- Consider neuroimaging before lumbar puncture if there is concern for increased intracranial pressure or if encephalitis is possible.

CURRENT THERAPY

- Symptomatic and supportive management includes analgesia, antipyretics, antiemetics, and intravenous fluids.
- Hospitalization is recommended for infants (younger than 1 year), elderly patients (older than 65 years), and immunocompromised patients, as well as for patients presenting with altered mental status, seizures, focal neurologic signs, or the absence of classic viral CSF findings.
- Few medications, with the exception of acyclovir (Zovirax) for HSV, effectively treat viral meningitis.

Epidemiology

The true epidemiology of viral meningitis is unknown because it is not a reportable disease. However, the Centers for Disease Control and Prevention (CDC) estimate 25,000 to 50,000 hospitalizations per year. There is also yearly variation in disease burden. Causes of viral meningitis vary by age group, immune status, season, and geography. There is increased incidence in summer and early fall owing to the high prevalence of enteroviruses and arthropod-borne viruses (arboviruses). Common etiologic agents include enteroviruses, herpes simplex virus (HSV), arboviruses, lymphocytic choriomeningitis virus (LCMV), cytomegalovirus (CMV), varicella zoster virus (VZV), and Epstein-Barr virus (EBV). See [Table 1](#) for features of the common and some less-common viral agents that cause meningitis.

Pathophysiology

Viral infection begins at the mucosal surface of the respiratory tract or gastrointestinal tract, with viral replication occurring in regional lymph nodes. A secondary viremia then occurs that provides access to the central nervous system (CNS). Symptoms of viral meningitis are due to either an immune response to the virus within the CNS (e.g., enterovirus) or direct viral invasion of neural tissue (e.g., HSV1/2).

Prevention

To prevent spread of viral agents responsible for meningitis, hand-washing and other infection-control measures are most important. The infection-control precautions necessary during patient contact depend on mode of transmission of the virus (see [Table 1](#)). Vaccines are available for some of the viruses that are known to cause meningitis, including polio (an enterovirus), mumps, measles, and varicella.

Clinical Manifestations

Viral meningitis can be difficult to distinguish from bacterial meningitis. Fever, headache, and neck stiffness and pain are the usual presenting complaints. Headache can be localized to the frontal or retro-orbital areas and may be associated with photophobia. Although neck stiffness and pain are usually present, neck rigidity (positive Kerning's sign or positive Brudzinski's sign) is not always present on examination. Constitutional symptoms can include lethargy, myalgias, and nausea or vomiting. There is often a history of concomitant viral respiratory or gastrointestinal illness at the time of presentation. Seizures can occur with viral causes of meningitis, especially HSV, but should prompt consideration of other diagnostic possibilities.

In contrast to children and adults, neonates often present with nonspecific findings such as lethargy, irritability, and poor feeding. See [Table 1](#) for clinical manifestations associated with specific etiologic agents.

Viral meningitis can also manifest with signs of encephalitis, in which case the encompassing diagnosis is meningoencephalitis. Encephalitis or meningoencephalitis are likely if any of the following are present: altered mental status, seizures, focal neurologic deficits (including aphasia, anosmia, ataxia, cranial nerve deficits, motor weakness, or involuntary movements), or behavioral changes.

Diagnosis

Diagnosis of viral meningitis requires lumbar puncture for CSF studies including cell count, protein, glucose, Gram stain and culture, and specific viral studies. Although a lymphocytic pleocytosis is associated with viral infections, most viral CNS infections initially have a neutrophilic pleocytosis. However, neutrophilic pleocytosis is also associated with bacterial meningitis. In viral meningitis, though CSF protein is normal to slightly elevated, CSF glucose is normal, and no organisms are identified on CSF bacterial Gram stain or culture compared with elevated CSF protein, low CSF glucose, and positive CSF bacterial culture in bacterial meningitis.

recommended that patients are monitored at regular intervals to ensure their pain is controlled and to monitor for side effects from treatment.

Management of Complications

The disease can have relapses and remissions. Medications or alternative treatments should be reinstituted as needed. Tests should be run as needed based on side effect symptoms, and treatments stopped and others considered based on efficacy and patient tolerance.

VIRAL MENINGITIS

Method of

Joanna Thomson, MD; and Samir S. Shah, MD

CURRENT DIAGNOSIS

- Typical presentation includes fever, headache, and neck stiffness or pain. Constitutional symptoms include mild lethargy, myalgias, nausea, and vomiting.
- Neonates often present with nonspecific signs and symptoms including lethargy, irritability, and poor feeding.
- Cerebrospinal fluid (CSF) profile should be performed. Results show elevated white blood cell count (often but not always with mononuclear cell predominance), normal to slightly elevated protein, normal glucose, normal to slightly elevated opening pressure, and negative bacterial Gram stain and culture.
- Diagnostic polymerase chain reaction (PCR) and serologic studies can identify the etiologic agent.
- Consider neuroimaging before lumbar puncture if there is concern for increased intracranial pressure or if encephalitis is possible.

CURRENT THERAPY

- Symptomatic and supportive management includes analgesia, antipyretics, antiemetics, and intravenous fluids.
- Hospitalization is recommended for infants (younger than 1 year), elderly patients (older than 65 years), and immunocompromised patients, as well as for patients presenting with altered mental status, seizures, focal neurologic signs, or the absence of classic viral CSF findings.
- Few medications, with the exception of acyclovir (Zovirax) for HSV, effectively treat viral meningitis.

Epidemiology

The true epidemiology of viral meningitis is unknown because it is not a reportable disease. However, the Centers for Disease Control and Prevention (CDC) estimate 25,000 to 50,000 hospitalizations per year. There is also yearly variation in disease burden. Causes of viral meningitis vary by age group, immune status, season, and geography. There is increased incidence in summer and early fall owing to the high prevalence of enteroviruses and arthropod-borne viruses (arboviruses). Common etiologic agents include enteroviruses, herpes simplex virus (HSV), arboviruses, lymphocytic choriomeningitis virus (LCMV), cytomegalovirus (CMV), varicella zoster virus (VZV), and Epstein-Barr virus (EBV). See [Table 1](#) for features of the common and some less-common viral agents that cause meningitis.

Pathophysiology

Viral infection begins at the mucosal surface of the respiratory tract or gastrointestinal tract, with viral replication occurring in regional lymph nodes. A secondary viremia then occurs that provides access to the central nervous system (CNS). Symptoms of viral meningitis are due to either an immune response to the virus within the CNS (e.g., enterovirus) or direct viral invasion of neural tissue (e.g., HSV1/2).

Prevention

To prevent spread of viral agents responsible for meningitis, hand-washing and other infection-control measures are most important. The infection-control precautions necessary during patient contact depend on mode of transmission of the virus (see [Table 1](#)). Vaccines are available for some of the viruses that are known to cause meningitis, including polio (an enterovirus), mumps, measles, and varicella.

Clinical Manifestations

Viral meningitis can be difficult to distinguish from bacterial meningitis. Fever, headache, and neck stiffness and pain are the usual presenting complaints. Headache can be localized to the frontal or retro-orbital areas and may be associated with photophobia. Although neck stiffness and pain are usually present, neck rigidity (positive Kerning's sign or positive Brudzinski's sign) is not always present on examination. Constitutional symptoms can include lethargy, myalgias, and nausea or vomiting. There is often a history of concomitant viral respiratory or gastrointestinal illness at the time of presentation. Seizures can occur with viral causes of meningitis, especially HSV, but should prompt consideration of other diagnostic possibilities.

In contrast to children and adults, neonates often present with nonspecific findings such as lethargy, irritability, and poor feeding. See [Table 1](#) for clinical manifestations associated with specific etiologic agents.

Viral meningitis can also manifest with signs of encephalitis, in which case the encompassing diagnosis is meningoencephalitis. Encephalitis or meningoencephalitis are likely if any of the following are present: altered mental status, seizures, focal neurologic deficits (including aphasia, anosmia, ataxia, cranial nerve deficits, motor weakness, or involuntary movements), or behavioral changes.

Diagnosis

Diagnosis of viral meningitis requires lumbar puncture for CSF studies including cell count, protein, glucose, Gram stain and culture, and specific viral studies. Although a lymphocytic pleocytosis is associated with viral infections, most viral CNS infections initially have a neutrophilic pleocytosis. However, neutrophilic pleocytosis is also associated with bacterial meningitis. In viral meningitis, though CSF protein is normal to slightly elevated, CSF glucose is normal, and no organisms are identified on CSF bacterial Gram stain or culture compared with elevated CSF protein, low CSF glucose, and positive CSF bacterial culture in bacterial meningitis.

TABLE 1 Clinical and Laboratory Characteristics of Viral Meningitis

VIRUS	TRANSMISSION	KEY CLINICAL FEATURES	DIAGNOSIS	COMMENTS
Enterovirus	Fecal-oral	May have rash on exam (e.g., Coxsackie, hand-foot-mouth) Patients with impaired humoral immunity or those <2 wk old can present with a sepsis-like syndrome with multiorgan dysfunction, DIC, cardiovascular collapse	CSF enterovirus PCR	More prevalent in summer and fall
Herpes simplex viruses 1 and 2	Vertical transmission during birth (HSV2), horizontal transmission via contact (HSV1 or HSV2)	10%–30% of adults have symptoms of meningitis with primary HSV2 infection; look for genital vesicular lesions on exam Mollaret's meningitis: >3 episodes of fever and meningismus lasting 2–5 d, with spontaneous resolution; episodes may be months to years apart often due to chronic HSV2 CNS infection	CSF HSV1/HSV2 PCR	Meningitis is uncommon with nonprimary HSV2 infection
Arboviruses	Subcutaneous inoculation via mosquito or tick Prevention: Minimize tick and mosquito exposure with personal protection measures including insect repellents and covering exposed skin	Zika virus associated with Guillan-Barré syndrome and in newborn infants microcephaly; sexual transmission is possible	CSF arboviral PCR Zika RT-PCR (performed at CDC Arbovirus laboratory on CSF or serum within first 5–7 days of symptoms); Zika IgM cross reacts with other flaviviruses (e.g., Dengue)	More prevalent in summer and fall Geographic distribution within the United States: Eastern equine encephalitis: Eastern U.S. Western equine encephalitis: Western U.S. St. Louis encephalitis: Across the U.S. (majority of cases in Central and Eastern U.S.) West Nile virus: Across the U.S. California encephalitis (LaCrosse): Midwestern, mid-Atlantic, and Southeastern U.S. Zika virus: Small epidemics have been reported in Southeastern U.S. and Gulf Coast states
Lymphocytic choriomeningitis virus	Virus is present in rodent secretions, feces, and urine Ingestion of contaminated food, exposure of open wounds, or inhalation of aerosolized virus Lab workers, pet owners, and those living in impoverished conditions are highest risk for illness	Accompanied by a flulike illness	Serum LCMV titers (acute and convalescent) CSF findings: May have decreased glucose and WBC count >1000/mL	More prevalent in winter and spring
Cytomegalovirus	Exposure to infected body fluids (e.g., saliva, blood)		CSF CMV PCR	Reactivation of prior infection typically only occurs in the immunosuppressed
Epstein-Barr virus	Exposure to infected body fluids (e.g., saliva, blood)	Alice in Wonderland syndrome: altered body image and distortion of visual perception	CSF EBV PCR	Most common neurologic complication with primary infection
HIV	Exposure to contaminated blood or other body fluids (e.g., transfusion, sexual contact, percutaneous blood exposure)	During primary infection, a subset have meningitis or meningoencephalitis May expect thrush and cervical lymphadenopathy	HIV studies	Treatment with HAART
Human herpesvirus 6	Respiratory	Roseola: febrile illness followed by viral exanthem	CSF HHV6 PCR	HHV6 has been demonstrated in the CSF of asymptomatic persons Immunosuppressed persons at risk for symptomatic infection and reactivation

Continued

TABLE 1 Clinical and Laboratory Characteristics of Viral Meningitis—cont'd

VIRUS	TRANSMISSION	KEY CLINICAL FEATURES	DIAGNOSIS	COMMENTS
Varicella	Respiratory	Typical vesicular skin lesions of chickenpox on exam CSF pleocytosis has also been demonstrated with reactivation; can also occur in the absence of cutaneous findings of herpes zoster (“zoster sine herpete”)	CSF VZV PCR	Rarely diagnosed during acute chickenpox infection; usually a postinfectious complication Other neurologic sequelae of varicella infection are more common than aseptic meningitis; most common is cerebellar ataxia
Mumps	Respiratory	Parotitis on exam is the most prominent sign of infection Aseptic meningitis can precede or follow clinical exam findings CSF profile can demonstrate an unusually high protein with a mild pleocytosis and normal glucose	Serum titers	More common in winter and spring
Measles	Respiratory	CSF pleocytosis in $\leq 30\%$ of patients with measles; patients are usually without clinical meningitis	Serum titers	In the United States, most cases are imported (e.g., occur in returning travelers)
Influenza	Respiratory	Aseptic meningitis is a less common neurologic complication of influenza infection (encephalopathy is more common)	CSF influenza PCR	More prevalent in winter Increased risk of neurologic complication in young patients and in those with pre-existing medical disease

Abbreviations: CMV = cytomegalovirus; CNS = central nervous system; CSF = cerebrospinal fluid; DIC = disseminated intravascular coagulopathy; HHV = human herpesvirus; HSV = herpes simplex virus; LCMV = lymphocytic choriomeningitis virus; PCR = polymerase chain reaction; VZV = varicella zoster virus; WBC = white blood cell.

Studies to identify a specific virus as the etiologic agent are recommended for patients with severe illness or a complicated course. Viral cultures of CSF are not generally useful given their poor sensitivity, and serologic viral studies require both acute and convalescent titers to demonstrate antibody response to the suspected viral antigen. CSF PCR studies that detect viral DNA or RNA are more sensitive than viral culture and provide more rapid results than serologic viral studies (see Table 1). Multiplex PCR techniques allow for testing of multiple viruses and bacteria with a single CSF sample and a single test. Where available, multiplex PCR may result in considerable savings in time and effort, while improving diagnostic capacity. In some cases, it is useful to perform viral PCR studies on blood (HSV, EBV, CMV, and human herpesvirus [HHV]6), urine (CMV), stool (enterovirus), and skin vesicles (HSV) to further support the diagnosis. However, a positive PCR study from blood, urine, stool, or skin does not provide direct evidence of CNS infection by the same virus. For example, enterovirus isolated from the stool can represent asymptomatic infection or prior infection but may also be isolated from the stool at the same time as concomitant enteroviral meningitis.

Most other testing is not helpful, but further testing (including complete blood count, renal profile, liver function, pancreatic enzymes, and HIV studies) should be guided by the patient's presentation and clinical status.

Neuroimaging (computed tomography [CT] or magnetic resonance imaging [MRI]) should be obtained before lumbar puncture if there is concern for increased intracranial pressure. It is also recommended if symptoms of encephalitis are present (including altered consciousness, seizures, focal neurologic deficits, behavioral changes) to exclude other CNS disease.

Differential Diagnosis

The major item on the differential diagnosis for viral meningitis is bacterial meningitis. The bacterial meningitis score, validated in children 29 days to 19 years, is a clinical prediction rule that

identifies patients as at very low risk (0.1%) for bacterial meningitis if they lack all of the following: positive CSF Gram stain, CSF absolute neutrophil count (ANC) of at least 1000 cells/ μ L, CSF protein of at least 80 mg/dL, peripheral blood ANC of at least 10,000 cells/ μ L, and a history of seizure before or at the time of presentation. C-reactive protein (CRP) is not generally useful in differentiating between bacterial and viral infections, because CRP can be high in viral meningitis and low in the initial stages of bacterial disease. Although it is not yet routinely used, elevated serum procalcitonin levels (>0.5 μ g/mL in children and >0.2 μ g/mL in adults) and elevated CSF lactate (>35 mg/dL) are more sensitive and specific than CRP for distinguishing viral from bacterial meningitis; elevated values are more typical of bacterial infection.

Other diagnoses to consider include parameningeal infections (i.e., subdural or epidural empyema, brain abscess), meningitis due to fungi, mycobacteria, rickettsia, mycoplasma, parasites, and other CNS infectious or inflammatory processes including malignancy, drug exposure, rheumatologic disease (e.g., systemic lupus erythematosus), or autoimmune (e.g., anti-NMDA receptor encephalitis).

Treatment

Symptomatic care remains the mainstay of therapy for viral meningitis. Therapy should be directed at pain and fever control (e.g., ibuprofen [Motrin], acetaminophen [Tylenol], ketorolac [Toradol]), management of nausea and vomiting (e.g., ondansetron [Zofran]), and intravenous fluids. Hospitalization is recommended for patients younger than 1 year, the elderly, and the immunocompromised. Patients who present with altered mental status, seizures, focal neurologic signs, or a CSF profile that does not have the classic viral profile should also be hospitalized for clinical management and for antibiotic treatment until bacterial meningitis can be excluded. Advanced care including management of respiratory failure, cardiovascular instability, seizures, disturbed fluid and electrolyte balance, and cerebral edema may be necessary.

Empiric antibiotic coverage may be considered while awaiting CSF culture results in the young, elderly, and immunocompromised, especially if there is suspicion of bacterial meningitis or partially treated bacterial meningitis.

Acyclovir (Zovirax) should be initiated in cases of suspected HSV while waiting PCR confirmation. Dosing of acyclovir is age and weight dependent: 20 mg/kg per dose IV every 8 hours for patients younger than 12 years; 10 mg/kg per dose IV every 8 hours for patients older than 12 years.

In the immunocompromised patient, HHV6 may be treated with foscarnet (Foscavir)¹ or ganciclovir (Cytovene)¹, and CMV may be treated with ganciclovir, valganciclovir (Valcyte), foscarnet, or cidofovir (Vistide). Case reports suggest benefit of such antiviral therapies in the immunocompromised, but no controlled trials have been performed.

Complications

The prognosis of viral meningitis depends on cause and severity of illness as well as age. Non-HSV viral meningitis has low mortality rates in adults and children alike. Mortality and morbidity are associated with other organ system involvement, including meningoencephalitis. Although up to 10% of infants hospitalized with non-HSV viral meningitis experience seizures, altered mental status, or increased intracranial pressure during the acute illness, studies have shown no evidence of long-term neurodevelopmental delay. Most adults recover fully within a week without long-term sequelae. Persistent neurologic sequelae (including headaches, incoordination, concentration difficulties, muscle weakness, and focal neurologic deficits) occur more often in patients with meningoencephalitis.

HSV is associated with high rates of morbidity and mortality. Neonatal isolated CNS HSV has a 4% mortality rate even with acyclovir treatment; mortality is 50% without acyclovir treatment. Unfortunately, acute treatment does not affect morbidity, as 70% of infants with neonatal CNS HSV infection will suffer from neurodevelopmental impairments. Recent studies have demonstrated

improved outcomes in these infants with long-term oral acyclovir suppression therapy. Outside of the neonatal period, CNS HSV infection has a 28% mortality rate with antiviral treatment (70% mortality rate without treatment). Long-term neurologic sequelae occur in two-thirds of survivors who received antiviral therapy, compared with virtually all of those who did not receive treatment.

¹Not FDA approved for this indication.

ALCOHOL USE DISORDERS

Method of

Richard N. Rosenthal, MD

CURRENT DIAGNOSIS

Risky or Hazardous Drinking (Need Further Evaluation)

- Men who drink more than four standard drinks per day or 14 standard drinks per week
- Women and those older than 65 years who drink more than three standard drinks per day or more than seven standard drinks per week
- Drinking concurrent with any medical condition where alcohol is contraindicated

Alcohol Use Disorder

- Repeated failure to fulfill obligations at home, school, or work
- Increased risk of physical harm
- Drinking despite causing social or interpersonal problems
- Episodes of alcohol craving or strong urges
- Cannot cut down or stop
- Decreased time spent in other usual activities
- Drinking despite physical or psychological consequences
- Drinking more than intended
- Physical tolerance
- Preoccupied with drinking
- Withdrawal episodes

CURRENT THERAPY

All At-Risk Patients

- Assess: Screen patients with standard instruments and compute average standard drinks per week.
- Advise: Give feedback, express concern, present findings and conclusions, and recommend specific behavioral changes.
- Agree: Determine the patient's readiness to change, encourage reflection, listen empathically, elicit patient concerns, avoid arguing, express optimism, set a specific reduction or abstinence goal.
- Assist: Formulate concrete implementation plan, including avoiding high-risk situations, recording alcohol intake, and eliciting family and community support for patient goals.
- Arrange: Set up follow-up visits and refer patients meeting dependence criteria for specialty treatment.

Additionally for Alcohol-Dependent Patients

- Offer or arrange for detoxification if indicated.
- Offer or arrange for specialty alcoholism treatment and/or mutual help groups.
- Offer pharmacotherapy to support maintenance of abstinence: naltrexone (ReVia, Vivitrol), acamprosate (Campral), or disulfiram (Antabuse).
- Offer medication management support during follow-up visits.

Epidemiology

Alcohol use disorders are among the most prevalent mental disorders in the population, occurring at frequencies that rival those of mood and anxiety disorders. In any year, almost 8.5% of the US population older than 18 years meets criteria for a formal alcohol use disorder (alcohol abuse or dependence), and almost 4% meets criteria for alcohol dependence.

Economic and Medical Sequelae

Alcohol use disorders are important to identify and treat for several reasons. The first is the direct negative impact of chronic heavy alcohol exposure on cognitive, physical, social, and vocational functioning. The second is the well-described long-term medical sequelae of alcohol dependence such as hepatic cirrhosis, pancreatitis, and dementia. Chronic heavy drinking, even in the absence of a formal diagnosis of alcohol dependence, is associated with an increased risk of diabetes mellitus, hypertension, gastrointestinal bleeding, hemorrhagic stroke, and several forms of carcinoma. The third reason for identification and treatment is the public impact of alcohol use disorders, which covers associated traumatic injuries from motor vehicle and job-related accidents, alcohol-related crime, and their associated economic costs. More than \$180 billion is lost to the US economy each year as a result of alcohol-related crime, injury, health care costs, and lost productivity in the workplace.

Screening**Screening Rationale**

Screening for alcohol problems arrays patients on a continuum from abstinence to dependence and is a highly efficient way to identify patients who are at acute risk for the effects of alcohol abuse and dependence as well as those who do not currently meet formal alcohol-related diagnoses but who are at risk for long-term medical and social consequences of heavy alcohol exposure (Box 1). The US Preventative Services Task Force (USPSTF) found that screening could accurately identify patients whose levels or patterns of alcohol consumption do not meet criteria for alcohol dependence but that place them at risk for increased morbidity and mortality. The USPSTF also found good evidence that brief interventions that consist of behavioral counseling and follow-up can reduce alcohol consumption for 6 to 12 months or longer and that the benefits outweigh any potential harms. Thus, it is recommended that alcohol screening and brief interventions be performed in primary care settings to reduce alcohol problems for adults, including pregnant women.

Brief Screening

Every patient should be asked about alcohol use. Because drinking is normative in the United States, if drinking is denied, it is useful to determine if the patient used to drink but has stopped because of a past problem. After determining if a patient currently uses any alcohol, the simplest strategy is to ask about the number of heavy drinking days in the past year, where heavy drinking is defined as more than five drinks for men and more than four drinks for women in one day. If that threshold is reached (0=negative screen; >0=positive screen), which corresponds to at-risk or hazardous drinking, then further evaluation of alcohol-related problems is

BOX 1 Current Risk Terms**Abstinence**

- No alcohol use

Moderate Drinking

- Men: No more than 2 standard drinks per drinking d
- Women: No more than 1 standard drink per drinking d
- Elderly persons (>65 y): No more than 1 standard drink per drinking d

Risky or Hazardous Drinking

- Men
 - More than 4 standard drinks per drinking d
 - More than 14 standard drinks per wk
- Women
 - More than 3 standard drinks per drinking d
 - More than 7 standard drinks per wk
- Elderly persons (>65 y):
 - More than 3 standard drinks per drinking d
 - More than 7 standard drinks per wk

BOX 2 Standard Drinks

Each equivalent drink contains about 14 g of pure alcohol:

- 12 oz of beer or wine cooler
- 8–9 oz of malt liquor
- 5 oz of wine
- 3–4 oz of fortified wine (e.g., port)
- 1½ oz of 80-proof distilled spirits (or 1 jigger of liquor before mixing)

indicated through the use of screening instruments, such as the 3-item AUDIT-C, below. A standard drink is the same amount of alcohol contained in different volumes of alcoholic beverages (Box 2).

The Alcohol Use Disorders Identification Test (AUDIT) (Table 1) is a 10-item screen developed by the World Health Organization. Given its length, the AUDIT can be used as a self-report screener that patients can fill out in the waiting area before seeing the clinician. The minimum score is 0 and the maximum score is 40. A score of 8 or more for men or 4 or more for women, adolescents, and persons older than 65 years, like a positive endorsement of any heavy drinking days, indicates the need for further evaluation of alcohol use and an increased risk of an alcohol use disorder. For brevity, the AUDIT-C, a truncated version of the AUDIT consisting of the first three AUDIT questions focused on alcohol consumption, can be used as a part of a waiting-room health history form. A score of 6 or more for men or 4 or more for women on the AUDIT-C indicates a need for further evaluation.

Asking about alcohol consumption during a routine clinical interview is best bundled with other questions about lifestyle and health, such as diet, smoking, and exercise. In addition to giving the patient a pre-examination questionnaire to fill out such as the AUDIT, another screening strategy is to ask the CAGE questions (Box 3) during the clinical examination. A positive answer to any of these questions also indicates the need for further evaluation of alcohol use. Two or more CAGE questions answered affirmatively identifies a patient at high risk for alcohol dependence. Because the CAGE screens for consequences, it is not as sensitive for risky drinking.

There are other question sets that are more sensitive than the CAGE in specific demographic subsets, and these can also be easily asked during a routine history. The five-item TWEAK questionnaire (Table 2) may be a more optimal screening questionnaire for identifying women (including pregnant women) with risky drinking or alcohol use disorders in racially mixed populations.

The CRAFFT (Box 4) is a 6-item question set that has high sensitivity in screening adolescents for alcohol and other substance-abuse problems. For patients older than 65 years, the Short Michigan Alcoholism Screening Test—Geriatric (S-MAST-G) (Box 5) is useful in identifying those at risk for alcohol problems, because these patients might not need the same volumes of alcohol intake as others to develop alcohol-related problems. To complete the initial screening, one should compute the average number of drinks per week by multiplying the days per week on average that the patient drinks by the number of drinks consumed on a typical drinking day.

Laboratory testing for elevations of alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ -glutamyltransferase (GGT), or carbohydrate-deficient transferrin (CDT) have no incremental sensitivity over those of validated screening instruments, and they may be better suited to monitoring patients already in treatment for alcohol use disorders. The patient must still be asked about quantity and frequency of alcohol use. However, laboratory testing can provide indicators of covert heavy drinking (e.g., elevated GGT and CDT) when the patient does not reveal the extent of alcohol intake. CDT, which is perturbed less than other indices by nonalcoholic liver disease, may be a more specific and sensitive indicator of heavy drinking.

Diagnosis

Screening can identify those who are at risk for the sequelae of risky or hazardous drinking and who might benefit from a brief intervention conducted in the primary care office, but only a diagnostic evaluation can confirm the clinician's suspicion that the patient's use of alcohol meets syndromal criteria and warrants specific medical and psychosocial treatment beyond the brief intervention. According to Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) criteria (Table 3), the patient has a diagnosis of an alcohol use disorder if he or she has two or more of the following criteria over a 12-month period related to alcohol use: physical tolerance; symptoms of withdrawal; repeatedly drinking more than intended; unsuccessful reduction or quit attempts; repeated episodes of failure to fulfill obligations at home, school, or work; episodes of increased risk of physical harm; recurrent problems with significant others; increased time drinking or recovering from drinking; reduced time in other pleasurable or important activities; and continued drinking despite physical or psychological problems. With DSM-5, the term *alcohol dependence* describes the symptoms of physical tolerance and withdrawal, not the use disorder syndrome. Severity is defined as: Mild, 2–3 symptoms; Moderate, 4–5 symptoms; and Severe, 6 or more symptoms.

Rates of co-occurring mood and anxiety disorders are especially high among those with alcohol use disorders. Untreated mood and anxiety disorders tend to have a negative impact on alcoholism recovery. Among treatment-seeking patients in the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) sample with a current alcohol use disorder, 40% had at least one current independent mood disorder, and more than one-third had at least one current independent anxiety disorder. Heavy alcohol intake can also induce symptoms of mood and other mental disorders. To differentiate alcohol-induced symptoms from independent disorders, it is optimal to reassess symptoms of a mental disorder several weeks after cessation or significant reduction of alcohol intake.

Brief Intervention**Intention**

Although risky or hazardous drinking is not a formal diagnosis, it describes a group with a higher likelihood to develop alcohol problems compared with the general population (see Box 1). Thus, even without a formal diagnosis, it is beneficial to help the patient with risky drinking to change his or her drinking behavior. Several well-described short interchanges between the clinician and the patient, organized under the rubric of *brief interventions*, have

TABLE 1 Alcohol Use Disorders Identification Test (AUDIT)

QUESTIONS	SCORING				
	0	1	2	3	4
Consumption (AUDIT-C)					
How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week
How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more
How often do you have five or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
Personal Consequences					
How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
Social Consequences					
Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year
Has a relative, friend, doctor, or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year
Scoring and Interpretation					
Add all scores to obtain a total: >8 points for men or >4 points for women indicates a high risk of alcohol use disorder.					
AUDIT-C (first three AUDIT questions): >6 points for men or >4 points for women indicates a need for further evaluation.					

BOX 3 CAGE Questionnaire

- Have you ever felt that you should *Cut down* on your drinking?
 - Have people *Annoyed* you by criticizing your drinking?
 - Have you ever felt bad or *Guilty* about your drinking?
 - Have you ever taken a drink (*Eye opener*) first thing in the morning to steady your nerves or to get rid of a hangover?
- One yes response indicates need for further assessment. Two yes responses indicate risk of an alcohol use disorder.

BOX 4 CRAFFT Questionnaire

- Have you ever ridden in a **C**ar driven by someone (including yourself) who was high or had been using alcohol or drugs?
 - Do you ever use alcohol or drugs to **R**elax, feel better about yourself, or fit in?
 - Do you ever use alcohol or drugs while you are **A**lone?
 - Do you ever **F**orget things you did while using alcohol or drugs?
 - Do your **F**amily or **F**riends ever tell you that you should cut down on your drinking or drug use?
 - Have you ever gotten into **T**rouble while you were using alcohol or drugs?
- One yes response indicates need for further assessment. Two yes responses indicate risk of alcohol use disorder.

TABLE 2 TWEAK Questionnaire

FEATURE	QUESTION	ANSWER	SCORE
Tolerance	How many drinks does it take before you begin to feel the first effects of alcohol?	≥ 3	2
Worry	Have your friends or relatives worried or complained about your drinking in the past year?	Yes	2
Eye-opener	Do you sometimes take a drink in the morning when you first get up?	Yes	1
Amnesia	Are there times when you drink and afterward you can't remember what you said or did?	Yes	1
Kut	Do you sometimes feel the need to cut down on your drinking?	Yes	1
Scoring and interpretation: Two or more points indicate a possible alcohol problem.			

BOX 5 S-MAST-G Questionnaire

- When talking with others, do you ever underestimate how much you actually drink?
 - After a few drinks, have you sometimes not eaten or been able to skip meals because you didn't feel hungry?
 - Does having a few drinks help decrease your shakiness or tremors?
 - Does alcohol sometimes make it hard for you to remember parts of the day or night?
 - Do you usually take a drink to relax or calm your nerves?
 - Do you drink to take your mind off your problems?
 - Have you ever increased your drinking after experiencing a loss in your life?
 - Has a doctor or nurse ever said that he or she was worried or concerned about your drinking?
 - Have you ever made rules to manage your drinking?
 - When you feel lonely, does having a drink help?
- Two or more yes responses indicate a probable alcohol problem.

Abbreviation: S-MAST-G = Short Michigan Alcoholism Screening Test—Geriatric.

been validated in randomized trials as decreasing alcohol intake in those who drink too much but do not have a diagnosis of alcohol dependence. Brief intervention has been demonstrated to reduce weekly alcohol use, frequency of bingeing, liver enzymes associated with heavy drinking, blood pressure, emergency department visits, hospital days, and psychosocial problems, typically for 6 to 12 months, and to reduce drinking and hospital days at up to 4 years in one study. Because most at-risk patients seen in primary

care settings are subsyndromal for alcohol use disorders, the typical clinical interaction related to alcohol will be that of screening and then a brief intervention for positive cases. The two are typically referred to together under the acronym SBI (screening and brief intervention).

The basic intention of a brief intervention is to educate the patient about the risks of heavy alcohol use in such a way as to motivate him or her to reduce weekly alcohol consumption. The standard initial brief intervention takes about 15 minutes and consists of feedback, advice, and goal setting. It can be performed wholly in the primary care setting by the physician or other members of the health delivery team. Including alcohol screening, the USPSTF suggests five A's to conducting SBI: *assess* the patient's alcohol consumption with a screening tool and clinical evaluation as indicated; *advise* reduction of alcohol consumption to appropriate levels, including abstinence if indicated; *agree* on individual goals for reducing alcohol use, including abstinence if indicated; *assist* patients in obtaining the motivation, skills, or supports needed to institute changes in drinking; and *arrange* for follow-up support, including specialty treatment referral for dependent patients. The most effective interventions are multicontact ones that provide ongoing assistance and follow-up.

Procedure**Assess**

Screen patients with the AUDIT or with the CAGE, TWEAK, CRAFFT, or S-MAST-G questionnaires as appropriate, and compute average drinks per week.

Advise

Give feedback in the form of expression of concern, direct conclusions, and recommendations. Present medical findings, such as

TABLE 3 Diagnosis of Alcohol Use Problems

CRITERIA	TYPICAL SYMPTOMS AND HISTORY
Alcohol Use Disorder (≥2 in the last 12 mo)	
<i>Alcohol has caused or contributed to repeated:</i>	
Failure to fulfill obligations at home, school, or work	Hangovers at work, truancy at school, missing appointments
Episodes of increased risk of physical harm	Driving, swimming, or operating machinery under the influence of alcohol
Craving, or a strong desire or urge to use alcohol	Inability to refrain from drinking due to strong impulses
Problems with significant others	Spousal strife, physical fights
Development of physical tolerance	Drinks more for the same effect
Episodes of withdrawal syndrome (see below)	Morning shakes, nausea, anxiety
Drinking more than intended repeatedly	Bingeing episodes
Unsuccessful efforts to cut down or stop drinking	Failed New Year's resolution
Increased time planning for drinking, or recovering from drinking	Instead of being with kids, spends weekend mornings sleeping in
Reduced time in other pleasurable or important activities	Stopped socializing with friends, withdrew from hobby group
Drinking persists despite physical or psychological problems	Developed depressed mood, but kept on drinking
Alcohol Withdrawal (≥2 within hours to days after lowered blood alcohol levels)	
Autonomic hyperactivity	Heart rate ≥100 bpm, diaphoresis
Hand tremor	Hands shake when extended
Insomnia	Difficulty falling asleep
Nausea or vomiting	Feels queasy
Anxiety	Spontaneous report of fear
Psychomotor agitation	Inability to keep still, pacing
Hallucinations or illusions	Reports visual disturbances
Seizures	Tonic-clonic movements

elevated liver enzymes, to back up conclusive statements such as “I’m concerned that your alcohol intake exceeds safe limits.” Show the patient information comparing use with population norms and the associated health risks. Educate the patient about how alcohol can lead to medical, psychosocial, and legal consequences. Where possible, link the patient’s current symptoms to alcohol use. Recommend appropriate and specific changes in behavior, such as “I strongly recommend you cut down your drinking,” or in the case in which any drinking places the patient at high risk, “I strongly suggest you quit drinking.”

Agree

Determine the patient’s readiness to change drinking behavior, such as asking, “Do you think that cutting down on your drinking is something you are willing to talk about?” If the patient is ambivalent, avoid labeling the patient’s behavior with a diagnosis at this stage, which can increase resistance to change, but encourage the patient to reflect on the positive reasons for drinking and the negative consequences of drinking. Offer concerns that continued drinking at the same level will impede the patient’s achievement of goals such as decreased gastric distress or improved sleep patterns.

