndrome. It is also effective in atypical absence,¹ tonic/atonic seizures, and in myoclonic seizures,¹ although it may cause exacerbations in some patients with juvenile myoclonic epilepsy. It is one of the preferred drugs to treat elderly patients and pregnant women because of the good safety and pharmacokinetic profile. Lamotrigine levels should be closely watched and will increase significantly with coadministration of valproate; these two medications cause a synergistic therapeutic effect but could also increase adverse reactions (rash). It could cause a rash (5%) if the drug is titrated too quickly; this rash could progress into a life-threatening condition (Stevens-Johnson syndrome [0.1%]) and is more common in children with concomitant valproate use. If rash occurs, the medication should be stopped immediately. Other common side effects include tremor, insomnia, headaches, ataxia, and somnolence. Pregnancy increases lamotrigine clearance by 50%, necessitating dose adjustments; therefore lamotrigine levels should be monitored before, during, and after pregnancy, and doses should be adjusted accordingly.

Levetiracetam

Levetiracetam (Keppra) is one of the most widely used AEDs because of its good pharmacokinetics, favorable side effect profile, and multiple formulations, including parenteral and liquid (ease of administration). It is a “broad-spectrum” drug. It has a unique mechanism of action (binds to synaptic vesicle protein 2A-SV2A). It does not induce liver enzymes and therefore does not affect the metabolism of other drugs and does not bind to proteins in plasma. This medication needs to be dose-adjusted in patients with renal disease and after hemodialysis (add an extra 500 mg). It is one of the only AEDs that decreases the interictal epileptic burden, the other one being Depakote. It is approved as adjunctive treatment of primary generalized tonic-clonic seizures in adults and children 6 years of age and older with idiopathic generalized epilepsy, adjunctive treatment of focal onset seizures in adults and children 4 years of age and older, and adjunctive treatment of myoclonic seizures in adults and adolescents 12 years or older with juvenile myoclonic epilepsy. It is also used off-label for prophylaxis in patients after traumatic brain injury and in status epilepticus. Common adverse effects include behavioral changes (avoid in patients with psychiatric conditions), somnolence, asthenia, headache, dizziness, and flu-like symptoms. It does not have any serious idiosyncratic reactions and is safe for the elderly and probably safe to take during pregnancy. Consider obtaining levels during pregnancy, because clearance is increased during pregnancy, necessitating dose adjustments.

Brivacetam

Breviracetam (Briviact) is a chemical analog of levetiracetam, with a similar mechanism of action but a higher affinity (20-fold) for the SV2A receptor. It exhibits linear kinetics with a good side effect profile like levetiracetam. It is indicated as adjunct treatment of focal-onset seizures with or without secondary generalization in adults and children aged 16 years and older. It does not have added therapeutic benefit if coadministered with levetiracetam. It may increase serum concentrations of carbamazepine epoxide and phenytoin.

Oxcarbazepine

Oxcarbazepine (Trileptal) is an analogue of carbamazepine but without the toxic epoxide. Thus it is better tolerated than carbamazepine (Tegretol). It is metabolized to 10 monohydroxy metabolite (MHD), which confers its pharmacologic effect. It is used as monotherapy or adjunctive therapy in focal epilepsies in adults and as

monotherapy in the treatment of focal epilepsies in children 4 years and older and as adjunctive in children 2 years and older. It may exacerbate myoclonic seizures and absence seizures. It interacts with oral contraceptives, thereby reducing its efficacy. Hyponatremia is rare in children but may be higher in elderly populations. Other side effects include dizziness, fatigue, and headache, and these are dose dependent. Patient who develop rash with carbamazepine (Tegretol) may develop rash if treated with oxcarbazepine (Trileptal) because of cross-reactivity.

Tiagabine

Tiagabine (Gabitril) works by reversible inhibition of the GABA-transporter-1, thereby increasing the availability of GABA in the synaptic cleft. It is approved as an add-on medication in the treatment of refractory focal-onset seizures. It can worsen absence seizures and cause status epilepticus in patients with primary generalized epilepsy. Common side effects include tremor, nervousness, dizziness, abdominal pain, diarrhea, and emotional lability.

Topiramate

Topiramate (Topamax) is a broad-spectrum AED with multiple mechanisms of action. It works by inhibiting sodium conductance and weakly carbonic anhydrase, blocks the AMPA glutamate receptor, and enhances GABA. It is approved for the treatment of focal-onset seizures or primary generalized epilepsy as add-on and in the treatment of Lennox-Gastaut syndrome. Enzyme inducers (e.g., phenytoin) decrease levels of topiramate by 50%. This medication will need dose adjustments in patients with renal failure. Topiramate (Topamax) reduces the levels of oral contraceptives, thereby decreasing its effectiveness. Common side effects include word finding difficulties, weight loss (decreased appetite), paresthesias in fingers and mouth, kidney stones, and anhidrosis due to the carbonic-anhydrase effect of this drug, acute myopia in close-angle glaucoma, ataxia, and tiredness. Usually doses >400 mg are poorly tolerated.

Zonisamide

Zonisamide (Zonegran) is a “broad-spectrum” AED used in the treatment of focal epilepsy with or without secondary generalization. It is also effective in the treatment of myoclonus (JME)¹ and absence seizures (T-type calcium channel blockade).¹ This AED has a structure similar to the sulfonamides; therefore it is contraindicated in patients with allergies to these antibiotics. It has a long-half life (>60 hours); therefore it can be taken once a day, which increases compliance. The major mechanism of action is by the blockade of sodium channels, it also works on T-type calcium channels and weak inhibition of carbonic anhydrase. Enzyme inducers and valproate (Depakote) decrease half-life. The most common adverse reactions include anorexia with associated weight loss, headache, mental slowing, confusion, ataxia, dizziness, kidney stones (1%) oligohidrosis, and paresthesias (carbonic anhydrase inhibition).

Vigabatrin

Vigabatrin (Sabril) is a structural analogue of GABA and binds irreversibly to the GABA-T (GABA transaminase), thereby increasing GABA concentrations in the brain. It is indicated for treatment of epileptic spasms in tuberous sclerosis¹ and in refractory focal-onset epilepsies. It may exacerbate absence seizures and myoclonic seizures and, like tiagabine, may cause generalized spike-and-wave status epilepticus in patients with absence seizures or primary generalized epilepsy. This AED causes visual field defects (nasal constriction and concentric constriction with preserved central vision), and these may be irreversible. Other side effects include fatigue, dizziness, headache, tremor, and double vision.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Rufinamide

Rufinamide's (Banzel) mechanism of action is probable modulation of sodium channels (prolongation of inactive state of the channel). It is indicated as adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in both children and adults.

Lacosamide

Lacosamide (Vimpat) has a novel mechanism of action by enhancing the slow inactivation of voltage-gated sodium channels. It is approved for the adjunctive treatment and conversion to monotherapy and monotherapy treatment of focal onset epilepsies. It is also used off label for the treatment of status epilepticus in the intensive care unit because of availability of IV formulation. This medication does not have significant drug interactions.

Clobazam

Clobazam (Onfi) is a benzodiazepine with a 1,5 substitution instead of the common 1,4 substitution; therefore it has less anxiolytic and sedative effects. It works by binding to the GABA-A receptor. It is approved for the adjunctive treatment of Lennox-Gastaut syndrome. It may also be effective in the treatment of primary or focal seizures with secondary generalized seizures,¹ as well as catamenial epilepsy.¹ It has no significant clinical interactions. Side effects include sedation, dizziness, ataxia, and weakness. No idiosyncratic reactions have been identified.

Perampanel

Perampanel (Fycompa) is a noncompetitive AMPA receptor antagonist and is indicated in the adjunctive treatment of focal-onset seizures with or without secondary generalization and in primary generalized seizures in adults and adolescents 12 years of age and over. The recommended dose is 8 to 12 mg/d for focal seizures and 8 mg/d for primary generalized seizures. This medication has a black box warning because of severe psychiatric and behavioral reactions (aggressiveness, suicidality, homicidal threats and ideations, and irritability). Common adverse effects include somnolence, headache, dizziness, and fatigue.

Eslicarbazepine

Eslicarbazepine (Aptiom) is a prodrug to *s*-licarbazepine with a mechanism of action similar to oxcarbazepine (Trileptal) sodium channel blockade. It is approved as monotherapy or adjunct therapy for the treatment of focal-onset seizures. Common adverse effects include dizziness, nausea, diplopia, and headache.

Cannabidiol

Cannabidiol, also known as CBD oil,² is a phytocannabinoid and is one of more than 100 active components found in cannabis. A double-blinded, randomized, placebo-controlled study of CBD oil found that it was effective in the treatment of Dravet syndrome.¹ The study found that the median frequency of convulsive seizures per month decreased from 12.4 to 5.9 with the cannabidiol group compared with a decrease from 14.9 to 14.1 in the placebo group. Common side effects included abnormal liver function tests, vomiting, diarrhea, and fatigue.

Special Populations

Women

Epilepsy is one of the most common conditions occurring in women of reproductive age (1.1 million). Women of reproductive age and with epilepsy and taking AEDs should be counseled on the possibility of teratogenicity from AED therapy and the potential interaction with contraception. Some AEDs (enzyme inducers) affect oral contraceptives (OCPs), leading to decreased effectiveness and unwanted pregnancies. These AEDs are phenobarbital, phenytoin, carbamazepine, oxcarbazepine, eslicarbazepine,

felbamate, topiramate (at higher doses greater than 200 mg/d), lamotrigine (doses greater than 300 mg/d), primidone, rufinamide, and clobazam. OCPs can reduce the levels of lamotrigine, leading to breakthrough seizures. In patients taking these AEDs, a second barrier method versus changing to a non-enzyme-inducing AED is recommended. Seizures during pregnancy will remain the same or decrease, but around 15% to 30% will have an increase in seizure frequency. Most (84%–92%) women with epilepsy who were seizure free 9 months before pregnancy will remain free of seizures during the pregnancy. Blood levels of lamotrigine, phenytoin, and, to a lesser extent, carbamazepine, and possibly levetiracetam and the active oxcarbazepine metabolite (MHD), will decrease during pregnancy because of increased clearance, and therefore these AED levels should be monitored and medication dosages adjusted as needed. The risk from seizures to the fetus (especially convulsive seizures) is higher than the risk to the fetus from AEDs. More than 90% of female patients with epilepsy will deliver a normal baby. The rates of congenital malformations in women with epilepsy taking AEDs is around 4% to 6% (double that of general population) but remain low. Risk of malformations increases with polytherapy and with higher dose of AEDs. Valproate/valproic acid is the AED that carries the highest teratogenicity (6%–10%), mostly associated with neural tube defects. It also produces long-term cognitive problems, with a reduction in children's IQs when mothers take valproate (Depakote) during pregnancy. Therefore valproic acid is contraindicated and should not be used as a first-line treatment in women of childbearing potential. Women with epilepsy and of childbearing potential should be supplemented with folic acid at a dose of 0.4 mg/d to decrease the risk of congenital malformations if they become pregnant. Breastfeeding is an important concern in the postpartum period in women taking AEDs. Even though some AEDs (e.g., primidone and levetiracetam) transfer into breast milk, breastfeeding is encouraged. The baby should be monitored for increased sedation if mothers are on those two AEDs.

Elderly Patient

The current world population is aging, and the risk for epilepsy increases dramatically after the age of 65. The recognition of seizures in this group may be more complicated because the presentation may be atypical. Also, many other conditions may mimic seizures in the elderly, making diagnosis a challenging proposition. The most common seizure type in the elderly is complex partial seizures and present with confusion, staring, change in mental status, and unresponsiveness. The most common cause of epilepsy in this group is cerebrovascular disease. Other conditions that may cause epilepsy include neurodegenerative conditions (Alzheimer's disease), head trauma, and brain tumors. When treating elderly patients, pharmacokinetic and pharmacodynamic properties of medications should be considered. Older people have reductions in protein binding, renal elimination, and hepatic metabolism, thereby conferring a higher risk for idiosyncratic reactions and altered kinetics. Gabapentin, lamotrigine, levetiracetam, pregabalin, and oxcarbazepine are usually well tolerated and recommended as first-line treatment in this patient population. AEDs with hepatic enzyme-inducing mechanisms are not recommended in elderly patients because of the potential for interactions with other drugs. Fortunately seizures in this population are easy to control, and monotherapy is usually effective.

Pharmacoresistant or Intractable Epilepsy

At least two AEDs will fail in monotherapy or polytherapy in 30% of patients with epilepsy, fulfilling the criteria for pharmacoresistance. These patients should be referred to an epilepsy center for further management, including evaluation by an epileptologist who will perform a detailed clinical and physical examination and will order further diagnostic tests including video EEG monitoring to record the patient's events for final diagnostic purposes and for evaluation for possible epilepsy surgery. Surgical resection of the epilepsy focus is the only available

¹Not FDA approved for this indication.

²Not available in the United States.

treatment to cure epilepsy. Seizure freedom rates after temporal lobectomy for mesiotemporal sclerosis is in the range of 70% to 90% and of 40% to 70% in neocortical resections. In patients who are not suitable candidates for epilepsy, surgery treatment with diets or neurostimulation is recommended. Dietary options include the ketogenic diet, the modified Atkin's diet, and the low glycemic index diet.

These diets can be used as an add-on therapy in combination with AEDs and devices (vagus nerve stimulator). These diets have a similar seizure reduction rates (around 50%) in half of patients. The low glycemic index diet is better tolerated and less restrictive than the modified Atkin's diet and the classic ketogenic diet.

Devices approved for the treatment of pharmacoresistant epilepsy in the United States include the vagus nerve stimulator (VNS) and the responsive nerve stimulator (RNS). The VNS works by delivering an intermittent mild current to the left vagus nerve. The mechanism of action is unknown but believed to include alterations in the reticular activating system, the central autonomic network, the limbic system, and the diffuse noradrenergic projection system. With long-term use, this device provides seizure reductions of around 50% in half of patients treated, with around 10% becoming seizure free. The new AspireSR generator combines traditional VNS therapy with seizure detection technology via changes in cardiac rhythms.

Responsive neurostimulation or RNS therapy (Neuropace) was approved by the Food and Drug Administration in 2013 for the treatment of refractory focal-onset seizures. This device continuously monitors and detects abnormal electrical activity that can lead to a seizure and then delivers electrical stimulation to the area of seizure generation to try to abort the seizure. It has two leads, and either subdural or depth electrodes or a combination of both can be used and placed close or over the epileptogenic zone. These leads are connected to the generator that seats on the skull. Treatment with the RNS system is recommended in patients who are not amenable to surgery and have multifocal epilepsy with no more than two discrete seizure onset zones. The median seizure reduction at 5 years was >65%, with 15% of patients achieving seizure freedom.

SLEEP DISORDERS

Method of

Meghna P. Mansukhani, MD; Bhanu Prakash Kolla, MD, MRCPsych; Erik Kent St. Louis, MD; and Timothy I. Morgenthaler, MD

Sleep is a universal biological imperative for all mammals. Sleep deprivation and sleep disorders are frequent and underappreciated determinants of health status. Sleep is essential for survival, and sleep loss and sleep disorders are associated with major health problems, including cardiovascular, metabolic, neuropsychiatric, and neoplastic disorders, as well as neurobehavioral-associated accidents and risks. Healthy sleep must be regarded along with nutrition and exercise as key pillars for good health.

Recent evidence has suggested that a chief purpose of sleep may be to maintain cerebral metabolic homeostasis, clearing waste products that accumulate during wakefulness such as beta-amyloid, a protein known to abnormally accumulate in Alzheimer's disease. Insufficient sleep quantity appears to be associated with a variety of health problems and may contribute to mortality and dementia risk. Total sleep deprivation, as well as selective deprivation of nonrapid eye movement (NREM) or rapid eye movement (REM) sleep, may be lethal in laboratory animals. Adequate sleep quality is similarly necessary to ensure optimal daytime functioning because basic vigilance, attention and cognitive performance, and overall quality of life are each substantially eroded by disordered sleep, and insufficient sleep and sleep-disordered breathing (SDB) pose significant health hazards. Unfortunately, insufficient sleep quantity and quality is a widespread public health crisis in children and adults worldwide in the developed world, and primary sleep disorders are a highly prevalent cause of morbidity, an important contributor to mortality, and a public health hazard that raises risk for motor vehicle collisions and catastrophic occupational injuries and accidents.

The clinical specialty of sleep medicine initially emerged during the 1970s and 1980s, surrounding growing clinical application of diagnostic polysomnography (PSG). While the main diagnostic use remains evaluation and initial treatment for SDB, PSG and related techniques have tremendous utility for the evaluation of selected patients with nocturnal events, periodic limb movement disorder (PLMD), narcolepsy and related primary central nervous system (CNS) hypersomnias.

In this chapter, we review the classification of common sleep disorders, a practical bedside approach toward interviewing and examining patients with sleep problems, advantages and limitations of diagnostic implements within the sleep laboratory, and summarize diagnostic and therapeutic approaches to common sleep disorders.