Empathic listening is generally more effective than a confrontational approach, and it is useful to express optimism about the patient’s capacity to change. Elicit what the patient’s concerns are about cutting down or quitting. Avoid arguing or challenging when the patient is unready to change, but schedule a follow-up visit to continue the dialogue and reassess drinking behavior. Restate your commitment to help when the patient is ready and that you remain open to questions.

When the patient concurs that a change in drinking would be beneficial, agree on a specific goal to cut down to particular daily and weekly limits for low-risk drinking or to stop drinking, if indicated, for a specific period of time. The agreement should be recorded and a copy given to the patient both as a reminder and motivator for behavioral change.

Assist

Work with the patient to formulate concrete steps to implement the drinking reduction plan. These steps include how to avoid high-risk drinking situations, how to keep a record of alcohol intake, and who can support the patient in meeting his or her goals. Provide resources in the form of patient educational materials, examples of which can be downloaded from the National Institute of Alcohol Abuse and Alcoholism (NIAAA) website (www.niaaa.nih.gov).

Arrange

Set up follow-up support and counseling visits or refer patients meeting dependence criteria for specialty treatment. Advise the patient to seek immediate medical treatment if withdrawal symptoms occur.

Treatment

Detoxification

Put simply, detoxification is medical stabilization that offers an opportunity to engage patients in alcoholism treatment, but it is not in itself treatment for alcohol dependence. Patients who drink more than 250 grams of alcohol daily are likely to experience physiologic withdrawal symptoms on cessation of drinking, but volume is not the only predictor of withdrawal severity. Although often mild, untreated alcohol withdrawal can result in seizures or delirium tremens (DTs), with increased risk of mortality.

Assessment

The Clinical Institute Withdrawal Assessment for Alcohol scale, Revised (CIWA-Ar) is a public domain scale that scores 10 signs and symptoms of withdrawal by severity ranging from not present to severe (Box 6). A score of less than 8 indicates mild withdrawal, characterized by increased autonomic activity with low-grade anxiety, diaphoresis, agitation, nausea, and elevated blood pressure,

temperature, and heart rate. Scores of 8 to 15 indicate moderate withdrawal, and scores of 15 or more indicate more severe withdrawal states. In severe withdrawal, in the context of autonomic hyperarousal, the patient can become disoriented and have a clouded sensorium, the hallmarks of delirium.

Prior history of severe withdrawal, such as DTs, is a reasonable predictor of similar future responses to alcohol withdrawal. Risk for withdrawal delirium is increased if the patient has a heart rate of greater than 120 bpm before treatment, a current infectious disease, withdrawal symptoms in the context of a blood alcohol concentration greater than 100 mg/dL, a prior history of either delirium or seizures, or a high CIWA-Ar score, indicating severe autonomic hyperactivity. Patients who have severe withdrawal symptoms, who are at high risk for seizures, or who have a medical condition likely to be exacerbated by withdrawal, such as type 1 diabetes or coronary artery disease, should have medically supervised inpatient detoxification.

Pharmacologic Therapy

Alcohol withdrawal is best treated with sedative hypnotic medications that are cross-tolerant with alcohol, such as benzodiazepines. Longer-acting benzodiazepines such as diazepam (Valium) and chlordiazepoxide (Librium) are easier to titrate against withdrawal symptoms and give a gradual offset in plasma concentration, but shorter-acting benzodiazepines such as lorazepam (Ativan)¹ are less likely to oversedate the patient. Rapid-onset benzodiazepines have a higher abuse liability and are generally best avoided. However, patients with severe hepatic impairment (elevated total bilirubin) are best treated with benzodiazepines that are not oxidized by the liver, such as oxazepam (Serax) or lorazepam.

Typical dosing is chlordiazepoxide 50 to 100 mg, diazepam 10 to 20 mg, oxazepam 20 to 40³ mg, or lorazepam 2 to 4 mg. The typical front-loading style of dosing is to administer medication at the higher end of the dose range every 1 to 2 hours so that the CIWA-Ar score is less than 8 for 24 hours.

With long-acting medications, once symptoms subside, there is often no need to taper doses. The short-acting benzodiazepines and long-acting benzodiazepines given to patients at high-risk for seizures or DTs are best given on a fixed-dose regimen of four times daily for the first 24 hours, with the patient reassessed 1 to 2 hours after each dose, and additional medication given as needed. On days 2 and 3, 50% of the dose can be given four times daily.

Long-acting barbiturates, such as phenobarbital¹, can be also used on a fixed-dose regimen of 60 mg every 4 to 6 hours, with a loading dose of 120 mg orally or intramuscularly every hour for acute withdrawal symptoms (e.g., pulse >110 bpm) or a CIWA-Ar score of 10 or more.

Anticonvulsants such as carbamazepine (Tegretol)¹, valproate (Depakote)¹, or gabapentin (Neurontin)¹ have also been used effectively in uncomplicated withdrawal, but they are unproved in preventing withdrawal-related seizures and in treating DTs.

Although phenothiazines and haloperidol (Haldol)¹ are somewhat effective compared with benzodiazepines in reducing withdrawal symptoms such as agitation, they are not as protective against seizures or delirium and thus are not recommended.

Thiamine (vitamin B₁) supplementation of 100 mg/day for 3 days can counteract the thiamine deficiencies that are common in alcoholic patients.

Psychosocial Interventions for Alcohol Use Disorder

In addition to brief interventions for risky alcohol use, the most opportune and practical psychosocial intervention that the primary care office can provide is clinical behavioral support for pharmacotherapy for alcohol dependence. Simply put, medication management support consists initially of feedback to the patient of screening and medical evaluation results and the negative health effects of continued heavy drinking, as in a brief intervention.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Patient: _____ Date: _____ Time: _____ (24-hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute: _____ Blood pressure: _____ mm Hg

Nausea and Vomiting – Ask, “Do you feel sick to your stomach? Have you vomited?” Observation:

- 0 no nausea and no vomiting
- 1 mild nausea with no vomiting
- 2
- 3
- 4 intermittent nausea with dry heaves
- 5
- 6
- 7 constant nausea, frequent dry heaves, and vomiting

Tactile Disturbances – Ask, “Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?” Observation:

- 0 none
- 1 very mild itching, pins and needles, burning, or numbness
- 2 mild itching, pins and needles, burning, or numbness
- 3 moderate itching, pins and needles, burning, or numbness
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

Tremor – Arms extended and fingers spread apart. Observation:

- 0 no tremor
- 1 not visible, but can be felt fingertip to fingertip
- 2
- 3
- 4 moderate, with patient’s arms extended
- 5
- 6
- 7 severe, even with arms not extended

Auditory Disturbances – Ask, “Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?”

- Observation:
- 0 not present
 - 1 very mild harshness or ability to frighten
 - 2 mild harshness or ability to frighten
 - 3 moderate harshness or ability to frighten
 - 4 moderately severe hallucinations
 - 5 severe hallucinations
 - 6 extremely severe hallucinations
 - 7 continuous hallucinations

Paroxysmal Sweats – Observation:

- 0 no sweat visible
- 1 barely perceptible sweating, palms moist
- 2
- 3
- 4 beads of sweat obvious on forehead
- 5
- 6
- 7 drenching sweats

Visual Disturbances – Ask, “Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?” Observation:

- 0 not present
- 1 very mild sensitivity
- 2 mild sensitivity
- 3 moderate sensitivity
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

Anxiety – Ask, “Do you feel nervous?” Observation:

- 0 no anxiety, at ease
- 1 mild anxious
- 2
- 3
- 4 moderately anxious, or guarded, so anxiety is inferred
- 5
- 6
- 7 equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

Headache, Fullness in Head – Ask, “Does your head feel different? Does it feel like there is a band around your head?” Do not rate for dizziness or light-headedness. Otherwise, rate severity:

- 0 not present
- 1 very mild
- 2 mild
- 3 moderate
- 4 moderately severe
- 5 severe
- 6 very severe
- 7 extremely severe

Agitation – Observation:

- 0 normal activity
- 1 somewhat more than normal activity
- 2
- 3
- 4 moderately fidgety and restless
- 5
- 6
- 7 paces back and forth during most of the interview or constantly thrashes about

Orientation and Clouding of Sensorium – Ask, “What day is this? Where are you? Who am I?”

- 0 oriented and can do serial additions
- 1 cannot do serial additions or is uncertain about date
- 2 disoriented for date by no more than 2 calendar days
- 3 disoriented for date by more than 2 calendar days
- 4 disoriented for place or person

Total CIWA-Ar Score _____

Rater’s Initials _____

Maximum Possible Score: 67

The CIWA-Ar is not copyright and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer.

The patient is then given the basis for the diagnosis of alcohol dependence, the rationale for abstinence, and recommendation for pharmacotherapy. The patient is given information about medication and the appropriate prescriptions and is encouraged to seek community support for sobriety in mutual help groups such as Alcoholics Anonymous or to follow a plan such as Rational Recovery. Follow-up visits consist of assessment of medication side effects, patient adherence to the medication regimen, assessment of abstinence or quantity and pattern of alcohol intake, and assessment of overall functioning. Problems with medication adherence are identified and addressed.

There are evidence-based psychosocial interventions that are typically performed in the context of specialty programs for alcohol dependence, but they can be offered by clinical personnel in the context of the physician's office. Cognitive behavior therapy, network therapy, behavioral family therapy, and motivational interviewing are effective approaches for the treatment of alcohol dependence. Motivational interviewing is especially adaptable for use in primary care settings in that it is an approach to interacting with the alcohol-dependent patient that can be learned quickly and executed by any staff with clinical contact. A motivational enhancement manual can be accessed at the NIAAA website (<http://www.niaaa.nih.gov/>).

Medication Management of Alcohol Dependence

There are currently four FDA-approved medications for the treatment of alcohol dependence. Any of these medications can and should be given concurrently with other interventions such as psychosocial treatment or mutual help groups.

Disulfiram (Antabuse) works by inhibiting the metabolism of ethyl alcohol, causing a buildup of acetaldehyde, a noxious substance, which causes a strong stereotypic aversive response (flushing, diaphoresis, nausea, tachycardia) in the patient. Standard dosing is 250 mg/day (range, 125–500 mg). The major clinical concern with disulfiram is patient noncompliance with the medication regimen. Thus, it is most likely to be effective when there is a concrete method for supporting compliance in place, such as directly observed therapy by a spouse or in a clinic.

More recently, the opioid antagonist naltrexone (ReVia) was approved for the treatment of alcohol dependence. It is dosed at 50 mg orally once daily. Naltrexone reduces days of heavy drinking and can reduce alcohol craving. Naltrexone in a long-acting intramuscular formulation (Vivitrol) allows once-monthly dosing (380 mg) and reduces the risk of noncompliance. It reduces heavy drinking overall and helps maintain abstinence in those who are abstinent at initial drug administration. Both oral and IM naltrexone formulations carry FDA black-box warnings related to findings of reversible elevations of liver enzymes at three to six times the standard dosage; however, naltrexone is safe at the recommended dose.

Acamprosate (Campral) is a taurine analogue that has been demonstrated to reduce relapse to any drinking as well as reducing heavy drinking in nonabstinent patients. It is dosed as two 333-mg tablets three times a day to patients who have ceased alcohol intake. It is excreted unchanged through the kidneys and has no interactions with other medications. Side effects are benign, and the most frequent is loose stools, which are mild to moderate and self-limited.

Topiramate (Topamax)¹ titrated over 5 weeks between 50 mg and 300 mg daily appears to reduce heavy drinking and days of any drinking over the short term (12 weeks) in alcohol-dependent patients who have not established abstinence prior to treatment. Common side effects include paresthesias, taste perversion, decreased appetite, and difficulty concentrating.

DELIRIUM

Method of

Kari R. Clouse, MD

CURRENT DIAGNOSIS

- Delirium is an acute, fluctuating syndrome of altered attention, awareness, and cognition.
- Hypoactive delirium presents with at least four of the following behaviors: unawareness, decreased alertness, reduced or delayed speech, lethargy, slowed movements, staring, apathy, diminished appetite, or new incontinence.
- Hyperactive delirium is distinguished by at least three of the following behaviors: hypervigilance, restlessness, fast or loud speech, irritability, combativeness, impatience, swearing, singing, laughing, uncooperativeness, euphoria, anger, wandering, easy startling, fast motor responses, distractibility, tangentiality, nightmares, or persistent thoughts.
- Mixed delirium is distinguished by a combination of hypoactive and hyperactive behaviors.
- The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, offers diagnostic criteria for delirium (see the diagnosis section).

CURRENT THERAPY

- Prevention is best achieved by assessing predisposing and precipitating risk factors.
- Treatment should be targeted at reversing underlying causes and implementing nonpharmacologic interventions.

¹Not FDA approved for this indication.

The patient is then given the basis for the diagnosis of alcohol dependence, the rationale for abstinence, and recommendation for pharmacotherapy. The patient is given information about medication and the appropriate prescriptions and is encouraged to seek community support for sobriety in mutual help groups such as Alcoholics Anonymous or to follow a plan such as Rational Recovery. DELIRIUM

Method of

Kari R. Clouse, MD

CURRENT DIAGNOSIS

- Delirium is an acute, fluctuating syndrome of altered attention, awareness, and cognition.
- Hypoactive delirium presents with at least four of the following behaviors: unawareness, decreased alertness, reduced or delayed speech, lethargy, slowed movements, staring, apathy, diminished appetite, or new incontinence.
- Hyperactive delirium is distinguished by at least three of the following behaviors: hypervigilance, restlessness, fast or loud speech, irritability, combativeness, impatience, swearing, singing, laughing, uncooperativeness, euphoria, anger, wandering, easy startling, fast motor responses, distractibility, tangentiality, nightmares, or persistent thoughts.
- Mixed delirium is distinguished by a combination of hypoactive and hyperactive behaviors.
- The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, offers diagnostic criteria for delirium (see the diagnosis section).

CURRENT THERAPY

- Prevention is best achieved by assessing predisposing and precipitating risk factors.
- Treatment should be targeted at reversing underlying causes and implementing nonpharmacologic interventions.

¹Not FDA approved for this indication.

- Pharmacologic therapies should be reserved for severely agitated patients, psychotic individuals, or those who threaten substantial harm to self or others.

Epidemiology

Delirium is a common medical condition seen in various care settings. Although rates vary by location, delirium prevalence in long-term care facilities has been reported up to 60% and as high as 80% in intensive care units (ICUs). Patients who suffer from delirium have longer hospital stays, higher costs of care, greater risk of long-term cognitive impairment, and increased mortality rates.

Risk Factors

Once viewed as a reversible process caused by a single underlying cause, delirium is now believed to be multifactorial. Several risk factors have been identified and can be divided into predisposing and precipitating factors as noted in Table 1. A complex relationship exists between predisposing factors and exposures to precipitating events. A vulnerable patient may only require a small triggering incident whereas a healthy patient may be subject to multiple noxious insults, but both could result in delirium.

Pathophysiology

Delirium is a complex, multifactorial neurobehavioral syndrome and the exact pathophysiology is difficult to elucidate. Recent evidence suggests that several different sets of interacting biologic factors instigate the disruption of large-scale neuronal networks in the brain, leading to acute cognitive dysfunction. Ultimately, multiple insults can result in neuronal cell apoptosis and decreased synaptic plasticity. Contributing biologic factors may include neuroinflammatory processes, neurotransmitter disruption, and circadian rhythm dysregulation. For example, insults such as severe infection, surgery, and trauma are known to increase inflammatory cytokines and endotoxins. The inflammatory process is thought to degrade the blood-brain barrier, activate microglia, cause

endothelial dysfunction, alter cerebral blood flow causing hypoperfusion, and change neurotransmitter levels. Alteration of neurotransmitter levels, such as excess dopamine, depletion of acetylcholine, or melatonin deficiency are likely involved in the development of delirium. However, treatments targeted at correcting these imbalances have mixed outcomes, further accentuating the complexity of the illness. Moreover, predisposing factors such as cognitive dysfunction, advanced age, and chronic medical conditions affect the magnitude of neuronal resiliency needed to withstand precipitating events.

Prevention

Delirium is considered to be preventable 30% to 40% of the time. To minimize the possibility of delirium, modifiable variables should be assessed and eliminated. Resources available to help prevent, assess, and manage delirium can be found on the ICU Delirium and Cognitive Impairment Study Group website (<http://www.icudelirium.org>). The delirium prevention mnemonic “ABCDEF” outlines a bundle of measures beneficial in the prevention and management of delirium in the ICU.

Assess for and manage pain

Both spontaneous awakening and breathing trials (SAT, SBT)

Choice of sedation and analgesia

Delirium monitoring and management

Early mobility

Family or companion involvement

Clinical Manifestations

Delirium presents as an acute, fluctuating syndrome of confusion, altered attention, reduced perceptual awareness of surroundings, disorganized thinking, and cognitive impairment. Three subtypes of delirium have been identified:

- Hypoactive (at least four of the following): unawareness, decreased alertness, reduced or delayed speech, lethargy, slowed movements, staring, apathy, diminished appetite, or new incontinence.
- Hyperactive (at least three of the following): hypervigilance, restlessness, fast or loud speech, irritability, combativeness, impatience, swearing, singing, laughing, uncooperativeness, euphoria, anger, wandering, easy startling, fast motor responses, distractibility, tangentiality, nightmares, or persistent thoughts.
- Mixed (combination of hypoactive and hyperactive behaviors).

Diagnosis

Unfortunately, lack of recognition by health-care professionals is a significant issue and the diagnosis of delirium is commonly missed. The key to early identification is having a high clinical suspicion of the syndrome. According to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, the following five criteria must be fulfilled to accurately diagnosis delirium.

1. A disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment) exists;
2. An additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception) exists;
3. The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day;
4. The disturbances in criteria 1 and 2 are not explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal such as coma;
5. There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiologic consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or to a medication), exposure to a toxin, or is due to multiple etiologies.

Several assessment tools exist to identify this complex syndrome. One of the most effective and commonly used is the Confusion

TABLE 1 Risk Factors for Delirium

PREDISPOSING FACTORS	PRECIPITATING FACTORS
Cognitive impairment	Environmental triggers
Dementia	Sleep deprivation
Depression	Physical restraints
Medical comorbidities	Foley catheter
Sensory loss	Arterial catheter
Chronic medical conditions	Gastric tube
Persistent pain	Multiple IV infusions
Pressure ulcers	Lack of visitors
Urinary incontinence	Length of stay in ICU
Malnutrition	Medical insults
Alcohol abuse	Medications
Terminal illness	Infection
Geriatric factors	Hypoxia
Dehydration	Ischemia
Age >65 years	Severe illness
Elder abuse	Uncontrolled pain
Frequent falls	Surgery
Functional dependence	
Polypharmacy	

Assessment Method (CAM). When performed by a trained individual, this instrument is reported to have 94% to 100% sensitivity and 90% to 95% specificity in detecting delirium. It can also be used as an indicator of severity. For efficiency, a shortened version of this test, CAM-Short (CAM-S) also exists, but lacks the ability to characterize severity. Several other evaluation methods are available and can be found on the Hospital Elder Life Program website (<http://www.hospitalelderlifeprogram.org/delirium-instruments>). A basic laboratory and imaging workup is routinely indicated. For most patients this includes a complete blood count, complete metabolic panel, urinalysis, chest radiograph, and electrocardiogram. Individual scenarios may warrant additional diagnostic investigation such as a computerized tomography scan, electroencephalogram, lumbar puncture, or supplementary laboratory tests.

Differential Diagnosis

Several clinical scenarios can mimic delirium. This contributes to the underdiagnosed nature of this syndrome. Multiple mnemonics have been created to aid in identification of underlying clinical conditions that might cause or contribute to delirium. One helpful mnemonic is "I WATCH DEATH."

Infection	Urinary tract infection, pneumonia, sepsis, human immunodeficiency virus, syphilis, abscess
Withdrawal	Alcohol, barbiturates, sedative-hypnotics
Acute metabolic	Acidosis, alkalosis, electrolyte disturbance, hepatic/renal failure, dehydration
Trauma	Head injury, postoperative state, hyper/hypothermia, burns
CNS pathology	Cerebrovascular accident, tumors, metastasis, seizures, hemorrhage, encephalitis, meningitis, vasculitis
Hypoxia	Anemia, cardio/pulmonary failure, hypotension
Deficiencies	Thiamine, B ₁₂ , niacin, folate
Endocrinopathies	Hyper/hypothyroid, hyper/hypoglycemia, adrenal dysfunction, parathyroid disorders
Acute vascular	Hypertensive emergency, subarachnoid hemorrhage, sagittal vein thrombosis
Toxins/drugs	Medications, alcohol, illicit drugs, synthetic cannabinoids, pesticides, industrial poisons, carbon monoxide, cyanide, solvents, synthetic cathinones
Heavy metals	Lead, mercury, manganese

Additional memory aids can be located on the ICU Delirium and Cognitive Impairment Study Group website (<http://www.icudelirium.org>).

Treatment

The treatment of delirium consists of both nonpharmacologic and pharmacologic therapies and should be centered on the patient's medical condition, risk factors, and environmental insults. For initial symptom management, nonpharmacologic tactics are the first-line strategy. The most widely disseminated approach is the Hospital Elder Life Program, a multicomponent hospital intervention strategy involving health-care professionals, families, caregivers, and patients. The program has proven effectiveness and demonstrated reductions in the cost of care (<http://www.hospitalelderlifeprogram.org>). *Pharmacologic therapies should be reserved for severely agitated patients, psychotic individuals, or those who threaten substantial harm to self or others.* Low starting doses should be used. Currently, there are no antipsychotic medications that are Food and Drug Administration–approved for prevention or treatment of delirium. Clinical trials are currently evaluating the effectiveness of dexmedetomidine, a sedative α_2 -agonist, in ICU patients requiring sedation for agitated delirium. Types of management are outlined in Tables 2 and 3.

Monitoring

Once identified, regular monitoring of delirium can focus treatment targets. Multiple screening tools are available and can be found at the Hospital Elder Life Program website. Situations that warrant a significant and prompt reevaluation include a dramatic vital change, new focal neurologic deficits, respiratory distress, escalating behaviors, or danger to self or others.

TABLE 2 Nonpharmacologic Management of Delirium

Target and address underlying causes first
Medication review and appropriate management
Nutritional and fluid replacement
Sleep enhancement through proper sleep hygiene, relaxation, and creation of quiet, soothing, warm environment
Adequate pain control, preferably nonopioid
Cognitive orientation by family or companion involvement, consistent medical staff, clocks, and calendars
Early and continued mobilization
Improved exposure to daylight to promote circadian rhythm
Sensory enhancement with glasses, hearing aids, or other adaptive equipment
Daily cognitive assessment with standardized tool

TABLE 3 Pharmacologic Management of Delirium

Typical Antipsychotics¹

Haloperidol (Haldol) 0.5–2.0 mg bid orally every 4 hours or intramuscularly every 30–60 minutes prn; maximum dose 20 mg in 24 hours
Most commonly used agent

Atypical Antipsychotics¹

Quetiapine (Seroquel) 25–200 mg orally bid
Risperidone (Risperdal) 0.25–2 mg orally divided once daily to bid
Olanzapine (Zyprexa) 2.5–10 mg orally once daily
Ziprasidone (Geodon) 20–80 mg orally bid
Aripiprazole (Abilify) 10–30 mg orally once daily

Benzodiazepines¹

Lorazepam (Ativan) 0.5–1.0 mg orally every 4 hours prn
Reserve for alcohol withdrawal
Can worsen delirium caused by other factors

¹There are no antipsychotic medications and benzodiazepines that are FDA approved for prevention or treatment of delirium.

Complications

Long-term complications of delirium are significant. Patients with delirium can experience postoperative setbacks, prolonged hospitalization, loss of functional independence, posttraumatic stress disorder, and permanently reduced cognitive function. These individuals are at high risk for readmission, particularly if over the age of 75. Medications used to treat delirium can result in many adverse effects such as extrapyramidal symptoms, cardiac conduction abnormalities, hypotension, somnolence, and anticholinergic effects. Finally, delirium is associated with increased mortality, with rates ranging from 14.5% to 37%.

CURRENT DIAGNOSIS

- Screen for substance use in all primary care and emergency settings.
- The clinical interview remains the mainstay of diagnosis.
- Clinicians should have a low threshold for ordering a urine drug test.
- Collateral information should be obtained from family or other sources.
- DSM-5 offers current diagnostic criteria for substance use disorders (see [Box 1](#)).

CURRENT THERAPY

- Effective pharmacologic and psychosocial treatments exist.
- Formal detoxification is indicated for dangerous withdrawal states or in patients with serious medical comorbidity.
- Pharmacologic relapse prevention treatment options are substance-specific, and particularly useful options exist for nicotine and opioids.
- Psychosocial treatments remain the mainstay of substance treatment, and these range along a continuum of intensity from outpatient counseling to long-term residential treatment.
- Patients should be referred to self-help groups (e.g., Narcotics Anonymous) to complement other therapies.
- Indefinite remission is an attainable goal for many—a relapse does not constitute total failure but gives opportunity to re-evaluate the treatment approach.

Epidemiology

Widespread pathologic use of intoxicating substances, both legal and illegal, remains one of the greatest public health concerns facing our nation. According to the 2010 National Survey on Drug Use and Health, 22.6 million Americans (8.9% of the population) aged 12 years and older used an illicit drug within the past month. By order of frequency, these include marijuana, nonmedical use of prescription drugs, cocaine, hallucinogens, inhalants, and heroin. In addition, 69.6 million Americans (27.4%) aged 12 years and older used tobacco within the past month, mostly in the form of cigarettes. Each year in the United States, approximately 443,000 people die of an illness attributable to cigarette smoking, making this the foremost cause of preventable death. The estimated annual economic cost of drug abuse is over \$600 billion in the United States alone: \$185 billion for illicit drugs, \$235 billion for alcohol, and \$193 billion for tobacco. These costs include only direct health-related, crime-related, and lost-productivity costs, thus underestimating the full impact of drug abuse on society.

From 2002 to 2010, the rate of past-month cigarette use among 12- to 17-year-olds has steadily dropped from 13.0% to 8.3%. The 2010 Monitoring the Future survey data confirm that cigarette smoking has continued to fall to the lowest rate in the survey's history (i.e., past month use among 12th graders is now at 19%). Since 2000, overall rates of illicit drug use have slowly dropped, but use of marijuana has recently slowed its rate of decline and initiation of illicit prescription drugs is now on the rise. In 2006, new users of illicit prescription drugs caught up with

BOX 1

DSM-5 Diagnostic Criteria for "Substance Use Disorder"

A problematic pattern of use leading to clinically significant impairment or distress as manifested by two or more of the following in a 12-month period:

1. Often taken in larger amounts or longer period than intended.
2. Persistent desire or unsuccessful efforts to cut down or control use.
3. Great deal of time spent in activities necessary to obtain, use, or recover from effects.
4. Craving, or strong desire or urge to use.
5. Recurrent use resulting in failure to fulfill major role obligations at work, school, or home.
6. Continued use despite having persistent/recurrent social or interpersonal problems caused or exacerbated by the substance.
7. Important social, occupational, or recreational activities are given up or reduced because of use.
8. Recurrent use in situations in which it is physically hazardous.
9. Continued use despite knowledge of having a persistent/recurrent physical or psychological problem likely to have been caused or exacerbated by the substance.
10. Tolerance (needing increased amounts for desired effect, or diminished effect with same amount).
11. Withdrawal (manifested by characteristic syndrome or taking more to relieve/avoid withdrawal).

Specify current severity:

Mild: Two to three criteria are met

Moderate: Four to five criteria are met

Severe: Six or more criteria are met

new users of marijuana for the first time; however, since then, first-time use of marijuana has regained its ascendancy, with 2.4 million first-time users estimated in 2010. As of 2010, 48.2% of 12th graders still report having used an illicit drug at some point in their life. Despite advances in our understanding and treatment of substance use disorders, drug abuse remains an epidemic, especially in the areas of drugged driving and drug use (including tobacco) in pregnancy.

Diagnosis

With the publication of the DSM-5 in 2013, the diagnostic categories of substance abuse and substance dependence have been entirely eliminated. In the interest of consistency and clarity, and based on large population data, these have been replaced with a new diagnostic entity: "substance use disorder" ([Box 1](#)). It is no longer necessary for the clinician to decide between two different diagnoses. Those familiar with DSM-IV terminology will find the new criteria quite familiar, as they essentially represent a combination of the old abuse and dependence criteria, with two notable exceptions: one, legal problems has been eliminated; and two, a craving criterion has been added. When diagnosing a substance use disorder, the specific substance for which criteria are met must be listed. In addition, it is also important to document the severity of the disorder based on the number of symptoms present. Examples of specific diagnoses using the new nomenclature would be "alcohol use disorder, moderate" or "alprazolam use disorder, severe." This simpler, evidence-based, diagnostic schema should eliminate some of the confusion previously surrounding the term "dependence," which was often mistaken to be synonymous with "physiological dependence." It has long been understood, in the context of certain prescribed drugs, that the presence of tolerance and withdrawal is not pathological in nature; rather, these represent an expected state of neuroadaptation. This fact is reflected in the new criteria for opioid use disorder; stimulant use disorder; and sedative, hypnotic, or anxiolytic use disorder. For these three

categories, the tolerance and withdrawal criteria are not considered to be met if present when the substance is taken solely under appropriate medical supervision. It should be noted this exception does not apply to cannabis, even if it is “prescribed.”

Despite the importance and usefulness of the DSM-5, many patients (and clinicians) may still be left wondering if the problem at hand would appropriately be characterized as “addiction.” In a 2011 public policy statement, the American Society of Addiction Medicine offered the following short definition of addiction, which has been well received: *“Addiction is a primary, chronic disease of brain reward, motivation, memory and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social and spiritual manifestations. This is reflected in an individual pathologically pursuing reward and/or relief by substance use and other behaviors. Addiction is characterized by inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one’s behaviors and interpersonal relationships, and a dysfunctional emotional response. Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death.”*

Tobacco and Nicotine

Nicotine is the main addictive component in tobacco, which is administered via smoking (e.g., cigarettes, cigars, pipes, bidis, hoo-kah) or in smokeless formulations (e.g., dip, snuff, snus, chew). However, smoking tobacco is clearly not equivalent to taking nicotine. Cigarette smoking causes nicotine, brain monoamine oxidase (MAO), and other effects in the smoker, some resulting from the smoke and others resulting from the nicotine.

Following administration, nicotine rapidly binds to nicotinic acetylcholine receptors in the central nervous system (CNS), where it acts as a mild psychostimulant and mood modulator in a nonimpairing yet profoundly addictive manner. When the user is tired, smoking has a stimulating effect. When the user is anxious or stressed, smoking exerts a calming effect. Smoking is like an injection without the needle, and given its short half-life, repeated self-administration serves to effectively relieve unpleasant withdrawal

symptoms from the nicotine itself. Repeated use quickly leads to both physiologic and psychological dependence.

As with other drugs of abuse, cue-induced cravings play an important role in maintaining the addiction. For example, the smell of the smoke, the sound of a lighter, and the feel of a cigarette on the lips all contribute to an overall process addiction beyond just addiction to the nicotine itself. Tobacco use is also strongly associated with alcohol use, with which it has synergistic toxic effects.

Toxicities from tobacco use are well described and include severe pulmonary disease, cardiovascular disease, and carcinomas of the upper aerodigestive tract and bladder. Even secondhand smoke, previously considered harmless, is now correctly regarded as a serious health risk to the nonsmoker and a “drug” itself. Cigarette smoke contains more than nicotine (up to 4700 components, all of which affect the smoker). Additionally, secondhand tobacco exposure in utero can cause addiction and lead to serious health-related consequences.

Although quitting remains difficult for even the most motivated tobacco users, effective treatments for nicotine dependence now exist. Clinical trials indicate a combination of counseling and medications offers the best chance for success and should be offered to patients who are willing to make a quit attempt. A wide range of FDA-approved nicotine replacement therapies are readily available and have similar rates of efficacy (Table 1). Patches (Nicoderm CQ), gums (Nicorette), and lozenges (Commit) are available over the counter, but the nasal spray (Nicotrol NS) and inhaler (Nicotrol Inhaler) are available by prescription only. Recently, “electronic cigarettes” have gained in popularity, but unlike other nicotine products, they are not regulated as a drug by the FDA.

Non-nicotine prescription medications with proven efficacy are available. Bupropion HCl (Wellbutrin) is an antidepressant that was serendipitously noted to dramatically reduce nicotine cravings in some patients, and it is now widely used for this purpose (as Zyban). Varenicline (Chantix) was specifically developed to treat nicotine dependence and represents a considerable advancement, with improved smoking cessation rates. It acts as a partial agonist at the nicotine receptor and effectively serves to satisfy cravings while simultaneously blocking the effects of exogenously

TABLE 1 Pharmacotherapy for Nicotine Dependence

DRUG	MECHANISM OF ACTION	DOSAGE	INSTRUCTIONS	COMMENTS
Nicotine patch (Nicoderm CQ)	NRT	7 mg, 14 mg, 21 mg	1 patch daily	Tapering doses recommended to discontinue
Nicotine gum (Nicorette)	NRT	2 mg, 4 mg	Chew slightly then “park” on oral mucosa	Tapering doses recommended to discontinue
Nicotine lozenge (Commit)	NRT	2 mg, 4 mg	Absorbed through oral mucosa; minimize swallowing	Tapering doses recommended to discontinue
Nicotine inhaler (Nicotrol Inhaler)	NRT	4 mg/cartridge	6–16 cartridges/day	By prescription only; tedious administration
Nicotine nasal spray (Nicotrol NS)	NRT	0.5 mg/spray	1–2 sprays each nostril q1h; max 80 sprays/day	By prescription only
Bupropion HCl (Wellbutrin, ¹ Zyban)	Inhibits reuptake of NE and DA	150 mg SR tab, 300 mg XL tab	300 mg PO (divided qd [XL tab]-bid [SR tab]) daily × 7–12 wk	Helps with comorbid depression; can help prevent weight gain
Varenicline (Chantix)	Partial agonist at $\alpha_4\beta_2$ nicotinic acetylcholine receptor	0.5 mg, 1 mg	0.5 mg PO qd × 3 d, then 0.5 mg PO bid × 4 d, then 1 mg PO bid × 11 wk	May smoke during 1st wk; may continue additional 12 wk
Nicotine vaccine (NicVAX)	Antibody sequestration of nicotine	n/a	n/a	In clinical trials

Abbreviations: DA = dopamine; max = maximum; n/a = not applicable; NE = norepinephrine; NRT = nicotine replacement therapy; SR = sustained release; XL = extended release.

¹Not FDA approved for this indication.

administered nicotine. Although probably the most effective agent, varenicline carries significant risk of psychiatric side effects. The “nicotine vaccine” (NicVAX),¹ a novel approach, is currently in phase III clinical trials, and appears promising.

Nicotine replacement, bupropion, and varenicline are all considered first-line pharmacotherapy. Bupropion, but not varenicline, may also be used in combination with nicotine replacement therapies. All pharmacotherapy options are enhanced with coadministration of counseling or behavioral therapies. Helpful resources for patients interested in quitting include www.smokefree.gov (a government website dedicated to helping people quit smoking), 1-800-QUIT-NOW (a free phone-based services with coaches and educational materials) and a variety of resources available through the American Cancer Society and American Heart Association.

Cannabis

Cannabis (marijuana, pot, weed, grass, ganja, hash) remains the most-used illicit drug in the world. In Americans older than 12 years, 45% have used cannabis at least once, and 7.4% have used it in the past month. Cannabis is readily harvested from *Cannabis sativa*, and typically it is smoked, although it may also be ingested or vaporized. Despite a recent trend advocating legitimate medicinal use, it is still listed in Schedule I by the Drug Enforcement Agency (DEA), with high potential for abuse and no currently accepted medical use. Delta-9-tetrahydrocannabinol (THC) is the active ingredient, which exerts its desired psychoactive effects at CB₁ receptors diffusely throughout the CNS. Marijuana’s THC concentration has been steadily increasing as a result of selective plant breeding. Annual analysis of DEA seizures indicates average THC concentrations increased from approximately 1% in 1975 to approximately 10% in 2008. To what extent this makes the drug more dangerous or more addictive remains unclear.