The International Classification of Sleep Disorders

The International Classification of Sleep Disorders (ICSD) provides a common nomenclature and taxonomy for disorders of sleep for clinicians and researchers alike. The most current ICSD, ICSD-3, divides sleep disorders into six distinct categories. The ICSD-3 nomenclature is shown in [Box 1](#), and the most common sleep complaints and disorders are presented and discussed in detail throughout this chapter.

Clinical Approach to the Sleep Medicine Patient: The Interview and Examination

The three most common clinical presenting sleep-related complaints are hypersomnia, insomnia, and unusual behaviors or events at night (parasomnias). Hypersomnia, which is excessive sleepiness during waking hours, is often multifactorial and may be related to insufficient sleep quantity, quality, or timing; SDB; sedating medications; or certain medical, psychiatric, or neurologic conditions. Insomnia may be regarded as a problem in initiating or maintaining sleep under conditions that are normally conducive to sleep. Parasomnias are unusual behaviors that are often dangerous to the patient or bed partner during sleep.

treatment to cure epilepsy. Seizure freedom rates after temporal lobectomy for mesiotemporal sclerosis is in the range of 70% to 90% and of 40% to 70% in neocortical resections. In patients who are not suitable candidates for epilepsy, surgery treatment with diets or neurostimulation is recommended. Dietary options include the ketogenic diet, the modified Atkin's diet, and the low glycemic index diet.

These diets can be used as an add-on therapy in combination with AEDs and devices (vagus nerve stimulator). These diets have a similar seizure reduction rates (around 50%) in half of patients. The International Classification of Sleep Disorders

The International Classification of Sleep Disorders (ICSD) provides a common nomenclature and taxonomy for disorders of sleep for clinicians and researchers alike. The most current ICSD, ICSD-3, divides sleep disorders into six distinct categories. The ICSD-3 nomenclature is shown in [Box 1](#), and the most common sleep complaints and disorders are presented and discussed in detail throughout this chapter.

Clinical Approach to the Sleep Medicine Patient: The Interview and Examination

The three most common clinical presenting sleep-related complaints are hypersomnia, insomnia, and unusual behaviors or events at night (parasomnias). Hypersomnia, which is excessive sleepiness during waking hours, is often multifactorial and may be related to insufficient sleep quantity, quality, or timing; SDB; sedating medications; or certain medical, psychiatric, or neurologic conditions. Insomnia may be regarded as a problem in initiating or maintaining sleep under conditions that are normally conducive to sleep. Parasomnias are unusual behaviors that are often dangerous to the patient or bed partner during sleep.

Insomnia

- Chronic insomnia disorder
- Short-term insomnia disorder
- Other insomnia disorder
- Isolated symptoms and normal variants
- Excessive time in bed
- Short sleeper

Sleep-Related Breathing Disorders

The continuum of obstructive sleep-disordered breathing: snoring, Upper-airway resistance syndrome, and obstructive sleep apnea (OSA)

Obstructive sleep apnea (OSA) disorders

- OSA, adult
- OSA, pediatric

Central sleep apnea syndromes

- Central sleep apnea with Cheyne-Stokes breathing
- Central apnea due to medical disorder without Cheyne-Stokes breathing
- Central sleep apnea due to high altitude periodic breathing
- Central sleep apnea due to a medication or substance
- Primary central sleep apnea
- Primary central sleep apnea of infancy
- Primary central sleep apnea of prematurity
- Treatment-emergent central sleep apnea

Sleep-related hypoventilation disorders

- Obesity hypoventilation syndrome
- Congenital central alveolar hypoventilation syndrome
- Late-onset central hypoventilation with hypothalamic dysfunction
- Idiopathic central alveolar hypoventilation
- Sleep-related hypoventilation due to a medication or substance
- Sleep-related hypoventilation due to a medical disorder
- Sleep-related hypoxemia disorder

Isolated symptoms and normal variants

- Snoring
- Catathrenia

Central Disorders of Hypersomnolence

- Narcolepsy Type I
- Narcolepsy Type II
- Idiopathic hypersomnia
- Kleine-Levin syndrome
- Hypersomnia due to a medical disorder
- Hypersomnia due to a medication or substance
- Hypersomnia associated with a psychiatric disorder
- Insufficient sleep syndrome

Isolated symptoms and normal variants

- Long sleeper

Circadian Rhythm Sleep-Wake Disorders

- Delayed sleep-wake phase disorder
- Advanced sleep-wake phase disorder

- Irregular sleep-wake rhythm disorder
- Non-24-hour sleep-wake rhythm disorder
- Shift work disorder
- Jet lag disorder
- Circadian rhythm sleep-wake disorder not otherwise specified

Parasomnias

NREM-related parasomnias

- Disorders of arousal (from NREM sleep)
- Confusional arousals
- Sleepwalking
- Sleep terrors
- Sleep-related eating disorder

REM-related parasomnias

- REM sleep behavior disorder
- Recurrent isolated sleep paralysis
- Nightmare disorder

Other parasomnias

- Exploding head syndrome
- Sleep-related hallucinations
- Sleep enuresis
- Parasomnia due to a medical disorder
- Parasomnia due to a medication or substance
- Parasomnia, unspecified
- Isolated symptoms and normal variants
- Sleep talking

Sleep-Related Movement Disorders

- Restless legs syndrome
- Periodic limb movement disorder
- Sleep-related leg cramps
- Sleep-related bruxism
- Sleep-related rhythmic movement disorder
- Benign sleep myoclonus of infancy
- Propriospinal myoclonus at sleep onset
- Sleep-related movement disorder due to a medical disorder
- Sleep-related movement disorder due to a medication or substance
- Sleep-related movement disorder, unspecified

Isolated symptoms and normal variants

- Excessive fragmentary myoclonus
- Hypnagogic foot tremor and alternating leg muscle activation
- Sleep starts (hypnic jerks)

Other Sleep Disorders

- Fatal familial insomnia
- Sleep-related epilepsy
- Sleep-related headaches
- Sleep-related laryngospasm
- Sleep-related gastroesophageal reflux
- Sleep-related myocardial ischemia

Abbreviations: CNS = central nervous system; NREM = non-rapid eye movement [sleep]; REM = rapid eye movement [sleep].

Insomnia is a subjective complaint. To some patients it is not at all bothersome to require 20 to 30 minutes to fall asleep, while to others it seems very wrong. While insomnia is fundamentally a subjective symptom, the manifestations follow common patterns. Sleep latency, the time taken to fall asleep, varies significantly, but initial sleep latency longer than 30 minutes may be considered prolonged, once proper sleep-conductive conditions have been established (lights off, dark and quiet sleep environment without distracting stimuli). There is also significant variation in what degree of subjective sleep disruption reflects sleep-maintenance insomnia, as normal individuals may briefly awaken as often as

10 to 15 times each hour, with most such arousals being below the threshold of conscious awareness. Multiple nocturnal awakenings that are disturbing to the patient, especially when there is difficulty reinitiating sleep and prolonged wake after sleep-onset time, may be regarded as sleep-maintenance insomnia. Patients admitting to insomnia should be asked to estimate what amount of their problem is ascribable to an active mind or worries, restless legs, or body pain. Disturbing influences in the sleep environment such as the ambient light, temperature, and noise conditions in the bedroom should be sought. A precise diagnosis is not possible without detailed knowledge of sleep and wake behavior over the entire

circadian cycle during a more protracted time, such as 1 to 2 weeks. A sleep diary can be very helpful in gaining needed insights for diagnosis. Increasingly, helpful information about timing and duration of sleep may be logged in applications for personal mobile computing devices.

The patient and physician may at times have difficulty differentiating between hypersomnia and complaints of fatigue (a sense of lacking enough energy to carry out usual daily activities, without the tendency toward dozing or nodding off inadvertently). A quick, incisive bedside test that helps distinguish between hypersomnia and fatigue is the Epworth Sleepiness Scale (ESS), a short questionnaire asking the patient his or her likelihood of dozing inadvertently during usual permissive daytime sedentary settings including reading, watching television, or traveling in a car. An online version is available at <http://www.stanford.edu/~dement/epworth.html>. Scores over 10 are considered abnormal and indicative of a possible underlying primary sleep disorder and suggest the need for further evaluation. Complaints of hypersomnia must be placed into the context of the sleep history with particular emphasis on the quantity, timing, and quality of sleep.

Patients may also present with complaints of disturbing or unusual activities during sleep (parasomnias). Key diagnostic points in determining the diagnosis for parasomnias include their onset, duration, frequency, time of night, stereotypy, injuries sustained, and whether there is any further behavioral change following the parasomnia episode.

Collateral history obtained from a bed partner may be particularly instructive. Patients should be asked whether they are reported to snore, whether the snoring is intermittent or constant, and if the snoring volume is related to sleeping in a supine position. Disruptive snoring loud enough to be heard outside a closed bedroom door, or witnessed stop-breathing episodes indicating apnea or self-awareness of arousals related to a snort or gasp, are particularly suggestive symptoms of obstructive sleep apnea (OSA). Symptoms such as morning dry mouth and sore throat, frequent morning headaches, or heartburn may indicate a higher likelihood of significant SDB. Patients should be asked about awareness of restless legs symptoms or movements during sleep, and whether they have been told of peculiar sleep-related behaviors or evidence of acting out their dreams, yelling or thrashing in sleep, or exhibiting sleep walking or other amnesic behaviors during sleep.

In addition to a detailed sleep history, taking a thorough general medical history is important because sleep disorders are frequently tightly linked to other diseases. OSA is closely associated with hypertension, coronary artery disease, cerebrovascular disease, atrial fibrillation, obesity, and the metabolic syndrome. Congestive heart failure, even when well compensated, is frequently associated with central sleep apnea syndrome. Restless legs syndrome and periodic limb movements in sleep (PLMS) are more common in patients with systemic iron deficiency or renal impairment, or in those with spinal cord or peripheral nerve pathologies. Hypoventilation is more prevalent in patients with neuromuscular disease; advanced obstructive lung disease; kyphosis; and in traumatic, vascular, neoplastic, or degenerative disorders that affect the medullary centers of the brain. Various genetic syndromes such as trisomy-21 produce craniofacial abnormalities predisposing to OSA due to anatomic narrowing of the upper airway.

Physical examination in sleep medicine focuses on signs indicating predisposition or associated sequelae of SDB. Careful inspection of the oropharynx and nares is particularly important because significant oropharyngeal narrowing is the chief anatomic substrate for obstructive SDB, while nasal septal deviation or other nasal obstruction, in addition to a thickened neck and overweight body habitus, may also contribute toward sleep apnea. Careful inspection for signs of neuromuscular disease, such as weakness of cervical flexor or extensor muscles, fasciculations or thoracoabdominal paradox, may help detect the underlying cause for sleep-related hypoventilation. Elevated blood pressure, a cardiac gallop, wet rales, and peripheral edema may be present as signs of systemic hypertension, heart failure, or cor pulmonale associated with untreated SDB.

Diagnostic Tools in the Sleep Laboratory

Polysomnography

Laboratory polysomnography (PSG) is the “gold standard” for formal assessment of suspected SDB, hypersomnia, or parasomnias. PSG is a diagnostic test most often performed in a sleep laboratory; attended by trained technicians; and combining evaluation of sleep, breathing, and movement. During PSG, several polygraphic physiologic variables are analyzed, including electroencephalography (EEG) as well as chin electromyography (EMG) to allow determination of sleep staging, limb EMG leads to analyze periodic leg movements that may disrupt sleep, oronasal airflow measured by a thermistor and nasal pressure sensors, electrocardiography, and respiratory effort measured by inductance plethysmography or piezocrystal monitors. Body position is also analyzed to delineate effects of sleeping position on breathing.

Each 30-second epoch of the PSG is subsequently scored by a sleep technologist as either wake, NREM sleep (N1 or N2 light NREM, or N3 slow wave sleep), or REM sleep according to well-defined guidelines. Sleep architecture, or the composition of sleep by different stages, varies greatly by age, but in middle-aged adults is approximately 60% to 75% N1-N2, 10% to 20% N3, and 15% to 25% REM sleep. Children usually have higher, and elderly individuals have lower, percentages of N3 and REM. Arousals from sleep and their mechanisms, whether due to breathing, movement, or spontaneous causes, are determined. Accordingly, a precise determination of the duration of a patient's total sleep time, sleep efficiency (total time spent asleep divided by time in bed), and disrupting influences on sleep, such as abnormal respiration or movement, may be determined. The effects of confounding medications and medical disorders on sleep architecture, such as selective-serotonin reuptake inhibitors (SSRI) that suppress and delay REM sleep, or benzodiazepines that reduce the N3 and REM amounts and increase sleep stage shifting leading to heightened light NREM N1 and N2, must also be considered.

Attended PSG is advantageous because it allows precise measurement of sleep and relevant cardiorespiratory and neurologic behaviors and allows intervention with therapeutic positive airway pressure (PAP) trials if indicated. Disadvantages of PSG include patient inconvenience, a foreign sleep environment, and expenses due to highly trained personnel and technology. For those patients whose disease severity is difficult to predict, or who may have other complicating medical illnesses that would render interpretation of an out-of-center cardiopulmonary sleep test inaccurate (such as those with significant cardiopulmonary or neurologic diseases), or those who may require noncontinuous PAP modalities, or for those with parasomnia symptoms, attended PSG and treatment design is needed. Split-night PSG remains a cost-effective strategy for many patients.

PSG is currently the only way to actually measure sleep; although the sleep state is currently defined by the variables measured in PSG (EEG, EMG, and EOG), the science of sleep medicine may develop other ways of characterizing the sleep state that are more convenient, precise, and correlate even better with health and disease.

Home Sleep Apnea Testing

PSG is comprehensive, but for patients with characteristic clinical presentations for OSA syndrome, it is often possible to arrive at a diagnosis using a significantly reduced number of recording channels that may be conducted in the home setting. A recent systematic review concluded that many commercially available home monitoring devices do not perform well in sensitivity or specificity. The best out-of-center testing devices use similar measures as PSG but exclude EEG, EMG, or EOG channels needed to score sleep. Thus, these devices typically measure at a minimum airflow using thermistors and nasal pressure transducers, breathing effort using respiratory impedance plethysmography, oxygen saturation using pulse oximetry, and snoring. Using these signals, the frequency of apneas and hypopneas per hour of recording, called the respiratory event index (REI), may be determined. Some testing devices add markers for sleep, such as actigraphy (see below),

position sensors, or pattern recognition of pulse or autonomic variability to estimate sleep time (called peripheral arterial tonometry). Home sleep apnea testing (HSAT) devices are thus far only considered for evaluation of OSA syndrome and are not suitable for diagnostic evaluation of other sleep disorders. Because of limited sensitivity, they are best employed when there is a high pretest probability that the patient has at least moderately severe OSA syndrome. Patients appropriate for HSAT would be those who satisfy three criteria: have a high likelihood of having at least moderately severe OSA, will be good candidates for either autotitrating continuous PAP (CPAP) or an oral appliance, and do not have underlying diseases that either will obscure HSAT or who may have other disorders that require PSG for diagnosis. Because of the poor sensitivity of HSAT, a negative result should be cause for PSG: the patient should have had a high pretest probability for having at least moderately severe OSA.

For medically uncomplicated patients fitting the above criteria, using HSAT followed by APAP most often leads to similar results as attended PSG with CPAP therapy based upon in-lab titration of pressure. This strategy is increasingly being used, largely owing to reduced costs. These good results depend, however, upon expert PAP mask fitting and follow-up. It is best to remember that treatment is chronic and requires ongoing follow-up. More is written about this in the section on OSA below.

Multiple Sleep Latency and Maintenance of Wakefulness Testing

The multiple sleep-latency test (MSLT) provides an objective measure of sleepiness compared with normal individuals lacking primary sleep disorders. The chief clinical indication for MSLT is for evaluation of narcolepsy and related primary CNS hypersomnias such as idiopathic hypersomnia and Kleine-Levin syndrome. A MSLT is carried out during the daytime in a sleep laboratory following nocturnal PSG, with four or five nap opportunities at standard times and intervals, usually at 9:00 and 11:00 AM and 1:00, 3:00, and 5:00 PM. Careful inspection of each nap is subsequently performed to determine the timing of sleep onset relative to commencement of each nap, and whether REM sleep occurs during each nap. A mean sleep latency is then calculated from the average initial sleep latency from each nap. Mean sleep latencies shorter than 8 minutes are considered abnormal and indicative of pathologic excessive daytime sleepiness. Whether or not a sleep-onset REM period (a SOREM, i.e., reaching REM sleep within 15 minutes of sleep onset during a nap) is captured is also considered and tabulated. More than one SOREM is abnormal and is consistent with the diagnosis of narcolepsy.