Acute psychoactive effects of cannabis include euphoria, relaxation, heightened sensations, increased appetite, distorted sense of time, slowed reaction time, illusions and hallucinations, paranoia, and anxiety. Acute somatic effects include conjunctival injection, xerostomia, increased heart rate and blood pressure, muscle relaxation, and reduced intraocular pressure. There is no known risk of dangerous overdose, and withdrawal symptoms are generally mild but include irritability, cravings, diminished appetite, and insomnia. Cannabis is now recognized as unequivocally addictive. Abusers of this drug rapidly develop tolerance and commonly demonstrate loss of control and continued use despite negative consequences—the hallmarks of addiction. It is estimated that 1 million Americans sought treatment for cannabis as their primary drug of choice in 2010.

Not surprisingly, with more than 400 chemicals identified in its smoke, cannabis is dangerous with respect to long-term health. Chronic cannabis use is associated with lung cancer, chronic obstructive pulmonary disease, cardiovascular disease, impaired immunity, persistent disruption of memory and attention, and various psychiatric disorders, most commonly anxiety disorders and depressive disorders. There is a growing body of evidence that cannabis abuse can lead to lasting psychosis (i.e., schizophrenia) in predisposed persons.

Currently, treatment of cannabis dependence remains entirely psychosocial. Various existing drugs (including fluoxetine [Prozac],² lithium, buspirone [Buspar]²) have been investigated. However, well-controlled clinical trials to support their use are lacking. Preliminary data suggest that dronabinol (Marinol) may be of some utility in relieving cravings and withdrawal symptoms without causing intoxication. Rimonabant (Acomplia),³ a CB₁ antagonist previously prescribed for weight loss in Europe, showed promise but has failed to achieve FDA approval because of psychiatric side effects.

¹Not FDA approved for this indication.

²Not available in the United States.

³Exceeds dosage recommended by the manufacturer.

Cocaine, Methamphetamine, and Other Stimulants

As a class, cocaine and other stimulants work primarily by enhancing dopamine transmission in a dose-dependent fashion, either directly (amphetamines) or by blocking reuptake (cocaine). Cocaine and a variety of amphetamines (e.g., amphetamine/dextroamphetamine [Adderall], dextroamphetamine [Dexedrine], methamphetamine [Desoxyn], methylphenidate [Methylin, Ritalin]) are available for legitimate medical use as Schedule II drugs. Cocaine (in solution) is still used as a topical anesthetic, and amphetamine derivatives are used to treat attention-deficit/hyperactivity disorder (ADHD), narcolepsy (amphetamine and methylphenidate), and obesity (methamphetamine only). Any of these agents may be abused and carry significant potential for addiction. Even newer “safer” agents such as modafinil (Provigil) and armodafinil (Nuvigil) are associated with abuse and dependency, albeit less commonly than with traditional stimulants.

Prescription stimulant abuse can involve using excessive doses to achieve a euphoric high, or via nonmedical use or diversion of prescriptions (e.g., students sharing medication to facilitate studying). When taken at prescribed doses for an appropriate condition, even methamphetamine is generally safe and effective. In contrast, when it is synthesized in clandestine laboratories and smoked or injected in extreme quantities, methamphetamine (crystal meth, ice, crank, speed) is alarmingly dangerous. No other commonly abused drug is so strongly associated with permanent brain damage, resembling that seen in traumatic brain injury victims. As ADHD becomes more recognized and treated, physicians must be aware of the potential for abuse of their well-intentioned prescriptions. To this end, several recent pharmacologic developments have introduced improved options for treatment. Time-released formulations of methylphenidate (e.g., Concerta) and amphetamine/dextroamphetamine (Adderall XR) are considered to have less abuse potential than the short-acting formulations. Better still, the formulation of lisdexamfetamine (Vyvanse) includes the amino acid lysine coupled with the amphetamine molecule, consequently acting as a prodrug with the least abuse potential of all ADHD stimulants.

Cocaine and other stimulants induce sympathomimetic effects including tachycardia, hypertension, mydriasis, and diaphoresis. These drugs are commonly associated with seizures, myocardial infarction, hemorrhagic strokes, dyskinesias and dystonias, and psychosis when taken at the doses typically used to achieve euphoria. Withdrawal is generally experienced as a crash and includes fatigue, depressed mood, increased appetite, and cravings. Considered nonaddictive until about 1980, cocaine is now widely recognized as one of the most addictive drugs, particularly in the base form (crack or freebase). MDMA (methylenedioxymethylamphetamine), or ecstasy, shares the pharmacodynamic properties of the stimulants, combined with serotonergic effects of the hallucinogens.

Currently, no medication has demonstrated efficacy in treating cocaine or stimulant dependence. Pharmacologic treatment remains symptomatic during the acute withdrawal phase. Stimulant-induced psychosis and mania respond well to traditional psychotropics when warranted; however, to date, no medications have reliably demonstrated efficacy in preventing relapse. A “cocaine vaccine,”² which enlists the immune system to develop antibodies rendering cocaine useless, is currently in phase II clinical trials and holds promise for the future. In the meantime, traditional psychosocial treatments remain the mainstay of clinical care.

Opioids

Opioids are categorized as endogenous (endorphins, enkephalins, dynorphins), opium alkaloids (morphine, codeine), semisynthetic (heroin, oxycodone [Roxicodone, OxyContin]), or synthetic (methadone [Dolophine], fentanyl [Sublimaze, Duragesic]). The last three categories have a wide range of clinical uses including analgesia, anesthesia, antidiarrhea, cough suppression, and detoxification and maintenance therapy.

²Not available in the United States.

Opioids exert their clinical effect at mu, delta, and kappa opioid receptors. The effect on mu receptors is considered the most important, with its activation directly linked to both analgesic and euphoric effects. Most humans subjectively experience opioids with a neutral to aversive response. However, when used in sufficient quantities by genetically vulnerable persons, some users experience energy, relief of emotional pain, and a euphoria many describe as a “total body orgasm.” Intoxication manifests with miosis, impaired consciousness, slurred speech, bradycardia, and depressed respiration. Overdose is potentially fatal via respiratory depression, but it is quite amenable to treatment with repeated doses of intravenous naloxone (Narcan). The withdrawal syndrome is characterized by a constellation of miserable but not life-threatening symptoms including mydriasis, piloerection, muscle cramps, diaphoresis, vomiting, lacrimation, rhinorrhea, chills, insomnia, cravings, and autonomic hyperactivity.

Since pain was recognized as “the fifth vital sign” in the 1990s, concurrent with heavy marketing campaigns from pharmaceutical companies, the United States has experienced a veritable explosion of widespread opioid prescribing for nonmalignant pain. An entire industry of pain management has developed, with the unfortunate side effect of having a sizable proportion of its output being used nonmedically. It is important for prescribers to recognize that the abuse potential of prescription opioids matches, or in some cases even exceeds, that of heroin. Today, oxycodone has a street value of approximately \$1.00 per milligram.

The most common method of abuse involves simply taking more than prescribed, usually by the appropriate route of administration. Alternatively, opioid abusers commonly take their medications via nasal insufflation or inject them intravenously. The time-release property of certain medications, such as oxycodone (OxyContin), is easily circumvented by crushing the pills, which greatly enhances the euphoric effect. Even transdermal fentanyl patches (Duragesic) are abused via any number of methods, such as applying heat to a worn patch, employing complex extraction techniques described on the Internet, or simply sucking on the patch itself (a common finding by the coroner). Once the prescription is finished early, the user must either supplement the supply or face the unpleasant effects of withdrawal.

There is no shortage of easy methods to obtain opiates illegally. These include seeing multiple prescribers (doctor shopping), purchasing online at foreign “pharmacies,” and general trade or purchase on the black market. Also alarming is the growing problem of diversion from hospitals and pharmacies by health care professionals, who are not immune to the disease of addiction. Many

states are implementing controlled substance databases aimed to curb the problem of abuse of opioids and other prescription drugs.

Acute detoxification from opioids is achieved via one of two basic strategies: symptomatic treatment with unrelated medications, or substitution with a cross tolerant (opioid) drug with less abuse potential (Table 2). The first strategy may employ the use of clonidine (Catapres),² an α_2 -adrenergic agonist, to help with the autonomic component of withdrawal. This is commonly done in combination with other symptomatic treatments on an as-needed basis, such as diazepam (Valium) for anxiety, loperamide (Imodium) for diarrhea, and promethazine (Phenergan)² or ondansetron (Zofran)² for nausea.

The second strategy typically involves either methadone or buprenorphine (Subutex). Methadone, a pure mu agonist with a half-life of about 36 hours, is usually started in the 20- to 30-mg range and titrated cautiously by 10 mg every 4 to 7 days. Maintenance therapy with methadone occurs only in highly regulated methadone clinic settings. Buprenorphine, a partial agonist at the mu receptor (and kappa antagonist) is administered sublingually and has a half-life similar to that of methadone. It was approved in 2002 for office-based treatment of opioid addiction, making pharmacotherapy much more widely available. Caution should be used to not administer buprenorphine too soon (before onset of withdrawal syndrome), or acute withdrawal can actually be precipitated. Buprenorphine is available either alone or in combination with naloxone (Suboxone). Here, the role of naloxone is solely to deter intravenous abuse, because naloxone is inactive when taken sublingually as prescribed.

Buprenorphine and methadone are useful in managing acute withdrawal as well as long-term (months to years) maintenance therapy for preventing relapse to heroin or the opioid of choice. As maintenance therapy, these agents serve to block euphoria, satisfy cravings, and reduce illicit use, with consequent verifiable harm reduction. Buprenorphine, with a built-in ceiling effect because of its unique pharmacology, is much safer than methadone, which is often fatal in overdose. Increasingly, buprenorphine is being used as an analgesic as well (Butrans), and it may be an ideal choice in patients with comorbid pain and addiction who have demonstrated an inability to safely use other opioids.

Also approved for prevention of opioid relapse is naltrexone, an opioid antagonist, which is available in oral (ReVia) and intramuscular depot formulations (Vivitrol).

²Not available in the United States.

TABLE 2 Useful Medications in Treating Opioid Use Disorders

DRUG	UTILITY	FORMS	ADMINISTRATION	NOTES
Naloxone (Narcan)	Overdose; additive to prevent abuse ¹	SC, IM, IV	0.4–2 mg q2–3 min prn	$T_{1/2}$ = 1 h, wears off quickly
Naltrexone (ReVia, Vivitrol)	Prevention of relapse	PO, IM	ReVia: 50–100 mg PO daily; Vivitrol: 380 mg IM q4wk	Potential for hepatotoxicity; precipitates withdrawal; useful for ETOH as well
Clonidine (Catapres, Catapres-TTS patch) ¹	Withdrawal	PO, transdermal	0.1–0.2 mg PO tid prn; 0.1–0.3 mg/24 h transdermal via weekly patch	Monitor for hypotension
Methadone (Dolophine)	Withdrawal; maintenance	PO	Start 20–30 mg PO qd Target 80–120 mg PO qd	Restricted to methadone clinics
Buprenorphine (Subutex, Suboxone [with naloxone], Buprenex injection ¹)	Withdrawal; maintenance	SL, IM, IV	Start 2–4 mg SL qd-bid Target 4–32 mg SL daily divided qd-tid	Requires special DEA certification

Abbreviations: DEA = Drug Enforcement Administration; ETOH = ethanol.

¹Not FDA approved for this indication.

Sedative-Hypnotics

This class of drugs includes a wide array of compounds (benzodiazepines, barbiturates, and various related compounds) (Table 3), most of which have at least some potential for abuse. Overall, these medications do much more good than harm, and are useful in treating anxiety disorders, insomnia, seizures, and muscle spasms. They are also important in managing withdrawal states and as a component of surgical anesthesia. These drugs act as CNS depressants, and their primary mechanism of action is to enhance inhibitory GABA neurotransmission. The risk of toxicity is by respiratory depression, which is magnified by concomitant use of opioids or other CNS depressants, such as alcohol.

Sedative-hypnotic intoxication and withdrawal states closely resemble those of alcohol, except for a more protracted time course of withdrawal. Anxiety, restlessness, insomnia, tremor, nystagmus, tachycardia, and hypertension usually appear 2 to 12 hours after the last dose, and symptoms gradually resolve over 1 to 2 weeks. Withdrawal seizures, psychosis, and delirium are fairly common. Detoxification is best accomplished on an inpatient basis and typically involves tapering doses of a long-acting benzodiazepine (e.g., clonazepam [Klonopin], diazepam, clorazepate [Tranxene]) at a rate of about 10% of initial daily

requirement per day. Acute sedative overdose is managed primarily with supportive care and airway management. Flumazenil (Romazicon) 0.2 to 0.5 mg/min IV may be used with caution for acute overdose of benzodiazepines because it can precipitate severe acute withdrawal symptoms.

Since their introduction in the 1960s, benzodiazepines have largely replaced barbiturates, given their enhanced safety profile. However, barbiturates still in common use include phenobarbital and butalbital. Phenobarbital, used mainly for treating seizures, is considered to have low potential for abuse. Butalbital, compounded with caffeine plus acetaminophen or aspirin (Fioricet, Fiorinal), has moderate abuse potential, typically in combination with other drugs. Carisoprodol (Soma), although not a barbiturate, is metabolized into meprobamate, a barbiturate-like drug. Commonly taken in combination with opioids and other sedatives, carisoprodol is highly abused.

Alprazolam (Xanax) stands out among its peers as the single most abused, most addictive, and yet currently most prescribed sedative-hypnotic. Its rapid onset (T_{\max} 1–2 h) and relatively short half-life (6–14 h) contribute to its abuse liability and propensity for withdrawal seizures. Diazepam, historically the most prescribed sedative, also has relatively rapid onset and significant abuse potential, but its long half-life makes it an ideal agent for use in treating withdrawal from other sedatives. Flunitrazepam (Rohypnol, “roofies”) is a benzodiazepine that causes anterograde amnesia and is now illegal in the United States because of its use in drug-facilitated sexual assaults.

γ -Hydroxybutyric acid (GHB) and baclofen (Lioresal) also act as GABAergic CNS depressants, with intoxication and withdrawal states consistent with the class. Oddly, GHB is considered a Schedule I drug with high abuse potential and no accepted medical use, but marketed as sodium oxybate (Xyrem), GHB is available as a Schedule III drug (with special restrictions) when used to treat narcolepsy. Baclofen, on the other hand, appears to have rather low abuse potential and may actually play a role in the treatment of alcoholism.¹

Relatively new drugs such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta) are benzodiazepine-like drugs with CNS depressant activity, approved for short-term treatment of insomnia, and have at least some potential for abuse and dependence. Clonazepam is generally considered to have the lowest potential for euphoria and abuse and is the agent of choice if a benzodiazepine must be given to patients with a relative contraindication, such as a history of any drug abuse or dependence.

Conclusion

Despite intensive supply-reduction strategies, improved primary prevention efforts, and the many recent pharmacotherapy advances, drug abuse remains largely unchanged in its overall scale, with the exceptions of increasing use, abuse, and dependence of both marijuana and prescription opioids. Another notable exception is the significant reduction in tobacco use since the turn of the century. It is estimated that 25% of patients seen in office settings and 50% of those seen in emergency department settings have active problems related to substance abuse. All patients in primary care settings must be screened for tobacco, alcohol, and illicit drug abuse. Patients should be asked directly about substance use at the initial point of contact (e.g., emergency departments, primary care offices), and clinicians should maintain a healthy degree of skepticism toward patients' responses, remembering that most patients minimize substance use. When any suspicion exists, urine drug screens should be readily utilized without hesitation or fear of communicating mistrust. A variety of affordable quick screen kits are available, which can be sent out for laboratory confirmation of positive results if necessary.

Physicians and other health care professionals are in a unique position to intervene with drug abuse at the individual level,

TABLE 3 Common Sedative-Hypnotics, Equivalent Dose Conversions

GENERIC NAME	TRADE NAME	DOSE (mg)
<i>Benzodiazepines</i>		
Diazepam	Valium	10
Alprazolam	Xanax, Niravam	0.5–1
Lorazepam	Ativan	2

¹Not FDA approved for this indication.

because it is encountered commonly in clinical practice. The problem must first be identified, and depending on the skill set of the primary provider, patients should be treated or referred to an appropriate treatment provider. There is an initiative to incorporate formal SBIRT (screening, brief intervention, and referral to treatment) into routine clinical practice. Current procedural terminology (CPT) codes and a reimbursement schedule for screening and brief intervention may be located online at <https://www.samhsa.gov/sbirt/coding-reimbursement>. Screening may involve the written or verbal assessment of substance use to determine whether the patient exhibits problematic levels of use. The brief intervention aspect of SBIRT targets those with milder substance use problems and provides effective strategies for intervention before the need for more extensive or specialized treatment arises. Referral to specialized treatment is recommended for patients with moderate-to-severe substance use disorders. Data suggest this approach is successful in modifying problematic substance-use behavior. In addition to formal treatment, physician referral to local 12-step recovery meetings (Alcoholics Anonymous, Narcotics Anonymous) has proved beneficial. Local chapters provide physicians with names and telephone numbers of members willing to welcome newcomers (www.aa.org).

Physicians are usually well equipped to treat the sequelae of drug abuse, but they often forget that addiction is a treatable disease entity itself. Treatment ranges in intensity along a continuum including medically managed inpatient detoxification, partial hospitalization, intensive outpatient treatment, and outpatient care. The American Society of Addiction Medicine provides patient placement criteria that dictate the appropriate level of treatment based on a multidimensional assessment. Health care professionals should be familiar with the treatment centers in their area, which can place the patient in the appropriate level of care.

It is important to remember that relapse is a characteristic of addiction and does not equate to treatment failure, but rather indicates a need for an adjustment in the treatment level or monitoring. Other chronic diseases, such as diabetes or hypertension, necessitate the ongoing monitoring and adjustment of treatment interventions as needed, and so is the case with addiction. Recently published data on the treatment and monitoring of recovering physicians (a subgroup of addicts that boasts a 5-year success rate greater than 78%) teaches us the lesson that adequate initial treatment coupled with ongoing monitoring is critical. Sustained recovery from substance use disorders is attainable and is characterized by voluntary sobriety, improved personal health, and improved citizenship.

EATING DISORDERS

Method of

Sarah Forsberg, PsyD; and James Lock, MD, PhD

Bulimia Nervosa

CURRENT DIAGNOSIS

- Binge eating episodes occur at least once per week for 3 months (eating objectively large quantities of food accompanied by a loss of control while eating).
- Compensatory purging episodes occur at least once per week for a period of 3 months (e.g., self-induced vomiting, laxatives, diuretics, excessive and driven exercise, enemas).
- Shape and weight are overvalued in self-worth and self-esteem.
- Weight is at or above expected range given age, height, and historical growth curves.

CURRENT TREATMENT

- Cognitive behavioral therapy (CBT) is the most evidence-based treatment for bulimia nervosa (BN).
- Interpersonal psychotherapy (IPT) is an appropriate alternative.
- Family-based treatment (FBT) is useful for adolescents with BN.
- Antidepressant treatment (selective serotonin reuptake inhibitors [SSRIs]) may be useful in augmenting psychotherapy, or as an alternative in the event that psychotherapy is not effective, is refused, or is unavailable. It is not as effective as CBT and thus not a front-line approach.

Diagnosis

To diagnose bulimia nervosa (BN), an individual must engage in recurrent binge episodes with compensatory behaviors (e.g., self-induced vomiting, diuretic or laxative use, excessive exercise). A binge is a discrete episode of eating a quantity of food that is more than the average person would eat in the same setting. While bingeing, there is a loss of control or sense of being unable to stop eating. A disproportionate emphasis on weight and shape in one's self-evaluation is also required in diagnosing BN. DSM-5 criteria require that these episodes occur at a minimum of once weekly for 3 months. Unlike individuals with anorexia nervosa (AN), who may binge and purge, individuals with BN are within or above a normal weight range.

Significant health consequences may accompany BN. Laboratory studies often reveal electrolyte abnormalities, which can lead to cardiac arrhythmias and cardiac arrest in severe cases. Physical examination may detect enamel decay and parotid gland enlargement because of recurrent vomiting. When ipecac¹ is used to induce vomiting, severe cardiac and skeletal myopathies may develop. Laxative abuse is associated with metabolic acidosis and elevated serum amylase levels. BN has an elevated risk for mortality (crude mortality rate is estimated at 2% per decade) and suicide. Most common comorbid psychiatric diagnoses are mood, anxiety, personality disorders (specifically borderline personality), and substance use disorders.

Epidemiology

BN behaviors typically first occur in middle adolescence (ages 14–16), with onset of full syndrome BN in later adolescence and early adulthood (ages 17–24). The lifetime prevalence estimate of DSM-5 BN for females was 2.6% in one study, and while less is known

¹Not FDA approved for this indication.

EATING DISORDERS

Method of

Sarah Forsberg, PsyD; and James Lock, MD, PhD

Bulimia Nervosa

CURRENT DIAGNOSIS

- Binge eating episodes occur at least once per week for 3 months (eating objectively large quantities of food accompanied by a loss of control while eating).
- Compensatory purging episodes occur at least once per week for a period of 3 months (e.g., self-induced vomiting, laxatives, diuretics, excessive and driven exercise, enemas).
- Shape and weight are overvalued in self-worth and self-esteem.
- Weight is at or above expected range given age, height, and historical growth curves.

CURRENT TREATMENT

- Cognitive behavioral therapy (CBT) is the most evidence-based treatment for bulimia nervosa (BN).
- Interpersonal psychotherapy (IPT) is an appropriate alternative.
- Family-based treatment (FBT) is useful for adolescents with BN.
- Antidepressant treatment (selective serotonin reuptake inhibitors [SSRIs]) may be useful in augmenting psychotherapy, or as an alternative in the event that psychotherapy is not effective, is refused, or is unavailable. It is not as effective as CBT and thus not a front-line approach.

Diagnosis

To diagnose bulimia nervosa (BN), an individual must engage in recurrent binge episodes with compensatory behaviors (e.g., self-induced vomiting, diuretic or laxative use, excessive exercise). A binge is a discrete episode of eating a quantity of food that is more than the average person would eat in the same setting. While bingeing, there is a loss of control or sense of being unable to stop eating. A disproportionate emphasis on weight and shape in one's self-evaluation is also required in diagnosing BN. DSM-5 criteria require that these episodes occur at a minimum of once weekly for 3 months. Unlike individuals with anorexia nervosa (AN), who may binge and purge, individuals with BN are within or above a normal weight range.

Significant health consequences may accompany BN. Laboratory studies often reveal electrolyte abnormalities, which can lead to cardiac arrhythmias and cardiac arrest in severe cases. Physical examination may detect enamel decay and parotid gland enlargement because of recurrent vomiting. When ipecac¹ is used to induce vomiting, severe cardiac and skeletal myopathies may develop. Laxative abuse is associated with metabolic acidosis and elevated serum amylase levels. BN has an elevated risk for mortality (crude mortality rate is estimated at 2% per decade) and suicide. Most common comorbid psychiatric diagnoses are mood, anxiety, personality disorders (specifically borderline personality), and substance use disorders.

Epidemiology

BN behaviors typically first occur in middle adolescence (ages 14–16), with onset of full syndrome BN in later adolescence and early adulthood (ages 17–24). The lifetime prevalence estimate of DSM-5 BN for females was 2.6% in one study, and while less is known

¹Not FDA approved for this indication.

about males, at minimum they are estimated to account for between 10% to 25% of all cases. Symptoms may persist for a number of years, with intermittent periods of remission. A review of existing treatment studies suggests that approximately 45% of patients fully recover, with 27% improving considerably and the remaining 23% exhibiting a chronic course.

Etiology

BN can be explained by a confluence of biological, sociocultural, psychological, and familial factors. From a biological standpoint, BN clusters in families; in twin studies, about half of the variance in heritability can be explained by genetic factors. Serotonin levels may be reduced, and imaging studies show abnormal serotonergic circuitry in the orbital-frontal cortex. Internalization of cultural ideals of beauty may present as a focus on thinness for women, where for males there is often pressure to be muscular with low body fat. Participation in sports where weight and appearance are tied to performance (e.g., gymnastics, wrestling) may increase risk in males. Early puberty and childhood obesity are common precipitants, as are experiences with peer weight-related teasing. Personality characteristics of individuals with BN may include perfectionism, impulsivity, and instability in interpersonal relationships. Childhood sexual and physical abuse increases the risk for BN.

Treatment

Given the significant physical, social, and emotional consequences associated with BN, effective treatment requires addressing wide-ranging difficulties. Over 70 randomized controlled treatment trials (RCTs) exist for adults with BN, yet only four focus on adolescents. Most studies have examined behavioral therapies, medications, or a combination thereof. CBT is established as the treatment of choice for adults with BN and has been subjected to a large number of RCTs. The underlying assumption of CBT is that bulimic behaviors are maintained by dysfunctional attitudes about shape, weight, and physical appearance, which thereby lead to an overemphasis of these aspects in self-evaluation. Excessive dieting typically ensues, resulting in physiologic and psychologic deprivation that increases vulnerability to binge eating. Feelings of guilt and fear about weight gain are mitigated through engaging in purging behaviors. CBT targets this cycle through the use of self-monitoring to increase an awareness of patterns in behaviors, thoughts and emotions that maintain BN.

CBT is found to be more effective than no treatment, pill placebo, nondirective supportive psychotherapy, nutritional counseling, stress management, and antidepressant medication therapy. Response to CBT is good, with approximately 50% recovered and 20% with significant reductions in symptoms at the end of treatment. CBT is acceptable and feasible with adolescents, however a more recent RCT had a 20% rate of abstinence, compared to previous rates of 56% in a case series and 36% in a guided self-help (GSH) version at the end of treatment. When compared to an alternative intervention, IPT, CBT demonstrates a greater probability of remission and reduction in symptoms at the end of treatment. However, these initial differences appear to diminish at a 1-year follow-up, suggesting that, while less efficient, IPT is a viable alternative. IPT was adapted for BN to target interpersonal factors thought to contribute to the development and maintenance of the disorder. IPT has yet to be studied with adolescents.

More recently, CBT has been expanded to address other maintaining features of eating disorders more broadly (e.g., interpersonal difficulties, clinical perfectionism, low self-esteem, and mood intolerance). Enhanced CBT (CBT-E) addresses these features and is delivered in a focused or broad (addressing aforementioned maintaining features) format. For individuals with more complex psychopathology, the broad version may be more effective. Further, a novel treatment, integrative cognitive affective therapy for BN (ICAT-BN), may be preferable to CBT-E for individuals with greater affective lability and stimulus seeking.

Other interventions show promise in the treatment of BN and require further examination. For adolescents, FBT may be helpful, demonstrating higher rates of binge/purge abstinence (40%) than

supportive psychotherapy in one study, and than CBT (FBT: 39% vs. CBT: 20%) in another. Derived from FBT for AN, parents are supported to directly change dysfunctional eating behaviors. For adults, dialectical behavior therapy (DBT) has been shown to significantly decrease binge/purge episodes when delivered in an individual format. Similar effects were found when an appetite-awareness component was added to standard DBT.

Antidepressants (SSRIs) are the most studied medication treatment for BN. Fluoxetine (Prozac) demonstrates greater reductions in binge eating, purging, and eating-related cognitions than placebo when prescribed at higher doses (60 mg/day). A small pilot study of fluoxetine with adolescents suggests it is acceptable and may decrease BN symptoms. Antidepressants alone are not as effective as when combined with CBT, or as CBT alone.

Binge Eating Disorder

CURRENT DIAGNOSIS

- Recurrent episodes of binge eating, defined as eating an objectively large amount of food in a discrete period of time with an experience of loss of control.
- Binge eating is associated with at least three of the following: eating rapidly; eating until uncomfortably full; eating outside of physical hunger; eating alone because of embarrassment; and subsequent feelings of disgust, depression, or guilt.
- There is marked distress associated with binge eating.
- These episodes occur at least once per week over 3 months.
- There is no associated compensatory behavior (e.g., purging), and bingeing does not occur in the context of another eating disorder diagnosis (anorexia or bulimia nervosa [BN]).

CURRENT TREATMENT

- CBT and IPT have good evidence of efficacy among adults.
- GSH CBT may be effective for those with less psychopathology.
- DBT requires further study to determine if good outcomes are sustained over time.
- There is no evidence-based treatment for young patients with binge eating disorder (BED)-pharmacologic treatments should be considered as an adjunct to psychotherapy.

Diagnosis

Binge episodes are characterized by eating quantities that are larger than others would eat in a similar setting and are accompanied by a feeling of being out of control. Individuals with BED do not engage in compensatory behaviors (e.g., self-induced vomiting, excessive exercise) as in BN. DSM-5 criteria require that the episodes occur at a minimum frequency of once per week over a 3-month period. Binge eating (BE) is commonly associated with feelings of guilt and embarrassment and may result in attempts to hide eating. Further, during binge episodes, eating is often rapid and results in feeling uncomfortably full. Most individuals with BED have at least one comorbid psychiatric diagnoses (79% of respondents in one study).

Epidemiology

Lifetime prevalence of BE among adult females was 3% and 3.6% in two separate studies, and 2.1% in males. It occurs at equal rates across ethnic and racial groups. BE most typically onsets in later adolescence or early adulthood, although it does occur in children and is often associated with overweight and obesity as well as psychological symptoms. Among obese adolescents, an estimated 1% meet the criteria for BED and up to 26% experience BE/loss of control eating. In BED, obesity often predates dieting and subsequent BE, with women having an earlier onset of both dieting and BE.

Remission rates in BED are higher than in other eating disorders, although duration and severity is similar to BN.

Etiology

The etiology of BED is unknown. Restrictive dieting, body image dissatisfaction, pressure to be thin, low self-esteem, depressive symptoms, and limited social support increase the risk for the onset of adolescent BE. Increased rates of BE in families suggests there may be a genetic link. Potential medical causes for BE include CNS tumors, Kleine-Levin syndrome, Kluver-Bucy syndrome, Prader-Willi syndrome, and gastrointestinal pathology, and these causes should be ruled out during assessment. Comorbid psychiatric disorders are common among adults with BED, including mood disorders, anxiety disorders, and, at lesser frequency, substance use disorders and personality disorders. There are high rates of obesity among individuals with BED; however, psychiatric symptoms are linked to the severity of BE rather than obese status.

Treatment

Treatment for adults with BED has received considerable attention in RCTs compared to other eating disorder diagnoses. Most treatments target reduction in BE, psychological symptoms, and weight loss for those who are overweight. CBT has been applied in multiple formats (group, GSH, CD-ROM delivered, and in combination with medication) and appears to have the highest rates of abstinence. Individual CBT outperformed group CBT in one trial, and a GSH version was more effective in reducing BE than behavioral weight-loss (BWL). CBT targets underlying dysfunctional attitudes and behaviors that maintain BE. An alternative treatment, IPT, is a time-limited psychodynamic therapy targeting interpersonal difficulties that underlie the disorder. IPT is helpful in reducing the frequency of BE. IPT, CBT, and motivational intervention (MI) all lead to improvements in cognitive restraint, disinhibition, and shape and weight concerns thought to maintain BE.

Dialectical behavior therapy (DBT) is another treatment adapted for BED with the aim of targeting affected regulation difficulties formulated to be a maintaining mechanism of BE. Women in a small trial comparing group DBT to a waitlisted group had significantly greater decreases in BE and related eating disorder thoughts and behaviors, with over half abstinent from BE at follow-up. However, when compared to supportive psychotherapy, the rate of abstinence, while achieved more quickly in the DBT group, did not differ between the groups at follow-up. Pilot data suggest comprehensive DBT (individual, group, and skills coaching) may be effective.

Pharmacologic treatments targeting BE and weight loss have been tested alone and in combination with psychotherapy. There may be improvement in weight loss with addition of pharmacotherapy. The combination of CBT with topiramate (Topamax)¹ resulted in greater weight loss and better psychosocial outcomes than CBT with fluoxetine.¹ A high dose of the SSRI escitalopram (Lexapro)¹, anti-conulsants topiramate and zonisamide (Zonegran)¹, lisdexamfetamine (Vyvanse) at a dose of 50 mg or 70 mg, and the selective norepinephrine reuptake inhibitor atomoxetine (Strattera)¹ were each associated with significantly decreased binge eating and weight in separate placebo-controlled trials.

¹Not FDA approved for this indication.

Anorexia Nervosa

CURRENT DIAGNOSIS

- Persistent restriction of energy (caloric) intake relative to requirements, leading to significantly low weight (e.g., accounting for age, sex, developmental trajectory, and physical health).

- Fear of becoming fat or ongoing behavior interferes with weight gain.
- Disturbance in the perception of shape, weight, overvaluation of weight, and shape in self-evaluation, or lack of acknowledgment of seriousness of low weight.
- Either meets criteria for restricting type—with absence of binge or purge behaviors, or binge eating/purging type.

CURRENT TREATMENT

- FBT for adolescents with AN is the most evidence-based approach.
- Adolescent-focused therapy (AFT) may be a helpful alternative.
- There are no first-line treatments for adults with AN.
- CBT may prevent relapse in weight-restored individuals.

Diagnosis

AN is characterized by dietary restriction that is severe enough to lead to seriously low weight, fear of weight gain, and difficulty or inability to accurately perceive shape or weight. Secondary amenorrhea is no longer required for a diagnosis of AN in DSM-5. Individuals may be classified as AN-restricting type or AN-binge/purge subtype. The definition of low weight is less than “minimally normal” among adults or “minimally expected” among children and adolescents. Growth charts normed by age and gender are necessary to calculate expected BMI for individuals under 18 and growth curves may help detect deviations from an individual’s growth trajectory. A BMI at or below the 10th percentile is a benchmark reflecting malnourishment associated with AN, and BMI below 18.5 kg/m² may be used as guidelines. When an individual meets all criteria for AN, but despite significant weight loss weighs within or above the median BMI range, atypical AN may be diagnosed.

A wide variety of medical and psychiatric symptoms accompany AN. Potentially life-threatening medical conditions may develop as a result of semistarvation. Vital sign abnormalities (bradycardia, orthostasis, hypothermia) and amenorrhea are common consequences of malnutrition. Bone loss resulting in osteopenia and, in more severe cases, osteoporosis may occur. Abnormal laboratory findings may occur in some patients with AN who use laxatives, diuretics, and diet pills and who engage in self-induced vomiting.

The lifetime rate of comorbid psychiatric diagnoses among adolescents with AN is approximately 55%. Most commonly, these comorbidities include anxiety disorders (social anxiety, separation anxiety), generalized anxiety and obsessive compulsive disorder [OCD]), depression, and substance abuse. There is significant overlap in OCD symptoms and AN, thus careful consideration must be given to the content of obsessions and compulsions in diagnosis. In AN, obsessional preoccupations are related to eating, food, weight, and shape, and compulsions may appear as calorie counting, excessive exercise routines, and mealtime rituals. Depressive symptoms such as dysphoric thought, low energy, difficulty concentrating, and low self-esteem also manifest in AN and may not indicate a separate depressive disorder.

Epidemiology

Peak age of onset for AN is between 14 and 18 years. Lifetime prevalence of females with a DSM-5 diagnosis of AN in the United States is estimated to be between .8% and 3.6%, based on method of data collection. The incidence of AN among males is less studied, but recent estimates suggest that 1 out of every 4 cases are male. Little is known about the prevalence of AN across racial and ethnic groups. A recent study did not reflect significantly higher rates of AN among non-Hispanic white adolescents as compared to Hispanic and non-Hispanic black peers; however, other evidence suggests that it is less common among persons of African origin.

AN has the highest mortality rate of any psychiatric illness, with reports as high as 5% per decade. Rates of chronicity obtained from long-term adult follow-up studies (AN diagnosis persisting greater than 5 years) are estimated between 7% and 15%. Death occurs most commonly secondary to medical complications of starvation or suicide. Prognosis for adolescents with short duration (less than 3 years) is better than adults.

Etiology

The causal mechanisms of AN are multiply determined through the interface of biological/genetic, psychological, and sociocultural factors. Heritability estimates from twin studies range from 48% to 74%, and family aggregation studies report that AN occurs at about five times the expected rate in affected families. The interactional effect between genes and developmental processes is reflected in studies demonstrating greater heritability among 17-year-old twins as compared to 11-year-old twins. Hormonal changes during adolescence could mediate gene expression during puberty, explaining this difference.