There are several considerations prior to performing and interpreting a valid MSLT. Patients should be instructed to sleep well for at least 2 weeks preceding the study, to allow at least 6 to 7 hours per night (and when possible, extending time in bed to 8-9 hours), and many sleep specialists document the quantity of sleep before the test with actigraphy monitoring or a sleep diary to ensure adherence to this recommendation and exclude the contaminating influence of insufficient sleep quantity. If it is safe and practically possible to do so, patients should be instructed to taper or discontinue sedative, stimulant, or REM suppressant medications (i.e., opiate analgesics, antidepressants, or other psychotropic or CNS active drugs) with the oversight and permission of other relevant treating primary care, psychiatry, and pain physicians at least 2 weeks prior to MSLT, and certain psychotropic drugs such as fluoxetine (Prozac) with a long elimination half-life should be discontinued for at least a month prior to MSLT to avoid decrease in MSLT sensitivity for delay of REM latency. Patients should undergo a full-night diagnostic PSG the night before a MSLT study to ensure that there is not another primary sleep disorder, such as SDB or PLMD, that could provide an alternative reason for significant sleepiness and to ensure that sufficient sleep quantity of 6 hours or more is obtained.

While the MSLT is designed to assess sleepiness, the maintenance of wakefulness test (MWT) is used to assess the ability to remain awake. The MWT is most useful when an objective

measure of the effectiveness of treatment for disorders causing hypersomnolence is needed. The patient is seated in a dim room in a comfortable, semi-reclined position and asked to remain alert but passive for four 40-minute periods that are 2 hours apart. EEG, EOG, and chin EMG are measured, and the signals are analyzed to detect any epochs of unequivocal sleep during each 40-minute period. Normal patients have a mean time to epochs of unequivocal sleep of 30.4 minutes; however, the data is not normally distributed, and 42% of all patients remain awake for the entire 40 minutes on all four opportunities. Since simulated and actual driving performance is compromised with sleep times of 19 minutes or less on MWT, this is a reasonable threshold for the distinction of clinically significant daytime sleepiness, and driving or other safety sensitive tasks should be curtailed when sleep latencies are 19 minutes or shorter.

Actigraphy Monitoring

Wrist actigraphy monitoring is utilized to provide a rigorous estimation of sleep quantity and its circadian pattern. The actigraphy monitor may be worn like a wristwatch and contains an accelerometer that detects movements, which are recorded over time periods lasting up to weeks. The magnitude and pattern of movements may be analyzed and modeled to infer the sleep-wake pattern and provides a graphic representation of the patient's sleep schedule. The test is used in the evaluation of suspected circadian rhythm disorders, to assess response to treatment of insomnia, and for investigating patients with hypersomnia prior to PSG and MSLT to more accurately document the adequacy of sleep prior to the assessment for sleepiness. Recent applications utilizing the accelerometer in smartphones and wrist-worn fitness devices show promise, but most have not been validated as diagnostic tools.

Diagnostic and Therapeutic Approach to Common Sleep Disorders

Insomnia

The insomnia disorders all share three basic components: repeated complaints of insomnia, which may involve difficulties falling asleep, staying asleep, poor sleep quality, or waking undesirably early; an adequate time and opportunity for sleep; and a complaint of resultant daytime impairment. Insomnia is the most common of sleep complaints: nearly 45% of people were affected intermittently within the past year in some large studies, and up to 15% suffer chronic insomnia disorders. Risks for insomnia include female sex, older age, and a psychiatric or medical comorbidity. Chronic insomnia should be distinguished from short-term insomnia, which may occur in anyone occasionally (e.g., the night before an important job interview, or during increased stress). Per the ICSD-3, the sleep disturbance and associated daytime symptoms have to occur at least three times a week for at least three months to meet criteria for chronic insomnia disorder (see [Box 1](#)). Insomnia may begin in childhood, continue throughout a patient's lifetime, and appear as a manifestation of neurologic hyperarousal, with demonstrable increases in cerebral metabolism via functional MRI and increases in beta and theta EEG activity as well as generalized increased metabolism and stress hormone production compared with normals in either wake or sleep states. To a lesser extent, these same markers for hyperarousability are seen in other causes of primary insomnia (see [Box 1](#)).

In the past, insomnia was classified into primary and secondary, with secondary insomnia being far more common. Secondary insomnia was thought to be a result or accompaniment of an underlying illness. This may be incorrect. For example, it has previously been thought that treatment of secondary insomnia ought to focus on treatment of the underlying disorder. Newer evidence indicates that this approach may be suboptimal for the following reasons: secondary insomnia does not reliably improve when the underlying disorder does; secondary insomnia in general responds to treatment directed at insomnia; and in some cases, the underlying disorder, such as depression, responds better to treatment when the insomnia is addressed directly and concurrently. Furthermore,

in several illnesses, such as depression, insomnia may predate the depression by months, and insomnia is a risk factor for future development of many psychiatric illnesses. In addition, primary insomnia was further divided into subtypes of idiopathic insomnia, psychophysiologic (learned) insomnia and paradoxical insomnia (sleep state misperception). Secondary insomnia was also divided into various subtypes such as inadequate sleep hygiene, insomnia due to medical condition, mental disorder, drug or substance. However, it is rare to encounter patients who fit under one of these subtypes exclusively. Most patients with insomnia, primary and secondary, tend to have some diagnostic criteria listed under many of these subtypes. Thus, in the current ICSD-3 insomnia is no longer classified into primary and secondary insomnia and no distinction is made between various etiologic subtypes of primary and secondary insomnia.

Chronic insomnia may be preceded in predisposed individuals by precipitating factors such as illness or stress and may be propagated by behavioral or maladaptive cognitive factors. Some individuals do not appear to require precipitating or propagating factors to develop chronic insomnia and have underlying predisposition toward insomnia. They are prototypic for an underlying predisposition toward insomnia. These individuals manifest insomnia from infancy and persist despite optimization of sleep hygiene and habit. However, in most cases of insomnia, precipitating and/or propagating influences may be found through careful interview and help establish a secure diagnosis.

In these individuals, identifiable precipitating causes that may be traumatic, stressful periods or struggles, medical illness, drugs, or toxins. However, even when the cause is removed, a conditioned response built upon associated and at times maladaptive sleep-related behaviors ensues. Instead of beginning to relax for sleep under permissive circumstances, the affected patient experiences paradoxical arousal as they approach their sleep conditions. The patient under the influence of the precipitating cause may have spent many hours worrying, uncomfortable, clock-watching, or otherwise raising their anxiety levels. Propagating factors include these same behaviors that help maintain sleeplessness once it has begun and may additionally include irregular sleep schedules and the use of drugs. Abuse of alcohol may contribute or be secondary to the sleep disturbance.

Effective treatment strategies for insomnia focus on removing any residual precipitating influences and mitigating or eliminating propagating influences. The main therapies for insomnia are sleep hygiene, behavioral therapies, cognitive therapies, and pharmacologic therapies. Patients often respond best to combined modalities. There is high-level evidence that combined cognitive/behavior therapies (CBT) are at least as effective as pharmacologic therapy for most patients with insomnia. CBT also appears to have enhanced rates of insomnia remission, so these approaches ought generally to be employed first. The addition of hypnotics to CBT has resulted in more rapid remission in some, but not all, studies. Growing recognition of the adverse effect profile of sedative-hypnotic drugs, particularly zolpidem (Ambien), which has been associated with heightened risks of falls and sleep walking, sleep eating, and related amnesic behaviors, has also encouraged a shift toward an earlier application of behavioral approaches to coping with insomnia.

In childhood, the most common causes of insomnia are behavioral. Insomnia may occur when parents fail to establish and enforce an appropriate nightly bedtime, so that their child may subsequently stall and refuse to go to bed in a timely fashion. In other cases, insomnia may occur when a child cannot fall asleep until a usual condition is present, such as being held, rocked, or fed. Appropriate advice and treatments include strict limit-setting for bedtime resistance; maintaining regular sleep schedules with avoidance of napping during the daytimes; and curtailing disrupting influences, such as television watching, gaming, and computer use. Suggesting a nightly cell phone or personal device (i.e., iPod, iPad, or Wii U) check-in procedure is especially helpful in teenage children, and caffeinated soda and excessively stimulating activities should be avoided during the evenings. Selected children benefit from incentives such as a patient-parent contract that offers

privileges for slightly later bedtimes on weekends after the child adheres regularly to a specified sleep schedule during school nights.

Four considerations for restoring normal sleep hygiene to discuss with all insomnia patients in the office include these three central concepts:

- Maintain a regular sleep schedule. Go to bed and arise at the same time each day. Ideally, the schedule should match the patient's biologic clock, with nocturnal sleep and bedtime/rise time matching their tendency for sleepiness and alertness (sleep education/hygiene).
- Avoid lying sleepless in bed. After 20 to 30 sleepless minutes spent trying to fall asleep, the patient should be instructed to leave the bedroom to pursue a quietly distracting activity, such as reading mundane material or watching a boring television program, and waiting until he or she feels sleepy enough to return to bed. Patients should explicitly avoid reading in bed, listening to the radio in bed, or watching television in bed if they are having difficulty initiating or maintaining sleep. This is a practical form of stimulus control (Table 1).
- Avoidance of clock-watching behavior. Patients should be instructed to remove clocks from their bedrooms or hide the clock face so as to make the insomnia period timeless and of uncertain duration. Falling asleep should not be a race against time, and repetitive checking of the time only serves to reinforce anxiety and further activate the mind (see stimulus control, Table 1). For the same reason, when watching television, discourage patients from watching news shows with scrolling tickertape newswatches with clock time shown.
- Schedule thinking time earlier in the evening, well in advance of the sleep period. Patients who worry, plan, or think out their problems in bed should be encouraged to schedule a time earlier in the evening, well in advance of their normal bedtime, to attempt to work out these concerns prior to carrying them into bed. This "constructive worry" or "worry time" represents a practical form of cognitive and stimulus control therapy.

There are numerous other associated issues and behaviors that may be useful for application in selected patients, such as cutting down overall time in bed (sleep restriction), establishing a regular and relaxing bedtime routine (such as by taking a relaxing bath, listening to soothing music, or having a light snack before bed), avoiding daytime naps, avoiding caffeinated beverages after noon-time, and establishing a regular morning exercise routine and avoiding evening exercise. It is important for the physician to avoid overloading the patient with too many considerations and tasks at once, however, as the burden of implementing these suggestions then becomes tantamount to too many obtrusive "swing thoughts" during a golf swing. One or two concepts to start with are sufficient, and once mastered and implemented, the patient can gradually phase in other ideas over time. Relaxation training and cognitive behavioral therapy can be very helpful in selected receptive patients who have failed the above typical self-help measures, and as a last resort, periodic or even scheduled chronic pharmacotherapy can also be implemented.

There are now several highly effective and tolerable hypnotic medications available for short-term, intermittent, and chronic use. The class of nonbenzodiazepine receptor agonists (the so-called "Z" drugs, or zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta]) are preferred by most sleep specialists but some of them remain costlier than the older generation choices, including the benzodiazepines—which have adverse effects on sleep architecture—as well as diphenhydramine (Benadryl) and trazodone (Desyrel),¹ which each have less specific sleep-promoting effects and more adverse effects and potential for drug-drug interactions, especially in elderly patients. The clinical pharmacology of the most commonly prescribed and most useful hypnotic medications are summarized in Table 2. A concern with each of these may be the potential for habituation of efficacy; fall risk; and the potential to cause sleepwalking, sleep eating, or other

¹Not FDA approved for this indication.

TABLE 1 Therapeutic Tools for Treating Insomnia

THERAPY TYPE	SPECIFIC THERAPIES/COMPONENTS	GOALS
Education/sleep hygiene	Improve knowledge about behaviors that foster or hinder healthy sleep	Improve opportunity and environment for sleep
Behavioral therapies	Stimulus control <ul style="list-style-type: none"> • Unmodified extinction • Graduated extinction • Positive routines/faded bedtime with response cost • Scheduled awakenings Sleep restriction	Dissociate anxiety or conditioned autonomic response from the process or location of going to sleep
	Relaxation training <ul style="list-style-type: none"> • Progressive muscle relaxation • Passive relaxation • Autogenic training-biofeedback • Imagery training • Meditation • Hypnosis Paradoxical intention	Increase pressure for sleep by decreasing the time allotted for sleep, increasing the probability of successful sleep attempts Reduce physiologic and/or cognitive arousal that hinders or disrupts sleep
		Reduce performance anxiety that confounds ability to successfully go to sleep
Cognitive therapies	Cognitive restructuring Decatastrophizing Reappraisal Attention shifting	Decrease unrealistic expectations about sleep, misconceptions, or misattributions regarding causes of insomnia, consequences of insomnia, ability to control sleep; produce a more appropriate and adaptive mind-set
Pharmacologic therapies	Hypnotics Sedating antidepressants Herbal supplements	Enhance sleepiness at appropriate times or to enhance convenience of sleep time and/or duration

TABLE 2 Clinical Pharmacology of Hypnotic Medications

	MECHANISM OF ACTION	DOSAGE (mg)	DURATION OF ACTION ($t^{1/2}$)	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Older Hypnotics					
Diphenhydramine (Benadryl)	H1	25–50	Intermediate (2.4–9.3 h)	Dry mouth, constipation, urinary retention	Nonsignificant
Trazodone (Desyrel) ¹	SRI	50–150	Short (3–6 h)	Dry mouth, dizziness, rash	CYP substrate; several others
Triazolam (Halcion)	BRA	0.125–0.5	Short (1.5–5.5 h)	Tolerance	CYP induction
Temazepam (Restoril)	BRA	7.5–30	Intermediate (8–18 h)	Tolerance	Nonsignificant
Melatonin ²	MT1–MT2	1–3	Ultra-short (35–50 min)	Hangover type effect	None
Newer Hypnotics					
Zolpidem (Ambien)	NBRA	5, 10	Short (2–2.6 h)	Amnestic behavior	Numerous
Zaleplon (Sonata)	NBRA	5, 10	Short (1 h)	Headache, amnestic behavior	Several
Eszopiclone (Lunesta)	NBRA	1–3	Intermediate (6 h)	Headache, amnestic behavior, rash possible	Nonsignificant
Ramelteon (Rozerem)	MT1-MT2	8, 16 ³	Short (1–2.6 h)	Hyperprolactinemia	Ketoconazole (Nizoral), rifampin
Doxepin (Silenor)	H1	3, 6	Intermediate (12–15 h)	Dizziness, tachycardia	Nonsignificant
Suvorexant (Belsomra)	Orexin antagonist	10–20	Intermediate (12 h)	Headache, dizziness, abnormal dreams	CYP3A4 inducer

Abbreviations: $t^{1/2}$ = half-life of drug; h = hours; H1 = antihistaminergic H1 receptor blocker; SRI = serotonin reuptake inhibitor; BRA = benzodiazepine receptor agonist; CYP substrate = metabolized by cytochrome metabolism, susceptible to enzyme inhibition and elevated serum levels by multiple drugs; CYP induction = cytochrome enzyme inducer, may cause multiple potential drug-drug interactions via this mechanism; NBRA = nonbenzodiazepine benzodiazepine receptor agonist; MT1/MT2 = melatonin type 1 and type 2 receptor agonist.

¹Not FDA approved for this indication.

²Available as dietary supplement.

³Exceeds dosage recommended by the manufacturer.

amnesic behaviors during sleep. If these adverse effects result, the hypnotic drug should be promptly discontinued with a shift toward the use of cognitive behavioral therapy strategies. In women, zolpidem should be used with particular caution given the slower metabolism of the drug, thereby promoting vulnerabilities to carryover sedation and unpleasant “hangover” type feelings or driving safety risks during the commute the next morning. Pharmacologic therapy of insomnia may be bolstered by the advent of suvorexant (Belsomra), a novel hypocretin antagonist that has a wake-suppressing rather than sleep-promoting mechanism of action. However, it should be noted that the higher doses that were primarily studied were determined as overly sedating and unsafe by the FDA and only the lower doses were approved. Further clinical experience will likely be necessary to establish the role of this medication as a treatment for insomnia.

Sleep-Disordered Breathing

Breathing during sleep is carefully regulated to maintain homeostasis of oxygen, carbon dioxide, and blood pH. The mechanisms and homeostatic set points for ventilation vary systematically between wake, non-REM sleep, and REM sleep. In wake, the resulting ventilatory pattern is governed by careful integration of classic feedback systems designed to keep blood pH at approximately 7.40, arterial P_{aCO_2} at approximately 38 to 45 mm Hg, and P_{aO_2} greater than approximately 60 mm Hg with cortical influences that govern functions such as speaking, laughing, eating, singing, and other voluntary activities. During non-REM sleep, ventilation is considerably more rhythmic and is governed almost exclusively by the chemoresponsive feedback systems indicated above; during REM sleep, the chemoresponsive feedback system is further influenced by additional input from REM-influenced neurons, resulting in a less rhythmic and less-carefully regulated metabolic milieu.

Significant deviation from these norms is termed “sleep-disordered breathing” (SDB), and is marked by several distinct event types. Apneas are total or near-total cessations of airflow. Hypopneas are significant declines in tidal volume sufficient to result in significant reduction in oxygenation. Excess effort for breathing may result in arousals from and disturbance of sleep, and are termed respiratory effort-related arousals (RERAs). These types of events are often related as a rate, either as the apnea-hypopnea index (AHI; apneas+hypopneas per hour of sleep), the respiratory disturbance index (apneas+hypopneas+RERAs per hour of sleep), or the REI (apneas+hypopneas per hour of recording when sleep is not measured directly). In addition to these types of SDB, the general baseline minute ventilation may fall to the point where sustained hypoventilation takes place during sleep, termed sleep-related alveolar hypoventilation.