Perfectionistic and avoidant personality features are associated with AN, and are likely heritable. Neurocognitive features including cognitive rigidity and an overly detailed style of information processing are common and may represent an endophenotype as those who are recovered as well as unaffected siblings who demonstrate similar cognitive styles. Common developmental challenges associated with adolescence may also precipitate or emerge as a consequence of AN—these include navigating issues of autonomy, self-efficacy, and intimacy. Sociocultural factors including exposure to a Westernized “thin ideal” of beauty for females and an overly muscular ideal for males may be internalized, thereby triggering extreme dieting or exercise. Further, activities where weight or appearance is intertwined with performance may also elevate risk (e.g., gymnastics, ballet, wrestling, figure skating).

Treatment

Given the severity of psychological, social, and health consequences of AN, both close medical monitoring and psychotherapy are the standard of care. In severe cases, inpatient medical monitoring may be required, and standard criteria for hospitalization are available for physicians. Findings from RCTs among adults are inconclusive because of dropout rates as high as 50%. Medication trials of antidepressants (serotonin reuptake inhibitors and tricyclics) have high dropout rates and little to no improvement in weight or eating disorder behaviors. Therefore, these should not be used independent of psychotherapy. CBT may help prevent relapse for individuals who are already weight-restored. For underweight individuals, findings are mixed, and nonspecific therapies such as nonspecific supportive clinical management (NSCM) showed better outcomes compared to IPT and CBT at end of treatment. However, improvements in NSCM appear to decline over time, and IPT may catch up to CBT.

Recent treatment studies have focused on improving retention. For example, an enhanced version of outpatient CBT (CBT-E), which employs motivational enhancement strategies, retained 64% of the original sample, improving on previous trends in attrition. Individuals completing treatment had clinically significant improvements in weight and eating disorder psychopathology. When CBT-E was compared to focal psychodynamic therapy and treatment as usual (TAU) in the community, weight gain and improvements in eating disorder symptoms were more rapid. However, focal psychodynamic treatment had the highest rates of recovery at follow-up (35%), though these were only significantly higher than the TAU group.

FBT, otherwise known as Maudsley family therapy, has been studied in seven RCTs with superior outcome to other individual therapies. This outpatient treatment empowers parents to disrupt self-starvation and other behaviors that maintain AN. In the initial phase of treatment, parents take full control over managing eating-related behaviors. FBT demonstrates rates of remission ranging from 49% (full remission in weight and eating disorder thoughts and behaviors) to 89% for partial remission. Rates of relapse are

about 10% and there is minimal dropout, suggesting it is acceptable to families. FBT delivered in a parent-focused format may be just as effective, and preferable to conjoint FBT for families with high levels of expressed emotion.

Adolescent Focused Therapy (AFT) may be an alternative approach for individuals whose family members are unable to participate. The focus in AFT is on helping an adolescent move toward healthy individuation and increased self-efficacy. AN is conceptualized as an ineffective strategy that the adolescent has adopted in managing common developmental challenges. In AFT, adolescents learn new skills to support eating and weight gain and parents are involved in separated collateral sessions. CBT has also been studied in adolescents; when compared to TAU and hospitalization, it appeared to be the most cost-effective approach.

Avoidant-Restrictive Food Intake Disorder

CURRENT DIAGNOSIS

- Disturbance in eating/feeding resulting in persistent failure to meet nutritional and/or energy needs.
- The disorder must result in one of the following consequences: significant weight loss or faltering growth; significant nutritional deficiency; dependence on nutritional supplements or enteral feeding; and interference with psychosocial functioning.
- The eating/feeding disturbance is not better explained by another medical or psychiatric condition or by cultural or religious practices.

CURRENT TREATMENT

- There are no established treatments for this new diagnosis.
- CBT or family interventions that employ behavioral strategies are being explored as potential treatment options.

Diagnosis

Avoidant-restrictive food intake disorder (ARFID) is a new diagnosis included in the DSM-5, which reflects the recognition of “food neophobia” or extreme picky eating as challenges. Individuals with ARFID can be of any age and exhibit clinically significant feeding/eating difficulties, which result in failure to meet energy (caloric) or nutritional needs. In response, individuals have low weight or failure to meet expectations for growth, significant nutritional deficiency, a need for enteral feeding or oral nutritional supplementation, or impairment in psychosocial functioning. Although there may be failure to thrive or to make expected weight gain/weight loss, it is distinguished from AN by the absence of body image disturbance. Low weight can be determined through clinical judgment and examination of developmental trajectory using growth charts. Nutritional deficiency may be assessed through dietary history as well as physical examination. Related medical consequences may follow those seen in malnourished individuals with AN (e.g., bradycardia, anemia, hypothermia), and can be life threatening. Individuals with ARFID treated in an inpatient setting are more likely to require nasogastric feeding than those with AN. If limited food intake is better explained by cultural or religious practice, an eating disorder in which there is disturbance in experience of shape/weight, or current physiologic or psychiatric condition, ARFID is not diagnosed. Further, in the event of a coexisting medical diagnosis, food refusal is serious enough to warrant separate clinical attention. Thorough assessment should include examination of feeding, and eating history, psychiatric symptoms, development, and underlying medical causes must be ruled out before making a diagnosis.

Individuals with ARFID often exhibit selective eating, food neophobia, and hypersensitivity to sensory features of food (texture,

taste, temperature, appearance). Similar clinical presentations may have varying etiology, requiring individualized treatment plans. In some, development of food avoidance can be traced to a specific aversive event, trauma, or related gastrointestinal problem, or may arise out of a choking, swallowing, or vomiting phobia. Individuals may also have a lack of drive or interest in eating or heightened textural sensitivity, which is common in autism spectrum disorders.

Epidemiology

No data exist on prevalence, course, and outcome of this disorder. Surveillance studies are underway in the UK and Canada for related “food avoidance emotional disorder,” with overlap in clinical features. In pediatric inpatient ED programs, rates of ARFID are reported to be between 5% and 14% comprised of a higher proportion of males than other ED diagnoses. ARFID appears to arise most commonly in infancy and early childhood, but can occur at any age and last into adulthood. Preliminary data suggest ARFID occurs at equal rates in males and females. There is no evidence to guide for whom clinical intervention is warranted versus those whose symptoms resolve over time.

Treatment

There are no systematically studied treatments to date for ARFID; however, behavioral interventions with contingency management have been successfully utilized among children who have food neophobia in the context of a developmental disability. Given limited data, individualized treatment plans are best derived through assessment of medical history, temperament, psychiatric symptoms, and development. Food avoidance may be treated through use of behavioral strategies (e.g., shaping, chaining, contingency management, extinction) that systematically desensitize individuals to a wider range of foods. Related anxiety management techniques (relaxation training, visualization for mastery) and cognitive strategies derived from CBT may address maintaining psychiatric features. CBT was successfully applied in a case study of young adults with food neophobia. In most severe cases of malnutrition, hospitalization for medical stabilization purposes may be needed before outpatient therapy.

GENERALIZED ANXIETY DISORDER

Method of

Natalie C. Dattilo, PhD; and Andrew W. Goddard, MD

CURRENT DIAGNOSIS

- Generalized anxiety disorder (GAD) is the most common psychiatric disorder seen in the primary care setting.
- GAD is characterized by feelings of dread, negative anticipation, and worry that are difficult to control and may include

hypervigilance, excessive reassurance seeking, and behavioral avoidance of anxiety-provoking situations.

- Symptoms of GAD most often include agitation, irritability, restlessness, muscle aches or tension, dizziness, fatigue, racing heart, dry mouth, nausea, decreased sexual desire, sleep or appetite disturbances, and an inability to relax.
- A thorough medical examination and laboratory work may be indicated to rule out underlying physiologic causes, adverse reaction to medication, caffeine or substance use, and drug or alcohol withdrawal.
- Symptoms that are persistent, disruptive, or distressing warrant treatment.
- The Generalized Anxiety Disorder – 7 (GAD-7) is a screening instrument used to assess symptoms of GAD in primary care settings. Scores of 5, 10, and 15 are taken as the cut-off points for mild, moderate, and severe anxiety, respectively. When used as a screening tool, further evaluation is recommended when the score is 10 or greater.

CURRENT THERAPY

- Effective treatments for GAD include serotonergic antidepressants, certain forms of psychotherapy, or a combination of both.
- Educate the patient and family members about treatment options as well as realistic treatment expectations.
- Depending on the patient's preference, treatment may include a selective serotonin reuptake inhibitor (SSRI) or a serotonin norepinephrine reuptake inhibitor (SNRI), starting at low doses with careful titration so as not to exacerbate anxiety symptoms.
- Treatment may also include a trial of cognitive-behavioral therapy (CBT) monotherapy or in combination with medication management.
- Refer to or consult with a psychiatrist for patients with severe or particularly complex cases or for patients with a less-than-expected response to treatment.
- Refer to a CBT specialist for patients with a preference for behavioral, skills-based, or nonmedication therapy or for whom pharmacotherapy may be contraindicated.

Epidemiology

Anxiety disorders are among the most prevalent psychiatric disorders in the world. In the United States, it is estimated that an anxiety disorder is diagnosed in approximately 16 million adults each year and approximately 30 million meet criteria for an anxiety disorder over the course of their lifetimes. Second to depression, anxiety disorders are the most common mental health problem seen by physicians in the general medical setting. In fact, patients with anxiety are more likely to present initially to a generalist physician office than to a mental health care provider.

Anxiety disorders tend to be chronic and disabling and impose a high individual and societal burden. It has been estimated that the United States spends approximately \$40 billion to \$60 billion per year for costs associated with anxiety disorders. These include not only direct costs associated with treatment but also indirect costs associated with lost productivity. Thus early detection and treatment is critically important.

Risk Factors

Risk factors associated with anxiety disorders include personal or family history of anxiety; recent increase in stressful life events; lack or perceived lack of social support; ineffective emotional coping strategies; being female; experiencing childhood adversity, including trauma or witnessing a traumatic event; having a chronic health condition or serious illness; having an acute or chronic pain condition; and substance abuse. Having a genetic predisposition to developing an anxiety disorder is likely, although environmental stressors clearly play a role. Research has also shown that patients

taste, temperature, appearance). Similar clinical presentations may have varying etiology, requiring individualized treatment plans. In some, development of food avoidance can be traced to a specific aversive event, trauma, or related gastrointestinal problem, or may arise out of a choking, swallowing, or vomiting phobia. Individuals may also have a lack of drive or interest in eating or heightened textural sensitivity, which is common in autism spectrum disorders.

Epidemiology

No data exist on prevalence, course, and outcome of this disorder. Surveillance studies are underway in the UK and Canada for related “food avoidance emotional disorder,” with overlap in clinical features. In pediatric inpatient ED programs, rates of ARFID are reported to be between 5% and 14% comprised of a higher proportion of males than other ED diagnoses. ARFID appears to arise most commonly in infancy and early childhood, but can occur at any age and last into adulthood. Preliminary data suggest ARFID occurs at equal rates in males and females. There is no evidence to guide for whom clinical intervention is warranted versus those whose symptoms resolve over time.

Treatment

There are no systematically studied treatments to date for ARFID; however, behavioral interventions with contingency management have been successfully utilized among children who have food neophobia in the context of a developmental disability. Given limited data, individualized treatment plans are best derived through assessment of medical history, temperament, psychiatric symptoms, and development. Food avoidance may be treated through use of behavioral strategies (e.g., shaping, chaining, contingency management, extinction) that systematically desensitize individuals to a wider range of foods. Related anxiety management techniques (relaxation training, visualization for mastery) and cognitive strategies derived from CBT may address maintaining psychiatric features. CBT was successfully applied in a case study of young adults with food neophobia. In most severe cases of malnutrition, hospitalization for medical stabilization purposes may be needed before outpatient therapy.

GENERALIZED ANXIETY DISORDER

Method of

Natalie C. Dattilo, PhD; and Andrew W. Goddard, MD

CURRENT DIAGNOSIS

- Generalized anxiety disorder (GAD) is the most common psychiatric disorder seen in the primary care setting.
- GAD is characterized by feelings of dread, negative anticipation, and worry that are difficult to control and may include

hypervigilance, excessive reassurance seeking, and behavioral avoidance of anxiety-provoking situations.

- Symptoms of GAD most often include agitation, irritability, restlessness, muscle aches or tension, dizziness, fatigue, racing heart, dry mouth, nausea, decreased sexual desire, sleep or appetite disturbances, and an inability to relax.
- A thorough medical examination and laboratory work may be indicated to rule out underlying physiologic causes, adverse reaction to medication, caffeine or substance use, and drug or alcohol withdrawal.
- Symptoms that are persistent, disruptive, or distressing warrant treatment.
- The Generalized Anxiety Disorder – 7 (GAD-7) is a screening instrument used to assess symptoms of GAD in primary care settings. Scores of 5, 10, and 15 are taken as the cut-off points for mild, moderate, and severe anxiety, respectively. When used as a screening tool, further evaluation is recommended when the score is 10 or greater.

CURRENT THERAPY

- Effective treatments for GAD include serotonergic antidepressants, certain forms of psychotherapy, or a combination of both.
- Educate the patient and family members about treatment options as well as realistic treatment expectations.
- Depending on the patient's preference, treatment may include a selective serotonin reuptake inhibitor (SSRI) or a serotonin norepinephrine reuptake inhibitor (SNRI), starting at low doses with careful titration so as not to exacerbate anxiety symptoms.
- Treatment may also include a trial of cognitive-behavioral therapy (CBT) monotherapy or in combination with medication management.
- Refer to or consult with a psychiatrist for patients with severe or particularly complex cases or for patients with a less-than-expected response to treatment.
- Refer to a CBT specialist for patients with a preference for behavioral, skills-based, or nonmedication therapy or for whom pharmacotherapy may be contraindicated.

Epidemiology

Anxiety disorders are among the most prevalent psychiatric disorders in the world. In the United States, it is estimated that an anxiety disorder is diagnosed in approximately 16 million adults each year and approximately 30 million meet criteria for an anxiety disorder over the course of their lifetimes. Second to depression, anxiety disorders are the most common mental health problem seen by physicians in the general medical setting. In fact, patients with anxiety are more likely to present initially to a generalist physician office than to a mental health care provider.

Anxiety disorders tend to be chronic and disabling and impose a high individual and societal burden. It has been estimated that the United States spends approximately \$40 billion to \$60 billion per year for costs associated with anxiety disorders. These include not only direct costs associated with treatment but also indirect costs associated with lost productivity. Thus early detection and treatment is critically important.

Risk Factors

Risk factors associated with anxiety disorders include personal or family history of anxiety; recent increase in stressful life events; lack or perceived lack of social support; ineffective emotional coping strategies; being female; experiencing childhood adversity, including trauma or witnessing a traumatic event; having a chronic health condition or serious illness; having an acute or chronic pain condition; and substance abuse. Having a genetic predisposition to developing an anxiety disorder is likely, although environmental stressors clearly play a role. Research has also shown that patients

suffering from anxiety are generally more sensitive to physiologic changes than nonanxious patients. This heightened sensitivity leads to diminished autonomic flexibility, which may be the result of faulty central information processing in anxiety-prone persons.

Pathophysiology

Current evidence suggests that anxiety symptoms are likely caused by dysregulation in the central nervous system fear circuit. Physical and emotional manifestations of this dysregulation can result in a state of hyperarousal. Several neurotransmitter systems have been implicated in the development of this state.

The most commonly considered are the serotonergic and noradrenergic neurotransmitter systems. Very simply, it is believed that an underactivation of the serotonergic system and an overactivation of the noradrenergic system are involved, resulting in dysregulation of physiologic arousal and the emotional experience of this arousal. Disruption of the γ -aminobutyric acid (GABA) system has also been implicated because of the response of many of the anxiety-spectrum disorders to treatment with benzodiazepines.

There has also been some interest in the role of corticosteroid regulation and its relation to symptoms of fear and anxiety. Corticosteroids might increase or decrease the activity of certain neural pathways, affecting not only behavior under stress but also the brain's processing of fear-inducing stimuli. The stress response is hardwired into the brain and is most often triggered when survival of the organism is threatened. The stress response, however, can be triggered not only by a physical challenge or threat but also by the mere anticipation (or fear) of threat. As a result, when humans chronically and erroneously believe that a threatening event is about to occur, they begin to experience the physical and psychological symptoms of anxiety and panic.

Finally, a subcortical neural structure, the amygdala, serves an important role in coordinating the cognitive, affective, neuroendocrine, cardiovascular, respiratory, and musculoskeletal components of fear and anxiety responses (fear expression). It is central to registering the emotional significance of stressful stimuli and creating emotional memories. The amygdala receives input from neurons in the sensory cortex. When activated, the amygdala stimulates regions of the midbrain and brainstem, causing autonomic hyperactivity, which can be correlated with the physical symptoms of anxiety.

Prevention

No biological markers are specific enough yet to detect anxiety early, and there is no available evidence to suggest that current medications prove efficacious in preventing these disorders. Therefore, it is important to screen for specific risk factors, such as family history and substance abuse. If a person is anxiety prone, he or she should first be encouraged to adopt healthy lifestyle habits. Exercise has been shown to relieve tension, anxiety, and stress. Patients should avoid stimulants such as caffeine and nicotine, which can exacerbate symptoms. Reducing alcohol intake should be encouraged as well. Educating patients on healthy sleep habits can prevent conditioned (or secondary) insomnia issues. It is also recommended that anxiety-prone persons reduce subjective levels of stress by practicing effective methods of relaxation and other stress management activities, like meditation, yoga, social connection, gratitude journaling, and pleasant event scheduling.

Clinical Manifestations

GAD is characterized by subjective feelings of worry, dread, or anticipation of negative events and can include hypervigilance and avoidance of anxiety-producing situations. Physical symptoms can include jitteriness or shakiness, trembling, muscle aches and tension, sweating, cold or clammy hands, dizziness, or vertigo; fatigue; racing or pounding heart; hyperventilation; sensation of a lump in the throat, choking sensation, or dry mouth; numbness and tingling in the hands, feet, or other body parts; upset stomach, nausea, vomiting, or diarrhea; decreased sexual desire; and sleep and appetite disturbances.

Psychological symptoms include, most predominantly, unrealistic or excessive worry and apprehension, hypervigilance or an inability to relax, distractibility, indecisiveness, and insecurity. Patients often express feelings of impatience, agitation, irritability, and fear. They may ask multiple questions repeatedly in an attempt to quell the anxiety through excessive information or reassurance seeking. In GAD, the worries a patient may express tend to be nonspecific and all-encompassing. They tend to be "worst-case scenario" and "what if?" thinkers. Some patients also exhibit specific phobias such as fear of being far from home or fear of social contact. Patients with GAD may report difficulty falling asleep because they "can't turn their mind off" at night. If a patient reports these symptoms or displays one of several behavioral manifestations of GAD leading to significant distress and/or impairment of function, the condition is unlikely to remit on its own and treatment is warranted.

Diagnosis

A diagnosis of GAD is made when a patient meets the specific diagnostic criteria outlined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5). Persons with GAD experience uncontrollable, excessive anxiety and worry involving several areas of functioning on most days for at least 6 months. The anxiety must be associated with at least three of the following symptoms: restlessness, fatigue, impaired concentration, irritability, muscle tension, or sleep problems. Patients tend to express chronic excessive nervousness, exaggerated worry, tension, and irritability that appear to have no cause or are more intense than the situation warrants. Physical signs such as headaches, trembling, twitching, or sweating often develop, which lead to further worries. GAD symptoms tend to wax and wane over time, with short-term exacerbations of acute anxiety in response to stress. Symptoms show substantial overlap with those of other medical and psychological disorders, particularly major depressive disorder, substance abuse disorders, and other anxiety disorders, which tends to complicate diagnosis.

Differential Diagnosis

It is important to perform a thorough medical workup when initially assessing the patient with anxiety symptoms. The differential diagnosis can include several organic causes, such as endocrine dysfunction, intoxication or withdrawal, hypoxia, metabolic abnormalities, and neurologic disorders. It is also important to rule out other comorbid psychiatric disorders. Severe depression, bipolar disorder, prodromal schizophrenia, delusional disorder, and adjustment disorder can often be accompanied by severe anxiety. Many organic causes can be ruled out by a thorough history and basic laboratory work, including thyroid-stimulating hormone, urine toxicology, electrocardiogram, complete blood count, and metabolic panel. The most common medical conditions associated with anxiety are presented in [Box 1](#).

The list of drugs suspected of causing anxiety is extensive. Drugs commonly associated with anxiety include stimulants such as amphetamine, cocaine, methamphetamine, and caffeine. Drugs such as lysergic acid diethylamide (LSD) and 3,4-methylenedioxymethamphetamine (MDMA, or "ecstasy") can also cause acute and chronic anxiety. Prescription medications to consider include sympathomimetics, antihypertensives, and nonsteroidal antiinflammatory drugs (NSAIDs).

Treatment and Monitoring

Current practice guidelines indicate that the treatment of an anxiety disorder begins with education. Many people are confused, scared, or frustrated by the symptoms and behavior and are reassured to know they are not alone and that there are effective interventions. The patient should receive an appropriate medical workup, such as a physical examination, and studies (e.g., electrocardiogram, thyroid-stimulating hormone) when indicated. After ruling out a medical condition, developing a good working alliance with the patient provides a basis for ongoing disease management and prevents unnecessary utilization or overutilization of the medical system, as well as potential exacerbation of symptoms.

BOX 1 Medical Conditions Often Associated With Anxiety Symptoms

Cardiopulmonary

Angina
Mitral valve prolapse
Pulmonary embolism
Chronic obstructive pulmonary disease (COPD)
Asthma

Endocrine

Hyperthyroidism
Pheochromocytoma
Cushing syndrome
Menopause

Gastrointestinal

Gastroesophageal reflux
Irritable bowel syndrome (IBS)
Gastritis

Neurologic

Dementia
Substance intoxication or withdrawal
Seizure disorder
Migraine

A combination of psychotherapy and medication management is recommended as first-line treatment for GAD. CBT has the strongest empirical support to date for the treatment of anxiety. Mindfulness-based stress reduction (MBSR) has an emerging evidence base as an effective alternative or complementary behavioral treatment program for anxiety. Both offer a skills-based approach to treatment. In CBT, the therapist and patient work collaboratively and in an active and problem-solving manner. It is structured and generally short term with an emphasis on reducing symptoms and preventing “flare-ups” by monitoring and changing unhelpful or inaccurate thinking patterns that result in feelings of anxiety and worry. Another critical component of CBT for GAD is learning and applying behavioral relaxation techniques (e.g., diaphragmatic breathing, guided imagery, progressive muscle relaxation) and distress tolerance skills (e.g., mindfulness, acceptance). Volumes of evidence support the efficacy of CBT interventions for GAD, but success requires commitment to treatment on the part of the patient. Its efficacy is also contingent upon the ability of the therapist and the length of time in treatment. Studies show that when compared with patients undergoing monotherapy, patients treated with a combination of CBT and medication experience nearly twice the remission rate.

SSRIs have been shown to be the best-tolerated class of medication, and response rates are significantly higher than placebo for GAD. SSRI medications include fluoxetine (Prozac),¹ fluvoxamine (Luvox),¹ citalopram (Celexa),¹ escitalopram (Lexapro), paroxetine (Paxil), and sertraline (Zoloft).¹ Some improvement in symptoms should be noted within 3 or 4 weeks, and the dose should be increased if no improvement is seen. In treating any anxiety disorder, SSRIs should be started at low doses and gradually titrated up to therapeutic levels to avoid an initial exacerbation of anxiety. Pharmacotherapy options for the treatment of GAD are presented in Table 1.

Benzodiazepines, which have been commonly used in the past to treat anxiety disorders, are not recommended except in cases of extreme impairment of function and only for very short-term use. The tolerability and lack of addiction potential make the SSRIs more desirable for long-term management, but the delay in response makes short-term symptom relief with a benzodiazepine desirable for those with the greatest impairment. Because of the risk

TABLE 1 Pharmacotherapy for the Treatment of Generalized Anxiety Disorder

DRUG	STARTING DOSE	TARGET DOSE
Selective Serotonin Reuptake Inhibitors		
Paroxetine (Paxil)*	10 mg qd	10–60 mg qd
Escitalopram (Lexapro)*	5–10 mg qd	10–20 mg qd
Sertraline (Zoloft)	12.5–25 mg qd	50–200 mg qd
Fluoxetine (Prozac)	10 mg qd	20–40 mg qd
Serotonin-Norepinephrine Reuptake Inhibitors		
Venlafaxine (Effexor XR)*	37.5 mg qAM	150–300 mg qAM [†]
Duloxetine (Cymbalta)*	30 mg qd	60–90 mg qd
Other		
Buspirone (BuSpar)	5 mg bid–tid	10 mg tid

for rebound anxiety when withdrawing from benzodiazepines with short half-lives, such as alprazolam (Xanax), many prefer the longer-acting benzodiazepines, such as clonazepam (Klonopin).¹ However, the addiction potential and the potential for abuse with either drug make this the treatment option of last resort.

If the patient does not respond to the combination of CBT and medication, a reevaluation of symptoms might reveal a comorbid disorder missed on the first examination. Comorbid psychiatric disorders significantly lower the likelihood of recovery from anxiety and increase recurrence rates. Some clinicians try switching to a different SSRI before considering the next step in treatment; however, a referral to a psychiatrist or integrated care consultant for further evaluation and management may be necessary. Treatment-refractory anxiety can be extremely frustrating for the patient, the patient’s family, and the treating physician. If benzodiazepine treatment was initiated, this frustration can and does often lead to an increased dependence on the medication and a requirement of increasingly higher doses to achieve the same effect. For long-term gains, therapy in addition to medication treatment should be recommended.

Education is critical to reassure the patient that effective treatment is available, but that patience may be necessary until the right combination of modalities is found. Although all anxiety disorders display a significant amount of chronicity, most patients have an improved outcome with appropriate treatment. Response rates improve when comorbidity is low. Patients with an earlier onset of symptoms (childhood or adolescence) can generally expect a more chronic course and their anxiety symptoms may be more difficult to treat. Patients rarely have a spontaneous remission of symptoms, but most can continue to function despite the symptoms. Nevertheless, time to resolution of symptoms is shortened and overall functioning typically improves with treatment.

Pharmacotherapy often helps to prevent relapse, and rates are improved when effective treatment is continued for 12 months. When considering termination of pharmacologic treatment, the risk for relapse in GAD should be discussed with the patient. When discontinuing the SSRIs, a slow taper is recommended, with close monitoring for withdrawal symptoms (e.g., headache, gastrointestinal upset, restlessness, and other flu-like symptoms). Also monitor for rebound anxiety symptoms. If relapse occurs, reinstituting treatment is indicated, and many patients opt for indefinite treatment to maintain remission of symptoms. Lifelong management with pharmacotherapy or psychotherapy, or both, is not unusual for many patients. For many, a maximum reduction of symptoms, rather than a full remission, is an acceptable outcome.

Association for Behavioral and Cognitive Therapies	www.abct.org
Mental Health America	www.mentalhealthamerica.net/conditions/anxiety-disorders
National Institute of Mental Health	www.nimh.nih.gov/index.shtml

Complications

Untreated anxiety disorders can lead to, or worsen, other mental and physical health conditions, including bruxism (teeth grinding), cognitive impairment, depression, gastrointestinal disorders, headache, insomnia, heart disease, substance abuse, and significantly impaired quality of life.

Conclusion

Anxiety disorders are highly prevalent in the United States. GAD is one of the most common psychiatric conditions seen in primary care, second only to major depression. This condition can be disabling and costly to the patient and to the health care system. Despite the prevalence of anxiety disorders, patients often remain undiagnosed and untreated, and patients with unrecognized anxiety disorders tend to be higher utilizers of general medical care. Patients with anxiety disorders can present with multiple somatic complaints and comorbid disorders, causing great effort and expense in identifying the cause of unexplained symptoms. Once an anxiety disorder is identified, patients may be treated using well-tested and efficacious pharmacologic and psychotherapeutic treatments. Helpful resources for patients and families are listed in Table 2.

MOOD DISORDERS: DEPRESSION, BIPOLAR DISEASE, AND MOOD DYSREGULATION

Method of
Andrei Novac, MD

CURRENT DIAGNOSIS

- Clinical evaluation of mood disorders starts with a thorough psychosocial and medical history.
- Identify symptoms and patterns of the appearance of mood changes.
- Differentiate between unipolar and bipolar symptom patterns.
- Use collateral history, if possible.
- For recent-onset disorder, rule out new medical disorders. Always check thyroid function.

CURRENT THERAPY

- Any underlying medical conditions must be treated simultaneously.
- The mainstay of treatment for all mood disorders remains the combination of pharmacology and psychotherapy.
- Monitor frequently for suicidality.
- Allow for at least 2 to 4 weeks for response before a medication switch.
- Switch medication early in cases of intense side effects.
- Monitor for hypomanic switch on medications in undiagnosed bipolarity.

Mood disorders and mood dysregulation encompass a broad range of human experiences. They can be divided into three types of manifestations: (1) psychiatric disorders, which make up a major chapter in medical texts; (2) a variety of mood syndromes, often comorbid, less well classified, that coexist with medical and psychiatric disorders alike; and (3) an aggregate of reactive transient behavioral manifestations outside the pathologic realm, inherent to human nature. Only the first two areas will be the focus of this chapter. Mood disorders and mood dysregulation are among the most common manifestations of human suffering. They are not mutually exclusive; dysregulation of mood may be present both as an independent symptom and as part of a mood disorder. They all deserve particular attention because they can gravely impact the level of functioning, compliance, treatment outcome, and quality of life.

Mood Disorders*

Both the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), and the ICD-10 classify mood disorders into similar types. These include major depressive disorders (unipolar, single episodes, and recurrent), persistent depressive disorder (dysthymia), bipolar I disorder, bipolar II disorder, cyclothymic disorder, mood disorder due to medical conditions, substance-induced mood disorders, and the “unspecified” unipolar and bipolar disorders. In addition, the DSM-5 has included new clinical entries, such as disruptive mood dysregulation disorder, persistent depressive disorder (dysthymia) with intermittent major depressive disorders, and premenstrual dysphoric disorder. The previously entitled “not otherwise specified” syndromes are now called “unspecified mood disorders.” New to the DSM-5 are the following *specifiers* that apply to *both* bipolar and unipolar disorders: (a) with anxious distress (a mixture of mood disorder and anxiety

*In this chapter, no DSM-5 or ICD-10 diagnostic codes are included. The clinician is advised to consult the DSM-5 for specific diagnostic codes.

*In this chapter, no DSM-5 or ICD-10 diagnostic codes are included. The clinician is advised to consult the DSM-5 for specific diagnostic codes.

disorder), (b) with mixed features, (c) with melancholic features, (d) with atypical features, (e) with psychotic features, (f) with catatonia, (g) with peripartum onset, and (h) with seasonal pattern.

Epidemiology

Most recent data regarding prevalence comes from the National Comorbidity Survey, which has exposed in detail the rates of subtypes of mood disorders: unipolar, bipolar, and the subthreshold disorders. The lifetime prevalence of any mood disorder was found to be 21.4% (female 24.9%, male 17.5%), with major depression occurring at a lifetime prevalence of 16.9% (female 20.2%, male 13.2%) and 12-month prevalence of 6.8%. Persistent depressive disorder (dysthymia) occurs at a lifetime prevalence of 2.5% (female 3.1%, male 1.8%) and 12-month prevalence of 1.5%. The DSM-5 specifies the prevalence for dysthymia as being approximately 0.5% and for the chronic form of major depressive disorder, 1.5%. Bipolar disorders present with a lifetime prevalence of 4.4% (female 4.5%, male 4.3%). If broken down, bipolar I disorder occurs at a lifetime prevalence of 1.0%, and 0.6% of new cases over 12 months. Bipolar II disorder occurs at a prevalence of 1.1% and 0.8%, respectively. Subthreshold bipolar disorder is twice as common at 2.4% lifetime and 1.4% new cases over 12 months.

Risk Factors

For unipolar major depressive disorders, risk factors include gender (women at greater risk), age (18–44 years of age at greater risk), marital status (separated and divorced at greater risk), family history (relatives with depression), early parental death, life events (negative stressful events, chronic exposure to stress), low confidence, and urban environments. For bipolar disorder, risk factors are similar. In addition, for bipolar disorder, higher rather than lower socioeconomic status and suburban environments have been cited as risk factors.

Individuals with anxiety disorder, chronic exposure to stress and trauma, substance abuse, psychotic disorders, and chronic medical conditions are all known to be at risk for mood disorders.

Additionally, results from the World Health Organization (WHO) World Mental Health Surveys revealed that 22.9% of adult mood disorders and 31% of anxiety disorders are attributable to childhood adversity. Certain types of adversity, such as frequent childhood bullying, result in a high risk of poor social health and economic outcomes with an increase of suicidality, depression, anxiety disorders, and alcohol dependency, nearly four decades after exposure. In addition, psychiatric symptoms that are present in childhood constitute a risk factor for adult psychopathology, including mood disorders. Anxiety/depression, labile affect, and manic symptoms are all predictors for future onset of bipolar spectrum disorder. Acute and transient psychotic disorder resulted in 28% onset of affective disorder, but only 15% schizophrenia at 1-year follow-up. Finally, a more recently identified risk factor for mood disorders constitutes a gene environment interaction that results in methyltetrahydrofolate reductase (MTHFR) deficiency, and inadequate homocysteine metabolism, a risk factor for depressive disorders. MTHFR activity can be evidenced by readily available genetic testing (i.e., GeneSight).

Depressive Disorder (Unipolar Mood Disorder)

Major Depression

The mainstay of major depressive disorder is a major depressive episode. The DSM-5 provides criteria according to a threshold of symptoms, yet all mood disorders have to be understood as lying on a continuum. Therefore even individuals who do not meet all criteria have to be carefully followed, and in many cases preventive treatment is warranted.

At least five or more of the following symptoms during the same 2-week period are required: (1) depressed mood most of the day, nearly every day (sadness, feelings of emptiness, tearfulness); (2) marked diminished interest or pleasure in almost all activities; (3) significant weight loss or weight gain or fluctuations in appetite; (4) insomnia or hypersomnia; (5) psychomotor retardation or agitation nearly every day; (6) fatigue or loss of energy; (7) feelings of

worthlessness and/or inappropriate guilt; (8) inability to concentrate, think, and make decisions; and (9) recurrent thoughts of death and/or suicidal ideations. These symptoms (1) cause significant distress or impairment in social, occupational, and/or personal functions and (2) are not due to a general medical condition. In the DSM-5, contrary to previous classifications, bereavement and depression are not mutually exclusive. In fact, bereaved individuals can also develop major depression, which would warrant additional medical treatment (see Table 3).

Following are some forms of manifestations:

- Major depressive disorder, single episode: Episodes may occur only one time in life or may occur again years later, usually triggered by major stressful events.
- Major depressive disorder, recurrent type: Episodes reoccur at shorter intervals. Often the distance between episodes shortens with advancement in age. The first few episodes are more likely to be triggered by stressful life events, while in time the condition becomes self-maintained and self-triggered.
- Depressive disorder with catatonic features (motoric immobility, catalepsy, stupor, extreme opposition, posturing, echolalia).
- Major depression occurring after giving birth may predict further depressive episodes years later. Postpartum depression has also been associated with bipolar disorder.

Depressive disorder can also take a chronic course. Some patients present with *melancholic features* (profound loss of pleasure, depression worse in the morning, early morning awakening, severe psychomotor retardation, severe anorexia and weight loss). Melancholia may be a predictor of relatively good response to medications. *Atypical depression* features are characterized by inverted functional shift (weight gain and increased appetite, craving for sweets, hypersomnia, leaden paralysis, long-standing interpersonal rejection sensitivity). Table 1 presents the subtypes (specifiers) of mood disorders according to the DSM-5. These subtypes are encountered both in unipolar and in bipolar mood disorders. Under these new DSM-5 classifications, conditions such as catatonia, seasonal affective disorders, and atypical depression may occur both in individuals with unipolar disorder and in individuals with bipolar disorders.