Obstructive SDB: Snoring and OSA

The dynamic upper-airway obstruction, which occurs as a result of sleep in some persons, leads to a continuum of SDB varying from mild snoring to hypopneas to obstructive apneas. The likelihood and extent of upper-airway collapse is determined by the neural input into the dilating upper-airway muscles, influence of sleep state, and upper-airway anatomy. Obstructive events are more likely to occur in REM sleep when muscle tone is lowest, during transitions from lighter non-REM sleep to deep non-REM sleep when sleep is unstable, or when muscle tone is decreased by substances such as alcohol or drugs. The single biggest risk factor for snoring or OSA is obesity, wherein fatty deposition reduces upper-airway dimension, humoral factors reduce net dilating forces of the muscles, and the mechanical effects of obesity reduce lung volumes and the stabilizing effect of tracheal traction on the upper airway. Beyond obesity, many but not all patients have a predisposing anatomy of a narrowed oropharynx, such as a low-lying palate or redundant soft palate tissue, a thickened tongue base, or a narrow hypopharynx, although nasal anatomy with septal deviation or chronic congestion may also aggravate the problem.

Snoring without other symptoms, signs, or polysomnographic evidence of upper-airway obstructions such as hypersomnia,

frequent associated arousals, or significant airflow limitation is termed primary snoring. While snoring may be a socially objectionable symptom or disruptive to the patient’s sleep partner, snoring in isolation is otherwise not considered to be abnormal and such patients may be reassured if their bed partners are not bothered by their snoring. If treatment is desired, options include relieving nasal obstruction if present, commercially available lubricant throat sprays, mandibular positioning devices, and nasal or upper-airway surgical approaches such as nasal septal repair or uvulopalatopharyngoplasty (UPPP, or UP3 procedure). An otorhinolaryngology consultation may be helpful in determining which surgical approaches may be most beneficial for the individual.

OSA is an extremely common public health problem present in at least 2% to 4% of the general population and has been linked to development of hypertension and is a risk factor for incidental development of stroke, coronary artery disease, congestive heart failure, and atrial fibrillation. OSA has been shown to be associated with a wide variety of endothelial and metabolic abnormalities that favor vascular disease, and when patients with moderate to severe OSA are compared to normals or treated OSA patients, they appear to have a higher mortality and cardiovascular event frequency. Thus, the two main reasons to detect and treat OSA are to improve symptoms and to decrease cardiovascular risks. There are good data to show that treatment of OSA improves symptoms and quality of life. Data regarding the reversal of cardiovascular risk are not as firm, but most experts agree that at least moderate and severe OSA ought to be treated, regardless of symptom severity.

OSA severity is rated by the polysomnographic AHI, the hourly rate of apneas and hypopneas averaged over the total sleep time, or, in the case of HSAT, by the REI. An AHI of 4 per hour or less is considered normal. Mild OSA is diagnosed with an AHI of 5 to 14 per hour, moderate OSA with AHI of 15 to 29 per hour, and severe OSA with AHI being 30 per hour or higher. In most laboratories, correlation of the AHI with specific sleep stages and body positions is usually performed to determine whether positional therapy may be offered, as many patients have OSA only during the supine sleep position (position-dependent OSA), and some manifest OSA only during REM sleep in the supine position.

A form of OSA called the upper-airway resistance syndrome is defined by a clinical complaint of hypersomnia, often accompanied by snoring but without an abnormally high frequency of overt apneas or hypopneas resulting in significant decline in oxygen saturation. PSG confirms repetitive arousals related to the increased respiratory effort (respiratory effort-related arousals, or RERAs, during PSG) required to overcome upper-airway obstruction. Because of the similar pathogenesis and treatment response to relieve upper-airway obstruction, this is considered a variant of OSA.

Therapeutic options for snoring and sleep apnea include reducing nasal congestion or obstruction, positional therapy, nasal continuous positive airway pressure, oral appliances, the nasal expiratory positive airway pressure device, oral pressure therapy (OPT), or surgical management (Table 3). Patients with OSA have higher morbidity from vascular events and higher motor vehicle accident rates. Assessment and appropriate counseling for weight loss, cardiovascular risk factors, and driving while untreated (or extreme caution) should be part of a treatment plan.

Weight loss. Weight loss may reduce soft tissue in the neck, making the oropharynx less compressible. The improvement in lung volumes accompanied by weight loss also favor enhancement of longitudinal traction on the upper airway, the so-called “tracheal tug.” About 30% to 40% of patients who are able to achieve substantial weight loss may become cured of their OSA. Careful follow-up is needed because many remissions are not permanent. Alcohol and other substances that reduce upper-airway tone or cause sedation or reduced responsiveness worsen OSA and should be prudently avoided.

Positional therapy. Among the lifestyle or behavioral changes, positional therapy involves employing one or more simple strategies to enforce sleep only in nonsupine body positions, usually

on the side. One method is the "tennis ball in T-shirt" approach. The patient wears a snug-fitting T-shirt with a pocket sewn onto the back between the shoulder blades with two or three tennis or wiffle balls inserted into it to discourage the patient from turning onto the back during sleep. Other options include similar commercially marketed shirts or vests (the FDA-approved ZZoma sleep apnea pillow, the "snoring backpack," and similar strategies) and body pillows propped or wedged behind the patient or hugged by the patient. A correctional device for positional sleep apnea is also approved in the European Union. Unfortunately, shoulder or hip pain often limits the application of positional therapy, especially in elderly persons, and long-term adherence or compliance remains poor, with only about one-third of patients able to perpetuate positional therapy strategies in long-term follow-up. Patients with position-dependent OSA should be counseled to be cautious for development of severe OSA problems during any future

anticipated prolonged periods of supine sleep, such as postoperative recovery periods following surgery or following a major injury.

Positive airway pressure. The mainstay of treatment for OSA for the majority of patients remains positive airway therapy (PAP). The main components of PAP appliances are the blower unit, which delivers calibrated pressures to hold open the airway; tubing to conduct the pressurized air to the patient; an interface such as a nasal or oronasal mask; and a harness to hold the mask firmly to the patient's face during use. Of the PAP therapies, continuous positive airway pressure (CPAP), which delivers a continuous set pressure between 5 and 20 cm H₂O, is usually first tried in the setting of PSG; in many sleep centers, the practice of performing split-night PSG (an initial diagnostic phase followed by a treatment phase of CPAP titration toward an optimal pressure for the individual patient) allows diagnosis and treatment prescription to occur in an efficient manner. If an optimal pressure cannot be determined by

laboratory titration or data is not available to guide prescription of a specific pressure for a patient, application of an autotitrating PAP device may be considered, offering flexibility for delivering a relatively wide range of self-adjusting treatment pressures as the patient changes sleep position and enters different sleep stages through the night with accordingly varying apnea severity. Autotitrating PAP has been found to be efficacious in most patients diagnosed with OSA by HSAT. However, close clinical follow-up is needed in all patients who have recently started PAP.

PAP is typically delivered through an interface chosen as most comfortable by the patient, either a nasal mask, nasal pillows, or an oronasal. Nasal pillows, a type of cannula that provides a tight seal within the nares, and a newer tube-like frame that sits in front of and not within the nares are most effective at lower treatment pressures; they may be favored by many patients with claustrophobia but may dislodge at higher pressures or with frequent nocturnal movement. Nasal masks of various types are used in many patients, but if mouth breathing and consequent leak are a problem, a chin strap may be added, or an oronasal face mask may be substituted. Many newer PAP machines offer the feature of pressure relief during exhalation, which may enhance patient tolerability at higher level PAP pressures by “giving way” as the patient expires. Bilevel positive airway pressure (BPAP) may also be employed at higher treatment pressures if CPAP is not well tolerated. Setting a pressure delta ≥ 4 cm between the inspired and expired pressure may also add a degree of positive pressure ventilation for patients with concurrent sleep-related hypoventilation from an intrinsic pulmonary disease or neuromuscular respiratory muscle weakness.

Oral appliances. Oral appliances may be fitted by a dental sleep specialist. They provide a means of advancing the mandible that pull the tongue base forward slightly, opening the oropharyngeal airway to some degree and obviating some apnea and hypopnea events. The device is most effective for mild to moderate severity and supine position-dependent OSA and generally less predictably effective for most cases of severe OSA. However, the use of oral appliances is increasing due to greater availability of competent dental professionals working with the devices, awareness that for some patients adherence is better with OAs than PAP, and improvements in appliance design that allow enhanced efficacy in some instances. Because oral appliances are less reliably effective in controlling SDB, repeat testing—either with out-of-center sleep testing or PSG after maximal adjustment—is needed to confirm efficacy.

Nasal valve appliances. An expiratory nasal resistance valve appliance (Provent) was approved by the FDA for treatment of OSA. The device may be an alternative for some patients with OSA who fail to tolerate CPAP therapy. The device is a small, disposable oval appliance that is affixed over each of the patient's nares by self-adhesive with an airflow port that offers resistance to expiratory airflow, thereby producing expiratory positive airway pressure and preserving nasal and oropharyngeal airway patency with minimal impedance to inspiratory airflow. The device was proven to significantly reduce polysomnographic AHI and subjective sleepiness on the ESS in a sham-controlled randomized trial. Because they are disposable, a new device must be affixed each night. Appropriate patient characteristics and long-term results are not yet clear, but these may be considered in patients who do not prefer CPAP or oral appliances and are agreeable to follow-up to ensure efficacy.

Oral pressure therapy. A newer option for treatment of mild to moderate OSA is OPT (Winx), which combines an oral appliance with negative intraoral pressure to help keep the tongue and soft palate in a more anterior position, enlarging the retrolingual and retropalatal space. There is as yet limited experience with the device; however, this may be an option for some patients who are averse to or intolerant of other therapies.

Surgery. Surgical modifications of the upper airway are principally of two basic approaches, palatal approaches, tongue-based procedures (genioglossus advancement, hyoid myotomy and suspension, lingualplasty), or maxillomandibular advancement (MMA). Palatal approaches such as UPPP, or “UP3” performed

by otorhinolaryngologists are effective for relief of snoring but mostly ineffective for treatment of OSA, especially if severity is moderate or greater in degree. MMA appears to be quite effective in mild to moderate OSA and can even be applied with good effect even in selected severe OSA cases; however, morbidity from perioperative pain is considerable and long-term outcomes remain unclear. A hypoglossal nerve stimulation implant (Inspire) is a novel surgical treatment for PAP-intolerant patients. A recently published randomized controlled trial demonstrated efficacy and reasonable tolerability; however, this device was only recently FDA approved and there is limited clinical experience with it, thus, its future role and scope of use in OSA management remains to be determined.

Central Sleep Apnea Syndrome

Central sleep apnea syndrome results from an unstable ventilatory drive during sleep, resulting in periods of insufficient ventilation and compromise of gas exchange despite a patent oropharyngeal airway. Clinically, patients may share similar symptoms with those with OSA, including snoring, except patients with central sleep apnea more frequently complain of insomnia than hypersomnia. Central sleep apnea has a heterogeneous pathophysiology and may be idiopathic or due to high-altitude-induced periodic breathing, due to Cheyne-Stokes breathing, or narcotic-induced. Neurologic causes—such as brainstem infarction or neurodegenerative disorders, including multiple system atrophy—may also cause central apnea. In heart failure, the presence of central sleep apnea syndrome or Cheyne-Stokes breathing imparts a poor prognosis. A high-quality clinical trial showed that on average, CPAP did not reduce mortality. However, central sleep apnea is often at least partially resistant to treatment with conventional nasal CPAP therapy, and while CPAP may effect improved mean oxygenation, frequent arousals that fragment sleep often continue. However, a recent large multicenter randomized control trial, the SERVE-HF study, showed elevated all-cause and cardiovascular mortality risk in patients with central sleep apnea and symptomatic heart failure with an estimated ejection fraction of $\leq 45\%$ who were randomized to ASV. Therefore, use of ASV in this patient population is not advised at the current time.

Treatment-Emergent Central Sleep Apnea Syndrome

Treatment-emergent central sleep apnea syndrome is a subtype of central sleep apnea wherein patients have significant obstructive/anatomical problems with ventilation, but also have unstable ventilatory patterns noted in patients with central sleep apnea syndromes. These patients have a clinical and PSG presentation of OSA, but once the upper airway is opened with CPAP, they experience frequent central apneic events that may or may not later resolve with continued exposure to PAP in the home setting. Some patients clearly continue to manifest frequent central sleep apneic events more than five times per hour, leading to the suboptimal outcomes of persisting clinical complaints of hypersomnia and medical risk. Treatment-emergent central sleep apnea syndrome may occur in as many as 4% to 15% of those with OSA. There is emerging evidence that alternative modes of PAP—particularly ASV—may be superior to conventional CPAP for treatment of treatment-emergent central sleep apnea syndrome. A randomized controlled trial recently showed that ASV more reliably relieves SDB, while CPAP fails to control SDB in up to one-third of cases. However, there is also evidence to suggest that treatment-emergent central sleep apnea resolves over time in a substantial number of patients who continue to remain on CPAP therapy.

Sleep-Related Hypoventilation

The causes of hypoventilation during sleep include primary pulmonary parenchymal disorders, neuromuscular conditions affecting bellows musculature, or restrictive physiology of the chest wall accompanying kyphoscoliotic disorders or morbid obesity. While each of these disorders may also ultimately cause daytime hypoventilation, sleep recumbency, especially supine sleep positioning, and REM sleep stage (which leads to relative paralysis

of the chest wall and sole dependency on diaphragmatic excursion to drive respiratory effort) often lead to exclusive or initial sleep-related hypoventilation with subsequent medical risk consequent to suboptimal nocturnal oxygenation. Failure to treat significant nocturnal hypoventilation may result in the development of sequelae of hypoxemia such as polycythemia, pulmonary hypertension, and right heart failure, or of hypercapnic respiratory failure. Treatment most often involves use of NIPPV (see Table 4). A newer modality of positive pressure ventilation, volume-assured pressure support ventilation (AVAPS™), consists of a short delivery of a provider-set tidal volume, which, when coupled with a set backup respiratory rate, assures delivery of a minimum minute ventilation, even when changes in the patient's muscular strength or ventilatory load change. These therapies are best titrated in the context of a supervised overnight laboratory polysomnogram under the direction of a sleep or pulmonary medicine specialist. One must be careful not to resort to the potentially dangerous solution of added oxygen therapy alone in severe COPD or neuromuscular etiologies of sleep-related hypoventilation, because as ventilation fails and hypercapnea results, the hypoxic drive to breathe may become the chief factor leading to continued ventilatory effort and oxygen in this context may precipitate acute respiratory failure in some individuals. A morning arterial blood gas on room air following PSG is indicated to assess for potential hypercapnia and assess the impact of ventilatory support. In the context of severe hypercapnia (i.e., P_{CO_2} of 55 or greater), serial arterial blood gases to monitor the effects of ventilatory support, oxygenation, and accumulating hypercapnia may help determine whether nocturnal mechanical ventilatory support is indicated.

Narcolepsy and Central Disorders of Hypersomnolence

Narcolepsy is the prototypical central disorder of hypersomnolence. Narcolepsy is categorized further as Narcolepsy Type I (previously called narcolepsy with cataplexy) and Narcolepsy Type II (previously called narcolepsy without cataplexy). Cataplexy is a distinctive and highly specific symptom characterized by emotionally provoked muscle atonia intruding into wakefulness that is seen in a minority of patients overall and may precede but more often follows onset of the main symptom of hypersomnia. In the absence of cataplexy, a diagnosis of Narcolepsy Type I may also be made if cerebrospinal fluid (CSF) hypocretin-1 concentration, measured by immunoreactivity, is <110 pg/mL or $<1/3$ of mean values obtained in normal subjects with the same standardized assay. In Narcolepsy Type II, there is no cataplexy, and the CSF hypocretin level does not meet the above criteria or has not been measured. In addition to sleepiness and cataplexy, the full clinical pentad of narcolepsy also includes symptoms of sleep paralysis (the inability to move the body upon awakening), hypnagogic hallucinations (the intrusion of dream imagery and mentation into conscious awareness following awakening), and sleep-maintenance insomnia (with frequent nocturnal arousals and difficulty maintaining sleep). However, narcolepsy is most frequently monosymptomatic, with the sole symptom being pervasive, enduring sleepiness and decreased vigilance with a tendency toward dozing off inadvertently in permissive settings and the overwhelming desire to nap during the daytime, especially in the afternoons. Naps are most often highly refreshing; scheduled naps can be utilized to therapeutic advantage or indeed, in rare patients, as the sole treatment for those bent on avoiding stimulant pharmacotherapy. Narcolepsy is relatively uncommon, affecting approximately 1:2000 of the general population. While the etiology of narcolepsy remains unknown, most experts continue to favor a long hypothesized autoimmune cause. Major advances in the understanding of the neurobiology of narcolepsy over the past two decades have included the clear linkage of the HLA DQB1*0602 haplotype in up to 90% patients having narcolepsy with cataplexy, discovery of wake-promoting hypocretin/orexin peptides produced by the perifornical posterolateral hypothalamus, and low to unmeasurable CSF hypocretin in nearly 90% of narcolepsy with cataplexy patients. Within the last few years, epidemic narcolepsy-cataplexy following H1N1 vaccination in

Europe and Asia also provided further support for the autoimmune hypothesis of narcolepsy. Unfortunately, these tantalizing discoveries have not yet yielded clear insight into pathogenic mechanisms nor more specific therapies for patients, and the mainstay of treatment for the condition remains the use of older stimulant and wake-promoting medications, or prescribed therapeutic napping, as naps are most often highly refreshing and restorative in narcolepsy patients. Supportive laboratory evidence for narcolepsy includes a relatively normal polysomnogram to exclude other causes of hypersomnia such as OSA or PLMD, followed by a confirmatory MSLT, which demonstrates mean sleep latency shorter than 8 minutes and two or more sleep-onset REM periods during four or five nap opportunities.