Persistent Depressive Disorder (Dysthymia)

Persistent depressive disorder, the new designation for dysthymic disorder, is a chronic form of depression in which the depressed mood has persisted for at least 2 years (in children for at least 1 year), as manifested by at least two of the following symptoms: (1) poor appetite or overeating, (2) insomnia or hypersomnia, (3) low energy or fatigue, (4) low self-esteem, (5) poor concentration or difficulty making decisions, and (6) feelings of hopelessness. These manifestations are distinct from any major depressive episode, there have been no manic symptoms, and there is significant distress or impairment in social, occupational, or personal functioning. Dysthymia can occur in any age and can co-occur with major depressive disorder.

The following clinical forms have been identified: (1) with pure dysthymic syndrome: no full criteria of major depression have been met in the past 2 years; (2) with persistent major depressive episode: full criteria of a major depressive episode have been present in the past 2 years; (3) with intermittent major depressive episodes, with current episode: full criteria for major depressive episodes are currently met but there have been periods of at least 8 weeks in the last 2 years when major depression criteria have not been met; (4) with intermittent major depressive episodes, without current episode: no current major depression is identified (only symptoms of dysthymia) but there has been one or more major depressive episode in the past 2 years. Persistent depressive disorder may also qualify for any of the specifiers described in Table 1. (Note: Table 1 specifiers can apply to any of the unipolar and bipolar forms of mood disorders.) The term “minor depression” to distinguish from “major depression” has also been used in earlier contributions. Minor depression refers to two to four symptoms of depression lasting for more than 2 weeks but less than 2 years. This clinical variant falls within the spectrum of persistent depressive disorder (dysthymia).

TABLE 1 Subtypes of Mood Disorders (Specifiers) Common to Both Unipolar and Bipolar Mood Disorders

SUBTYPE WITH	PRESENTATION	FEATURES
Anxious distress (with elements of mood disorder and anxiety disorder)	During the majority of days of depressive, manic, or hypomanic episode	Feeling keyed up or tense, feeling restless, unable to concentrate, fear that something awful may happen, etc.
Mixed features	Meets criteria for either mania, hypomania, or depression	With mixed symptoms (if manic, there is associated dysphoria and depression), observable by others
Melancholic features	During the most severe period	Severe anhedonia, worse in the morning, early-morning awakening, psychomotor retardation or agitation, weight loss or gain
Typical features	During majority of days of a major depressive episode	Inverted functional shift (hypersomnia, hyperphasia, weight gain), leaden paralysis, long-standing pattern of interpersonal rejection sensitivity
Psychotic features	The presence of delusions and/or hallucinations	Mood-congruent psychosis (delusions/hallucinations include themes consistent with the type of mood [manic or depressed]) Mood-incongruent psychosis
Catatonia	The presence of catatonia	Catatonic features are present during most of depressive or manic episodes
Peripartum onset	Mania, hypomania, major depression in bipolar I or II disorders	During pregnancy or in the 4 weeks following delivery
Seasonal pattern	At least one type of episode (mania, hypomania, or depression) within a seasonal pattern	Temporal relationship between an episode and a particular time of the year (fall or winter, in bipolar I or II)

Disruptive Mood Dysregulation Disorder

This condition occurs in childhood or adolescence between the ages of 6 and 18. It is characterized by (1) severe recurrent temper outbursts manifested verbally (verbal rages) and/or behaviorally (physical aggression toward people or property) that are grossly out of proportion in intensity or duration to the situation or provocation; (2) temper outbursts that are inconsistent with developmental level; (3) temper outbursts that occur on average three or more times per week; (4) a mood between temper outbursts that is persistently irritable or angry most of the day, nearly every day, and is observable by others; (5) the previous criteria, which have been present for 12 or more months (with no lapse in symptoms for a duration of 3 or more months); and (6) an age of onset that is before 10. Diagnosis should not be made before age 6 or after 18.

Disruptive mood dysregulation disorder (DMDD) was introduced into the DSM-5 for a subgroup of children with mood dysregulation and as an alternative to the diagnosis of childhood bipolar disorder. Some of these patients do move on to develop bipolar disorder. There is a significant overlap between disruptive mood dysregulation disorder and the onset of bipolar disorder. In one study of children in psychiatric hospitals, 30.5% met criteria for DMDD by parent report and 15.9% by inpatient unit observation.

Premenstrual Dysphoric Disorder

- The condition is characterized by the majority of menstrual cycles that include five symptoms. The following symptoms occur in the final week before the onset of menses and begin to improve within a few days after the onset of menses.
- One or more of the following symptoms must be present: (1) marked affective lability (mood swings, feeling suddenly sad or tearful, increased sensitivity to rejection); (2) marked irritability or anger or increased interpersonal conflict; (3) marked depressed mood, feelings of hopelessness, or self-deprecating thoughts; (4) marked anxiety, tension, and/or feelings of being keyed up or on edge.
- One or more of the following symptoms must be present to reach a total of five symptoms: decreased interest in usual activities; subjective difficulty in concentration; lethargy; easily fatigued; marked changes in appetite, overeating, or specific food cravings; hypersomnia or insomnia; a sense of being overwhelmed

or out of control; physical symptoms such as breast tenderness or swelling, joint or muscle pain, or bloating or weight gain.

Substance/Medication-Induced Depressive Disorder

This diagnosis is used when persistent disturbance in mood predominates the clinical picture and is characterized by depression and diminished interest or pleasure in activities. These symptoms occur during or soon after substance intoxication or withdrawal or after exposure to a medication. The substance in question has to be known to cause symptoms of depression.

Depressive Disorder Due to Another Medical Condition

This diagnosis is used when a depressive disorder is triggered by a medical condition (diagnosed by physical examination and laboratory findings) known to cause symptoms of depression. These may include disorders of the central nervous system (CNS), systemic disorders (lupus, cancer), and so forth.

Other Specified Depressive Disorders

These are depressions that do not fully meet the criteria of the previously described conditions. However, they may appear in one of the following forms:

- Recurrent brief depression (symptoms of depression lasting from 2 to 13 days at least once per month) not associated with menstrual cycles
- Short-duration depressive episode (lasting from 4 to 13 days), with at least four symptoms of major depressive episode associated with clinical distress and impaired functioning that persist but never meet criteria of major depression
- Depressive episode with insufficient symptoms (at least one of the symptoms of major depression associated with distress and impairment persisting for at least 2 weeks with no prior history of major depression)

These “other specified depressive disorders” are helpful to clinicians in refining the description of a clinical pattern exhibited by a particular patient.

Unspecified Depressive Disorder

Finally, the previously used designation of “not otherwise specified” now reads “unspecified depressive disorder” (when none of the criteria are fully met, yet the patient is suffering from a mood disorder).

Bipolar Mood Disorders

Manic Episode

A manic episode is characterized by a period of at least 1 week with abnormal and persistently elevated, expansive, or irritable mood. At least three of the following should also be present: (1) inflated self-esteem or grandiosity, (2) decreased need for sleep (yet still feeling rested), (3) more talkative than usual or inability to stop talking, (4) flight of ideas or racing thoughts, (5) distractibility, (6) increase in goal-oriented activities (socially, sexually) or psychomotor agitation, and (7) excessive involvement in pleasurable activities with little regard for consequences (e.g., sexual indiscretions, unwise investments). These symptoms (1) result in marked impairment in most areas of life and (2) are not due to substance abuse or general medical conditions.

Hypomania

A hypomanic episode is similar to, but less intense than, a manic episode. At least three symptoms from the same symptom cluster (inflated self-esteem, decreased need for sleep, excessive talking, racing thoughts, hyperactivity, increased involvement in pleasurable activities) are required, but the condition is not severe enough to cause marked impairment in social, occupational, and personal functioning, and it does not necessitate hospitalization. However, functional impairment is noticeable over time.

Bipolar I disorder requires only one full manic episode for the diagnosis. Usually, individuals with bipolar I disorder also have both manic and depressive episodes, but the depressions can range from severe and disabling to very brief and unnoticed. Therefore a history of a depressive episode is not required for the diagnosis.

Bipolar II disorder is characterized by long periods of hypomania, with occasional major depressive episodes. Such individuals are usually not hospitalized for their hypomania and tend to function relatively well between depressive episodes. Hypomanic states are episodic and exhibit an unequivocal change in functioning that is uncharacteristic for the individual when not symptomatic. These changes are observable by others. Depressions tend to be severe and disabling. Bipolar II disorders do not include full manic episodes.

Mixed States and Rapid Cycling

The particular specifiers for bipolar disorder are mixed states and rapid cycling. *Mixed states* refers to manic or hypomanic episodes with at least three of the following depressive symptoms: prominent dysphoria or depressed mood, diminished interest in activities, psychomotor retardation, fatigue or loss of energy, feelings

of worthlessness, and recurrent thoughts of death. Often there is a rapid alternation between mania and depression (rapid cycling). Contingent upon severity, mixed states are usually accompanied by severe impairment. *Rapid cycling* refers to bipolar disorder that includes at least four episodes of illness per year. In addition, bipolar disorders may include any of the specifiers described in Table 1.

Cyclothymic Disorder

Cyclothymic disorder is a cycling mood disorder lasting for 2 years or more and is characterized by numerous periods with hypomanic symptoms and depressive symptoms that do not meet criteria for bipolar disorder or major depression. During a 2-year period (1 year in children and adolescents), hypomanic and depressive periods have been present for at least half the time, and the individual has not been without symptoms for more than 2 months at a time. Criteria for major depression, mania, or hypomanic episodes have never been met. However, in the long run, some patients may develop symptoms of bipolar affective disorder. These symptoms should not be attributable to the effect of a substance (drug abuse, medication) or another medical condition (hyperthyroidism, Cushing disease, etc.). The condition is significantly impairing and includes psychological distress. Cyclothymia has the specifier (subtype) “cyclothymia with anxious distress.” This condition consists of cyclothymia and features of anxious distress as outlined in Table 1. A variety of subclinical forms of *subthreshold cyclothymia* may be encountered in clinical practice. Such patients tend to develop overt symptoms of cyclothymia, or even bipolar disorder, when exposed to a variety of psychosocial stressors, substance abuse, and/or a variety of medications. Finally, Table 2 presents subtypes of bipolar disorder currently listed in the DSM-5 as “other specified bipolar and related disorders” and “unspecified bipolar and related disorder.”

Specifiers for Bipolar and Related Disorders

Please refer to Table 1 for specifiers of depressive disorders that apply to bipolar disorders as well.

Diagnosis

When faced with symptoms of mood disorder, a clinician has to decide whether these are transient manifestations related to life circumstances or symptoms of treatable psychopathology. The clinical evaluation of patients with mood disorders starts with a thorough history of the present illness. A thorough medical history is paramount given the numerous medical disorders that present

TABLE 2 Other Specified and Unspecified Bipolar Disorders

SUBTYPE	PRESENTATION	FEATURES
Substance/medication-induced bipolar and related disorder	Persistent disturbance of mood characterized by mania, hypomania, with or without depressed mood, which occurs soon after substance intoxication or withdrawal or after administration of a medication	<ul style="list-style-type: none"> Substance involved is capable of producing described mood symptoms Does not occur in the course of delirium There is significant stress or impairment
Bipolar and related disorder due to another medical condition	<ul style="list-style-type: none"> Persistent period of abnormally elevated expansive or irritable mood Evidence from history, physical examination, and laboratory findings that disturbance is a direct pathophysiologic consequence of another medical condition 	<ul style="list-style-type: none"> With manic features With manic or hypomanic-like episode With mixed features (depression is also present)
Other specified bipolar and related disorder	Symptoms of bipolar disorder, but do not meet full criteria	<ul style="list-style-type: none"> Short-duration hypomanic episodes (2–3 days) and major depressive episodes Hypomanic episodes with insufficient symptoms and major depressive episodes Hypomanic episode without prior major depressive episode Short-duration cyclothymia (less than 24 mo)
Unspecified bipolar and related disorders	Patients with bipolar symptoms and clinical distress and impairment; however, the clinician chooses not to specify the reason that the criteria are not met	

with depression or mania. Mood disorders are, in general, recurrent conditions. Past history will provide not only a suspicion toward a diagnosis but also clues toward clinical manifestations, which, in the cases of depression and mania, are often similar to previous episodes. An early history of childhood behavioral problems can constitute a precursor of mood disorders. The Mental Status Examination provides further clues to the diagnosis. For depressive states, patients often exhibit psychomotor retardation; slow speech; constricted affect; and slow, observable mental activity. For mania and hypomania, the opposite can be observed. Patients show increased psychomotor activity, pressured speech, full or labile affect, and elevated mood. Often they will appear unrealistically optimistic. In general, the diagnosis of mood disorder is aided significantly by obtaining a collateral history from friends or family members. The value of the Mental Status Examination is enhanced if the clinician knows the patient from before the mood disorder episode. A variety of psychological tests and depression rating scales exist, including the Beck Depression Inventory, the Hamilton Depression Rating Scale, and the Profile of Mood States (POMS) Depression Scale. While extremely useful in quantifying symptoms of depression, psychological testing is time consuming and not necessary for the initial diagnosis of a mood disorder.

A thorough account of all symptoms present in a patient can point to treatment choice and outcome. Depression symptoms can be classified into at least three major groups:

- Emotional symptoms: sadness, dysphoria, emotional numbness
- Physical symptoms: low energy, sluggishness with difficulties in initiating activities, difficulties concentrating, sleep and appetite problems

- Cognitive (mental) symptoms: pessimism, loss of enthusiasm, hopelessness, thoughts of death

Not all three groups of symptoms are present from the beginning. In many individuals, the presence of cognitive symptoms may be a sign of chronicity. At other times, it may have been a pre-morbid feature or a constant presence between episodes. Cognitive symptoms tend to respond both to medication and to psychotherapy (cognitive-behavioral techniques), and their monitoring is paramount to suicide prevention. If a mood disorder is secondary to a medical condition, the diagnosis will be made both by monitoring for mood symptoms and by pathognomonic medical findings.

Differential Diagnosis

Given the multitude of clinical manifestations, a differential diagnosis both between subtypes of mood disorders and between mood and other psychiatric disorders is necessary. Table 3 presents comparisons and differences between subtypes of mood disorders and guidelines to the differential diagnoses.

Given the frequent overlap of anxiety and mood disorders, it is useful to inquire about the presence of anxiety disorder in a systematic manner. Anxiety disorder symptoms can also be classified into at least three major groups:

- Emotional symptoms: anxiety and/or fear, either fluctuating or in the form of attacks
- Physical symptoms: palpitations, tachycardia, diaphoresis, sweaty palms, sensation of a knot in the throat, muscle tension, shortness of breath, GI symptoms, insomnia, and so forth
- Cognitive symptoms: (1) intrusive thoughts (such as “What if...,” “I should have...,” other specific exaggerated worries), (2) racing thoughts, (3) ruminative thoughts, and so forth

TABLE 3 Guidelines to the Differential Diagnoses

DIAGNOSIS	SIMILARITIES	DIFFERENTIATING DETAILS	CLINICAL CLUES	TREATMENT RESPONSE
Major depression (MDD) versus persistent depressive disorder (dysthymia) (PDD)	Depressed mood; depressive cognition (pessimism); vegetative symptoms (physical)	MDD: Acute or subacute onset; possible recent life stressors; often more numerous symptoms PDD: May overlap with MDD; chronic, fluctuating course	MDD: Usually a marked drop in functionality PDD: Significant chronic impairment; often symptoms are ego-syntonic; “personality disorder” flavor	MDD: Antidepressants and/or initial anti-anxiety medications; consider psychotherapy PDD: Cognitive-behavioral psychotherapy; antidepressants (often long term); sometimes enhancement pharmacology
Mixed mania versus agitated depression	Psychomotor agitation; dysphoria; mood swings	Mixed mania: Labile affect; often rapid switch with brief euphoric states Agitated depression: No euphoric states; severe anxiety, including sympathetic symptoms	Mixed mania: Personal and family history Agitated depression: Anxiety symptoms, often subtle, precede depressive symptoms	Mixed mania: Mood stabilizers; caution regarding antidepressants: can cause worsening Agitated depression: Antidepressants and sedating mood stabilizers; avoid long-term tranquilizers
Mania versus cyclothymia	Intermittent states of high energy and euphoria with or without recurrent depression	Mania: Distinct states of high energy; depression is sometimes unnoticed Cyclothymia: Distinct cycling from depression to hypomania	Mania: More often severe insomnia without fatigue; severity of mania and insomnia directly related Cyclothymia: May take unpredictable forms; fluctuation of mood and sleep	Mania: Mood stabilizers; caution about antidepressants; atypical antipsychotics if needed Cyclothymia: Same as above, according to clinical judgment

TABLE 3 Guidelines to the Differential Diagnoses—cont'd

DIAGNOSIS	SIMILARITIES	DIFFERENTIATING DETAILS	CLINICAL CLUES	TREATMENT RESPONSE
Substance abuse disorder versus cyclothymia	Intermittent use of stimulant abuse may mimic cycling mood disorder; may coexist	Substance abuse: Substance abuse tends to escalate Cyclothymia: Cyclothymia may remain constant for years (even lifelong)	Substance abuse: Look for specific syndromes; drug screen Cyclothymia: Negative drug screens; no withdrawals; no drug culture history	Substance abuse: Rehabilitation; treat underlying psychiatric symptoms Cyclothymia: Mood stabilizers and/or antidepressants and/or atypical antipsychotics
Personality disorder versus mood disorder	More often overlap; requires concomitant treatment	Personality disorder: Long-term pervasive history since adolescence Mood disorder: More often episodic	Personality disorder: Borderline personality disorder includes mood lability/depressive episodes; often narcissistic personality, includes grandiose/hypomanic states Mood disorder: More often symptoms are egodystonic	Personality disorder: Acute decompensation; long-term psychotherapy; mood stabilizers; atypical antipsychotics Mood disorder: See treatment of mood disorders
Bereavement versus MDD	May overlap; attention to recent major loss; sometimes similar picture; bereavement and MDD may co-occur	Bereavement: Tends to improve over time MDD: Tends to worsen over time	Bereavement: Preoccupation with loss persists MDD: Duration of average major depressive episode is 9 mo	Bereavement: Social support; grief counseling; psychotherapy; if MDD present, treat as MDD MDD: See treatment of MDD
Terminal illness–related mood (TIRM) changes versus MDD	May overlap; attention to symptom patterns	MDD has better response to medications TIRM dominated by sadness and grief	Fear of and preoccupation with death often progress with progression of medical condition	Both warrant trial with antidepressants, recommended prior to any end-of-life decisions Experimental only: Treatment with entheogen-enhanced psychotherapy (psilocybin, LSD, MDMA)*
Primary mood disorder versus mood disorder arising from medical condition	Clinical picture may be identical	Primary mood disorder: May be triggered by external stressful events Medical condition: Often onset is insidious; sometimes precedes medical condition	Neurologic, endocrine, infectious, systemic, and blood disorders [†]	Treat both primary medical condition and mood disorder; treatment same as for primary mood disorder

*Not yet approved for use in the United States.

[†]Medical conditions complicated by mood disorders: Addison disease, AIDS, anemia, brain tumors, chronic pain, complex partial seizures, Cushing disease, cerebrovascular accident, dementia, diabetes mellitus, encephalitis, head trauma, hepatitis, hyperparathyroidism, hyperthyroidism, hypopituitarism, hypothyroidism, infectious mononucleosis, influenza, lupus erythematosus disseminatus, meningitis, multiple sclerosis, pneumonia, porphyria, rheumatoid arthritis, scleroderma, sleep apnea, toxoplasmosis, and others.

Because of the long-term, chronic, egosyntonic nature of these symptoms, they are often not readily volunteered by the patient unless specifically asked about. Between mood disorders and anxiety disorders, there is a comorbidity of over 50%, with generalized anxiety, panic disorders, and posttraumatic stress disorders constituting both a risk factor for and a possible complication of mood disorders. Please note that the DSM-5 allows for a specifier “with anxious distress” that can be applied to both unipolar and bipolar mood disorders. Depending on the primary diagnosis, the clinician may choose between adding this specifier or the comorbid separate diagnosis of “anxiety disorder” in addition to mood disorder.

Treatment

As a general rule, the treatment approach to mood disorders relies on the combination of psychopharmacology and psychotherapy. An accurate initial diagnosis directs the first choice of treatment. Close monitoring of treatment with frequent visits usually predicts better outcome. In general, response is considered to be a 50% reduction of symptoms, while remission refers usually to the absence or only minimal symptoms for 6 months or more. By Tohen and colleagues' opinion, relapse is considered a return of symptoms within 6 months, while recurrence is after 6 months of remission.

Treatment of Unipolar Depression (Major Depression and Dysthymia)

Given the fact that many depressive disorders occur along a spectrum, the treatment of major depression and dysthymia will be covered together.**

Psychopharmacology

First, a thorough medical workup should be performed in any new case of mood disorder. The National Institutes of Health (NIH)-sponsored STAR*D study (Sequenced Treatment Alternatives to Relieve Depression) recommends the initial choice of a selective

**The newly introduced DSM-5 diagnosis, disruptive mood dysregulation disorder, is a condition of childhood and adolescence. Prior to the publication of the DSM-5, many of these patients were diagnosed as bipolar. Many clinicians prefer to initiate treatment with psychotherapy, which includes addressing a variety of family issues, before initiating psychopharmacologic intervention. Premenstrual dysphoric disorder, also newly introduced in the DSM-5, is treated, depending on the intensity of symptoms, by using protocols similar to those utilized in the treatment of dysthymic and/or cyclothymic disorders.

serotonin reuptake inhibitor (SSRI) (citalopram [Celexa]). In the study, nonresponders were then switched to sertraline (Zoloft) and/or venlafaxine XR (Effexor XR). In clinical practice, other factors have to be weighed when choosing the first antidepressant. Prior response history to a specific antidepressant or to an overall treatment modality should take precedence in the first choice of treatment. If such a history is unavailable, any family history of response to a specific treatment should be considered. Response to treatment seems to be similar among blood relatives. Table 4 includes a list of the more common medications used in clinical practice for the treatment of unipolar and bipolar disorder. Given the possibility of manic switch with antidepressants, it is recommended that in bipolar depression, mood stabilizers be started concomitantly with antidepressants.

Although myriad side effects are known to exist for each medication, all SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) are generally well tolerated. Any trial of medications should be continued for 4 to 6 weeks before failure is declared. However, clinical judgment in assessing each circumstance, especially regarding suicide risk, is crucial. Often in the initial phase of response, the physical symptom of low energy remits first while

TABLE 4 Medications Used for the Treatment of Unipolar and Bipolar Depression

MEDICATION GROUP	MEDICATION	USUAL DAILY DOSE	CAUTIONS
SSRI	Fluoxetine (Prozac)	10–80 mg	All can cause sedation, agitation, insomnia, GI side effects, sexual dysfunction
	Sertraline (Zoloft)	25–200 mg	
	Paroxetine (Paxil)	5–60 mg	
	Citalopram (Celexa)	10–40 mg	
	Escitalopram (Lexapro)	5–20 mg	
	Fluvoxamine (Luvox)*	100–300 mg	
SSRIs with combined action	Vilazodone (Viibryd)	10–40 mg	Same as above
	Functions of SSRI and a 5-HT _{1A} receptor agonist		
	Vortioxetine (Brintellix)	5–20 mg	
	Functions of SSRI and multiple serotonin receptor agonists and antagonists		
NSRI	Venlafaxine XR (Effexor XR)	37.5–225 mg	Insomnia, sedation, possible HTN
	Desvenlafaxine (Pristiq)	50–100 mg	
	Levomilnacipran ER (Fetzima)	40–120 mg	
Dopamine/norepinephrine agonist	Bupropion SR, XL (Wellbutrin SR, XL)	100–450 mg	Agitation, GI side effects, possible HTN
Stimulants (usually used to enhance effects of other antidepressants)	Methylphenidate (Ritalin)*	10–60 mg	Agitation, insomnia, psychosis, HTN, seizures
	Dextroamphetamine (Dexedrine)*	5–60 mg	
	Amphetamine/dextroamphetamine mixed (Adderall)*	5–60 mg	
Second-generation neuroleptics	Olanzapine (Zyprexa)*	2.5–20 mg (in unipolar depression, olanzapine 5 mg, plus fluoxetine 20 mg [Symbyax])	Metabolic syndrome, sedation
	Quetiapine (Seroquel)	50–300 mg (up to 800 mg in bipolar disorder)	Oversedation, metabolic syndrome, cardiovascular complications in elderly
	Aripiprazole (Abilify)	2–30 mg	Oversedation, metabolic syndrome, hyperprolactinemia
	Risperidone (Risperdal)*	0.5–6 mg	Somnolence or agitation from akathisia, extrapyramidal symptoms
	Lurasidone (Latuda) mainly for bipolar disorder	20–120 mg per day	
Tricyclic antidepressants	Amitriptyline (Elavil)	50–300 mg	All can cause anticholinergic effects, sedation; occasional agitation, weight gain
	Imipramine (Tofranil)	50–300 mg	
	Doxepin (Sinequan)	50–300 mg	
	Desipramine (Norpramin)	50–300 mg	
	Nortriptyline (Pamelor)	20–200 mg [†]	
	Maprotiline (Ludiomil)	100–225 mg	
	Protriptyline (Vivactil)	20–60 mg	

TABLE 4 Medications Used for the Treatment of Unipolar and Bipolar Depression—cont'd

MEDICATION GROUP	MEDICATION	USUAL DAILY DOSE	CAUTIONS
Mixed action (presynaptic and postsynaptic, multiple neurotransmitter action)	Mirtazapine (Remeron)	15–30 mg	Sedation, weight gain
	Trazodone (Desyrel)	150–600 mg	
	Clomipramine (Anafranil)*	50–300 mg [†]	
MAOI (dietary restrictions are obligatory)	Phenelzine (Nardil)	15–90 mg	Hypertensive crisis, occasional sedation/activation
	Tranylcypromine (Parnate)	30–60 mg	
Mood stabilizers	Lithium carbonate/citrate/ER*	600–1800 mg (attaining blood level from 0.6 to 1.2 mEq/L)	Signs of toxicity: tremor, nausea, vomiting, staggering gait; monitor kidney and thyroid function
	Valproate (valproic acid, Depakote ER)*	250–1500 mg (attaining blood level from 50 to 100 mcg/mL)	Oversedation, GI side effects, may affect blood levels of other medications, weight gain
	Lamotrigine (Lamictal)/ER*	50–300 mg	A variety of severe skin rashes, Stevens-Johnson syndrome
	Carbamazepine (Tegretol)*	200–1000 mg (attaining blood level from 5 to 12 mdg/mL)	Monitor blood count for aplastic anemia/agranulocytosis, possible Stevens-Johnson syndrome, sedation

Abbreviations: ER = extended release; GI = gastrointestinal; HTN = hypertension; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor.

*Not U.S. Food and Drug Administration approved for this indication.

[†]Exceeds dosage recommended by the manufacturer.

cognitive symptoms of depression (persistent thoughts of death) persist. The coexistence of higher energy and thoughts of death may constitute a temporary suicide risk in the initial phase of antidepressant treatment. Currently, biological markers for the prediction of treatment response and side effects are being considered. Reference electroencephalography (rEEG), renamed Psychiatric EEG Evaluation Registry (PEER), by using quantitative EEG technology compares variations of normal awake EEG readings with a large database of medication responders. Results are available for antidepressants, mood stabilizers, stimulants, second-generation antipsychotics, and so forth. The validity of PEER has been supported by a wealth of published literature. The AmpliChip CYP450 Test is a method that predicts side effects by measuring the activity of genes that control the P450 hepatic enzyme system and implicitly the ability to metabolize a specific drug. Both methods are promising, but high cost has so far prevented general use.

Given the risk of suicide, close monitoring during treatment of major depression is required. The choice of medication and adjustment has to be tailored according to the most dominant initial presentation. For patients with severe insomnia, an SSRI is indicated. If the initial choice (e.g., citalopram [Celexa], escitalopram [Lexapro], or sertraline [Zoloft]) shows little impact in improving sleep, the temporary addition of a sleep aid is a reasonable choice. Alternatively, some clinicians prefer to avoid hypnotics, which may allow close monitoring of the natural improvement in sleep during the first 2 weeks of SSRI treatment. This in turn may predict a good response. For many years, in patients with hypersomnia and hyperphagia—a variant known as “atypical depression”—the first choice was a monoamine oxidase inhibitor (MAOI). Currently, for atypical depression, clinicians prefer as a first choice a norepinephrine/serotonin reuptake inhibitor (venlafaxine [Effexor], desvenlafaxine [Pristiq]) or a norepinephrine/dopamine active medication (bupropion [Wellbutrin]). Response to medications is often difficult to predict. Again, early in treatment, a thorough medical workup, which should always include a thyroid panel, should be the norm. Sometimes switches to other classes of antidepressants (dopamine enhancers, tricyclics) are necessary before a result is obtained. Pharmacologic augmentation with mood stabilizers, neuroleptics, and thyroid hormone has been used in cases of treatment-resistant depression. In cases where severe anxiety, insomnia, and poor appetite dominate the picture, the early addition of a second-generation neuroleptic (olanzapine [Zyprexa]¹,

¹Not FDA approved for this indication.

TABLE 5 Biological Treatments for Medication-Resistant Mood Disorders

TYPE OF INTERVENTION	REPORTED RESPONSE	CURRENT AVAILABILITY
Electroconvulsive therapy (ECT)	50.9%–53.2% remission rate	Common
Transcranial magnetic stimulation (TMS)	41.5%–56.4% response rate, 26.5%–28.7% remission rate	Accepted by several insurance plans
Vagal nerve stimulation (VNS)	53% response rate, 33% remission after 1 year	Rare (neurosurgical)
Deep brain stimulation (DBS)	29% response rate at 1 year	Rare (neurosurgical)
Ketamine (Ketalar) infusion*	79% response rate	Very rare (only in selective institutions)
Anterior cingulotomy	33.3% response rate, after 30 mo	Very rare (only in selective institutions, neurosurgical)

*Not U.S. Food and Drug Administration approved for this indication.

quetiapine [Seroquel XR], risperidone [Risperdal]¹, and aripiprazole [Abilify]) is recommended. Medication resistance (after several failed trials) dictates the reassessment of diagnosis to further rule out psychiatric and medical comorbidity. For medication-resistant mood disorders, Table 5 presents a list of further biological treatments. Some of these treatments are promising but have yet to be included as routine choices in some of the most difficult-to-treat patients.

Psychotherapy

For mood disorders, cognitive-behavioral and interpersonal psychotherapy have been considered therapies of choice. The former directly addresses the negative, pessimistic bias of the depressive thinking, which is a maintenance factor of depressed mood. The

¹Not FDA approved for this indication.

latter addresses social and interpersonal functioning by enhancing coping abilities. Their popularity has been increasing; however, they require special training and supervision. In clinical practice, though, the most readily available therapies remain supportive and insight-oriented psychotherapy. They too complement the effect of pharmacology. Brain imaging studies have revealed that the activity of the subgenual anterior cingulate cortex (Brodmann area 25) predicts the outcome of response to cognitive-behavioral psychotherapy in depression. As a general rule, therapies should have specific goals that need to be discussed with patients at the onset of treatment. This needs to be part of an overall “informed consent” approach to treatment. Given the availability of a variety of clinicians with different levels of expertise that provide psychotherapy, it is important to monitor results and coordinate care. If “split” treatment (pharmacology and psychotherapy provided by different clinicians) is chosen, communication between parties of the treatment team remains a crucial requirement for rapid response and recovery. Other therapeutic measures, such as an increase in physical activity, normalization of sleep, and improvement of social support, are particularly important in promoting recovery.

Treatment of Bipolar Disorders (Bipolar Type I, Type II, Mixed Type, and Cyclothymia)

The treatment of bipolar disorder has been well refined over the years by a large body of literature. For acute mania, the treatment with mood stabilizers and/or antipsychotics has remained the main approach for the past several decades. Severe forms of mania and psychosis usually require hospitalization. Table 6 indicates intervention options for different phases of bipolar disorder.

As indicated in the table, some of the medication choices overlap between different clinical presentations. For chronic forms of bipolarity, such as mixed bipolar and cyclothymic disorder, a variety of new approaches has been developed, including social rhythm therapy. The latter includes monitoring and optimization of social interactions, sleep, and circadian rhythms that seem to benefit bipolar patients. Chronic bipolarity, with its significant impairment and suicide risk, remains a major problem, often requiring multidisciplinary consultations and referral to a tertiary institution. In treatment-resistant cases, employment of electroconvulsive therapy and other novel biological approaches can be lifesaving. Even with partial treatment response, maintenance is paramount. Life-long maintenance treatment is likely to prevent suicide and further functional deterioration. More recently, suicide prevention both in chronic mood disorders and in personality disorders has been reported with maintenance treatment of lithium carbonate and clozapine (Clozaril).¹ Among bipolar patients, chronic depression is one of the most treatment-resistant conditions in psychiatry. One

2018 study revealed a significant response when 7,000-lux bright white light was administered daily for four to six weeks, in conjunction with mood stabilizers. The response rate was 68.2% compared to 22.2% in the placebo group. Among the treatment cases, no mood polarity switches occurred. Further replication of these findings may reveal bright light to be a new modality of treatment for bipolar depression, which is readily available and free of significant side-effects.

Mood Dysregulation

Mood dysregulation is a broad phenomenon encountered both in clinical and in nonclinical settings. For clinicians, a variety of difficult-to-classify syndromes remain relevant (referred to here as “mood syndrome variants”). These mood syndrome variants present anecdotal but clinically pertinent manifestations collected from the medical literature of the past century. Psychiatric and medical disorders often coexist with different degrees of mood dysregulation. A more detailed description of each clinical entity in Table 7 is beyond the scope of this chapter. As seen from the table, different forms of mood dysregulation can occur both within and outside DSM diagnoses. For instance, atypical depression has been included in the DSM, whereas other syndromes, such as neurasthenia, remain unclassified. When encountered, any of the listed syndromes should raise suspicion of an underlying mood disorder. A diagnosis of “unspecified depressive disorder” (311) can be made, and the entire mood disorder treatment armamentarium should be considered.

Clinical Course and Prognosis of Mood Disorders

Given the heterogeneity of mood disorders, there is great variation in clinical outcome. Clinical course and outcome depend on whether treatment was available, whether an individual is sensitive or resistant to the treatment, and the degree of compliance. Many individuals with mild and subsyndromal disorders remain undiagnosed, whereas others with severe forms of mood disorders refuse treatment. As a general rule, most untreated mood disorders tend to become chronic. Episodic disorders, such as bipolar I and II and depression, recurrent type, may show more frequent recurrences with advancement in age. Other patients with hyposymptomatic presentations and infrequent episodes may show long-term remissions. Such remissions are favored by stable, low-stress lifestyles. Dyslipidemia, hypertension, type 2 diabetes, coronary vascular disease, and stroke are among the numerous medical complications of chronic mood disorders. Some of these complications are direct side effects of long-term use of psychotropic medications, in particular second-generation antipsychotics. They all contribute to shortened life expectancy of individuals with mood disorders. Table 8 demonstrates the severe impact on life expectancy of bipolar disorder. Mortality comes from suicide, cardiovascular disease, and respiratory disorders. However, treatment can at least partially reverse these trends.

Prevention

Primary prevention of mood disorders requires a concerted effort to educate the public and policymakers for funding of prevention. Depression Awareness Week and other community efforts enhance awareness and decrease stigma. Primary prevention may also include the promotion of general health and healthy work environments and addressing of major social problems, including the avoidance of early trauma and family problems, as well as prevention of excessive stress and trauma in adults. These are all known to be associated with mental illness. Populations at risk need to be identified in primary care settings. Secondary prevention requires availability of mental health services, including early detection, education about the need for adequate treatment, and continuity of care to prevent impairment. Tertiary prevention would include continuation of treatment to prevent comorbidity of other psychiatric disorders and catastrophic complications, including suicide. Finally, in the case of mood disorders, quaternary prevention would include long-term follow-up, monitoring of recurrences, and medical comorbidity (accidents, cardiovascular, respiratory,

¹Not FDA approved for this indication.