Idiopathic hypersomnia is a closely related condition often difficult to distinguish from narcolepsy without cataplexy, although a few nuanced clinical features tend to distinguish it from narcolepsy, chiefly a characteristically reported unrefreshing nocturnal sleep and nap quality. Idiopathic hypersomnia has previously been further subclassified as variants with or without prolonged sleep period, although these phenotypes are overlapping and current diagnostic standards have eliminated this distinction. Other similar enigmatic and poorly understood primary CNS hypersomnias include posttraumatic hypersomnia when there is a history of temporally related antecedent substantial head injury, and recurrent hypersomnia, also known as the Kleine-Levin syndrome, which in addition to hypersomnia includes other neuropsychiatric sequelae such as cognitive and behavioral changes like hypersexuality and hyperphagia. Hypersomnia is also commonly associated with as many as 50% of those with myotonic dystrophy type 1.

The mainstay of treatment for each of these conditions is stimulant and wake-promoting agent therapy, with the goal of improved vigilance and psychomotor functioning. Stimulants and wake-promoting agents range in intensity from lower to higher intensity and efficacy/tolerability options, from modafinil (Provigil) and armodafinil (Nuvigil) on the milder end of the spectrum—although selected narcolepsy patients respond quite well to these drugs—to methylphenidate (Ritalin), and to the amphetamine/dextroamphetamine (Adderall). Relevant clinical pharmacology of the stimulant medications commonly used in clinical practice are summarized in Table 4. Pitolisant (Wakix), a selective H3 subtype histamine inverse agonist/antagonist proven effective as a wake promoting agent for narcolepsy, recently received European Medicines Agency marketing authorization but is currently unavailable in the United States. Patients with uncontrolled hypersomnias should be cautioned against driving, operating dangerous machinery, or engaging in other similarly dangerous activities or hobbies while they are drowsy, as they may be prone to sudden and unpredictable sleep attacks. Sodium oxybate (gamma hydroxy butyrate) is an FDA approved tightly controlled substance for the treatment of sleepiness and cataplexy in patients with narcolepsy. Sodium oxybate (Xyrem) is usually given in two divided doses, before bedtime and in the middle of the night; it can be dangerous in the setting of uncontrolled OSA or respiratory conditions and central nervous system depressants. Other REM suppressing medications such as tricyclic antidepressants, SSRIs and SNRIs are also used in the treatment of cataplexy.

Circadian Rhythm Sleep Wake Disorders

Circadian rhythm sleep disorders result in misalignment of the timing of the sleep period relative to the desired bed and rise times, resulting in concurrent insomnia and hypersomnia symptoms despite normal total sleep time. The most common circadian rhythm disturbances are actually exogenous influences on the patient and his/her circadian axis, which in these cases is functioning normally but is unable to adjust rapidly enough to the required new temporal milieu. These exogenous disorders include jet lag disorder and shift work disorder, resulting either from imposed transmeridian travel or alternating work shifts, respectively, that disturb the patient's environmental entraining cues and homeostatic drives for sleep and wakefulness, thereby resulting in misalignment of the patient's endogenous biological sleep drive and typical sleep

TABLE 4 Clinical Pharmacology of Stimulant and Wake-Promoting Medications

	MECHANISM OF ACTION	DOSAGE (mg)	DURATION OF ACTION ($t_{1/2}$)	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Modafinil (Provigil)	Unknown	100–600 ³	Intermediate (15 h)	Tremor, jitteriness, palpitations, hypertension	Oral contraceptives
Armodafinil (Nuvigil)	Unknown	150–450 ³	Intermediate (15 h)	Tremor, jitteriness, palpitations, hypertension	Oral contraceptives
Methylphenidate (Ritalin)	DNRI	15–100 ³	Short (2–4 h)	Tremor, jitteriness, palpitations, hypertension	Nonsignificant
Methylphenidate SR (Concerta) ¹	DNRI	18–72	Intermediate (3.5 h)	Tremor, jitteriness, palpitations, hypertension	Nonsignificant
Amphetamine/dextroamphetamine (Adderall)	DNRI	15–100 ³	Intermediate (10–13 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion (Wellbutrin)
Dextroamphetamine (Dexedrine)	DNRI	15–100 ³	Long (10–28 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion
Lisdexamfetamine (Vyvanse) ¹	DNRI	20–100 ³	Short (<1 h as prodrug) (10–28 h as dextroamphetamine)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion
Methamphetamine (Desoxyn) ¹	DNRI	15–100 ³	Intermediate (9–15 h)	Tremor, jitteriness, palpitations, hypertension, QTc prolongation	Beware MAOIs, SSRIs, SNRIs, TCAs, bupropion

¹Not FDA approved for this indication.³Exceeds dosage recommended by the manufacturer.Abbreviations: $t_{1/2}$ =half-life of drug; h=hours; DNRI=dopamine and norepinephrine monoamine reuptake inhibitor; QTc=corrected QT interval; MAOI=monoamine oxidase inhibitor; SSRI=serotonin selective reuptake inhibitor; SNRI=selective norepinephrine reuptake inhibitor; TCA=tricyclic antidepressant (the potential interaction with all these agents is largely theoretical concern for potentiation of serotonin syndrome).

schedule to the clock time and environment to which they must rapidly adapt.

Jet lag disorder results when an individual crosses across several transmeridian time zones in a single day. Crossing one or two time zones is usually not too difficult for the traveler to accommodate, but crossing three time zones typically causes symptoms of jet lag. Flying eastward is generally much more difficult than flying westward, as patients more easily accommodate phase delay than phase advancing, or “loss” of time. Treatments for jet lag syndrome usually involve efforts to rapidly reentrain the patient to the new environment, and protocols for advance preparation including setting back (for eastward travel) or setting ahead (for planned westward travel) one’s daily routine 2 to 3 weeks prior to the trip so that the traveler is already partially reset in his or her circadian routine before departing. Also critical is attempting to rapidly adapt to the new time zone, such as by seeking regular sunlight exposure during the daytime and avoiding light exposure in the evening. Brief use of a hypnotic medication and regular daily doses of melatonin⁷ 0.5 to 5.0 mg at bedtime for the first few nights after arrival can help reset the sleep schedule in the new time zone.

Shift-work sleep disorder results from workers who must constantly and regularly alter or rotate their work schedules between different shifts (so-called “swing shifts”) or workers who must accommodate a regularly scheduled second or third shift (i.e., shifts other than a day shift). Shift workers often have difficulty adapting and shifting their sleep-wake schedules and develop symptoms of

insomnia or hypersomnia. Shift workers must be educated to prioritize regularly obtaining a sufficient quantity of sleep, regardless of their work circumstances. Swing shift workers should also be counseled to avoid working more than five night shifts in a row, as night shift work frequently leads to a greater degree of sleep deprivation over time. Shift workers should also be counseled to avoid rotating swing shifts whenever possible, to strictly avoid scheduling overtime duty, and to avoid long commutes (and to exercise special caution to avoid drowsy driving). Judicious use of caffeinated beverages, or prescribed stimulant therapy with modafinil may be helpful for enhancing vigilance in some patients, but should be used with caution as they might interfere with sleep initiation.

The two most common endogenous circadian disorders are delayed sleep-wake phase disorder (DSWPD) and advanced sleep-wake phase disorder (ASWPD), disorders that are most prevalent in opposite extremes of life. DSWPD is seen most often in adolescents and young adults who are biological night owls in their circadian preference, preferring a delayed bedtime and rise time (i.e., bedtimes well past midnight and subsequent arising times in the late morning or early afternoon). DSWPD patients have an extreme and enduring form of this tendency, however, resulting in persisting misalignment of the patient to societal norms. Adolescent and young adult patients present with profound intractable initial insomnia due to their inability to fall asleep at a conventional bedtime as required for school or most daytime occupations, and profound daytime hypersomnia due to their inability to arise and function in the morning hours. Diagnosis is easily recognized by clinical history and sleep diaries, with or without adjunctive actigraphy to objectively verify the pattern of consistent delayed

⁷Available as a dietary supplement.

sleep-phase periods. Contrarily, ASWPD is more common in elderly individuals who are biological larks (i.e., preferring an early bedtime and early rise time by nature). However, the ASWPD elderly are unable to stay awake for desired evening activities (often even unable to go out to dinner with friends), and awaken undesirably early in the morning with a consequent inability to fall back asleep in early morning hours. The presentation can mimic depression, whose hallmark biological sign is often noted to be an early morning awakening; care should be taken to carefully distinguish between these two diagnoses. Treatment of each is difficult; options include specifically timed bright light therapy, with or without light restriction, and timed administration of low dose melatonin. The time of administration differs for the two disorders, and is determined by the patient's own endogenous dim light melatonin onset and arise time, and the phase response curve for light and melatonin administration. Bright light therapy is administered at approximately 2500 lx intensity for at least 30 minutes. The timing of bright light administration is first thing in the morning after arising in DSWPD, where a phase-advancing influence is desired; for ASWPD patients, bright light is prescribed in the late afternoon and early evening hours where it will have a phase-delaying effect. Weeks to a few months of regular therapy are necessary to achieve effect. Adherence is difficult and compliance unable to be verified. Specifically timed melatonin usually given at very low doses for this indication (contrary to its use in higher supraphysiologic doses as a hypnotic agent by many patients in other contexts of insomnia, or its high-dose use in REM sleep behavior disorder [RBD]) may also be administered, but its dose and timing are complicated; it must be given in accordance with the circadian phase response curve to have optimal effects and to avoid complicating the problem. For most patients with DSPS, melatonin 0.5 mg should be administered at approximately 6 PM (i.e., after the time point of 8 hours following the usual rise time, when the phase response curve shifts so that melatonin administration will have a phase-advancing effect); in ASWPD, melatonin would instead be given prior to the time point of 8 hours following the patient's usual rise time (so as to have a phase-delaying effect). Adjunctive light restriction is recommended in the late afternoon and evenings for DSWPD to avoid precipitating additional phase delays—such as the avoidance of working with luminescent computer screens or viewing video media from close distance in the late evenings—and some experts advocate the use of commercially available blue light restricting glasses as biologically reasonable, as blue light stimuli in evening hours may exacerbate phase delay and confound other recommended treatment effects. However, the efficacy of blue light restriction currently lacks explicit evidence from large clinical trials. As a last resort, the measure of chronotherapy, a progressive delay of bedtime every few days, is prescribed, with the bed and rise times being progressively and successively delayed until the desired bed and rise times are achieved. Attempts to then entrain the patient on this schedule with the aforementioned measures are again attempted with scheduled bright light and prescribed timed melatonin dosing. This is a lengthier process for DSWPD patients and necessitates work restriction during the approximate 2-week time frame necessary to achieve a turnaround of the desired patient's sleep/wake schedule.

Parasomnias and Other Nocturnal Events

Parasomnias are nocturnal events that disrupt sleep but usually do not appreciably disturb sleep quality. As such, nocturnal events do not typically present with symptoms of insomnia or hypersomnia unless there are other comorbid primary sleep disorders such as OSA, which is a frequent comorbidity presenting along with the parasomnias, especially in adult patients.

Parasomnias may arise from either NREM or REM sleep. The NREM parasomnias are essentially all variations on the theme of disorders of arousal, where the behavioral sleep state lingers into awakening, leaving arousal from sleep incomplete. Consequent clinical manifestations are surprisingly heterogeneous and often age related, with specific syndromes such as sleep terrors (also

called night terrors) in children, sleep walking and confusional arousals seen in children and adults, and sleep-related eating behavior seen almost exclusively in adults, especially those receiving zolpidem or other newer prescribed hypnotics. NREM disorders of arousal are especially common in children in the first decade of life and are regarded as a relatively normal variant (and perhaps in some cases simply representing an exaggerated manifestation of the physiological difficulty in arousing from the characteristically deeper N3 NREM sleep inherent in the developing brain). As such, pediatric parasomnias are frequently outgrown; however, in some patients, they do endure throughout life. In adult patients who present with newly evolved nocturnal events proven to be NREM disorders of arousal, one should be highly suspicious of comorbid primary sleep disorders that provoke arousing events, such as SDB or PLMD.

REM parasomnias include nightmares and RBD. Nightmares are undesirable, disturbing dreams that lead to sudden arousal from sleep with heightened autonomic sequelae of sweating, hypervigilance, tachycardia, and tachypnea. Nightmares and vivid dreaming are present in between 10% and 50% of normal young children and in about 50% of adults, but become abnormally disturbing in content or frequency much less frequently, and the true prevalence of nightmare disorder remains unknown. Patients who present with a chief complaint of frequent nightmares should be reassured as to their biological nature and receive a detailed physical and neurologic history and examination to exclude potential provoking comorbid causes such as a recent medication change in type or dosage, mood or anxiety disorder, or primary sleep disorder such as SDB. If no certain readily reversible triggering cause may be identified, referral for consideration of hypnosis, behavior treatment in the form of imagery rehearsal therapy, or pharmacotherapy with clonazepam (Klonopin)¹ may be helpful in some cases. Nightmares that involve flashbacks of previous traumatic events, most often also with similar daytime flashbacks, suggest the alternative diagnosis of posttraumatic stress disorder (PTSD) and the need for psychiatric evaluation. Recent evidence has suggested that alpha-blocking medications such as prazosin (Minipress)¹ or terazosin (Hytrin)¹ may be helpful in suppressing nightmares associated with PTSD.

RBD is characterized by potentially injurious dream enactment behaviors that mirror frightening dream content (characteristically involving fighting off attackers or defending oneself against assailants). In RBD, bed partners will describe objective witnessed dream enactment manifested by violent limb thrashing movements such as punching or kicking and screaming or shouting vocalization during sleep. While RBD patients rarely leave the bed and sleepwalk, falls or other injurious behavior to self or the bed partner are frequent. Importantly, RBD is strongly associated with future development of neurodegenerative disorders. Elderly patients newly diagnosed with RBD harbor up to an 91.9% risk of developing Parkinsonism within 15–25 years of symptom onset, with a shorter-term risk of 30% to 50%, so that all patients with RBD require serial neurologic examinations and follow-up. RBD in young adults may, however, be caused by antidepressant medications, especially the SSRIs, and removal of the offending drug may lead to resolution of dream enactment in some cases. Diagnosis of RBD is by clinical history as well as confirmatory evidence for increased REM sleep muscle tone evident on polysomnographic electromyogram (EMG) leads in the chin and limbs (known as REM sleep without atonia). Treatment options include melatonin, initially at doses of 3 to 6 mg and gradually titrating toward 12 mg nightly as needed to suppress witnessed injurious behaviors, or clonazepam (Klonopin)¹ 0.5 to 1.0 mg increased to 2 to 3 mg nightly. Great care should be taken to first exclude comorbid OSA prior to use of clonazepam, a potential respiratory and upper-airway suppressant.

Nocturnal epilepsies or psychogenic nonepileptic spells may also arise from sleep or apparent sleep and are additional diagnostic considerations in the differential diagnosis of parasomnias. A high

¹Not FDA approved for this indication.

degree of stereotypy (one attack being essentially identical to the next) with multiple attacks within a single night are features suggestive of organic partial extratemporal (frontal lobe) epilepsy, even in the absence of EEG changes between or during an episode. In children, benign rolandic epilepsy may lead to stereotyped episodes of facial twitching and drooling, with or without secondary generalized tonic clonic seizures. Children or adults with autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) may present with bizarre brief motor behavior (typically of 10- to 60-second duration) without postictal sleepiness. ADNFLE has recently been mapped in several kindreds as a channelopathy, producing a defect of the neuronal nicotinic acetylcholine receptor. Psychogenic nonepileptic spells are instead characterized by nonstereotypic and often prolonged attacks that arise from a behavior state of apparent sleep that is instead confirmed during video-EEG PSG to represent normal waking EEG background. Distinguishing features for the differential diagnosis of nocturnal events are shown in [Table 5](#).

Sleep-Related Movement Disorders

Sleep-related movement disorders include restless legs syndrome (RLS), periodic limb movement disorder (PLMD), leg cramps, bruxism, rhythmic movement disorder, and others.

RLS and PLMS

Diagnosis of RLS is based completely on a clinical history and typically requires four central elements of the described symptoms: an uncomfortable urge to move the legs, with or without uncomfortable leg sensations; temporary relief by movement; symptoms occurring solely or predominantly at rest; and nocturnal worsening of symptoms. About 50% of patients with RLS will carry a positive family history of the disorder, but positive family history is not necessary for the diagnosis. The nature of the symptoms as described by the patient may be quite variable with regard to the symptom quality, location or distribution, temporal occurrence, frequency, and severity. RLS symptoms are usually described as

uncomfortable, although not really painful, with a sense of a creepy-crawly or prickling discomfort, often below the knees and centered about the shins or calves, but sometimes more proximally in the thighs, or even isolated to the feet and ankles. Symptoms may occur in the arms as well, especially proximally near the shoulders. Augmentation is common, occurring in about 50% of patients treated with dopaminergic drugs and involves a worsening of the symptoms: symptom onset occurs earlier during the day, becomes more intense, and spreads up to the arms. RLS has been linked to deficient iron stores and dopaminergic neurotransmission in the brain and is more common in patients with parkinsonism, multiple sclerosis, epilepsy, and in those with chronic renal insufficiency.

While periodic limb movements of sleep (PLMS) are seen in 80% to 90% of RLS patients, PLMS are not necessary for the diagnosis of RLS. Furthermore, PLMS are also extremely frequent in the general population, seen in 5% to 15% of younger adults and as many as 45% of elderly individuals. PLMD is diagnosed when PLMS is thought to cause daytime hypersomnia in the absence of other sleep disorders.

Nonpharmacologic treatments including warm or cool baths, massage, stretching, or even the application of spontaneous compression devices have been reported to be effective anecdotally and in small case series, but an evidence base for these measures remains poor, and most patients seeking medical care for the symptom have severe enough symptoms to merit pharmacologic treatment.

Iron and pharmacologic treatments for RLS are outlined in [Table 6](#). Iron deficiency, or even low normal body iron stores, may worsen or precipitate symptoms. Measuring a serum ferritin should be considered early in all RLS patients, with iron replacement therapy begun if serum ferritin values are less than 50 mcg/L. Iron therapy can be constipating or cause GI distress, and the formulation of iron with added vitamin C (Ferrex 150 Plus, Vitelle Irospan) is often better tolerated by those who cannot stomach ferrous sulfate.

TABLE 5 Distinguishing Features of Nocturnal Events

	PREMONITORY SYMPTOMS	BEHAVIORAL CHARACTERISTICS	DURATION	FREQUENCY	EEG/PSG FINDINGS
NREM Parasomnias					
Night terrors	None	Inconsolable screaming	Minutes	1 or less nightly	Arousal from N2-N3
Confusional arousals	None	Confused, amnesic	Seconds to minutes	1 or less nightly	Arousal from N3 > N2
Sleepwalking	None	Ambulation, amnesia	Minutes	1 or less nightly	Arousal from N3 » N2
REM Parasomnias					
Nightmares	Dream recall	Arousal, frightened, palpitations	Seconds	Generally 1/nightly	Arousal from REM
RBD	Variable dream recall	Thrashing, complex motor behavior	Seconds to minutes	>1/night, second > first half	REM sleep without atonia
Epilepsies					
BECTS	Facial twitching, hypersalivation	Focal motor or GTC, postictal	Seconds to minutes	>1/night	Arousal from NREM, IEDs EEG pattern
ADNFLE	Bizarre stereotyped motor behavior	Focal motor, bizarre motor	Seconds, < 1 min	1 or multiple attacks/night	Arousal from N2
TLE	Aura variable	CPS, postictal	1–2 min	1 or multiple attacks/night	Arousal from N2
Psychogenic spells	Variable	Variable	often > 5 min	1 or multiple attacks/night	Normal awake EEG

Abbreviations: NREM = nonrapid eye movement sleep; N2 = stage 2 NREM sleep; N3 = stage 3 NREM sleep; REM = rapid eye movement sleep; IEDs = interictal epileptiform discharges; EEG = electroencephalogram; PSG = polysomnogram; BECTS = benign epilepsy of childhood with centro-temporal spikes; ADNFLE = autosomal dominant nocturnal frontal lobe epilepsy; TLE = temporal lobe epilepsy; RBD = REM sleep behavior disorder.

TABLE 6 Clinical Pharmacology of Treatments for Restless Leg Syndrome

	MECHANISM OF ACTION	DOSAGE	TYPICAL ADVERSE EFFECTS	INTERACTIONS
Iron Replacement				
Ferrous sulfate ¹	Fe	324 mg tid	Nausea, constipation	None
Ferrous fumarate + vit C ¹	Fe	200/125 mg tid	Nausea, constipation	None
Carbidopa-Levodopa (Sinemet) ¹	DA	25/100 1–2 prn	Nausea, dizziness, ICD	None
Pramipexole (Mirapex)	DA	0.125–1.0 mg ² qhs	Nausea, dizziness, ICD	None
Ropinirole (Requip)	DA	1–6 mg ² qhs	Nausea, dizziness, ICD	None
Rotigotine (Neupro)	DA	1–3 mg qam	Nausea, dizziness, ICD	None
Gabapentin (Neurontin) ¹	Unknown	300–1200 ² mg qhs	Nausea, dizziness, pedal edema, weight gain	None
Gabapentin Enacarbil (Horizant)	Unknown	600 mg	Nausea, dizziness, pedal edema, weight gain	None
Pregabalin (Lyrica) ¹	Unknown	100–600 mg qhs	Nausea, dizziness, pedal edema, weight gain	None
Tramadol (Ultram) ¹	MRA	50 mg 400 mg qhs	Nausea, dizziness	None
Oxycodone ¹	MRA	5–15 mg	Nausea, dizziness	None

¹Not FDA approved for this indication.²Exceeds dosage recommended by the manufacturer.

Abbreviations: mg = milligrams; Fe = iron replacement; DA = dopamine agonist; MOR = mu opiate receptor agonist.

Carbidopa-levodopa (Sinemet)¹ may be used for patients with only intermittently disturbing symptoms, but chronic nightly use of carbidopa-levodopa, especially above a dosage of 200 mg daily, may raise the risk of augmentation. For nightly use, the newer dopaminergic agonist medications pramipexole (Mirapex) or ropinirole (Requip) remain a mainstay of treatment. Pramipexole may be initiated at 0.125 to 0.25 mg nightly and titrated every few days to the 0.375 to 0.50 mg range or beyond if needed for symptom control. Doses beyond 1.0 mg³ are typically not additionally effective and appear to raise augmentation risk. Ropinirole may be initiated at 0.5 to 1.0 mg with gradual upward titration to the 4 to 6 mg³ range as needed and tolerated. Generally, dosing 1 hour prior to bedtime is sufficient, but if earlier evening or late afternoon symptoms emerge, cautious application of divided doses may be utilized, and some experts advise at least a low morning dosage administered daily to achieve a more chronic steady state of dopamine administration since this may be a sensible strategy to minimize augmentation risk. For either initial first-line therapy, or particularly when patients are beginning to experience earlier symptom onset during the day and may have failed the other short-acting dopaminergic drugs pramipexole and ropinirole, a rotigotine (Neupro) patch has been an advent in RLS management and often may be substituted for those other agents to provide more day-long symptom relief and reduce a growing augmentation tendency. Rotigotine offers several other advantages, as its transdermal delivery system provides continuous day-long release of medication that may minimize peak/trough serum concentration variation and minimize the occurrence of other potential adverse effects. Rotigotine also appears to result in augmentation less frequently than other dopaminergic drugs. All patients receiving dopaminergic agents should be counseled upfront about the approximate 15% idiosyncratic risk of impulse control disorder symptoms (such as pathologic gambling, shopping, or hoarding/punding behaviors), and be forewarned that should such problems result, the medication must be withdrawn and another

nondopaminergic drug substituted for symptom control. Typical dose-related adverse effects are also described further in Table 6.

Gabapentin (Neurontin) is increasingly becoming an alternative first-line medication for RLS, dosed 300 to 1200² mg every night at bedtime as needed and tolerated. Gabapentin may be the agent of choice in patients with comorbid anxiety, pain and insomnia or in patients who are intolerant, resistant to, or have developed augmentation with dopamine agonist medications. On the other hand a dopamine agonist is still generally the first choice for pharmacologic treatment of RLS in severe cases and may be preferred over gabapentin in patients with comorbid depression, obesity, metabolic syndrome, OSA and history of falls. Gabapentin enacarbil (Horizant) is a prodrug of gabapentin that is better absorbed and carries an indication for RLS, but generic gabapentin is also frequently effective and well tolerated, and there has been no head-to-head trial showing superiority of the more expensive prodrug gabapentin enacarbil over that of gabapentin. Other alternatives include clonazepam¹ and tramadol (Ultram).¹ For patients unresponsive to these measures, opiate treatment with oxycodone (Roxicodone)¹ 5 to 15 mg at bedtime, hydromorphone (Dilaudid),¹ or methadone (Dolophine)¹ are often effective. A large randomized trial showed that the combination oxycodone-naloxone (Targiniq ER)¹ resulted in substantial improvements in RLS symptoms in patients who had previously shown inadequate response to dopamine agonists. Small case series suggest other alternatives for refractory RLS such as carbamazepine (Tegretol),¹ oxcarbazepine (Trileptal),¹ and lamotrigine (Lamictal).¹ The impact of comorbid OSA should also be considered, as optimization of treatment for SDB may improve both subjective RLS symptoms as well as PLMD frequency in many patients.

Sleep-Related Leg Cramps

Sleep-related leg cramps are a common and enigmatic problem affecting 7% to 10% of children and up to 70% of elderly adults. Unfortunately, despite their extremely common occurrence and

¹Not FDA approved for this indication.³Exceeds dosage recommended by the manufacturer.¹Not FDA approved for this indication.²Not available in the United States.

impact on the quality of life of cramp sufferers, little is known about the pathophysiology or treatment of this condition. Cramps are painful, involuntary sustained muscle contractions, lasting 2 to 10 minutes and affecting the unilateral or bilateral calves, thighs, or feet, with residual tenderness of the affected muscle lasting up to an hour or longer. The clinical approach to sleep-related leg cramps is to first determine whether they are also present during daytime in addition to sleep. If daytime cramping is prominent, exclusion of a precipitating neuromuscular disorder is paramount, including amyotrophic lateral sclerosis, peripheral neuropathy, myositis, or cramp-fasciculation syndrome. In elderly men, peripheral vascular disease and other systemic medical comorbidities are also common. (The reader is referred to the chapter on neuromuscular disorders for further advice on the diagnosis of these conditions.) A neurologic examination should be conducted on all cramp sufferers, and those having sensorimotor findings, fasciculations, or pathologic reflex findings should be referred for EMG, serum creatine kinase, or additional blood and urine tests for exclusion of symptomatic causes of neuropathy as appropriate. While additional testing for electrolyte abnormalities such as hypomagnesemia, hypocalcemia, hyponatremia, and hypokalemia can be considered, they are of extremely low yield. When examination findings are normal and cramps are isolated to the sleep state, further diagnostic work-up can usually be avoided. Symptomatic treatment measures for sleep-related leg cramps include tonic water with lemon and advising adequate hydration and nightly stretching of the calves and thighs. Prescription quinine (Qualaquin)¹ carries a FDA black box warning for leg cramp treatment and is essentially no longer used for this indication. For refractory frequent cramp sufferers, a sodium-channel blocking anticonvulsant such as carbamazepine¹, oxcarbazepine¹, or lamotrigine¹ may also be considered.

Sleep-Related Bruxism

Sleep-related bruxism, rhythmic grinding of the teeth during sleep, may lead to significant tooth wear and dental or jaw pain. The condition is usually idiopathic, although it may be associated with psychiatric conditions such as mood or anxiety disorders, especially if it is also present during daytime. Treatment usually involves dental referral for consideration of a fitted mouth guard, although in extreme cases pharmacotherapy with clonazepam¹ or consideration of botulinum toxin (Botox)¹ may be necessary.

Other Sleep-Related Movement Disorders

Sleep-related rhythmic movement disorder usually occurs in patients with psychomotor maldevelopment and involves repetitive head and neck or axial body movements. This behavior is not strictly voluntary and often persists during PSG into deep drowsiness or light NREM sleep, so behavioral treatments alone are often ineffective. Head banging behavior, sometimes into the headboard of the bed, can be injurious at times: a protective helmet or treatment with clonazepam¹ is advisable in some cases. Most other movement disorders, such as organic tremors, myoclonus, or dyskinesias generated by the basal ganglia, are suppressed during sleep but may reemerge during drowsiness or nocturnal awakenings.

Propriospinal myoclonus at sleep onset is characterized by myoclonic jerks having their primary and earliest onset in abdominal and axial muscles prior to spreading to the limbs and may be associated with thoracic spinal cord pathology. Spinal imaging with MRI is advised. Treatment with clonazepam¹ is usual for this uncommon diagnosis, although it is unfortunately often ineffective, and many cases of propriospinal myoclonus are instead found to represent a functional movement disorder.

Isolated Symptoms and Normal Variants

These conditions are felt largely to represent either normal variants or otherwise largely benign disorders. The definition of long and short sleepers are somewhat arbitrary, but may be considered as greater than 10 hours or shorter than 5 hours of habitual sleep.

Short or long sleep time are each assumed to be variants of normal behavior in the absence of hypersomnia or nighttime symptoms of insomnia.

Sleep talking, or somniloquy, in isolation is rarely of concern. History is often lifelong in such patients. When sleep talking is newly evolved in an elderly individual or a younger patient receiving antidepressant therapy, RBD should be considered in the differential diagnosis, and the patient should be questioned about other potential evidence for dream enactment behavior. A careful medication history and neurologic examination alone will usually dictate whether further evaluation with PSG may be indicated, but in most cases isolated sleep talking is not a cause for concern.

Sleep starts, hypnic jerks or physiologic myoclonus are near universal in their occurrence and often associated with recent excessive caffeine intake or emotional or physical stress. A history of occurrence of jerks limited to the arms, legs, or axial musculature causing arousal within the first 5 to 10 minutes of sleep, and lacking later recurrence during the night, is typical. Reassurance and avoidance of precipitating factors is advised; however, if hypnic jerks are excessive or recur later in the night, PSG is occasionally necessary to distinguish this benign diagnosis from PLMD or propriospinal myoclonus. Propriospinal myoclonus at sleep onset is characterized by myoclonic jerks having their primary and earliest onset in abdominal and axial muscles prior to spreading to the limbs and may be associated with thoracic spinal cord pathology. Spinal imaging with MRI is advised. Treatment with clonazepam¹ is usual for this uncommon diagnosis.

Other Sleep Disorders

Undesirable influences in the patient's sleep environment can serve to regularly distract or disturb him or her from initiating or maintaining sleep. Typical influences include a bed partner who snores loudly or who causes bed motion due to restless or disturbed sleep; pets who sleep in bed with the patient and cause awakening; environmental noise from neighborhood dogs, car alarms, or neighboring freeway or train way; too much outdoor ambient light; or undesirable household ambient temperature. There is considerable overlap in this category of environmental sleep disturbance with inadequate sleep hygiene, as activating stimuli in the environment may lead the patient toward chronic insomnia and characterizing undesirable sleep-related behaviors that serve to further disrupt restful sleep.

Sleep-Related Medical and Neurologic Disorders

Fatal familial insomnia is an exceedingly rare, autosomal dominant variant form of familial Creutzfeldt-Jakob disease, a prion disorder that leads to progressive insomnia and progressive cognitive impairment, with death inevitably occurring within 3 years of onset. Aggregate prion protein accumulates in the thalamus and other brain regions, and relentlessly progressive insomnia, panic disorder, hallucinosis, and dementia ensue. Unfortunately, no treatments are currently known for this rare disorder.

Conclusions

Sleep disorders are common and result in significant patient morbidity, daytime dysfunction, and impaired quality of life. Untreated sleep disordered breathing (SDB) may also raise the risk for hypertension, vascular events, and mortality. The most common presenting symptoms of sleep disorders include insomnia, characterized by difficulty initiating and maintaining sleep with poor sleep quality, and hypersomnia, the symptom of excessive daytime sleepiness. Evaluation begins with a detailed history and physical examination, which in select cases may require support and clarification by polysomnography and multiple sleep-latency testing. Fortunately, effective therapies are available for the majority of sleep disorders. Insomnia typically requires behavioral or pharmacologic interventions, while SDB may be effectively treated in most cases with positive airway pressure (PAP) therapy. Primary CNS

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

hypersomnias including narcolepsy require stimulant management in most cases, while most parasomnias benefit from clonazepam.¹ Circadian sleep disorders may require timed light and melatonin therapies. Patients having RLS and PLMD should be evaluated for iron deficiency and may enjoy symptom control through dopaminergic or other alternative symptomatic treatments. The majority of patients with sleep disorders benefit from a careful clinical evaluation and appropriately selected therapies.

¹Not FDA approved for this indication.