TABLE 6 Intervention Options for Phases of Bipolar Disorder

PHASE OF DISORDER	INTERVENTIONS
Acute	Hospitalization if necessary Antipsychotics, tranquilization, start mood stabilizers
Subacute	Antipsychotics/neuroleptics, mood stabilizers If already medicated, adjust dose
Rapid cycling/ mixed	As in acute phase; check thyroid; medical workup Rule out substance abuse May require treatment indefinitely
Cyclothymia	Mood stabilizers, long term, with or without antidepressants based on history Close initial monitoring May need treatment indefinitely

TABLE 7 Examples of Mood Syndrome Variants (MSVs) With Different Degrees of Mood Dysregulation as Encountered in the Literature Over the Past Century

I MSV WITH MANIFESTATIONS OF OTHER PSYCHIATRIC DISORDERS	II MSV WITH UNUSUAL SYMPTOMS (MASKED DEPRESSION)	III MSV AS PART OF OTHER CONDITIONS
Atypical depression Subaffective dysthymia Hysteroid dysphoria Pseudodementia Pseudoborderline Somatic depression Underground depression Neurasthenia Mood syndrome as part of personality disorders Mood syndromes and depression in schizophrenia	Mood dysregulation and thrill-seeking behavior (gambling, racing, substance abuse, hypersexuality) Reactive overeating Isolated sleep disturbance and mood dysregulation Atypical facial pain Dysphagia Monosymptomatic hypochondriasis Monosymptomatic delusions	Postpartum depression Depression secondary to chronic pain Substance- and medication-induced mood dysregulation* “Organic” mood disorders (due to central nervous system disorders) Vicarious traumatization [†]

Source: Novac and Djenderedjian, unpublished data.

*Medications more often associated with depression are, among others, reserpine, alpha-methyl dopa (Aldomet), some alpha- and beta-blockers, sedative hypnotics, cimetidine (Tagamet), indomethacin (Indocin), anticancer medications, oral contraceptives, and corticosteroids.

[†]It has been described as a form of secondary trauma in mental health professionals who treat victims of trauma.

TABLE 8 Causes of Mortality in Patients With Bipolar Disease: Index Group Compared to the General Population

CAUSE OF DEATH	OBSERVED DEATHS (% STUDY GROUP)	EXPECTED DEATHS (% REGISTRAR GENERAL'S* FIGURES)	MORTALITY RATIO (ACTUAL STUDY)
Suicide	15.7	0.67	23.4
Cardiovascular system	42.1	14	3.0
Respiratory system	33.3	1.08	30.8

(Data from Sharma and Markar [1994]).

and other medical conditions), to avoid overburdening the health system.

The high medical comorbidity rate recently found among patients with mood disorders varies by medical diagnosis and socioeconomic background. Chronic pain, neurologic conditions, gastrointestinal disorders, cardiovascular disorders, and the metabolic syndrome are the most common medical conditions associated with mood disorders. Except for thyroid disorders, the seriousness of the comorbid condition seems to be even higher among patients of lower socioeconomic background. This poses a significant medical and socioeconomic burden of untreated mood disorders.

OBSESSIVE-COMPULSIVE DISORDER

Method of

Rachna Kalia, MD; and Anne Walling, MB, ChB

CURRENT DIAGNOSIS

- Obsessive-compulsive disorder (OCD) is characterized by obsessions (recurrent, persistent, and intrusive unwelcome thoughts, urges, or images) and compulsions (repetitive behaviors or activities that the patient feels forced to perform in response to an obsession).
- Obsessions and compulsions are unwelcome and time-consuming, impair functioning, and usually cause significant anxiety or distress.
- The obsessions or compulsions are not attributable to any toxin, medication, or another medical condition.

TABLE 7 Examples of Mood Syndrome Variants (MSVs) With Different Degrees of Mood Dysregulation as Encountered in the Literature Over the Past Century

I MSV WITH MANIFESTATIONS OF OTHER PSYCHIATRIC DISORDERS	II MSV WITH UNUSUAL SYMPTOMS (MASKED DEPRESSION)	III MSV AS PART OF OTHER CONDITIONS
Atypical depression Subaffective dysthymia Hysteroid dysphoria Pseudodementia Pseudoborderline Somatic depression Underground depression Neurasthenia Mood syndrome as part of personality disorders Mood syndromes and depression in schizophrenia	Mood dysregulation and thrill-seeking behavior (gambling, racing, substance abuse, hypersexuality) Reactive overeating Isolated sleep disturbance and mood dysregulation Atypical facial pain Dysphagia Monosymptomatic hypochondriasis Monosymptomatic delusions	Postpartum depression Depression secondary to chronic pain Substance- and medication-induced mood dysregulation* “Organic” mood disorders (due to central nervous system disorders) Vicarious traumatization [†]

Source: Novac and Djenderedjian, unpublished data.

*Medications more often associated with depression are, among others, reserpine, alpha-methyl dopa (Aldomet), some alpha- and beta-blockers, sedative hypnotics, cimetidine (Tagamet), indomethacin (Indocin), anticancer medications, oral contraceptives, and corticosteroids.

[†]It has been described as a form of secondary trauma in mental health professionals who treat victims of trauma.

TABLE 8 Causes of Mortality in Patients With Bipolar Disease: Index Group Compared to the General Population

CAUSE OF DEATH	OBSERVED DEATHS (% STUDY GROUP)	EXPECTED DEATHS (% REGISTRAR GENERAL'S* FIGURES)	MORTALITY RATIO (ACTUAL STUDY)
Suicide	15.7	0.67	23.4
Cardiovascular system	42.1	14	3.0
Respiratory system	33.3	1.08	30.8

(Data from Sharma and Markar [1994]).

*Edinburgh Registrar General's Office.

and other medical conditions), to avoid overburdening the health system.

The high medical comorbidity rate recently found among patients with mood disorders varies by medical diagnosis and socioeconomic background. Chronic pain, neurologic conditions, gastrointestinal disorders, cardiovascular disorders, and the metabolic syndrome are the most common medical conditions associated with mood disorders. Except for thyroid disorders, the seriousness of the comorbid condition seems to be even higher among patients of lower socioeconomic background. This poses a significant medical and socioeconomic burden of untreated mood disorders.

OBSESSIVE-COMPULSIVE DISORDER

Method of

Rachna Kalia, MD; and Anne Walling, MB, ChB

CURRENT DIAGNOSIS

- Obsessive-compulsive disorder (OCD) is characterized by obsessions (recurrent, persistent, and intrusive unwelcome thoughts, urges, or images) and compulsions (repetitive behaviors or activities that the patient feels forced to perform in response to an obsession).
- Obsessions and compulsions are unwelcome and time-consuming, impair functioning, and usually cause significant anxiety or distress.
- The obsessions or compulsions are not attributable to any toxin, medication, or another medical condition.

- Patients may be unwilling to reveal symptoms of OCD or may lack insight into abnormal thoughts or behaviors.
- Patients with OCD may present with symptoms of depression, another comorbid psychiatric condition, or physical sequelae such as skin damage, fatigue, or insomnia.

CURRENT TREATMENT

- Selective serotonin reuptake inhibitors (SSRIs) and exposure and response prevention (ERP) behavioral therapy are first-line treatments for OCD with good evidence of effectiveness.
- SSRIs, clomipramine (Anafranil), serotonin-norepinephrine reuptake inhibitors (SNRIs), and monoamine oxidase inhibitors (MAOIs) have demonstrated efficacy in the treatment of OCD.
- Effective SSRI therapy often requires high dosages and 8 to 12 weeks of treatment. Long-term adherence is essential. If a patient fails an adequate trial of SSRI monotherapy, a trial of another SSRI is recommended.
- Evidence-based augmentation strategies for treatment-resistant cases include low-dose antipsychotics.
- Comorbid conditions, including depression with suicidal ideation, must be identified and addressed.

Epidemiology

Clinically significant OCD has an estimated lifetime prevalence in US adults of 1.9% to 3.0%. About 2.0% of adults report symptoms that meet criteria for the diagnosis within the prior year. Many more individuals suffer from OCD symptoms that do not reach diagnostic thresholds. Approximately 90% of patients with OCD suffer from at least one additional psychiatric condition, mainly anxiety (75.8%), mood disorders (63.3%), impulse control (55.9%), and substance use disorders (38.6%). Patients report that OCD persists for a mean of 8.9 years. The duration, high morbidity, and significant role impairment place heavy demands on patients and families. The World Health Organization (WHO) ranks OCD as one of the 10 most disabling medical conditions worldwide.

The mean age of onset of OCD is 19.5 years, and new cases are rarely diagnosed after age 35. The majority of childhood and adolescent cases are in males. Nearly a quarter of males report onset before 10 years of age. The onset in females tends to be in adolescence and early adulthood. In adults, the prevalence is approximately equal in men and women. No strong evidence supports racial or ethnic difference in the prevalence of OCD.

Risk Factors, Etiology, and Pathophysiology

Several studies confirm a familial pattern for OCD, especially in childhood-onset forms. Twin studies implicate both genetic and environmental factors. Multiple genes have been implicated, notably areas on chromosomes 9 and 15. Current theory focuses on dysregulation in a network of genes influencing the glutamatergic, serotonergic, and dopaminergic systems, and possibly other parts of the brain, as underlying the development of OCD. The heritability of OCD is estimated to be approximately 40% with the remaining variation attributed to adverse environmental factors. Suggested environmental triggers for OCD include perinatal events, psychosocial stress, trauma, and inflammatory processes, especially streptococcal infection. Neuroimaging and neuropsychiatric studies indicate OCD-related changes in the cortico-striato-thalamo-cortical (CSTC) circuit, known to be critical in evaluating and taking steps to neutralize perceived threats.

Obsessive-compulsive disorder has several subtypes. Some of the childhood-onset forms are comorbid with Tourette's and other chronic tic syndromes. In adults, the common associations with schizophrenia or schizoaffective disorder, bipolar disorder, and eating disorders could indicate that the conditions have

overlapping etiologies or that one condition is a risk factor for the other. Clinicians should have an increased awareness of the possibility of OCD in adolescent and young adult patients presenting with a range of psychiatric conditions.

Clinical Manifestations

The core features of OCD are obsessions and compulsions (Table 1). Most patients have both. Obsessions are recurrent, persistent, and intrusive thoughts, urges, or images that are unwelcome and usually cause significant anxiety or distress. Patients attempt to ignore obsessions or to suppress or neutralize them by imposing other thoughts or performing specific activities. Compulsions are repetitive behaviors (e.g., handwashing, organizing, or checking) or activities (e.g., praying, counting, or repeating words silently) that the patient feels forced to perform in response to an obsession. Compulsions are characterized by rigid rules and inflexible behaviors but are not connected in a realistic way with what they are designed to neutralize or prevent and are clearly excessive responses to the intrusive thoughts, urges, or images.

Children may be unable to articulate symptoms and adults may be unwilling to disclose experiences that they recognize as abnormal. Individuals with OCD tend to be secretive about their symptoms, because most of them retain insight into the abnormal nature of their fears or behaviors. The estimated 14% to 30% of patients who have poor insight often have more severe and intractable symptoms. By the time patients present to medical attention, OCD is usually impacting function in society and/or eliciting concern from others about the patient's symptoms. The reported average time from onset of symptoms to diagnosis is 11 years. Other psychiatric conditions are commonly comorbid with OCD, and many patients present or are misdiagnosed as suffering primarily from depression or anxiety. Physical symptoms such as skin damage ("intractable dermatitis") from recurrent handwashing or scratching may be the presenting feature of OCD.

Without intervention, OCD is usually a chronic relapsing condition with adult rates of spontaneous remission estimated at about

TABLE 1 Examples of Common Obsessions and Compulsions

OBSSESSIONS	COMPULSIONS
Contamination or infection ("germophobia")	Avoidance of people or situations perceived as dirty, infectious, or corrupting; excessive cleaning or use of protective materials (surgical gloves, masks, sanitizer)
Control: Fear of losing control of speech or actions in public; making inappropriate comments; doing shameful or hurtful activities in public; inviting ridicule or negative reactions from others	Avoidance of others and public places; guarded behavior and curtailed speech to minimize contact with others
Religious, especially unworthiness, sinfulness, guilt	Praying, ritualizing acts of penance, seeking forgiveness (expression depends on religious belief/tradition of patient)
Sexual: concerns about acting inappropriately or being deviant	Avoidance of sexual situations, materials
Symmetry, correctness, precision	Arranging, ordering, scheduling, checking; "correcting" work of others
Violence; fear of harming others or becoming dangerous	Vigilance, attention to violent incidents, requiring reassurance

20%. Remission in treated patients is associated with shorter duration of symptoms, emphasizing the need for prompt recognition and effective therapy. The risk of suicide is high in patients with OCD, particularly those with depression, posttraumatic stress disorder, or impulse control disorders. One large study reported that 20% made suicidal plans and 11% attempted suicide.

Diagnosis

The diagnosis is based on clinical symptoms consistent with *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) criteria for obsessions and compulsions (see [Table 1](#)). The obsessions and compulsions must be time-consuming, often regarded as requiring more than 1 hour per day, or cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Simple screening questions have been suggested ([Table 2](#)). Several more-detailed inventories are available to document symptoms and their impact, but these are of limited use in diagnosis in a primary care setting.

A diagnosis of OCD also requires eliminating other potential causes of symptoms, as described next.

Differential Diagnosis

Identifying underlying OCD may be challenging in patients presenting with depression, anxiety, or another comorbidity. Some key features help in distinguishing OCD from these conditions ([Table 3](#)).

TABLE 2 Examples of Screening Questions for Obsessive-Compulsive Disorder

Do you check things repeatedly or wash your hands over and over?
Do you have unpleasant or unusual thoughts that you can't seem to get rid of?
Do you need things symmetrically arranged or always in a certain order?
Do you have trouble discarding things, so that your house is quite cluttered?

TABLE 3 Key Features That Help with Differential Diagnosis

ALTERNATIVE DIAGNOSIS	SYMPTOMS TYPICAL OF OBSESSIVE-COMPULSIVE DISORDER (OCD)	SYMPTOMS TYPICAL OF ALTERNATIVE DIAGNOSIS
Depressive disorders	Focus and content of obsessions is usually broader	Content of depressive ruminations is self-criticism, failures, guilt, regret, or pessimism
Generalized anxiety disorder	Obsessions may not be reality based Rituals may be present	Worries focus on real-life problems, generally more vague Usually no rituals
Posttraumatic stress disorder	Intrusive thoughts are anticipation of future events	Intrusive thoughts are replay of actual events
Schizophrenia, mania	Content is related to OCD Insight usually present	Content is related to persecution, grandiosity, ideas of reference Insight usually absent
Hypochondriasis	Insight usually present Origin is external based	Insight usually absent Origin is misinterpretation of physical signs and symptoms

Insight distinguishes OCD from delusions and other features of schizophrenia. An important distinction is between OCD and obsessive-compulsive personality disorder (OCPD). In OCPD, behavior is ego-syntonic, that is, driven by desire or pleasure seeking rather than fear. Clinical OCD also needs to be distinguished from normal individuals who are meticulous and have rigid, inflexible thought processes or from individuals who describe compulsive behaviors such as eating or gambling that are or were pleasurable.

Obsessive-compulsive symptoms can occur in several neurologic conditions such as brain trauma, stroke, encephalitis, temporal lobe epilepsy, Prader-Willi syndrome, Huntington disease, Parkinson disease, carbon monoxide poisoning, or manganese poisoning, but these can usually be identified by the predominant other symptoms.

Treatment and Monitoring

Obsessive-compulsive disorder is a chronic condition with low frequency of spontaneous improvement but high probability of response to therapy if adherence and social support are maintained and comorbidities addressed. Short-term and long-term treatment goals should be established with each patient and those in his or her support system. Goals should focus on management of symptoms to optimize function and quality of life rather than complete resolution of symptoms. Adherence is critical to prognosis. Close follow-up must be secured, especially early in treatment. Given the secretive nature of the illness, the initial presentation may be the only chance to engage these patients in treatment, and must not be missed. Providing patients and families with educational information and access to community resources can help with adherence and social stabilization. Education for patients and others regarding what to expect from pharmacotherapy, including potential adverse effects and the lag period before benefit, can help ease anxiety and improve adherence and prognosis.

Once the diagnosis of OCD has been confirmed, the appropriate setting and strategy for treatment must be decided. The spectrum of treatment settings includes outpatient, adult partial-day programs, residential facilities, and inpatient psychiatric hospitalization. Factors such as suicide assessment, severity of illness, treatment cost, insurance coverage, and social support availability need to be explored to determine the optimal treatment environment.

Both pharmacotherapy and psychotherapy are recommended first-line treatment either alone or in combination ([Figure 1](#)). Combined therapy may be more effective than pharmacotherapy alone but has not been shown to be superior to behavioral therapy. Combination therapy may be most useful in patients with a coexisting psychiatric condition for which SSRIs are effective, those with poor response to initial monotherapy, or those who wish to discontinue medication as soon as possible. Practice guidelines recommend use of an approved symptom rating scale to monitor response to therapy, such as the 10-item Yale-Brown Obsessive Compulsive Scale (Y-BOCS).

Pharmacotherapy

SSRIs are first-line treatment agents for OCD ([Table 4](#)). Fluoxetine (Prozac), clomipramine (Anafranil), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft) are approved by the U.S. Food and Drug Administration (FDA) and appear to be equally effective. Medication selection depends on factors including adverse effect profile, cost, concomitant medications, comorbid medical conditions, previous experience with the medication, and patient preference. The selected medication should be initiated at low dose and slowly titrated to effective levels. The optimal response may require a dose exceeding the manufacturer's recommended maximum dose. The "start low, go slow" strategy minimizes adverse effects, especially in older patients, and improves adherence. Common adverse effects include gastrointestinal upset, agitation, insomnia, fatigue, and sexual side effects. Many adverse effects are transitory. Serotonin syndrome is a serious potential risk at high doses. Patients with OCD are at risk of suicide and self-harm, but studies do not indicate increased risk in those treated with SSRIs, including adolescents.

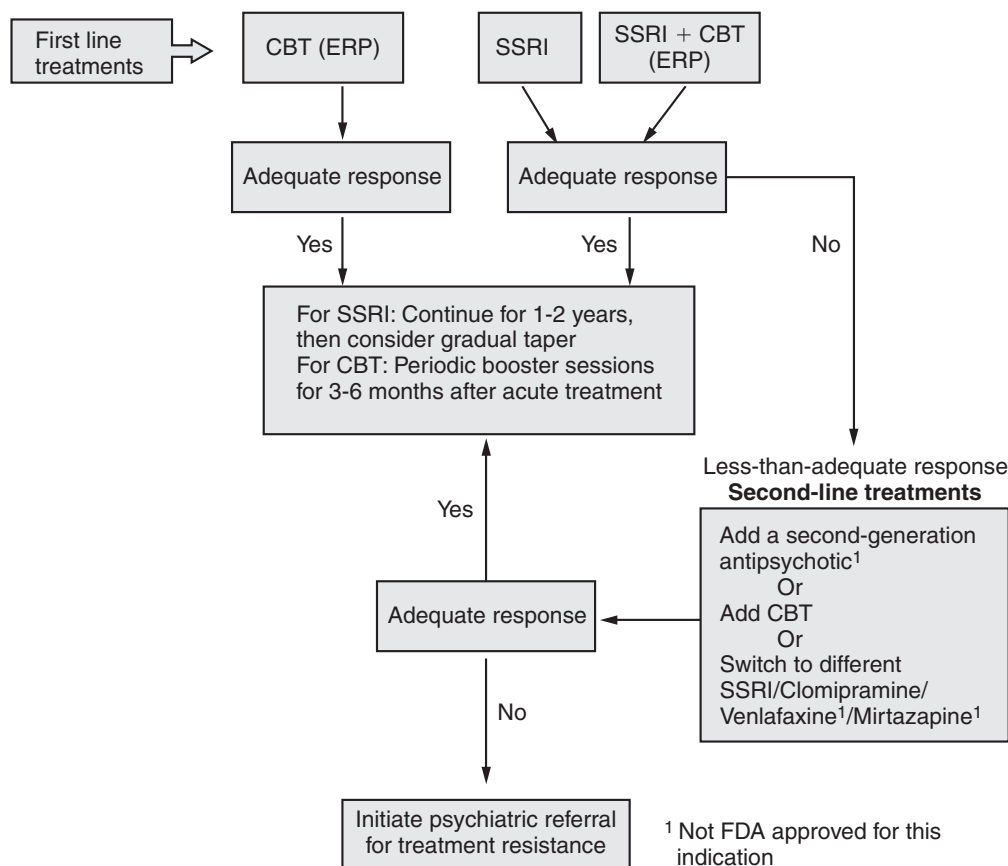

Figure 1 Treatment algorithm for obsessive-compulsive disorder.

TABLE 4 Dosing of Selective Serotonin Reuptake Inhibitors (SSRIs) to Treat Obsessive-Compulsive Disorder

SSRI	DOSAGE (mg/day)		
	STARTING	TARGET	USUAL MAXIMAL
Citalopram (Celexa)*	20	40	40
Escitalopram (Lexapro)*	10	20	40 [†]
Fluoxetine (Prozac)	20	40–60	80
Fluvoxamine (Luvox)	50	200	300
Paroxetine (Paxil)	20	40–60	60
Sertraline (Zoloft)	50	200	200

*Not U.S. Food and Drug Administration approved for this indication.

[†]Exceeds dosage recommended by the manufacturer.

Most patients will not experience substantial improvement for 4 to 6 weeks, and many require 10 to 12 weeks of treatment at optimal dosage. Although full remission of symptoms is reported in only about 10% of patients treated with SSRIs, 40% to 65% improve. The mean improvement in symptoms is 20% to 40%. Effective therapy should be maintained for at least a year and possibly indefinitely. If medication is discontinued, gradual tapering is recommended. Relapse rates in patients who discontinue medication after 2 years of treatment are 25% to 40% and up to 80% after shorter periods of treatment.

If response continues to be inadequate and adherence is confirmed, options include changing the primary agent to

clomipramine, venlafaxine (Effexor),¹ or mirtazapine (Remeron),¹ or augmentation with a second-generation antipsychotic agent. Referral to a psychiatric provider with expertise in OCD therapy may be the best option for treatment-resistant cases.

A patient may respond well to a different SSRI, but a full trial of several weeks at adequate dose is necessary before changing medication. Clomipramine is as effective as SSRIs but carries safety concerns. It is strongly serotonergic and anticholinergic and may increase risk of seizure or cardiac arrhythmia. Addition of risperidone (Risperdal)¹ and possibly aripiprazole (Abilify)¹ may benefit some treatment-resistant patients. The efficacy of quetiapine (Seroquel)¹ and olanzapine (Zyprexa)¹ is unclear. All antipsychotic agents require careful monitoring for adverse effects. Medications sometimes used for OCD but with only limited evidence of efficacy include topiramate (Topamax),¹ ondansetron (Zofran),¹ pindolol,¹ buspirone,¹ memantine (Namenda),¹ pregabalin (Lyrica),¹ N-acetylcysteine (Acetadote),¹ naltrexone (Vivitrol),¹ and riluzole (Rilutek).¹

Psychological Therapy

The strongest evidence for effective behavioral treatment of OCD supports exposure and response prevention (ERP), a form of cognitive-behavioral therapy (CBT) in which patients learn alternative responses to anxiety-provoking stimuli or situations. Weekly or twice-weekly sessions for a total of 20 to 30 hours are recommended followed by monthly “booster” sessions for 3 to 6 months. Studies report considerable reduction in symptoms in up to 80% of patients with improvement maintained for up to 5 years. Remote-delivery formats of ERP using the telephone, a computer, or the Internet may provide effective and more accessible alternatives to traditional therapist consultation. ERP therapy not only is first-line treatment for OCD but also has strong

¹Not FDA approved for this indication.

evidence of effectiveness as an augmentation strategy to pharmacotherapy.

Cognitive therapy focusing on recognizing and changing interpretation of unrealistic thoughts is also associated with improvement in 60% to 80% of patients with OCD and is a good alternative for those unwilling to undertake ERP.

Other Treatment Options

Deep brain stimulation at the ventral capsule/striatum was approved by the FDA in 2009 for refractory OCD. Good results are reported in about half of patients treated in small trials compared with sham stimulation. Neurosurgical procedures may be recommended for selected patients with intractable OCD. Robust trials of ERP, two or more treatments with different SSRIs, a course of clomipramine, and at least three trials of augmentation therapy are recommended before considering neurosurgical approaches. These include ablative surgeries such as anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, and limbic leucotomy. These last-resort invasive procedures have had mixed success and carry risk of serious adverse effects. The American Psychiatric Association (APA) warns that they should be performed only at specialist centers.

Table 5 provides a list of educational resources for patients and their families.

PANIC DISORDER

Method of

Cheryl Wehler, MD

CURRENT DIAGNOSIS

- Panic disorder (PD) is characterized by the presence of multiple untriggered panic attacks.
- These unexpected panic attacks are associated with significant anticipatory anxiety and/or changes in behavior to minimize the consequences or avoid another panic attack.
 - Patients worry about being negatively judged due to visible panic symptoms.
 - Patients worry about dying or “going crazy.”
- The panic attacks are not attributable to another medical condition or to the effects of a substance (medication or drug of abuse).
- The panic attacks are not better explained by another mental disorder.
- Patients frequently present with concern about somatic symptoms (e.g., fear of heart attack because of shortness of breath and chest discomfort).
- Assess patients for suicidality, as suicide risk increases with panic attacks or recent diagnosis of panic disorder.

CURRENT THERAPY

- Pharmacology and psychotherapy are effective treatments for PD.
- Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and benzodiazepines have demonstrated efficacy for the treatment of PD.
- The favorable safety profile of SSRIs and SNRIs make them first-line monotherapy agents.
- Although TCAs are effective, their side effects and greater toxicity in overdose limit their clinical utility.
- Monoamine oxidase inhibitors (MAOIs) also appear effective but are reserved for patients who are nonresponders to multiple first-line treatments because of their safety profile limitations.
- Benzodiazepines are not first-line monotherapy but are useful adjuncts to antidepressants if residual anxiety requires additional treatment.
- Although the more rapid response of benzodiazepines (compared with SSRIs/SNRIs) make them attractive, the inevitable physiological dependence make them less so.
- Patients with PD can be sensitive to medication side effects; therefore the adage “start low and go slow” is applicable to dosing.
- Cognitive behavioral therapy (CBT) or CBT with medications are first-line treatments for children and adults with PD.

Epidemiology

The 12-month prevalence estimate for panic disorder (PD) in the general population of the United States and Europe is approximately 2% to 3% in adults and adolescents. Non-Latino Caucasians and Native Americans have significantly higher rates than Latinos, African Americans, and Asian Americans. Adolescent and adult females are approximately twice as likely as males to be affected (although the clinical features of PD do not differ between males and females). The prevalence is highest in adult females. Prevalence rates decline in older individuals. The overall prevalence of PD is low in children (<14 years). PD is associated with the highest number of medical visits among all anxiety disorders.

evidence of effectiveness as an augmentation strategy to pharmacotherapy.

Cognitive therapy focusing on recognizing and changing interpretation of unrealistic thoughts is also associated with improvement in 60% to 80% of patients with OCD and is a good alternative for those unwilling to undertake ERP.

Other Treatment Options

Deep brain stimulation at the ventral capsule/striatum was approved by the FDA in 2009 for refractory OCD. Good results are reported in about half of patients treated in small trials compared with sham stimulation. Neurosurgical procedures may be recommended for selected patients with intractable OCD. Robust trials of ERP, two or more treatments with different SSRIs, a course of clomipramine, and at least three trials of augmentation therapy are recommended before considering neurosurgical approaches. These include ablative surgeries such as anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, and limbic leucotomy. These last-resort invasive procedures have had mixed success and carry risk of serious adverse effects. The American Psychiatric Association (APA) warns that they should be performed only at specialist centers.

Table 5 provides a list of educational resources for patients and their families.

PANIC DISORDER

Method of

Cheryl Wehler, MD

CURRENT DIAGNOSIS

- Panic disorder (PD) is characterized by the presence of multiple untriggered panic attacks.
- These unexpected panic attacks are associated with significant anticipatory anxiety and/or changes in behavior to minimize the consequences or avoid another panic attack.
 - Patients worry about being negatively judged due to visible panic symptoms.
 - Patients worry about dying or “going crazy.”
- The panic attacks are not attributable to another medical condition or to the effects of a substance (medication or drug of abuse).
- The panic attacks are not better explained by another mental disorder.
- Patients frequently present with concern about somatic symptoms (e.g., fear of heart attack because of shortness of breath and chest discomfort).
- Assess patients for suicidality, as suicide risk increases with panic attacks or recent diagnosis of panic disorder.

CURRENT THERAPY

- Pharmacology and psychotherapy are effective treatments for PD.
- Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and benzodiazepines have demonstrated efficacy for the treatment of PD.
- The favorable safety profile of SSRIs and SNRIs make them first-line monotherapy agents.
- Although TCAs are effective, their side effects and greater toxicity in overdose limit their clinical utility.
- Monoamine oxidase inhibitors (MAOIs) also appear effective but are reserved for patients who are nonresponders to multiple first-line treatments because of their safety profile limitations.
- Benzodiazepines are not first-line monotherapy but are useful adjuncts to antidepressants if residual anxiety requires additional treatment.
- Although the more rapid response of benzodiazepines (compared with SSRIs/SNRIs) make them attractive, the inevitable physiological dependence make them less so.
- Patients with PD can be sensitive to medication side effects; therefore the adage “start low and go slow” is applicable to dosing.
- Cognitive behavioral therapy (CBT) or CBT with medications are first-line treatments for children and adults with PD.

Epidemiology

The 12-month prevalence estimate for panic disorder (PD) in the general population of the United States and Europe is approximately 2% to 3% in adults and adolescents. Non-Latino Caucasians and Native Americans have significantly higher rates than Latinos, African Americans, and Asian Americans. Adolescent and adult females are approximately twice as likely as males to be affected (although the clinical features of PD do not differ between males and females). The prevalence is highest in adult females. Prevalence rates decline in older individuals. The overall prevalence of PD is low in children (<14 years). PD is associated with the highest number of medical visits among all anxiety disorders.

Risk Factors

Risks factors for PD include a disposition to negativity, experience of childhood physical and sexual abuse, and family history, indicating genetic vulnerability. Respiratory disorders such as asthma are associated with panic disorder. Smoking is a risk factor for panic attacks and PD. PD is associated with social and occupational/physical disability and high economic cost. PD may be comorbid with a variety of other psychiatric diagnoses, such as depression, bipolar affective disorder, and other anxiety disorders.

Diagnosis

PD is defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V) as recurrent unexpected panic attacks followed by at least 1 month of anticipatory anxiety about having another attack, and a significant change in behavior to avoid another panic attack. A panic attack, the core feature of panic disorder, is an abrupt surge of intense fear/anxiety with concurrent physical and cognitive symptoms (Box 1). To be diagnosed as having PD, a patient must have more than one panic attack that

BOX 1 DSM-5 Criteria for Panic Disorder

- Recurrent unexpected panic attacks. A panic attack is an abrupt surge of intense fear or intense discomfort that reaches a peak within minutes, and during which time four (or more) of the following symptoms occur:
 Note: The abrupt surge can occur from a calm state or an anxious state.
 - Palpitations, pounding heart, or accelerated heart rate
 - Sweating
 - Trembling or shaking
 - Sensations of shortness of breath or smothering
 - Feelings of choking
 - Chest pain or discomfort
 - Nausea or abdominal distress
 - Feeling dizzy, light-headed, faint, or unsteady
 - Chills or heat sensations
 - Paresthesia (numbness or tingling sensations)
 - Depersonalization (being detached from oneself) or derealization (feelings of unreality)
 - Fear of “going crazy” or losing control
 - Fear of dying
 Note: Culture-specific symptoms (e.g., tinnitus, neck soreness, headache, uncontrollable screaming or crying) may be seen. Such symptoms should not count as one of the four required symptoms [to diagnose PD].
- At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
 - Persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”)
 - A significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations)
- The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism, cardiopulmonary disorders)
- The disturbance is not better explained by another mental disorder (e.g., the panic attacks do not occur only in response to feared social situations, as in social anxiety disorder; in response to circumscribed phobic objects or situations, as in specific phobia; in response to obsessions, as in obsessive-compulsive disorder; in response to reminders of traumatic events, as in posttraumatic stress disorder; or in response to separation from attachment figures, as in separation anxiety disorder)

is not the result of an obvious trigger or cue. The best example might be a nocturnal panic attack in which the individual is waking from sleep, with no external cues, in a state of intense fear (panic) and experiencing physical and cognitive symptoms. Expected panic attacks, that is, those for which there is an obvious cue or trigger, also occur in patients with PD. In the United States and Europe, approximately half of individuals with PD experience expected panic attacks as well as unexpected panic attacks. The presence of expected panic attacks does not rule out the diagnosis but is insufficient to make the diagnosis of this disorder.

A thorough diagnostic evaluation, including a complete history and thorough physical examination, is necessary to rule out medical or substance-induced panic attacks and establish the diagnosis of PD. Atypical symptoms or features of a panic attack may be suggestive of a medical illness or pharmacologic substance as the precipitant. A workup that includes laboratory tests such as complete blood cell count, complete chemistry panel (including calcium level), thyroid-stimulating hormone (TSH) level, and urine drug screen may be helpful in determining a medical or substance-related cause. These tests may be followed by a chest radiograph, an electrocardiogram, and cardiac enzymes, as warranted. If the clinical examination or history is suggestive, a Holter monitor, EEG, CT scan, or urine catecholamine assay may be performed.

Clinical Manifestations

In the United States, the median age of onset for PD is 20 to 24 years. PD is rare in childhood but occurs in adolescents; their symptoms are similar to those in adults. Onset after age 45 is unusual. If untreated, the usual course is chronic, and attacks may wax and wane. Some individuals have a chronic course complicated by frequent attacks whereas others have rare episodic symptoms. A minority of individuals have full remission. Caffeine and several other substances can provoke a panic attack.

The severity and frequency of panic attacks vary widely. Individuals who have infrequent panic attacks resemble individuals with more frequent panic attacks with regard to symptoms, demographics, and family history. To be diagnosed with PD, an individual must have more than one full-symptom attack with more than four of the symptoms listed in Box 1. Individuals may, however, have limited-symptom attacks with fewer than four symptoms.

There are three symptomatic facets of PD: acute panic, anticipatory anxiety, and phobic avoidance. Phobic avoidance often includes restricting daily activities to minimize or avoid panic attacks. Panic disorder is associated with other psychopathology, such as other anxiety disorders, particularly agoraphobia.

Although medical illness can precipitate a panic attack, individuals with anxiety, particularly PD, may be hypervigilant and misinterpret mild physical symptoms as harbingers of a catastrophic or fatal illness. Individuals with PD often report feelings of anxiety that are associated with health or mental health concerns.

Panic attacks often contribute to the presentation of other psychiatric illnesses, such as other anxiety disorders and major depression. A thorough history that documents the onset of symptoms, possible triggers, and context of symptoms is critical to establishing the diagnosis of PD. In addition to the history of the present illness and current symptoms, a psychiatric review of symptoms, past psychiatric history, general medical history and current medications, substance use history, family history, and mental status exam are valuable in constructing a psychiatric differential diagnosis and then a final working diagnosis. For instance, an individual with a history of a past trauma presenting with flashbacks, nightmares, and triggered panic attacks may have posttraumatic stress disorder (versus panic disorder).

Suicidal behavior in individuals with anxiety disorders has long been attributed to co-occurring risk factors, such as depression. New research suggests that an anxiety disorder is associated with suicidal ideation and suicide attempts beyond the effects of co-occurring mental disorders. Panic attacks and a recent diagnosis of PD are associated with a higher rate of suicide attempts and suicidal ideation.

Differential Diagnosis

The differential diagnosis of PD is wide ranging (Table 1). PD is not diagnosed if panic attacks are the direct physiological consequence of another medical condition or substance. Medical conditions that can cause panic attacks include cardiopulmonary conditions such as arrhythmias and asthma or chronic obstructive pulmonary disease (COPD). Endocrine and neurologic disorders such as hyperthyroidism, pheochromocytoma, vestibular dysfunction, and seizures may also cause panic attacks. In addition, central nervous system (CNS) stimulants and withdrawal from CNS depressants may precipitate a panic attack. On the other hand, a panic attack may mimic a wide variety of medical disorders.

Treatment

PD is a common mental disorder. It is associated with social and occupational/physical disability and high economic cost. When symptoms cause significant distress or interfere with functioning, treatment is warranted. Regardless of the modality chosen, the goal of treatment is a reduction in the frequency and severity of panic attacks as well as the resultant anticipatory anxiety and avoidance behaviors.

Research has confirmed the efficacy of multiple psychosocial and pharmacologic interventions in treating PD. Choice of treatment depends on multiple factors, including patient preference; risks and benefits for an individual patient; cost; past treatment history; and co-occurring medical, psychiatric, or substance abuse issues.

Selective serotonin reuptake inhibitors (SSRIs), serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), and benzodiazepines have demonstrated efficacy for the treatment of PD. The favorable safety profile of SSRIs and SNRIs

makes them first-line monotherapy agents. Although TCAs are effective, their side effects and toxicity in overdose limit their clinical utility. Monoamine oxidase inhibitors (MAOIs) also appear effective but are reserved for patients who are nonresponders to multiple first-line treatments because of their safety profile. Benzodiazepines are not first-line monotherapy but are useful adjuncts to antidepressants if residual anxiety requires additional treatment (Table 2).

An important consideration when using psychopharmacologic treatments in PD is the side-effect profile of a particular agent. Because patients with PD can be acutely sensitive to medication side effects, it is prudent to start medications at low doses and gradually increase them to therapeutic doses as tolerated. An effective dose is patient dependent—the goal is to prevent (versus respond to) panic attacks. If a decision is made to discontinue a SSRI, SNRI, or TCA, the medication should be gradually tapered when feasible.

Cognitive behavioral therapy (CBT) and CBT with medications are first-line treatments for children and adults with PD. CBT presents the most evidence of efficacy from random control trials. CBT for panic disorder generally includes psychoeducation, episode monitoring and response, self-awareness of anxious automatic

TABLE 1 Differential Diagnosis of Panic Attacks

SYSTEM	POSSIBLE DIAGNOSES
Psychiatric	Mood disorder (panic attacks associated with depression or bipolar disorder) Anxiety disorders (panic attacks associated with social anxiety, specific phobia, posttraumatic stress disorder, generalized anxiety disorder, obsessive compulsive disorder) Agoraphobia Psychotic disorder (panic attacks associated with psychosis) Somatoform disorder Factitious disorder
Cardiac	Myocardial infarction Angina SVT or other arrhythmia Mitral valve prolapse Labile hypertension
Respiratory	Asthma COPD Pulmonary embolus
Neurologic	Seizure disorder Vestibular dysfunction
Endocrine	Thyroid disorder Hypoglycemia Adrenal dysfunction Hyperparathyroidism Pheochromocytoma
Substance Use	Excess caffeine
Substance	Psychostimulants
Substance	Caffeine
Withdrawal	Nicotine Alcohol or sedative Opioid

POSTTRAUMATIC STRESS DISORDER

Method of

Natalie C. Dattilo, PhD

CURRENT DIAGNOSIS

- Posttraumatic stress disorder (PTSD) is quickly becoming one of the most common psychiatric disorders seen in the primary care setting.
- PTSD is diagnosed after a person experiences symptoms for at least 1 month following a traumatic event. However, symptoms may not appear until several months or even years later and can persist as a chronic condition.
- The disorder is characterized by three main types of symptoms: (1) reexperiencing the trauma through distressing recollections, (2) emotional numbness and behavioral avoidance, and (3) increased arousal such as feeling jumpy and easily angered.
- A thorough medical examination and laboratory workup may be indicated to rule out contributing physiologic factors and comorbidities, substance use or misuse, and drug or alcohol withdrawal.
- Symptoms that are persistent, disruptive, or distressing warrant treatment.
- The PTSD Checklist-5 (PCL-5) is a 20-item self-report measure that assesses the 20 *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) symptoms of PTSD. The gold standard for diagnosing PTSD is a structured clinical interview such as the Clinician-Administered PTSD Scale (CAPS-5). When necessary, the PCL-5 can be scored to provide a provisional PTSD diagnosis.

CURRENT THERAPY

- Effective treatments for PTSD include serotonergic antidepressants, certain forms of trauma-based psychotherapy, or a combination of both.
- Educating the patient and family members about treatment options and setting realistic treatment expectations are critical.
- Depending on the patient's preference, treatment may include a selective serotonin reuptake inhibitor (SSRI) starting at low doses with careful titration so as not to exacerbate anxiety or agitation.

- Treatment may also include a trial of cognitive-behavioral therapy, cognitive processing therapy, or prolonged exposure therapy to boost response rates and prevent relapse.
- Refer to or consult with a psychiatrist for patients with severe or particularly complex cases or for patients with a less-than-expected response to treatment.
- Refer to a cognitive-behavioral therapy specialist for patients with a preference for behavioral, skills-based, or nonmedication therapy or for whom pharmacotherapy may be contraindicated.

Epidemiology

In the United States, it is estimated that PTSD is diagnosed in approximately 10.5 million adults (3.5%) each year, and approximately 20.4 million (6.8%) will meet criteria over the course of their lifetimes. The lifetime prevalence of PTSD among men is 3.6% and among women is 9.7%. The 12-month prevalence is 1.8% among men and 5.2% among women. As with depression and anxiety disorders, patients with PTSD are more likely to present initially to a general practitioner's office than to a mental health care provider.

Owing, in part, to increased public awareness, PTSD is quickly becoming one of the most frequently seen clinical problems in primary care. Symptoms frequently overlap with other complaints, such as insomnia, irritability, or pain. Most behavioral symptoms of PTSD are a result of anxiety and hypervigilance, and the clinical presentation shares many phenotypic similarities with other anxiety disorders, such as panic disorder (PD) and generalized anxiety disorder (GAD).

Risk Factors

Risk factors associated with PTSD include exposure to trauma, being female, having lower levels of education and income, being divorced or widowed, having a history of behavioral or psychological problems, family history of behavioral or psychological problems including substance abuse, recent increase in stressful life events, lack or perceived lack of social support, ineffective emotional coping strategies, experiencing childhood adversity or trauma, having a chronic health condition or serious illness, having an acute or chronic pain condition, and substance abuse. Although a genetic predisposition to developing PTSD is likely, environmental stress and early trauma clearly play a role.

Pathophysiology

Our current understanding of PTSD is incomplete; however, several neurobiologic systems have been implicated in the pathophysiology and vulnerability toward developing PTSD after trauma exposure. As in other anxiety disorders, PTSD symptoms are believed to be due to dysregulation of neuronal activity within the central nervous system (CNS), in particular the fear circuit. This dysregulation causes a state of hyperarousal, which gives rise to the physical and emotional manifestations of the condition. Several neurotransmitter systems have been implicated in the genesis of this hyperaroused state. Overstimulation of the CNS and the autonomic sympathetic activity it generates affect the prefrontal cortex and the limbic system (e.g., amygdala, hypothalamus), both of which play an important role in our ability to discern stimuli as aversive or threatening and regulate our stress response.

The two most commonly implicated neurotransmitter systems to date include the serotonergic and noradrenergic neurotransmitter systems. Very simply, it is believed that an underactivation of the serotonergic system and an overactivation of the noradrenergic system are involved. These systems interact with other neuronal circuits in various regions of the brain, including the locus ceruleus (LC) and the limbic structures, resulting in a dysregulation of physiologic arousal and the emotional interpretation of this arousal, respectively. Disruption of the γ -aminobutyric acid (GABA) system has also been implicated because of the response of many of the anxiety-spectrum disorders to treatment with benzodiazepines.

There has also been some interest in the role of corticosteroid regulation and its relation to symptoms of fear and anxiety.

thoughts and beliefs, controlled exposure to fear cues, modification of anxiety-reducing behaviors, and prevention of relapse. Psycho-social interventions, such as CBT, may enhance long-term outcomes by reducing the likelihood of relapse.

Although a genetic predisposition to developing PTSD is likely, environmental stress and early trauma clearly play a role.

Pathophysiology

Our current understanding of PTSD is incomplete; however, several neurobiologic systems have been implicated in the pathophysiology and vulnerability toward developing PTSD after trauma exposure. As in other anxiety disorders, PTSD symptoms are believed to be due to dysregulation of neuronal activity within the central nervous system (CNS), in particular the fear circuit. This dysregulation causes a state of hyperarousal, which gives rise to the physical and emotional manifestations of the condition. Several neurotransmitter systems have been implicated in the genesis of this hyperaroused state. Overstimulation of the CNS and the autonomic sympathetic activity it generates affect the prefrontal cortex and the limbic system (e.g., amygdala, hypothalamus), both of which play an important role in our ability to discern stimuli as aversive or threatening and regulate our stress response.

The two most commonly implicated neurotransmitter systems to date include the serotonergic and noradrenergic neurotransmitter systems. Very simply, it is believed that an underactivation of the serotonergic system and an overactivation of the noradrenergic system are involved. These systems interact with other neuronal circuits in various regions of the brain, including the locus ceruleus (LC) and the limbic structures, resulting in a dysregulation of physiologic arousal and the emotional interpretation of this arousal, respectively. Disruption of the γ -aminobutyric acid (GABA) system has also been implicated because of the response of many of the anxiety-spectrum disorders to treatment with benzodiazepines.

There has also been some interest in the role of corticosteroid regulation and its relation to symptoms of fear and anxiety.

Corticosteroids might increase or decrease the activity of certain neural pathways, affecting not only an individual's behavior under stress but also how the brain perceives and processes threatening stimuli. The stress response is hardwired into the brain and is most often triggered when survival of the organism is threatened. The stress response, however, can be triggered not only by a physical challenge or threat but also by the mere anticipation (or fear) of threat. As a result, when humans chronically and erroneously believe that a threatening event is about to occur, they begin to experience the physical and psychological symptoms of anxiety and panic.

The hypothalamic–pituitary–adrenal (HPA) axis is another neurocircuit implicated in the initiation of a stress response. The HPA axis assists with the adaptation to stress and the maintenance of homeostasis after challenge. It connects the CNS and the endocrine system, and a dysfunctional HPA axis is associated with numerous psychosomatic and psychiatric disorders. Corticotropin-releasing factor (CRF) is a molecule produced by cells in the hypothalamus in response to physical or psychological stress. Increased levels of CRF in the hypothalamus in response to stress results in the activation of the HPA axis and increased release of cortisol. It is believed that high CRF levels at the time of trauma may facilitate encoding of traumatic memory and enduring anxiety effects. Patients with PTSD exhibit increased cerebrospinal fluid levels of CRF and other abnormalities in the HPA axis system.

Finally, a subcortical neural structure, the amygdala, serves an important role in coordinating the cognitive, affective, neuroendocrine, cardiovascular, respiratory, and musculoskeletal components of fear and anxiety responses. It is central to registering the emotional significance of stressful stimuli and creating emotional memories. The amygdala receives input from neurons in the sensory cortex. When activated, the amygdala stimulates regions of the midbrain and brainstem, causing autonomic hyperactivity, which can be correlated with the physical symptoms of anxiety.

Prevention

No biological markers are specific enough yet to detect which individuals are more likely to develop PTSD after experiencing a trauma, and there is no available evidence to suggest that current medications prove efficacious in preventing this disorder. Therefore it is important to screen for specific risk factors, such as exposure to trauma (either recent or remote), family history of mental health issues, recent increase in stressful life events, or substance abuse. If a person is found to be at risk, but not symptomatic, he or she should first be encouraged to adopt healthy lifestyle habits. Aerobic exercise and other forms of physical activity have been shown to relieve stress and anxiety and improve mood relatively quickly. These patients should also be encouraged to avoid stimulants such as caffeine and nicotine, which can exacerbate symptoms and contribute to insomnia. It is also highly recommended that anxiety-prone persons manage stress by learning effective methods of behavioral relaxation, applied meditation, and other healthy stress reduction techniques.

Clinical Manifestations

PTSD can manifest in many ways. Behavioral signs may include increased alcohol consumption, change in communication, change in sexual functioning, emotional outbursts, inability to rest or relax, change in appetite, pacing, suspiciousness, self-destructive behavior, or social isolation. Cognitive signs may include changes in alertness, confusion, hypervigilance, memory problems, poor attention and concentration, poor decision making or problem solving, and suicidal ideation. Emotional signs may include agitation, anxiety, apprehension, depression, fear, feeling overwhelmed, grief, guilt, irritability, and loss of emotional control. Sleep is also affected for individuals suffering from PTSD, and they will often report insomnia or nightmares. Other common features include a sense of emotional detachment from others and unwanted or intrusive thoughts; however, these can be difficult for clinicians to identify and patients rarely self-report. Physical symptoms can include chills, difficulty breathing, dizziness, elevated blood pressure, fainting, fatigue, grinding teeth, headaches, muscle tremors,

nausea, pain, profuse sweating, rapid heart rate, twitches, and weakness. These symptoms cause significant distress and impairment of function.

Diagnosis

A diagnosis of PTSD is made when the patient meets specific diagnostic criteria as outlined in the DSM-5. In previous versions of the DSM, PTSD was categorized as an anxiety disorder. The diagnosis of PTSD now falls under its own category of mental disorders, called “Trauma and Stressor-Related Disorders,” owing to the myriad ways it can present clinically.

PTSD may develop after a person experiences, witnesses, or confronts a physically or psychologically traumatic event. The event may involve actual or threatened death, serious or life-threatening injury or threat of severe injury, or sexual violence or threat of sexual violence. An individual may directly experience the traumatic event; witness, in person, the traumatic event; or learn that the traumatic event occurred to a close family member or close friend. An individual may also develop PTSD after experiencing repeated or extreme exposure to aversive details of the traumatic events. Examples may be first responders collecting human remains or police officers repeatedly exposed to details of child abuse. Note: This does not apply to exposure through electronic media, television, movies, or pictures, unless exposure is work related.

The disorder is characterized by three main types of symptoms: (1) reexperiencing the trauma through distressing recollections, (2) emotional numbness and behavioral avoidance, and (3) increased arousal such as feeling jumpy and easily angered.

A diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when one or more of the following reexperiencing symptoms are present:

- Spontaneous or cued recurrent, involuntary, and intrusive distressing memories of the traumatic events (Note: In children repetitive play may occur in which themes or aspects of the traumatic events are expressed.)
- Recurrent distressing dreams in which the content or affect (i.e., feeling) of the dream is related to the events (Note: In children there may be frightening dreams without recognizable content.)
- Flashbacks or other dissociative reactions in which the individual feels or acts as if the traumatic event is recurring (Note: In children trauma-specific reenactment may occur in play.)
- Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic events
- Physiologic reactions to reminders of the traumatic events

A diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when two or more of the following emotional numbness or behavioral avoidance symptoms are also present:

- Inability to remember an important aspect of the traumatic events (not due to head injury, alcohol, or drugs)
- Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., “I am bad,” “No one can be trusted,” “The world is completely dangerous”)
- Persistent, distorted blame of self or others about the cause or consequences of the traumatic events
- Persistent fear, horror, anger, guilt, or shame
- Markedly diminished interest or participation in significant activities
- Feelings of detachment or estrangement from others
- Persistent inability to experience positive emotions

In addition to reexperiencing and avoidance, a diagnosis of PTSD can be made in adults, adolescents, and children over the age of 6 when two or more of the following marked changes in arousal and reactivity are also present:

- Irritable or aggressive behavior
- Reckless or self-destructive behavior
- Hypervigilance
- Exaggerated startle response
- Problems with concentration
- Difficulty falling or staying asleep or restless sleep

Finally, the diagnosis is made if the symptoms have been present for at least 1 month and cause clinically significant distress or impairment in functioning.

Differential Diagnosis

It is important to perform a thorough medical workup when initially assessing the patient with PTSD symptoms. Differential diagnoses can include several organic causes, such as endocrine dysfunction, intoxication or withdrawal, hypoxia, metabolic abnormalities, and neurologic disorders. It is also important to consider and rule out any cooccurring psychiatric disorders. Major depression with or without suicidality, bipolar disorder, panic disorder, delusional disorder, polysubstance dependence, and adjustment disorder can often accompany PTSD, in addition to relationship problems and difficulty at work or in social situations.

It is not uncommon for patients with PTSD to report chronic pain or present with “ill defined” or “medically unexplained” somatic symptoms such as headaches, dizziness, tinnitus, and blurry vision or medical issues including diabetes, obesity, and cardiovascular, respiratory, musculoskeletal, neurologic, or gastrointestinal problems. Frequently reported medical comorbidities with PTSD across various studies include cardiovascular disease, especially hypertension, and immune-mediated disorders. Because PTSD is associated with limbic dysfunction and alterations in the HPA axis, neuroendocrine and immune function can be significantly disrupted, and because of its impact on the CNS, pseudo-neurologic symptoms and disorders of sleep–wake regulation are also common.

It is also not uncommon for patients with PTSD to “self-medicate” or cope with their symptoms by drinking alcohol, smoking cigarettes, or using drugs, including cannabis and prescription pain medications or anxiolytics. Studies show that people with PTSD have more issues with drugs and alcohol both before and after being diagnosed with PTSD. In addition, having PTSD increases the risk that one will develop a drinking or drug problem, even in the absence of any prior drug or alcohol use.

Treatment and Monitoring

Current practice guidelines for the treatment of PTSD begin with education. Many people are confused, scared, or frustrated by the symptoms and behavior and are reassured to know they are not alone and that there are effective interventions. The patient should receive an appropriate medical workup, including a physical examination and studies (e.g., electrocardiogram, thyroid-stimulating hormone) when indicated. In addition to treating any cooccurring or underlying medical conditions, developing a good working alliance with the patient and family provides a basis for ongoing disease management and prevents unnecessary utilization or overutilization of the medical system, as well as potential exacerbation of symptoms.

A combination of psychotherapy and medication management is recommended as first-line treatment for PTSD. Psychological treatments with the most robust empirical support include trauma-focused psychotherapies utilizing exposure techniques, cognitive restructuring, relaxation/stress modulation training, and psychoeducation.

Cognitive-behavioral therapy (CBT) is the most effective nonmedication treatment for PTSD. The two types of CBT recommended for PTSD are cognitive processing therapy (CPT) and prolonged exposure (PE). In CPT one examines what he or she is thinking and telling him- or herself about the trauma and decides whether those thoughts are accurate or inaccurate. It can be done individually or in a group. PE works through repeated exposure to thoughts, feelings, and situations the person has been avoiding and helps him or her learn that reminders of the trauma do not have to be avoided. PE is done individually with a therapist. Both CPT and PE offer a skills-based approach to treatment. The therapist and patient work collaboratively and in an active and problem-solving manner. The work structured and generally short term with an emphasis on reducing symptoms. Volumes of evidence support

the efficacy of CBT interventions for PTSD, but success requires commitment to treatment on the part of the patient. Its efficacy is also contingent upon the ability of the therapist and the length of time in treatment. Studies show that when compared with patients undergoing monotherapy, patients treated with a combination of CBT and medication experience nearly twice the remission rate.

If combination therapy is initiated owing to symptom severity or patient preference, the SSRIs have been shown to be the best-tolerated class of medications, and response rates are significantly higher than placebo. This class of medication includes fluoxetine (Prozac),¹ fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), paroxetine (Paxil), and sertraline (Zoloft). Some improvement should be noted within 3 or 4 weeks, and the dose should be increased if no improvement is seen. In all cases, SSRIs should be started at low doses and gradually titrated up to therapeutic levels to avoid an initial exacerbation of anxiety or agitation. Pharmacotherapy and psychotherapy options for the treatment of PTSD are presented in [Tables 1A and 1B](#).

Benzodiazepines, which have been commonly used in the past to treat anxiety symptoms, are not recommended except in cases of extreme impairment of function, for short-term use only, and only after a thorough substance abuse history has been obtained. The tolerability and lack of addiction potential make the SSRIs more desirable for long-term management, but the delay in response makes short-term symptom relief with a benzodiazepine desirable for those with the greatest impairment. Because of the risk for rebound anxiety when withdrawing from benzodiazepines with short half-lives, such as alprazolam (Xanax), many prefer the longer-acting benzodiazepines, such as clonazepam (Klonopin).² However, the addiction potential and the potential for abuse with either drug make this the treatment option of last resort.

¹Not FDA approved for this indication.

²Not U.S. Food and Drug Administration (FDA) approved for this indication.

TABLE 1A Pharmacotherapy for the Treatment of Posttraumatic Stress Disorder

DRUG	STARTING DOSE	TARGET DOSE
Selective Serotonin Reuptake Inhibitors		
Paroxetine (Paxil)	10 mg qd	10–60 mg qd
Escitalopram (Lexapro)*	5–10 mg qd	10–20 mg qd
Sertraline (Zoloft)	12.5–25 mg qd	50–200 mg qd
Fluoxetine (Prozac)*	10 mg qd	20–40 mg qd

*Not US Food and Drug Administration approved for this indication.

TABLE 1B Evidence-Based Psychotherapy for the Treatment of Posttraumatic Stress Disorder

PSYCHOTHERAPY	DESCRIPTION	FORMAT
Trauma-Focused Cognitive-Behavioral Therapy (TF-CBT)		
Cognitive processing therapy (CPT)	Teaches you to reframe negative thoughts about trauma	Weekly individual or group meetings
Prolonged exposure (PE)	Teaches you to gain control by facing your fears	Weekly individual meetings

If the patient does not respond to the combination of CBT and medication, a reevaluation of symptoms might reveal a comorbid disorder missed on first examination. Comorbid psychiatric disorders significantly lower the likelihood of recovery from PTSD and increase recurrence rates. Many clinicians try switching between SSRIs before considering the next step in treatment, but a referral to a psychiatrist for further evaluation and management may be necessary if this strategy does not work. Treatment-refractory anxiety can be extremely frustrating for both the patient and clinician. This can lead to increased dependence on benzodiazepines and an escalation of doses required for the same effect.

When approaching the start of therapy, the clinician should reassure the patient that effective treatment is available but that patience may be necessary until the right combination of modalities is found. Although PTSD, like all anxiety disorders, displays a significant amount of chronicity, most patients have an improved outcome with appropriate treatment. Response rates improve when comorbidity is low. Patients with an earlier onset of symptoms (childhood or adolescence) can generally expect a more chronic course and may be more difficult to treat. Occasionally, patients can have a spontaneous remission of symptoms and many can continue to function despite their symptoms. However, time to resolution of symptoms is shortened and overall functioning can improve with treatment.

Pharmacotherapy often helps to prevent relapse, and rates are improved when effective treatment is continued for 12 months. When considering termination of pharmacologic treatment, the risk for relapse in all the disorders should be discussed with the patient. When discontinuing the SSRIs, a slow taper is recommended, with close monitoring for withdrawal symptoms (e.g., headache, gastrointestinal upset, restlessness, and other flu-like symptoms). Also monitor for rebound anxiety symptoms. If relapse occurs, reinstituting treatment is indicated, and many patients opt for indefinite treatment to maintain remission of symptoms. Lifelong management with pharmacotherapy or psychotherapy, or both, is not unusual for many patients. For many, a maximum reduction of symptoms, rather than a full remission, is an acceptable outcome.

Complications

Untreated anxiety disorders can lead to, or worsen, other mental and physical health conditions, including bruxism (teeth grinding), cognitive impairment, depression, gastrointestinal disorders, headache, insomnia, heart disease, substance abuse, and significantly impaired quality of life.

Conclusion

PTSD is a highly prevalent psychiatric condition that can be disabling and costly to the patient and to the health care system. Despite the prevalence of PTSD and other mental health disorders, a high percentage of patients often remain undiagnosed and untreated. These untreated patients also tend to be higher utilizers of general medical care. Patients with PTSD often present with multiple

somatic complaints and comorbid disorders, causing great effort and expense in identifying the cause of unexplained symptoms. Once PTSD is identified, patients may be treated using well-tested and efficacious pharmacologic and psychotherapeutic treatments. Helpful resources for patients and families are listed in Table 2.

SCHIZOPHRENIA

Method of

Brian J. Miller, MD, PhD, MPH; and Peter F. Buckley, MD

CURRENT DIAGNOSIS

- There are three primary symptom domains in schizophrenia:
 - Positive symptoms (i.e., hallucinations, delusions, disorganized thought, and abnormal psychomotor behavior)
 - Negative symptoms (i.e., restricted affect or avolition/asociality)
 - Cognitive symptoms (i.e., attention, language, memory, and processing speed)
- Symptoms last ≥ 1 month and there are continuous signs of illness for ≥ 6 months.
- There is significant impairment one or more major areas of functioning (work, interpersonal relations, or self-care).
- Rule out that psychosis is not due to a primary mood disorder, schizoaffective disorder, substance intoxication or withdrawal, or a general medical condition.

CURRENT THERAPY

- Antipsychotic medication, with monitoring for medication adherence and side effects.
- Adjunctive medications as needed, including antidepressants, mood stabilizers, benzodiazepines, beta-blockers, and anticholinergics.
- Aggressive monitoring for and management of medical comorbidities, substance use disorders, and suicidality, including collaboration with primary care physician.

- Psychosocial interventions.
- Involvement of family/support system in care.
- Long-term treatment, including outpatient medication management and therapy, with inpatient care for acute crisis intervention/illness exacerbation.

Schizophrenia is a complex, chronic, and often severe psychiatric disorder that is a leading cause of disability worldwide. Although the literal translation of the word schizophrenia is “split mind,” patients with this disorder do not have a “split personality” or “multiple personality disorder” (known as dissociative identity disorder). Rather, schizophrenia is a psychotic disorder that interferes with a person’s thinking, mood, behavior, and/or interpersonal relations. Schizophrenia often has devastating, lifelong consequences for affected individuals and their families and is associated with an increased risk of premature mortality, including deaths from suicide and cardiovascular disease. In this chapter, the epidemiology and diagnosis of schizophrenia are reviewed. We then discuss pharmacologic and psychosocial treatments for schizophrenia in the context of a chronic disease model. The risks of medical and substance use comorbidity and suicidality are also highlighted.

Epidemiology and Risk Factors

The etiology of schizophrenia is not known, but it is thought to involve interactions between genetic (or epigenetic) and environmental factors, including developmental problems that occur during gestation. The lifetime prevalence of schizophrenia is approximately 1% and is equal in men and women. The usual age of onset is in the late teens or early 20s to late 30s, although schizophrenia can have onset before age 10 (early onset) or after age 45 (late onset). The age of onset is usually younger for men than women.

Several lines of evidence support a genetic contribution to the risk of schizophrenia. There is a 40% lifetime risk of schizophrenia in a child of two parents with schizophrenia. Twin-twin concordance is 50% in monozygotic twins, and 12% in dizygotic twins. A recent genome-wide association study and meta-analysis found that schizophrenia is significantly associated with single nucleotide polymorphisms in the major histocompatibility complex region on chromosome 6p22.1 (which includes several immunity-related genes, particularly complement C4), although numerous other genes have been implicated. There are likely multiple candidate genes that increase the risk of schizophrenia, each with small effect size.

Replicated environmental risk factors for schizophrenia include season of birth (winter), advanced paternal age, prenatal stress throughout gestation (famine and acute maternal stress in the first trimester, prenatal infections with a myriad of different agents, loss of the father in the second or third trimester), obstetric complications (including gestational diabetes, low birth weight, asphyxia), severe childhood abuse, and cannabis use. It remains unclear whether some of these risk factors are causal to schizophrenia or represent early manifestations of disease.

Diagnosis

There are three primary symptom domains in schizophrenia: positive, negative, and cognitive symptoms. Positive symptoms are abnormalities of thought content, including hallucinations (abnormal sensory perceptions in the absence of external stimuli) and delusions (fixed, false beliefs), formal thought disorder (also called disorganized thinking), and abnormal psychomotor behavior (such as catatonia). Hallucinations are most commonly auditory but can occur in any sensory modality. Negative symptoms include impairments in emotional expression (blunted affect), motivation (avolition), social behavior (asociality), speech (alogia), and the ability to experience pleasure (anhedonia). Cognitive symptoms include impairments in attention, language, memory, processing speed, and executive function.

The most commonly used diagnostic criteria for schizophrenia are derived from the *Diagnostic and Statistical Manual of Mental*

Disorders, Fifth Edition (DSM-5). These criteria include the presence of two or more characteristic symptoms—delusions, hallucinations, disorganized speech, grossly abnormal psychomotor behavior (such as catatonia), or negative symptoms (i.e., restricted affect or avolition/asociality)—for a significant portion of time during a 1-month period (or less if successfully treated), with continuous signs of the disturbance persisting for at least 6 months. At least one of these two characteristic symptoms should include delusions, hallucinations, or disorganized speech. During this period, there is significant impairment in one or more major areas of functioning, including work, interpersonal relations, or self-care. It must also be established that the disorder is not better accounted for by a primary mood disorder, schizoaffective disorder, substance intoxication or withdrawal, or other general medical condition. From these criteria, it is important to note that delusions and hallucinations, although common, are not required for the diagnosis. Furthermore, although cognitive symptoms are also not required for the diagnosis, they are a tremendous cause of illness-related disability. A diagnosis of schizophrenia is most definitively made by interviewing the patient, obtaining collateral history from family and/or friends, and completing a medical workup (physical examination, routine blood and urine tests). According to DSM-5 (released May 2013), the diagnostic criteria no longer identify subtypes of schizophrenia, primarily because of a lack of utility for clinicians. Also of note, the Psychoses Workgroup for DSM-5 considered the addition of “attenuated psychosis syndrome” (i.e., prodromal or high-risk psychosis) as a diagnostic category. Ultimately, attenuated psychosis syndrome is listed in DSM-5 among conditions that require further research before consideration as a formal disorder. Nevertheless, the early identification of individuals with prodromal or high-risk psychosis, investigation of risk factors and biomarkers that might predict conversion to fulminant psychotic disorder, and early interventions for individuals with prodromal or high-risk psychosis are areas receiving significant attention and effort in the field.

Treatment

At present there is no cure for schizophrenia. Although there is significant clinical heterogeneity within the disorder, schizophrenia is usually a chronic condition that requires long-term treatment. Comprehensive treatment involves outpatient medication management and psychotherapy, psychosocial interventions, involvement of the family/support system, inpatient care for acute crisis intervention/illness exacerbation, and collaboration with primary care physicians. Currently, there is a vigorous research effort for diagnostic, prognostic and theranostic biomarkers in schizophrenia, toward a more “personalized medicine” approach for patients.

Antipsychotic medications play an important role in the pharmacologic management of schizophrenia. So-called first-generation antipsychotics (FGAs) have been in clinical use since the introduction of chlorpromazine (Thorazine) in the 1950s. These agents block the dopamine D2 receptor, and common side effects include extrapyramidal side effects (EPS) (e.g., Parkinsonism, dystonia). The newer or “second-generation antipsychotics” (SGAs), in addition to D2 receptor blockade, are also serotonin 5-HT2 receptor antagonists. While the risk of EPS is lower for SGAs than FGAs, SGAs are associated with a heightened risk of weight gain and the metabolic syndrome. [Table 1](#) provides a more detailed description of antipsychotic medications. The Texas Medication Algorithm Project (TMAP) currently recommends a trial of a single (non-clozapine) SGA for newly diagnosed patients with schizophrenia, or patients never before treated with an SGA. However, neither the TMAP nor the American Psychiatric Association (APA) guidelines for the treatment of schizophrenia preferentially endorse a particular antipsychotic. Clozapine (Clozaril) is primarily used for “treatment-refractory” schizophrenia, usually defined as a lack of/partial response to an adequate trial of monotherapy with two or three different antipsychotics.

Adjunctive medications may also play an important role in the pharmacologic treatment of some patients with schizophrenia. These include antidepressants for depression and anxiety, mood

stabilizers for depression or mood elevation, benzodiazepines for anxiety or agitation, beta-blockers for akathisia, and anticholinergics for EPS.

Medication nonadherence is a major treatment issue in patients with schizophrenia at all phases of the illness. Reasons for nonadherence are complex and multifaceted but may include medication side effects, impaired insight into illness, psychopathology in all three symptom domains, lack of efficacy, and comorbid substance use. Over 70% of patients in the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) Schizophrenia Trial

discontinued medication within the first 18 months of treatment. Medication nonadherence leads to dramatically increased risk of illness relapse, hospitalization, and suicidal behavior and should be routinely assessed in clinical visits. The use of rapid-dissolving oral or long-acting injectable medications may improve adherence in some patients.

Psychosocial interventions are also a cornerstone of the comprehensive treatment of patients with schizophrenia, and when utilized in combination with medication, are more effective than antipsychotics alone. Psychotherapy, including cognitive-behavioral

TABLE 1 Antipsychotic Medications

AGENT	MECHANISM OF ACTION*	TYPICAL DOSING	SIDE EFFECTS†	SIDE EFFECTS†	NOTES
First Generation					
Haloperidol (Haldol)	D ₂ -antagonist	1.5–15 mg/day	EPS/TD Akathisia	NMS Hyperprolactinemia	PO, IM, IV, and long-acting injection formulations
Loxapine (Adasuve)	D ₂ -antagonist	10 mg/day	Dysgeusia Sedation	Throat irritation	INH formulation; for treatment of acute agitation
Second Generation					
Aripiprazole (Abilify)	Partial D ₂ -agonist and 5-HT _{2A} antagonist	10–30 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Headache EPS/TD Akathisia	PO, rapid-dissolving PO, IM, and long-acting injection formulations; Transdermal patch system currently in clinical trials
Asenapine (Saphris)	D ₂ -antagonist/5-HT ₂ antagonist	10–20 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Sedation EPS/TD Akathisia	Rapid-dissolving PO formulation
Clozapine (Clozaril)	D ₂ -antagonist/5-HT ₂ antagonist	300–900 mg/day	Weight gain (+++) Dyslipidemia (+++) Glucose dysregulation (++) Agranulocytosis Sedation	Orthostatic hypotension Seizures Myocarditis EPS/TD	PO and rapid-dissolving PO formulations

TABLE 1 Antipsychotic Medications—cont'd

AGENT	MECHANISM OF ACTION	TYPICAL DOSING	SIDE EFFECTS	SIDE EFFECTS	NOTES
Aripiprazole lauroxil (Aristada)	Partial D ₂ agonist and 5-HT _{2A} antagonist	441 mg/month or 882 mg/4–6 weeks	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Headache EPS/TD Akathisia	Long-acting injection formulation
Brexpiprazole (Rexulti)	Partial D ₂ and 5-HT _{1A} agonist and 5-HT ₂ antagonist	1–4 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Increased triglycerides EPS/TD Akathisia	PO formulation
Cariprazine (Vraylar)	Partial D ₂ and D ₃ agonist	1.5–6 mg/day	Weight gain (+) Dyslipidemia (+) Glucose dysregulation (+)	Headache EPS/TD Akathisia	PO formulation

Abbreviations: D₂ = dopamine D₂ receptor; +++, severe risk; EPS = extrapyramidal side effects; 5-HT₂ = serotonin 5-HT₂ receptor; ++ = moderate risk; TD = tardive dyskinesia; + = mild or low risk; NMS = neuroleptic malignant syndrome.

*All first-generation and second-generation antipsychotics have an FDA black box warning for an “association with an increased risk of mortality in elderly patients treated for dementia-related psychosis.” All second-generation agents are D₂ and 5-HT₂ antagonists; however, many act on multiple receptors, including alpha-adrenergic, beta-adrenergic, histaminergic, muscarinic cholinergic, and D₁, and 5-HT₁ receptors.

†EPS and TD are possible side effects with all antipsychotics, but they occur less frequently with second-generation than first-generation drugs.

More frequent assessments may be warranted based on clinical status.

*Including obesity, diabetes, hypertension, and dyslipidemia.

†In all women of childbearing age.

‡For patients taking Ziprasidone (Geodon), which may prolong the QTc interval, and Clozapine (Clozaril).

§For patients taking Clozapine (Clozaril). CBC with differential required at baseline, then weekly for 6 months, then every other week for 6 months, then monthly thereafter. Baseline absolute neutrophil count (ANC) must be $\geq 1500/\text{mm}^3$ (or $\geq 1000/\text{mm}^3$ in patients with benign ethnic neutropenia) due to risk of agranulocytosis.

therapy, supportive therapy, and group therapy, promotes improved illness management and medication adherence. Involvement of the patient's family/support system in care, including family-based therapies and psychoeducation, has been shown to increase medication adherence and decrease illness relapse rates. Psychosocial rehabilitation, which may include assertive community treatment, social skills training, vocational rehabilitation, and cognitive remediation, can help maximize patients' psychosocial functioning. There is growing evidence that cognitive remediation therapy in combination with other psychosocial interventions, particularly vocational rehabilitation, can improve real-world functioning for patients with schizophrenia in a relatively short time period.