CURRENT THERAPY

- Blood pressure control is critical for patients with an intracranial hemorrhage.
- Small intracranial hemorrhages without midline shift or significant symptoms may be monitored, but surgical decompression is otherwise required.
- For patients requiring sedation, propofol is often preferred due to its short half-life, making it easier to monitor neurologic status.
- Mannitol can also be used to help lower intracranial pressure.
- For posttraumatic seizures, phenytoin is the preferred medication.
- If there is any concern for concussion, the athlete should immediately be removed from play.
- An athlete should never be allowed to return to play on the same day as the injury.
- After an initial rest period of 24 to 48 hours, an athlete should begin progressing through return-to-play and “return-to-learn” protocols.
- In the first 24 hours after injury, acetaminophen is the treatment of choice for associated headaches; nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin can worsen an undiagnosed intracranial hemorrhage.
- If headaches persist greater than 3 to 5 days, medications that do not have a risk for rebound headaches (e.g., tricyclic antidepressants) can be used.
- Good sleep hygiene is important for recovery. If insomnia persists more than 2 to 3 days after injury, medications can be considered.
- Typical recovery time is up to 2 weeks in adults and 4 weeks in children.
- Access to a multidisciplinary team including physical therapists, neurologists, and psychiatric providers is beneficial for athletes with complicated or prolonged recoveries.
- If an athlete has a history of a learning disability, depression, anxiety, or chronic headaches, recovery can be complicated by an exacerbation of their underlying disease.

SPORTS-RELATED HEAD INJURIES

Method of

Brandon Hockenberry, MD; Margaret Pusateri, MD; and Christopher McGrew, MD

CURRENT DIAGNOSIS

- Initial evaluation of any sports-related head injury should follow standard emergency medicine procedures.
- Presence of any “red flag” symptoms is concerning for a more serious head injury (skull fracture, intracranial hemorrhage) and requires emergency evaluation.
- If advanced imaging is indicated, a noncontrast computed tomography (CT) scan of the head is the initial study of choice.
- If no “red flag” symptoms are present, one of several validated neuropsychological tests should be administered to evaluate cognitive function (e.g., Sports Concussion Assessment Tool, version 5 [SCAT 5]).
- Ultimately, concussion is still a clinical diagnosis.
- Advanced neuroimaging, fluid biomarkers, genetic testing, helmet sensors, and video surveillance have all been purported as possible prognostic indicators but require further validation.

Introduction and Epidemiology

Sports-related head injuries include a heterogeneous group of insults to the brain caused by either direct impact to the head or by an impact to the body associated with energy transfer into the head.

In the United States, sports are one of the leading causes of head injuries. Specifically between the ages of 15 to 24, athletic activities are the second-leading cause of head injuries, and only motor vehicle accidents have a higher incidence. Athletic and recreational activities vary widely in terms of biomechanics and kinetics, resulting in a wide range of associated risks. Many sports are limited by the speed at which an athlete can run (rugby or soccer), but others allow athletes to compete at much higher speeds, some nearly equivalent to motor vehicles (cycling or skiing). These sports potentially put athletes at a higher risk of more severe head injuries.

Sports- and recreation-related traumatic brain injuries (SRR-TBIs) are monitored by the National Electronic Injury Surveillance System-All Injury Program (NEISS-AIP). According to the NEISS-AIP, there were more than 3.4 million visits to emergency departments (EDs) across the United States for SRR-TBIs between 2001 to 2012, or about 340,000 per year. The number of SRR-TBI-related visits has increased each year during this time frame, but it is unclear whether this is a true increase in incidence or simply an increase in reporting. The CDC’s “Heads Up” campaign, which attempts to increase awareness and prevent concussions and other TBIs, was launched in 2003 and could have had an impact on the increased number of ED visits. Additionally, there has been increased media attention focused on head injuries in sport, particularly surrounding American football.

hypersomnias including narcolepsy require stimulant management in most cases, while most parasomnias benefit from clonazepam.¹ Circadian sleep disorders may require timed light and melatonin therapies. Patients having RLS and PLMD should be evaluated for iron deficiency and may enjoy symptom control through dopaminergic or other alternative symptomatic treatments. The majority of patients with sleep disorders benefit from a careful clinical evaluation and appropriately selected therapies.

- Ultimately, concussion is still a clinical diagnosis.
- Advanced neuroimaging, fluid biomarkers, genetic testing, helmet sensors, and video surveillance have all been purported as possible prognostic indicators but require further validation.

Introduction and Epidemiology

Sports-related head injuries include a heterogeneous group of insults to the brain caused by either direct impact to the head or by an impact to the body associated with energy transfer into the head.

In the United States, sports are one of the leading causes of head injuries. Specifically between the ages of 15 to 24, athletic activities are the second-leading cause of head injuries, and only motor vehicle accidents have a higher incidence. Athletic and recreational activities vary widely in terms of biomechanics and kinetics, resulting in a wide range of associated risks. Many sports are limited by the speed at which an athlete can run (rugby or soccer), but others allow athletes to compete at much higher speeds, some nearly equivalent to motor vehicles (cycling or skiing). These sports potentially put athletes at a higher risk of more severe head injuries.

Sports- and recreation-related traumatic brain injuries (SRR-TBIs) are monitored by the National Electronic Injury Surveillance System-All Injury Program (NEISS-AIP). According to the NEISS-AIP, there were more than 3.4 million visits to emergency departments (EDs) across the United States for SRR-TBIs between 2001 to 2012, or about 340,000 per year. The number of SRR-TBI-related visits has increased each year during this time frame, but it is unclear whether this is a true increase in incidence or simply an increase in reporting. The CDC’s “Heads Up” campaign, which attempts to increase awareness and prevent concussions and other TBIs, was launched in 2003 and could have had an impact on the increased number of ED visits. Additionally, there has been increased media attention focused on head injuries in sport, particularly surrounding American football.

Concussions are by far the most common head injury associated with athletic activity. It is estimated that there are 1.7 to 3.0 million concussions per year related to sports and recreational activities. The overall rate is 2.5 concussions per 10,000 athletic events, and concussions make up 5% to 18% of reported injuries in the National Collegiate Athletic Association. It is estimated that 50% of concussions go unreported or undiagnosed. The most common severe head injury is a subdural hematoma, which accounts for >90% of all sport-related catastrophic head injuries. These are most often seen in American football, cheerleading, and skiing/snowboarding and occur in <1 per 100,000 athletic events. Fatalities from sports-related head injuries are very rare; however, subdural hematoma is a serious injury. In one study, it was reported that American football players with subdural hematoma had a fatality rate of 8.5% and a 48% rate of suffering permanent neurologic deficits.

Risk Factors

Every athlete is potentially at some risk for a head injury during activity. Many factors contribute to relative risk, with the type of activity being the largest contributing factor. In younger years, males sustain the most head injuries playing football or wrestling, whereas bicycling and basketball take over top spots after high school and college years. In females, bicycling and horseback riding contribute the most head injuries. It should be noted that some activities have higher incidence rates of head injuries than the above-mentioned activities (men's/women's ice hockey) but are not as commonly played and therefore do not contribute to the sheer volume of injuries that other activities do. With respect to concussion specifically, men's ice hockey and football have the highest incidence rates (5.5 to 6.5 concussions per 10,000 athletic events) in the high school and college populations. On the women's side, soccer and lacrosse have the highest rates (3 to 3.5 concussions per 10,000 athletic events).

Children and teens are at increased risk for head injuries because of their immature development and increased participation in activities that have higher risk for head trauma. Overall, 70% of all SRR-TBIs are in the age group of 0 to 19 years. In the young athlete, a larger head-to-neck ratio, smaller amount of neck/shoulder musculature, and thinner cranial bones all contribute to an increased chance that a blow to the head will cause a head injury. The active elderly have better balance, fewer falls, and fewer TBIs than their more chronically ill counterparts. Therefore increased age is not an independent risk factor for sport- and recreation-related TBI.

At the high school and college level, men have more concussions than women in sheer numbers but a lower incidence rate overall. Females may have greater risk because of decreased neck musculature compared with males. Female sex has been associated more commonly with abnormal imaging, surgical intervention, complication, and death. A history of previous concussion increases risk for future concussions compared with nonconcussed athletes, and the greatest risk for repeat concussion is during the 10-day period after the most recent concussion.

Pathophysiology

The pathophysiology of SRR-TBIs and sport-related concussion (SRC) is multifactorial. Several mechanisms have been identified. Biomechanically, a combination of acceleration, deceleration, rotational, and translational forces directly applied or transmitted to the head affect change at the level of individual cells. Metabolic derangements, neurotransmitter dysfunction, changes in cerebral blood flow, neuroinflammation, microstructural damage, and diffuse axonal injury have all been implicated as potential pathways. Helmet-based measurement studies have attempted to quantify head impacts, providing information on force, frequency, and location. However, results vary widely among athletes diagnosed with concussions. In addition, the accuracy of the data detected by helmet sensors and video surveillance systems has been called into question; it does not necessarily reflect the impact to the brain itself, and there is no evidence to support the use of such systems to attempt to diagnose SRC.

Assessment and Diagnosis of Sports-Related Head Injury

The initial assessment of any sports-related head injury should follow standard emergency medicine procedures. Assessment of the "ABCs" (airway, breathing, circulation) and evaluation for concomitant cervical spine injury should be the first step in management. The presence of any "red flag" symptoms ([Table 1](#)) should raise concerns for a serious head injury, such as an intracranial hemorrhage or skull fracture, and requires immediate evaluation in the ED, likely advanced head or neck imaging, and possible specialist consultation. The appropriate emergency action plan should be initiated and the athlete stabilized and transported to the designated medical facility.

Once in the ED, the decision whether to obtain images needs to be made. Some assessment tools have been developed such as the [PECARN](#) and [Canadian CT Head Injury algorithms](#). Glasgow coma scale score <14, palpable skull fracture, or presence of red flag symptoms would all be reasons to image acutely. The imaging test of choice after head injury is non-contrast head CT. A non-contrast CT will show fractures, intracranial hemorrhage, midline shifts, and signs of edema. CT with angiography will show decreased blood flow into cerebral vessels because of increased intracranial pressure. However, if increased intracranial pressure due to malignant brain edema or expanding hematoma is suspected, more invasive intracranial pressure monitoring is a more accurate measure and will be more useful to management ([Table 1](#)).

If no "red flag" symptoms are present and the athlete does not require emergency medical treatment, he or she should be removed from the field of play if there is any suspicion for possible SRC. Several brief neuropsychological tests have been developed to evaluate cognitive function. Examples of practical and validated tests include the [Sports Concussion Assessment Tool version 5 \(SCAT 5\)](#) and the [Standardized Assessment of Concussion \(SAC\)](#). The SCAT 5 is broken down into six steps: immediate or on-field assessment, symptom evaluation, cognitive screening, neurologic screening, delayed recall, and decision. In addition to an assessment of the aforementioned "red flag" symptoms, the immediate or on-field assessment section of the SCAT 5 also includes a review of observable signs (e.g., lying motionless on playing field, facial injury after head trauma, blank or vacant look), a memory assessment using the Maddocks Questions ([Table 2](#)), a measure of the Glasgow Coma Scale ([Table 3](#)), and a cervical spine assessment. It has been found that standard orientation questions (name, location, and year) are not reliable in the immediate assessment of SRC. The Maddocks Questions, which focus on sport-specific memory assessment, provide better information to help the examiner determine whether there is a concern for an SRC. Once the initial assessment is complete, if there is any concern for an SRC, the athlete should be removed from the sporting environment and not allowed to return to play on the day of injury.

TABLE 1 Red Flag Symptoms*

Persistent vomiting
Seizure
Severe "worst headache of my life"
Focal neurologic deficit
Blurred vision
Slurred speech
Significant drowsiness/poor awakening
Poor orientation to person/place/time
Declining mental status

*The presence of any of these symptoms should prompt consideration of ED evaluation and head imaging. If no red flags are present, the clinician may be able to send the athlete home safely and follow-up in the office the next day.

TABLE 2 Memory Assessment: Maddocks Questions*

What venue are we at today?

What half is it now?

Who scored last in the game?

What team did you play last week?

Did your team win the last game?

Note: Can be adapted to specific sports as necessary.

*These questions help make diagnosis of concussion. No official score cutoff is diagnostic; however, inability to answer them all correctly should raise suspicion for concussion or more severe head injury. Questions can be changed slightly if they are not relevant to a sport, such as swimming.

TABLE 3 Glasgow Coma Scale*

BEST EYE RESPONSE (E)	BEST VERBAL RESPONSE (V)	BEST MOTOR RESPONSE (M)
Eye opening spontaneously—4	Oriented—5	Obeys commands—6
Eye opening to voice—3	Confused—4	Localizes to pain—5
Eye opening to pain—2	Inappropriate words—3	Flexion/withdrawal from pain—4
No eye opening—1	Incomprehensible sounds—2 No verbal response—1	Abnormal flexion to pain—3 Abnormal extension to pain—2 No motor response—1

*Used to rate severity of head injury. Scores in each category are added for a total of 15 points. Athletes with concussion typically have a Glasgow Coma Scale score of 14 (losing 1 point in the verbal response category) or 15. Scores <14 should prompt a visit to the ED for head imaging.

Diagnosis of SRC remains a clinical diagnosis. Over the last two decades, multiple investigations have focused on the use of advanced neuroimaging (eg, f-MRI, EEG) and body fluid analysis (blood, saliva, cerebrospinal fluid) as potential tools to aid in the diagnosis of SRCs. (In addition, these modalities have also been explored as potential prognostic indicators, attempting to predict clinical recovery or assess the cumulative risk of repetitive trauma.) At this time advanced neuroimaging, fluid biomarkers, and genetic testing are important research tools but require further validation to determine their ultimate clinical utility in evaluation and diagnosis of SRC.

Clinical Manifestations

Clinical manifestations after an SRR-TBI and SRC can be varied. The brain itself is a complex organ. Depending on which area is injured, different symptoms may present. With regard to the more serious diseases, such as intracranial hemorrhages or diffuse axonal injury, the athlete is often critically injured, again demonstrating “red flag” symptoms and signs of increased intracranial pressure. However, SRC is an evolving injury within the acute phase and can often have an initially subtle presentation. Signs and symptoms rapidly change, especially over the first 24 to 48 hours. Classically, symptoms fall into one of four categories: physical (headache, nausea, dizziness), cognitive (difficulty concentrating, slowed reaction times), emotional (anxiety, irritability), and sleep disturbances (insomnia, hypersomnia). As part of the SCAT 5 and other concussion assessment tools, an in-depth symptom checklist is used to evaluate SRCs both initially and during follow-up. For example, Table 4 outlines the SCAT 5’s symptom checklist. It is important to note that there are no specific scoring guidelines that are diagnostic of concussion. The scores are most commonly used to monitor an athlete’s recovery, tracking

TABLE 4 SCAT 5 Symptoms Checklist*

SYMPTOM	SEVERITY
Headache	0 1 2 3 4 5 6
“Pressure in head”	0 1 2 3 4 5 6
Neck pain	0 1 2 3 4 5 6
Nausea or vomiting	0 1 2 3 4 5 6
Dizziness	0 1 2 3 4 5 6
Blurred vision	0 1 2 3 4 5 6
Balance problems	0 1 2 3 4 5 6
Sensitivity to light	0 1 2 3 4 5 6
Sensitivity to noise	0 1 2 3 4 5 6
Feeling slowed down	0 1 2 3 4 5 6
Feeling like “in a fog”	0 1 2 3 4 5 6
“Don’t feel right”	0 1 2 3 4 5 6
Difficulty concentrating	0 1 2 3 4 5 6
Difficulty remembering	0 1 2 3 4 5 6
Fatigue or low energy	0 1 2 3 4 5 6
Confusion	0 1 2 3 4 5 6
Drowsiness	0 1 2 3 4 5 6
More emotional	0 1 2 3 4 5 6
Irritability	0 1 2 3 4 5 6
Sadness	0 1 2 3 4 5 6
Nervous or anxious	0 1 2 3 4 5 6
Trouble falling asleep (if applicable)	0 1 2 3 4 5 6
Total number of symptoms	Of 22
Symptom severity score	Of 132

*There is no score cutoff that is diagnostic of concussion; it is simply used to monitor a patient’s improvement or decline over time. Higher scores at time of injury are associated with longer recovery times.

improvement or decline over time. Of note, higher scores at the time of initial injury are associated with longer recoveries.

Therapy (or Treatment)

Presence of red flag symptoms listed in Table 1 or a GCS of <14 should raise suspicion for a more severe SSR-TBI, such as a skull fracture or intracranial hemorrhage, rather than a typical concussion. If an athlete sustains a SSR-TBI other than concussion, they should be evaluated in the ED. In the event of an intracranial hemorrhage of any kind, the largest concern is increasing intracranial pressure. Strict blood pressure control is incredibly important because an increased blood pressure will increase the pressure in the bleeding vessel and thus the rate and severity of the bleed. Intracranial hemorrhages may be monitored if the bleed is small and not causing a midline shift or significant symptoms. However, definitive treatment with surgical decompression is preferred for subdural and epidural hemorrhages. Most patients will require intubation, sedation, and intracranial pressure monitoring. For sedation, propofol (Diprivan) is the preferred agent at many institutions because it has a short half-life and makes it easier to monitor the patient’s neurologic status. In the presence of malignant brain edema, mannitol (Osmitrol) can be added to decrease intracranial pressure when strict blood pressure and pain control has failed. For a TBI causing posttraumatic seizure, phenytoin (Dilantin)¹ remains the preferred medication, although many

¹Not FDA approved for this indication.

institutions will use older antiepileptic drugs such as valproate (Depakote)¹ or carbamazepine (Tegretol)¹ as treatments of choice.

Current recommendation for management of SRC is to remove the athlete from athletic activity and not allow to return the same day. The athlete should avoid physical exertion and mental activities that make symptoms worse. After an initial rest period of 24 to 48 hours, the patient should begin progressing both physical (non-contact) and mental activities. The athlete should return to normal activities of daily living as much as is tolerated without symptom exacerbation. The newest consensus statement on concussion in sport outlines not only a return to play protocol but also a “return to learn” protocol. These are outlined in [Tables 5 and 6](#). Children and adolescents should not return to sport until they have fully returned to school. It is important to note that there is no evidence to suggest that any medications or nutritional supplements will improve rate of recovery from concussion. Medications in concussion treatment are primarily used for symptomatic relief.

Monitoring Concussions

After concussion diagnosis, the clinically stable athlete can be sent home if a responsible adult is available. Sleep is encouraged, and the athlete does not need to be awakened for evaluation. The athlete should be followed up in a qualified health care provider's office within 24 to 48 hours for reevaluation. Follow-up examination should include a symptom severity checklist ([Table 4](#)), history, and neurologic examination at a minimum. Completing a full SCAT-5 evaluation is unnecessary if the athlete had one done at time of injury and still has symptoms. Advanced neuroimaging with MRI is not needed to monitor a concussion and by definition should be normal.

As the athlete returns to play, close supervision under a qualified healthcare provider such as a certified athletic trainer or physical

TABLE 6 Example of a Graduated “Return to Learn” Protocol as Outlined by the Consensus Statement on Concussion in Sport

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Daily activities that do not give the child symptoms	Typical activities of the child during the day as long as they do not increase symptoms (eg, reading, texting, screen time). Start with 5-15 minutes at a time and build up	Gradual return to typical activities
2	School activities	Homework, reading, or other cognitive activities outside of the classroom	Increase tolerance to cognitive work
3	Return to school part time	Gradual introduction of schoolwork. May need to start with a partial school day or increased breaks during the day.	Increase academic activities
4	Return to school full time	Gradually progress school activities until a full day can be tolerated.	Return to full academic activities and catch up on missed work

Unlike the return-to-sport protocol, there is not a minimum required time for each stage. Some children may be able to tolerate a full school day immediately after injury without difficulty, depending on symptom severity.

¹Not FDA approved for this indication.

TABLE 5 Graduated Return to Play Protocol as Outlined by the Consensus Statement on Concussion in Sport

STAGE	AIM	ACTIVITY	GOAL OF EACH STEP
1	Symptom limited activity	Daily activities that do not provoke symptoms	Gradual reintroduction of work/school activities
2	Light aerobic exercise	Walking or stationary cycling at slow to medium pace; no resistance training	Increase heart rate
3	Sport-specific exercise	Running or skating drills; no head impact activities	Add movement
4	Non-contact training drills	Harder training drills, eg, passing drills; may start progressive resistance training	Exercise, coordination and increase thinking
5	Full contact practice	After medical clearance, participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6	Return to sport	Normal game play	

Start step 1 after initial 24- to 48-hour period of rest. Each step should take a minimum 24 hours to progress through.

therapist is ideal but not always possible. When an athlete has progressed through the return to play protocol ([Table 5](#)), follow-up with an appropriate qualified health care provider should be made to obtain full medical clearance to return to full contact activity.

Management of Concussion Complications

Headaches are one of the most common symptoms of a concussion and often the symptom that bothers the athlete the most. In the acute period after the injury, medications have some potential to mask important symptoms. For the first 1 to 2 hours after the injury, it is important to be able to accurately monitor the patient for changing clinical picture, which could suggest that the head injury is not a concussion but rather an evolving epidural or subdural hematoma. For the first 24 hours, NSAIDs and aspirin should be avoided because they can thin the blood and potentially make an undiagnosed hematoma become a more significant bleed. Acetaminophen (Tylenol) is the preferred medication for headache in the first 24 hours. After the first day, it is safe to switch to ibuprofen (Motrin), which may have more benefit. If headaches are not improving after 3 to 5 days, it is advisable to switch to another medication that does not have the risk of creating rebound headaches. Tricyclic antidepressants are a good choice and work very well. Nortriptyline (Pamelor)¹ at a low dose (25 mg per day) is generally well tolerated in children¹ as well as adults, and may be stopped abruptly without withdrawal symptoms once the athlete is feeling well and ready to progress back to activities.

Sleep disturbances in athletes with concussion are also very common. Many will not sleep well the first night after injury and want to nap during the days. Other athletes may sleep much more than usual after initial injury. Although there are no clear studies proving the optimal amount of sleep, current trends are to try to return the athlete to normal sleep cycles and daily living as much as

¹Not FDA approved for this indication.

possible. Emphasizing sleep hygiene in the first few days is standard. If insomnia persists after 2 to 3 days, consider medications. Melatonin⁷ is over the counter, has very few side effects, and is generally well tolerated. The next step would be amitriptyline (Elavil)¹ at a low dose (10 to 25 mg per day). This can be especially effective if the athlete has both headaches and poor sleep because it is more sedating than nortriptyline.

A concussion is expected to last no more than 14 days in an adult and less than 4 weeks in the pediatric population. Each individual physician will have a different comfort level treating concussion; however, it is reasonable to consider a referral to a specialty physician once an athlete has passed the normal expected recovery time and is not categorized as a “prolonged concussion.” Each city or region will have a different culture about who takes care of the prolonged concussions. Neurologists, sports medicine physicians, and physical medicine and rehab physicians are all well equipped to take care of these athletes. Physical therapists, particularly those who specialize in vestibular rehabilitation, can be very helpful in patients with continued balance problems, concentration difficulties, and other visual symptoms. Last, neuropsychologists can be incredibly helpful in difficult cases. Some athletes have complicated clinical histories prior to the injury. Attention-deficit/hyperactivity disorder, depression, anxiety, and chronic headaches can all make the clinical picture very confusing when the athlete is having symptoms such as concentration difficulties, mood swings, insomnia, or headaches that are not improving as expected. It is important to remember that many athletes would not rate their symptom severity score as all zeros at baseline, so expecting them to achieve this goal post injury is impractical. When this scenario is suspected, referral for neuropsychiatric testing can help divide out which symptoms may be concussion related and which could be more chronic in nature.

Prevention

Helmets have been shown to reduce sports-related skull fractures and intracranial hemorrhages but have not been shown to decrease rates of concussion. Mouth guard use decreases the rate of dental injuries and lip lacerations but have not been definitively proven to decrease the rate of concussion or other brain injuries. Sport-specific rule changes have resulted in reduced rates of head injury. The most prominent and well-studied example is that of youth ice hockey. Introduction of the 2013 Canadian national body checking policy change disallowing body checking in Pee Wee hockey players under the age of 13 resulted in a 50% relative reduction in injury rate and a 64% reduction in concussion rate in 11-year-old and 12-year-old hockey players in Alberta. Reduction of contact practices in certain team sports such as American football reduces exposure to head injury as well. Finally, epidemiologic evidence demonstrated that the most likely period for repeat sports-related concussion is in the first 10 days after the most recent concussion, so disallowing contact activity during this interval has potential to reduce repeat concussions

⁷Available as a dietary supplement.

TRIGEMINAL NEURALGIA

Method of

Karlynn Sievers, MD; and Hugh Silk, MD, MPH

CURRENT DIAGNOSIS

International Headache Society Diagnostic criteria (classical):

- A. At least three attacks of unilateral facial pain fulfilling criteria B and C
- B. Occurring in one or more divisions of the trigeminal nerve, with no radiation beyond the trigeminal distribution
- C. Pain has at least three of the following four characteristics:
 1. Recurring in paroxysmal attacks lasting from a fraction of a second to 2 minutes
 2. Severe intensity
 3. Electric shock-like, shooting, stabbing, or sharp in quality
 4. Precipitated by innocuous stimuli to the affected side of the face
- D. No clinically evident neurologic deficit
- E. Not better accounted for by another diagnosis.

International Headache Society Diagnostic criteria (secondary)

Same as above, except E. Secondary trigeminal neuralgia is secondary to another disease process.

CURRENT THERAPY

- Medications
 - Carbamazepine: start 100 mg two times daily, and increase by 200 mg/day to max 1200 mg/day (number needed to treat = 2)
 - Alternative treatments are available but have not been proven to be as effective (see Table 1)
 - For patients with refractory or severe symptoms, surgical treatment (e.g., microvascular decompression, radiosurgery, alternative invasive procedures) can be helpful for some.

Epidemiology

The incidence of trigeminal neuralgia is estimated to be 5.9/100,000 women and 3.4/100,000 men. The peak incidence is in patients age 60 to 70 years. It has also been called “tic douloureux” because of facial spasms that often accompany the disorder.

Risk factors

Increasing age is a risk factor. It is rarely diagnosed in patients younger than 40 years of age. Other risk factors include multiple sclerosis (the incidence of trigeminal neuralgia in this population is 1% to 2%), stroke, and hypertension (especially in women). There is no racial predominance.

Pathophysiology

It is currently hypothesized that trigeminal neuralgia results from demyelination of the fifth cranial nerve, leading to electrical transmission of nerve impulses that are not mediated by neurotransmitters and that generate pain. Demyelination is most commonly caused by aberrant or tortuous blood vessels that cause nerve

possible. Emphasizing sleep hygiene in the first few days is standard. If insomnia persists after 2 to 3 days, consider medications. It is currently hypothesized that trigeminal neuralgia results from demyelination of the fifth cranial nerve, leading to electrical transmission of nerve impulses that are not mediated by neurotransmitters and that generate pain. Demyelination is most commonly caused by aberrant or tortuous blood vessels that cause nerve

TABLE 1 Treatment Options for TN, With Evidence of Effectiveness

	TREATMENT TYPE	EVIDENCE OF EFFECTIVENESS
Medical therapy	Carbamazepine (Tegretol)	Likely to be beneficial (gold standard)
	Oxcarbazepine (Trileptal) ¹	Likely to be beneficial*
	Baclofen (Lioresal) ¹	Likely to be beneficial,* particularly in patients with TN caused by MS
	Gabapentin (Neurontin) ¹	Unknown effectiveness
	Lamotrigine (Lamictal) ¹	Unknown effectiveness
Surgical therapy	Microvascular decompression	Trade-off between benefits and harms*
	Stereotactic radiosurgery	Trade-off between benefits and harms*
	Percutaneous destructive radiosurgical techniques	Trade-off between benefits and harms*

Abbreviations: TN = trigeminal neuralgia; MS = multiple sclerosis.

*Based on observational studies and/or consensus.

¹Not FDA approved for this indication.

compression but can also be attributed to sources such as multiple sclerosis or amyloid deposition.

There are two subcategories of the disorder—classical and symptomatic. With classical trigeminal neuralgia, there is no underlying cause for the demyelination other than vascular compression; with secondary trigeminal neuralgia, an alternate cause is responsible for the demyelination.

Prevention

There is no known method of prevention for trigeminal neuralgia.

Clinical manifestations

Trigeminal neuralgia is a clinical diagnosis made on the basis of recurrent attacks of unilateral facial pain. Pain is intense, and is usually described as sharp, shock-like, or stabbing. Any of the branches of the trigeminal nerve can be affected, but the maxillary branch is the most common, and the ophthalmic branch the least common. The pain lasts for seconds, and most patients are asymptomatic between attacks (though some patients will have a mild, dull, persistent ache in the area of the affected nerve). Attacks can recur infrequently or hundreds of times per day.

Often, patients have trigger zones that will set off paroxysms of pain with minimal stimulation. Activities such as chewing, teeth brushing, or touching a trigger area can set off attacks; sometimes even minimal stimulation such as a light breeze can trigger episodes. Not all patients have trigger zones; however, the presence of these is nearly pathognomonic for trigeminal neuralgia.

Diagnosis

Diagnosis is clinical, based on the commonly described symptoms listed above. Diagnosis of trigeminal neuralgia should be considered in all patients who describe unilateral intense facial pain on three or more occasions. Careful examination of the head and neck and thorough neurologic examination should be performed in all patients. Exam findings are typically normal in patients with trigeminal neuralgia, and so exam abnormalities should prompt reconsideration of the diagnosis. Sensory abnormalities (including vision or hearing loss), facial muscle weakness, or loss of corneal reflex are not associated with trigeminal neuralgia and warrant further workup.

Laboratory studies are typically not helpful in making the diagnosis. Temporal mandibular joint or dental radiographs may be helpful to rule out other pathology for those who present with mid or lower face symptoms. MRI of the brain can be helpful in distinguishing between classical and symptomatic trigeminal neuralgia and should be considered in all patients with new onset of symptoms. There is some early evidence that structural MRI techniques can help identify changes associated with trigeminal neuralgia and help predict those that will respond well to surgical intervention, but more research is needed in this area.

Differential Diagnosis

Differential diagnosis includes other types of headaches (migraine, cluster headache, paroxysmal hemicrania), dental sources (cracked teeth, caries), infectious causes (sinusitis, otitis media, postherpetic neuralgia), nervous system pathology (intracranial tumors, multiple sclerosis), temporomandibular joint syndrome, and giant cell arteritis. Many of these other diagnoses will have specific exam findings.

Treatment

Medical treatment should be initiated for all new cases of trigeminal neuralgia. Carbamazepine (Tegretol) has been shown in multiple randomized control trials to reduce pain in trigeminal neuralgia and is considered the gold standard for medical treatment. The number needed to treat is 2. Dosing starts at 100 mg two times daily and increases gradually in increments of 200 mg daily to a maximum dose of 1200 mg daily. Carbamazepine can have side effects such as drowsiness, dizziness, hepatotoxicity, pancreatitis, blood dyscrasias, and ataxia. Consensus opinion is that it has a greater than 50% failure rate for long-term (5 to 10 years) pain control. Oxcarbazepine (Trileptal)¹ can also be used, although data are lacking regarding its success in long-term pain control. Pimozide (Orap)¹ has been promoted as equal to carbamazepine; however, the studies are of low quality with no adverse effect comparison. Tizanidine (Zanaflex)¹ has been shown to be as effective as carbamazepine but also with low-quality studies. Lamotrigine (Lamictal)¹ can be used in patients who do not tolerate carbamazepine, but the dose must be titrated slowly, so it is not as effective in acute pain control. Baclofen (Lioresal)¹ and gabapentin (Neurontin)¹ may be useful in patients with multiple sclerosis who also have trigeminal neuralgia, but evidence is lacking regarding their effectiveness in classical trigeminal neuralgia.

Recent studies have shown botulinum toxin A (Botox)¹ to be an effective treatment in reducing both pain intensity and frequency of paroxysms in trigeminal neuralgia; adverse events include facial asymmetry and edema or hematoma at the injection site. Alcohol injections¹ and cryotherapy have also been used for trigeminal neuralgia pain.

For patients with refractory or severe symptoms, surgical treatment can be helpful for some. Microvascular decompression and radiosurgery are both common techniques for treatment of trigeminal neuralgia, with microvascular decompression generally considered to be first-line surgical intervention. Other surgical techniques can include radiofrequency thermocoagulation, glycerol rhizolysis, stereotactic radiosurgery, balloon compression, peripheral nerve section, partial sensory root section, and gamma-knife radiosurgery. Studies have noted sensory side effects, and most neurosurgical studies showed bias in their methodology. Treatment for secondary trigeminal neuralgia typically includes treating the underlying cause.

Monitoring

Although there is no standard protocol for monitoring patients with trigeminal neuralgia, the condition is extremely painful, and there have been incidents reported of patients accidentally overdosing on medications or taking their own lives. Therefore it is

¹Not FDA approved for this indication.

recommended that patients are monitored at regular intervals to ensure their pain is controlled and to monitor for side effects from treatment.

Management of Complications

The disease can have relapses and remissions. Medications or alternative treatments should be reinstituted as needed. Tests should be run as needed based on side effect symptoms, and treatments stopped and others considered based on efficacy and patient tolerance.

VIRAL MENINGITIS

Method of

Joanna Thomson, MD; and Samir S. Shah, MD

CURRENT DIAGNOSIS

- Typical presentation includes fever, headache, and neck stiffness or pain. Constitutional symptoms include mild lethargy, myalgias, nausea, and vomiting.
- Neonates often present with nonspecific signs and symptoms including lethargy, irritability, and poor feeding.
- Cerebrospinal fluid (CSF) profile should be performed. Results show elevated white blood cell count (often but not always with mononuclear cell predominance), normal to slightly elevated protein, normal glucose, normal to slightly elevated opening pressure, and negative bacterial Gram stain and culture.
- Diagnostic polymerase chain reaction (PCR) and serologic studies can identify the etiologic agent.