Although there is no “typical” patient with schizophrenia, the clinical course is often characterized by acute relapses of the illness

with the inter-episode absence or attenuation of symptoms. Multiple factors increase a patient's risk of illness relapse, including medication nonadherence, psychosocial stressors, substance use, medical illnesses such as infections, and the natural history of the disorder itself. Hospitalization may be required for acute exacerbations of psychotic symptoms, including hallucinations, delusions, and impaired self-care. Hospitalization may also be required if a patient represents an acute danger to self or others.

The concept of the recovery model and recovery-oriented care is a movement that is currently transforming the delivery of mental health services. Integral to the recovery model are certified peer specialists (CPS). A CPS is a licensed professional who has progressed in their own recovery from mental illness and works to assist patients with schizophrenia and other mental illness in regaining control over their own lives and over their own recovery process.

CPSs provide peer support services, serve as consumer advocates, are resources for psychoeducation, and offer the unique perspectives based on their individual experiences.

Comorbidity

Schizophrenia is associated with an increased risk of premature mortality, and cardiovascular disease is a leading cause of death in this patient population. Multiple factors contribute to this risk, including a high prevalence of smoking, poor health habits, poor health care, medication side effects, and (perhaps) the pathophysiology of the disorder itself. SGAs as a class are associated with weight gain and an increased risk of metabolic syndrome. Over 40% of the 1460 patients in the CATIE Schizophrenia Trial met the criteria for metabolic syndrome at baseline. Recommendations for monitoring of patients on SGAs, based on a consensus statement from the American Diabetes Association and the APA, are described in Table 2. Primary care physicians play an important collaborative role with psychiatrists in the detection and management of metabolic disturbances in patients with schizophrenia, in order to minimize the cardiovascular risks associated with these comorbidities.

Patients with schizophrenia are also at an increased risk of suicide, which is also a leading cause of premature mortality. The prevalence of completed suicide in patients with schizophrenia is about 10%, and suicide attempts occur with even greater frequency. Clinicians should routinely assess patients for suicidal ideation and, if present, explore risk factors for completed suicide, which include a suicidal plan and intent, previous suicide attempts, a family history of suicide, age, sex, access to lethal means, social isolation, and comorbid substance use. Medications, psychotherapy, and/or hospitalization may be required.

Comorbid substance use disorders predominate in patients with schizophrenia, with an estimated prevalence of 40% to 50%. Common substances of abuse include alcohol, marijuana, and cocaine. Patients with schizophrenia and comorbid substance use are at increased risk of medication nonadherence, illness relapse, hospitalization, suicidal and violent behavior, and an overall poor response to treatment. Furthermore, up to 70% to 90% of patients with schizophrenia are tobacco users, which contribute to the increased risk of medical comorbidity. Clinicians are encouraged to routinely screen for and address substance use in their treatment plans.

Conclusions

Schizophrenia is a complex, heterogeneous, and chronic psychiatric disorder. Comprehensive treatment usually involves long-term medication management and therapy, education for patients and their families, and psychosocial interventions. Primary care physicians play an important collaborative role in the detection and management of medical comorbidities, substance use disorders, and suicidality. Physicians, patients, and families are encouraged to become involved in the National Alliance on Mental Illness (NAMI; www.nami.org), which is a tremendous resource for help, support, education, and advocacy for patients with schizophrenia and other mental illness.

ACUTE RESPIRATORY FAILURE

Method of

Scott K. Epstein, MD

CURRENT DIAGNOSIS

- History and physical examination can give insight into the etiology of hypoxic and hypercapneic respiratory failure but may be insufficient to make a definitive diagnosis and guide therapy.
- An arterial blood gas is mandatory to define severity and whether hypoxic or hypercapneic (or both) respiratory failure is present.
- Additional diagnostic modalities, including chest radiograph, electrocardiogram, cardiac laboratory tests (troponin, brain natriuretic peptide), echocardiography, and selected use of a pulmonary artery catheter, can help identify a specific etiology.

CURRENT THERAPY

- Treatment of acute respiratory failure often begins with non-specific approaches such as oxygen and mechanical ventilation (noninvasive or invasive).
- The goal of mechanical ventilation is to improve gas exchange and rest the respiratory muscles while waiting for the beneficial effects of specific therapy aimed at the underlying cause (e.g., bronchodilators, antibiotics, and corticosteroids in acute exacerbations of chronic obstructive pulmonary disease [COPD]).
- Noninvasive ventilation avoids many complications associated with invasive ventilation and improves outcomes for patients with acute cardiogenic pulmonary edema and acute exacerbations of COPD.
- Invasive mechanical ventilation can be lifesaving but can cause clinical deterioration if not properly administered.
- Using low tidal volumes (6 mL/kg ideal body weight) can help avoid dangerous dynamic hyperinflation in acute exacerbations of COPD and further lung injury in acute lung injury (e.g., volutrauma, barotrauma).
- Once signs of improvement are evident, focus rapidly shifts to liberating the patient from the ventilator using spontaneous breathing trials to assess the need for ventilatory support followed by airway assessment to determine readiness for extubation.

The respiratory system serves many complex physiologic functions, the most important of which is gas exchange. Using the interface between the alveolar space and capillaries, O₂ is taken up and CO₂ is eliminated. Acute respiratory failure, a life-threatening entity, is present when this system fails, over the course of minutes to hours, resulting in hypoxemia (type I) or hypercapnia (type II), or both. Most patients with acute respiratory failure present with dyspnea, although the correlation with disease severity is poor. Indeed, dyspnea might seem mild in those with baseline chronic respiratory failure, and it might be absent in those with an underlying neurologic process (e.g., drug overdose). Other symptoms

and signs such as cough, chest pain, orthopnea, fever, tachypnea, rales, and wheezing are insensitive and nonspecific.

This chapter outlines the general pathophysiology and therapeutic approach to acute respiratory failure by using the examples of three common entities: acute lung injury (ALI), cardiogenic pulmonary edema (congestive heart failure [CHF]), and acute exacerbation of chronic obstructive pulmonary disease (COPD).

Definitions and Pathophysiology

Acute Hypoxic Respiratory Failure

Hypoxic respiratory failure is conventionally defined as an arterial oxygen tension (Pao₂) of less than 60 mm Hg. Because this definition ignores the inspired fraction of oxygen (Fio₂), some favor a Pao₂/Fio₂ ratio of less than 300. To account for the arterial CO₂ tension (Paco₂), others favor an alveolar–arterial (A–a) O₂ gradient greater than 250 mm Hg, using the equation

$$\begin{aligned} A - a \text{ O}_2 \text{ gradient} &= \text{PAO}_2 - \text{Pao}_2 \\ &= (713 \times \text{Fio}_2) - (\text{PAO}_2 + \text{Paco}_2/0.8) \end{aligned}$$

where 713 is the barometric pressure (760) minus the water vapor pressure. A normal A–a O₂ is less than 10 mm Hg, but this threshold value increases with age. The determination of Pao₂ requires an invasive test, an arterial blood gas. Oxygenation can be continuously monitored noninvasively by pulse oximetry, which provides an estimate of arterial oxygen saturation (Sao₂). In general, an Sao₂ of 0.90 corresponds to a Pao₂ of 60 mm Hg, but the relation depends on temperature, pH, Paco₂, and 2,3-diphosphoglycerate (2,3-DPG). Accuracy is adversely affected by low perfusion states, dark skin pigmentation, nail polish, dyshemoglobins (e.g., carboxyhemoglobin, methemoglobin), intravascular dyes, motion, and ambient light.

Clinicians tend to focus on Pao₂ and Sao₂, but the real parameter of interest is O₂ delivery (Do₂) to organs and tissues. Do₂ depends on cardiac output and O₂ carrying capacity of arterialized blood (Cao₂):

$$\text{Do}_2 = \text{CO} \times \text{Cao}_2$$

where

$$\text{Cao}_2 = k(\text{Hb} \times \text{Sao}_2) + 0.003 \text{ Pao}_2$$

where *k* is a constant. Do₂ decreases when cardiac output or hemoglobin is reduced despite a normal Pao₂ and Sao₂. The peripheral response to reduced Do₂ is an increased O₂ extraction ratio (O₂ER), allowing oxygen uptake (V̇O₂), an indicator of metabolic demand, to remain constant. Cellular and organ dysfunction occurs when Do₂ and O₂ER are outstripped by metabolic demand. The balance between Do₂ and demand can be estimated by examining the mixed venous O₂ saturation (Mvo₂) using the rearranged Fick equation:

$$\text{Mvo}_2 = \text{Sao}_2 - (\dot{\text{V}}\text{O}_2 / \text{CO} \times \text{Hb})$$

When Mvo₂ falls below 65% to 75%, imbalance is present.

When cellular injury is present, extraction capabilities are limited and cellular hypoxia occurs despite “adequate” Do₂. Under these circumstances, the Mvo₂ can be paradoxically normal. These parameters can be determined using a pulmonary artery catheter. The data obtained may be useful in individual patients, but

TABLE 1 Pathophysiologic Mechanisms of Acute Hypoxic Respiratory Failure

MECHANISM	A–a O ₂ GRADIENT	Paco ₂	RESPONSE TO 100% O ₂	CAUSE
Diffusion abnormality	↑	↑ Normal	↑↑	Severe interstitial lung disease
Hypoventilation	Normal	↑	↑↑↑	Narcotic overdose, obesity hypoventilation syndrome, respiratory muscle weakness
↓ Fio ₂	Normal	Usually ↓	↑↑↑	High altitude, smoke inhalation
↓ Mvo ₂	↑	Usually ↓	↑	ALI, shock, CHF, PE
Shunt	↑	Usually ↓	None or ↑	ALI, CHF, atelectasis, PE
\dot{V}/\dot{Q} mismatch	↑	↑, Normal, ↓	↑↑↑	Acute exacerbation of COPD, asthma, PE

Abbreviations: ↑ = increased; ↓ = decreased; A–a O₂ = alveolar–arterial O₂; ALI = acute lung injury; CHF = cardiogenic pulmonary edema; COPD = chronic obstructive pulmonary disease; Fio₂ = fraction of inspired oxygen; Mvo₂ = mixed venous oxygen saturation; Paco₂ = partial pressure of arterial CO₂; PE = pulmonary embolism; \dot{V}/\dot{Q} = ventilation–perfusion ratio.

randomized, controlled trials show no benefit when the pulmonary artery catheter is used routinely to guide therapy.

The pathophysiologic mechanisms of type I respiratory failure are listed in [Table 1](#). The most common mechanism is ventilation–perfusion (\dot{V}/\dot{Q}) mismatch, characterized by a widened A–a O₂ gradient, a dramatic increase in Pao₂ in response to supplemental O₂, and a variable Paco₂. When areas of low \dot{V}/\dot{Q} predominate (e.g., reduced ventilation with normal perfusion), the Paco₂ may be low as the patient hyperventilates in an effort (only partially effective) to increase the Pao₂. When areas of high \dot{V}/\dot{Q} predominate, much ventilation is wasted, and hypercapnia is also present. Areas of lung that are perfused but not ventilated characterize shunt. The resulting fall in Pao₂ depends on the percentage of cardiac output circulating through the shunt and the O₂ content of that blood. Supplemental O₂ has minimal or small effect on Pao₂ because the shunted blood is not exposed to the increased Fio₂. Therefore, treatment is aimed at decreasing shunt by improving ventilation to the affected area or reducing perfusion to that area. When shunt results from a unilateral process (e.g., pneumonia, atelectasis), placing the good lung down decreases shunt perfusion, and oxygenation improves.

Acute Hypercapneic Respiratory Failure

Hypercapneic respiratory failure is defined as a Paco₂ greater than 45 mm Hg. The equation used to determine Paco₂ provides insight into the three basic mechanisms underlying hypercapnia:

$$\text{Paco}_2 = k(\dot{V} \text{ CO}_2)/V_E(1 - V_D/V_T)$$

where k is a constant, V_E is total minute ventilation (respiratory rate times tidal volume) and V_D/V_T is the dead space. Therefore, hypercapnia can result from increased CO₂ production ($\dot{V} \text{ CO}_2$), increased physiologic dead space (V_D/V_T), and decreased minute ventilation ([Box 1](#)). Increased $\dot{V} \text{ CO}_2$ alone is usually insufficient

to cause hypercapnia because the respiratory system responds by increasing minute ventilation to keep Paco₂ normal (37–43 mm Hg). Conversely, with abnormalities of respiratory muscle function or respiratory drive or with increased dead space (and diminished reserve), the respiratory response to increased $\dot{V} \text{ CO}_2$ may be insufficient, and hypercapnia results.

Treatment

Treatment of acute hypoxemic and hypercapneic respiratory failure combines nonspecific (e.g., supplemental O₂, mechanical ventilation) and specific therapy ([Boxes 2](#) and [3](#)).

Oxygen Therapy

In the hospital, 100% O₂ is supplied from a wall source with a regulator determining flow rate in liters per minute. The final delivered

oxygen concentration (F_{IO_2}) depends on this flow rate and the amount of room air breathed by the patient. The O_2 flow rate is almost never sufficient to meet all of the patient's ventilatory demands, so varying amounts of room air are entrained to meet these needs. The final inspired oxygen concentration depends on the relative fraction of each gas, total minute ventilation, and the pattern of breathing (including the inspiratory-to-expiratory ratio). O_2 may be administered using nasal prongs, a facial mask, or high-flow devices designed to deliver higher F_{IO_2} (Table 2).

In hypercapnic patients (e.g., with acute exacerbation of COPD), high-flow O_2 can lead to worsening hypercapnia and acute respiratory acidosis. The mechanisms are multifactorial: worsening V/Q matching (increased dead space), decreased intracellular binding of CO_2 , and minute ventilation inadequate for the amount of CO_2 produced. Therefore, the goal in these patients is to

achieve a P_{aO_2} of 55 to 60 mm Hg (S_{aO_2} 88%–90%) with low-flow oxygen (~24%–28% O_2). If this (often delicate) balance between maintaining tissue oxygenation and avoiding significant respiratory acidosis cannot be achieved, short-term mechanical ventilation may be required. In most nonhypercapnic patients, high flow of oxygen (50%–100%) can be administered safely for 24 hours with a goal P_{aO_2} of between 65 and 80 mm Hg.

Mechanical Ventilation

Mechanical ventilation can be delivered noninvasively through a tight-fitting face mask or invasively via an endotracheal tube. The goals of mechanical ventilation are to correct severe arterial blood gas abnormalities, provide respiratory support while specific therapy is used, and unload and rest the respiratory muscles. The ventilator should be set to optimize patient-ventilator interaction and avoid dynamic hyperinflation and intrinsic positive end-expiratory pressure (PEEPi). PEEPi can worsen gas exchange, predispose to barotrauma, and cause hypotension.

Noninvasive Ventilation

Noninvasive ventilation is most commonly applied as continuous positive airway pressure (CPAP), when airway pressure is kept constant throughout the respiratory cycle, or by bilevel positive airway pressure (BiPAP), when inspiratory pressure support actively assists each inspiration. Noninvasive ventilation offers numerous advantages over invasive ventilation, including increased comfort; maintenance of normal swallowing, speech, and cough; less need for sedation; and avoiding the trauma of intubation.

The effective application of noninvasive ventilation starts with carefully explaining the procedure to the patient, followed by selection of a proper-fitting face mask. The mask is placed close to the face to acclimate the patient to high inspiratory flow. The mask is then secured using straps (but not too tightly), and ventilator settings are adjusted to minimize leaks and ensure comfort. The patient is reassessed frequently. Failure to improve within 2 to 4 hours (e.g., reduction in dyspnea, respiratory rate, accessory muscle use, and hypercapnia) signals noninvasive ventilation failure and need for intubation.

Noninvasive ventilation improves outcome (avoids intubation, decreases length of stay, improves survival) in a number of conditions (Table 3). Although randomized, controlled trials show dramatic benefit in acute exacerbation of COPD (AECOPD), other studies show no or uncertain benefit in community acquired pneumonia, acute respiratory distress syndrome (ARDS), pulmonary fibrosis, and routinely after planned extubation. One mechanism for improved outcome is the reduction in infection (pneumonia,

TABLE 2 Short-Term Oxygen Delivery Systems

DELIVERY SYSTEM	O_2 FLOW RATE (L/min)	F_{IO_2} RANGE	COMMENTS
Basic Systems			
Nasal cannula (prongs)	1–6	0.22–0.40	Comfortable Facilitates communication and oral intake Humidification required at high flow rates
Simple masks	5–6	0.30–0.50	Mask acts as reservoir to increase F_{IO_2} High flow combats CO_2 rebreathing Less comfortable Must be removed to facilitate communication and oral intake Easily displaced with movement
Reservoir Masks			
Nonrebreathing	4–10	0.60–1.00	One-way valve between the mask and the reservoir bag Inspired O_2 from wall source and reservoir bag
Partial rebreathing	5–10	0.35–0.90	Lacks one-way valve
Venturi masks	4–10	0.24–0.40	Uses Bernoulli principle (fixed amount of entrained room air added to O_2) Maximum delivered F_{IO_2} can be controlled Often used in COPD to avoid excessive F_{IO_2} and risk for hypercapnia

Abbreviations: COPD = chronic obstructive pulmonary disease; F_{IO_2} = fraction of inspired oxygen.

TABLE 3 Efficacy of Noninvasive Ventilation in Various Conditions

CONDITION	QUALITY OF EVIDENCE	COMMENT
AECOPD	Strong	↓ Need for intubation ↑ Survival
Acute cardiogenic pulmonary edema	Strong	↓ Need for intubation ↑ Survival
Hypoxemic respiratory in ICH with diffuse pulmonary infiltrates	Strong	↓ Need for intubation ↑ Survival
Facilitating weaning in select patients	Strong	↓ Duration of intubation Most effective in AECOPD
High risk for extubation failure	Strong	↓ Need for reintubation
Extubation failure in heterogeneous patient population	Moderate	Not effective, two RCTs
Routinely after extubation	Moderate	Not effective, single RCT
Extubation failure in AECOPD	Moderate	Single case-control study
Type I RF, diffuse infiltrates, not ICH	Moderate	↓ Need for intubation
Asthma	No RCTs	Probably effective in ↓ need for intubation
Obesity hypoventilation	No RCTs	Probably effective in ↓ need for intubation
Postoperative respiratory failure	Small RCTs	Probably effective in ↓ need for reintubation
Do not intubate patients	Observational studies	Most effective with CHF, COPD
Pulmonary fibrosis	Observational studies	Not effective

Abbreviations: AECOPD = acute exacerbation of chronic obstructive pulmonary disease; CHF = cardiogenic pulmonary edema; COPD = chronic obstructive pulmonary disease; FiO_2 = fraction of inspired oxygen; ICH = immunocompromised host; RCT = randomized, controlled trial; RF = respiratory failure.

sepsis) seen with noninvasive ventilation compared with intubated patients. Noninvasive ventilation should not be used in the presence of respiratory arrest, shock, excessive secretions, inability to protect the airway, an agitated or uncooperative patient, and facial abnormalities that preclude proper application of the mask.

Invasive Ventilation

Invasive mechanical ventilation is delivered via an endotracheal tube. The set parameters include FiO_2 and positive end-expiratory pressure (PEEP). For volume-assist control, the clinician chooses respiratory rate and tidal volume. For pressure support, the clinician chooses the inspiratory pressure level above PEEP, and the patient determines respiratory rate. The resulting tidal volume depends on inspiratory pressure level and patient factors including respiratory muscle strength and respiratory system mechanics. Initially the ventilator is set to meet most of the patient's minute ventilation, allowing respiratory muscle rest. Such full support should not be prolonged because diaphragmatic dysfunction can result. Most patients require sedation, but excessive sedation levels are associated with worse outcomes. Therefore, strategies to minimize continuous intravenous sedation using a sedation protocol or once-daily interruption of sedation are recommended.

Invasive mechanical ventilation, especially when prolonged, is associated with numerous complications including ventilator-associated pneumonia, sinusitis, airway injury, thromboembolism, and gastrointestinal bleeding. Therefore, once significant clinical improvement occurs, efforts should focus on rapidly removing the patient from the ventilator. This is achieved by daily screening for readiness (Box 4) followed by a 30- to 120-minute spontaneous breathing trial on minimal or no ventilator support. Patients tolerating the spontaneous breathing trial are extubated if they have a good cough, manageable respiratory secretions, and an adequate mental status to protect the airway. Approximately 25% of patients do not tolerate the spontaneous breathing trial; they should be returned to full ventilator support for 24 hours and undergo careful evaluation for reversible causes. The clinician should consider a more gradual approach to weaning these patients.

BOX 4

Screening Criteria to Assess Readiness to Undergo a Trial of Spontaneous Breathing

Required Criteria

$\text{PaO}_2/\text{FiO}_2 \geq 150$ or $\text{Sao}_2 \geq 90\%$ or $\text{FiO}_2 \leq 40\%$ and $\text{PEEP} \leq 5$ cm H₂O
Absence of hypotension

Additional Criteria (optional criteria)

Weaning parameters*

- Negative inspiratory force < -20 to -25 cm H₂O
- Respiratory rate (f) ≤ 35 breaths/min
- Spontaneous tidal volume (V_T) > 5 mL/kg
- $f/V_T < 105$ breaths/L/min

Absence of significant anemia (e.g., Hb ≥ 8–10 mg/dL)

Absence of fever (e.g., core temperature ≤ 38.5°C)

Adequate mental status: patient awake and alert or easily aroused

*Recent studies indicate that these parameters are often unnecessary in deciding whether to initiate trials of spontaneous breathing.

Abbreviations: Hb = hemoglobin; PEEP = positive end-expiratory pressure.

Specific Causes of Acute Respiratory Failure

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Patients with COPD can experience two or three exacerbations per year, especially if they are actively smoking; this results in 500,000 hospitalizations every year in the United States. Hospital mortality ranges from 2% to 11%, rising to 25% for those requiring critical care.

AECOPD is defined by increased sputum volume, purulence, and dyspnea. Physical examination is notable for tachypnea, use of accessory respiratory muscles, diminished breath sounds, prolonged expiratory phase with wheezing, thoraco-abdominal paradox (inward inspiratory abdominal motion), and Hoover's sign (inward inspiratory motion of the lower rib cage). The latter two physical signs indicate the presence of dynamic hyperinflation

and diaphragmatic dysfunction. AECOPD is further characterized by hypoxemia (resulting from V/Q mismatch) and hypercapnia. Patients with more severe underlying disease might demonstrate evidence of acute and chronic respiratory acidosis.

Etiology and Diagnosis

Approximately 50% of AECOPDs result from bacterial infection (e.g., *Pneumococcus* species, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Pseudomonas* species). The remainder result from viral infection and air pollution. In many cases a cause cannot be identified, although there is increasing appreciation that acute myocardial infarction and pulmonary embolism may be present in up to 25%. Pulmonary embolism may be suggested by a $Paco_2$ lower than baseline and the need for a higher than expected Fio_2 to maintain the Sao_2 at greater than 90%. Computed tomographic pulmonary arteriogram is recommended to make the diagnosis, because V/Q scanning is nondiagnostic in nearly half of COPD patients, and false-positive high-probability scans occur.

Treatment

Treatment for AECOPD is based on high-quality evidence consisting of numerous randomized, controlled trials and well-performed meta-analyses. Bronchodilator therapy is essential. Nebulized combination therapy (albuterol and ipratropium [DuoNeb]) is effective, but it is not demonstrably superior to single-agent therapy delivered via a metered-dose inhaler. Theophylline should generally be avoided because toxicity outweighs benefits.

Antibiotics improve outcome, especially in the presence of fever and increased sputum purulence and volume. Older agents, such as amoxicillin and tetracycline, appear to be less effective than newer macrolides and fluoroquinolones.

Corticosteroids enhance β -agonist activity and counteract the inflammatory state seen in AECOPD. Oral prednisone at a dose of 30 to 40 mg is recommended. Intravenous therapy (methylprednisolone [SoluMedrol] 125 mg every 6 hours for 72 hours followed by oral prednisone) should be used in the critically ill patient or when response to oral therapy is suboptimal.

There is no role for mucolytic agents or chest physiotherapy.

Admission to the intensive care unit (ICU) is indicated for patients with hemodynamic instability, confusion, lethargy and coma, severe dyspnea unresponsive to emergency management, or severely abnormal gas exchange despite initial therapy ($Pao_2 < 40$ mm Hg, $Paco_2 > 60$ mm Hg, pH < 7.25).

Randomized, controlled trials demonstrate that noninvasive ventilation decreases the risk for intubation and improves survival in AECOPD when there are severe dyspnea, hypoxemia, tachypnea, and significant respiratory acidosis ($Paco_2 > 45$ mm Hg and pH < 7.35). Patients who fail noninvasive ventilation or who are not candidates require intubation and mechanical ventilation.

A major risk is the development of dynamic hyperinflation (PEEPi), which can worsen gas exchange, predispose to barotrauma (e.g., pneumothorax), and cause hypotension. PEEPi is minimized by keeping delivered minute ventilation at 5 L/min or less; this is achieved by lowering tidal volume (e.g., 6 mL/kg ideal body weight) or respiratory rate (8–10 breaths/min), or by increasing inspiratory flow rate, allowing more time for expiration. PEEPi is suggested by an elevated plateau pressure or persistent expiratory flow at the time of the next ventilator breath. PEEPi can also increase work of breathing by increasing the patient's inspiratory effort to trigger the ventilator. When extrinsic PEEP is at or just below the PEEPi level, the patient triggers more easily and work of breathing is reduced.

The approach to weaning and extubation in AECOPD is similar to that for other conditions, although the risk of failing a spontaneous breathing trial is increased.

Acute Lung Injury and Acute Respiratory Distress Syndrome

ALI is the result of an acute process and is characterized by hypoxemia ($Pao_2/Fio_2 < 300$), bilateral diffuse alveolar infiltrates, and no evidence of cardiac etiology. When the Pao_2/Fio_2 is less than 200, the patient is said to have ARDS. ALI results from pulmonary and

extrapulmonary etiologies. Pulmonary causes include pneumonia, gastric aspiration, near drowning, toxic gas inhalation, and lung contusion. Extrapulmonary causes include sepsis, pancreatitis, fat embolism, drug overdose, nonthoracic trauma, and massive transfusion. Conditions that can mimic the clinical findings of ALI include CHF, diffuse alveolar hemorrhage (DAH), acute cryptogenic organizing pneumonia (COP), and acute eosinophilic pneumonia (AEP). These latter three entities can be diagnosed by bronchoscopy (DAH, AEP) or by open lung biopsy (COP), all are treated with high doses of corticosteroids. Studies indicate that corticosteroids do not improve the outcome of ALI/ARDS.

Differentiating cardiogenic pulmonary edema from ALI can be challenging, especially because these conditions can coexist. Physical findings of jugular venous distention and a positive third heart sound, abnormal electrocardiogram (ECG), elevated brain natriuretic peptide (BNP), and positive cardiac enzymes (troponin) point to a cardiac etiology. A chest radiograph showing cardiomegaly, vascular redistribution, widened vascular pedicle, perihilar alveolar infiltrates, and pleural effusions also suggests a cardiac cause. Bedside echocardiography can demonstrate reduced left ventricular function. A pulmonary artery catheter provides definitive evidence of an elevated pulmonary capillary wedge pressure and reduced cardiac output. That said, recent randomized, controlled trials demonstrate no improvement in survival with routine use of the pulmonary artery catheter in ALI.

ALI causes heterogeneous effects in the lung, resulting in poorly ventilated, atelectatic, dependent regions of lung. Traditional tidal volumes of 10 to 15 mL/kg can cause lung injury by creating significant shear stress by repeatedly opening these atelectatic areas (atelectrauma) and overdistending less affected areas (volutrauma, barotrauma). Indeed, experimental and clinical studies demonstrate that a lung-protective strategy, using a tidal volume of 6 mL/kg ideal body weight, improves survival in ALI. Using small tidal volumes often results in significant hypercapnia, which can have an independent protective effect (permissive hypercapnia). The application of PEEP recruits and opens atelectatic lung, thereby reducing harmful shear forces. The optimal level of PEEP remains uncertain: Recent multicenter studies found no difference in mortality in patients randomized to high (~ 14 cm H₂O) or low (~ 8 cm H₂O) PEEP when all patients received a tidal volume of 6 mL/kg ideal body weight.

Cardiogenic Pulmonary Edema

CHF occurs in patients with cardiomyopathy or acutely when ischemia is present. Diagnosis is suggested by jugular venous distension, a third heart sound, diffuse rales, abnormal ECG, and a chest radiograph showing cardiomegaly, diffuse alveolar infiltrates, and bilateral pleural effusion. A markedly elevated BNP or pro-BNP further suggests a cardiac etiology.

Therapy consists of oxygen, nitrates, diuretics, afterload reduction, and anti-ischemic therapy if the history or ECG is suggestive. Mechanical ventilation produces positive intrathoracic pressure, which improves cardiac function by decreasing both left ventricular preload and afterload, reversing hypoxemia, and decreasing work of breathing. In hemodynamically stable patients without active ischemia, CPAP at levels of 8 to 12 cm H₂O should be used. A meta-analysis of 15 randomized, controlled trials showed that noninvasive ventilation decreased the need for intubation and improved survival. CPAP and BiPAP appear to be equivalent, although many prefer BiPAP when hypercapnia is present.

Because cardiogenic pulmonary edema is rapidly reversible, intubated patients can often be extubated within 24 hours. That said, the transition from positive pressure ventilation to negative ventilation (e.g., T-piece or extubation) can precipitate pulmonary edema.

ASTHMA IN ADOLESCENTS AND ADULTS

Method of

Michael Schatz, MD, MS; and Matthew A. Rank, MD

CURRENT DIAGNOSIS

- Confirm the diagnosis by demonstrating an increase in FEV₁ by 12% or more after asthma therapy.
- Assess past severity by a history of exacerbations requiring hospitalization, intubation, or oral corticosteroids.
- Identify environmental exposures, allergic sensitization, and comorbidities that may be aggravating asthma.
- Assess current severity in patients not taking long-term control medications and assess control in patients who are taking long-term control medications based on symptom frequency, nocturnal awakenings, rescue therapy use, activity limitation, spirometry, and recent exacerbation history.

Abbreviation: FEV₁ = forced expiratory volume in 1 second.

CURRENT THERAPY

- Nonpharmacologic therapy includes asthma education (especially regarding inhaler technique, self-monitoring, and self-management), reduction in environmental triggers, addressing any relevant psychosocial issues, and immunotherapy for select patients.
- Preferred step therapy for long-term asthma management is (in order): low-dose inhaled corticosteroids; medium-dose inhaled corticosteroids or low-dose inhaled corticosteroids plus long-acting β -agonists; medium-dose inhaled corticosteroids plus long-acting β -agonists; high-dose inhaled corticosteroids plus long-acting β -agonists; high-dose inhaled corticosteroids plus long-acting β -agonists plus long-acting muscarinic antagonists; asthma biologics; and oral prednisone.
- Asthma exacerbations should be treated with high-dose inhaled β -agonists and early use of systemic corticosteroids.

Asthma is an extremely common chronic medical condition that causes substantial morbidity among its sufferers. In addition to discomfort, asthma can cause sleep disruption, missed school and work, limitations of recreational activities, and acute episodes requiring emergency hospital care. Although the past 30 years have seen the introduction of increasingly effective and convenient medications, recent surveys continue to suggest that asthma remains

suboptimally controlled in a substantial proportion of patients. The purpose of this article is to describe an approach to assessment and therapy that leads to optimal asthma control. It is based on the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma (<http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf>) but includes recommendations that stem from studies published since this guideline was released.

Diagnosis

The first step in evaluating a patient with asthma is to confirm the diagnosis. This is particularly important in patients with atypical symptoms or a poor response to asthma therapy. Asthma is confirmed by the demonstration of reversible airways obstruction, which most commonly is an increase in forced expiratory volume in 1 second (FEV₁) by 12% or more and at least 200 cc after an inhaled bronchodilator. For some patients, 2 to 4 weeks of chronic inhaled asthma therapy or 2 weeks of oral corticosteroid therapy is necessary to demonstrate reversibility. The latter is particularly important in adults with a history of smoking in whom chronic obstructive pulmonary disease (COPD) is a diagnostic consideration. In patients with normal pulmonary function, asthma can also be confirmed by means of methacholine (Provocholine) or exercise challenge. In addition, an elevated fractional exhaled nitric oxide (FENO >50 ppb) is consistent with a diagnosis of asthma.

Particularly important masqueraders of asthma include vocal cord dysfunction, panic attacks, hyperventilation, and cough due to postnasal drip, reflux, or angiotensin-converting enzyme (ACE) inhibitor therapy. All of these can also coexist with asthma, so their presence does not exclude asthma. Even when these conditions coexist with asthma, their diagnosis and appropriate therapy usually reduce the patient's respiratory symptoms.

Assessment

Assessment of asthmatic patients involves assessment of past severity, identification of aggravating factors, and definition of current status regarding treatment and clinical severity or control.

Past Severity

Asthma can be a mild, infrequent illness or a daily severe one. Certain severity markers identify patients who are more likely to experience severe exacerbations or to have symptoms that are more difficult to control and who thus require more careful surveillance. These include histories of asthma hospitalization, especially requiring intensive care or intubation, past requirement for oral corticosteroids, and exacerbation by aspirin or other NSAIDs. In patients with prior severe exacerbations, the rapidity of the onset of the exacerbation should be ascertained.

Aggravating Factors

Factors that appear to trigger asthma symptoms should be assessed because they may be targets for avoidance therapy. Certain aspects of the patient's environment that can contribute to asthma triggering should be specifically ascertained, including occupational exposures, age of the home, pets, carpeting, visible mold, passive smoke, and cockroach exposure. Patients with persistent asthma should have in vitro or skin tests to identify allergic sensitization to pollens, house dust mites, mold spores, animal dander, and cockroaches that can contribute to the maintenance of asthma inflammation or can trigger episodes. The presence of comorbidities that can aggravate asthma, including cigarette smoking, obesity, rhinitis, sinusitis, reflux, and COPD, should be identified and treated. Finally, psychosocial factors to assess include a history or symptoms of anxiety or depression, attitudes toward asthma and asthma therapy, adherence to therapy, and social support. These may be targets for therapy or may be necessary to understand in order to create an effective therapeutic plan and therapeutic alliance.

Current Status

Assessment of the current therapy the patient is actually taking is necessary for understanding the asthma's severity and to

Finally, psychosocial factors to assess include a history or symptoms of anxiety or depression, attitudes toward asthma and asthma therapy, adherence to therapy, and social support. These may be targets for therapy or may be necessary to understand in order to create an effective therapeutic plan and therapeutic alliance.

Current Status

Assessment of the current therapy the patient is actually taking is necessary for understanding the asthma's severity and to

TABLE 1 Classifying Asthma Severity and Initiating Treatment in Patients 12 Years and Older Not Currently Taking Long-Term Control Medications

COMPONENTS OF SEVERITY	CLASSIFICATION OF SEVERITY*			
	INTERMITTENT	PERSISTENT		
		MILD	MODERATE	SEVERE
Impairment				
Symptoms	≤2 d/wk	>2 d/wk but not daily	Daily	Throughout the d
Nighttime awakenings	≤2 ×/mo	3–4 ×/mo	>1 ×/wk but not nightly	Often 7 ×/wk
Short-acting β ₂ -agonist use for symptom control (not prevention of EIB)	≤2 d/wk	>2 d/wk but not daily, and not more than 1 time on any d	Daily	Several times per d
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function [†]	Normal FEV ₁ between exacerbations FEV ₁ >80% predicted FEV ₁ /FVC normal	FEV ₁ >80% predicted FEV ₁ /FVC normal	FEV ₁ >60% but <80% predicted FEV ₁ /FVC reduced 5%	FEV ₁ <60% predicted FEV ₁ /FVC reduced >5%
Risk				
Exacerbations requiring oral systemic corticosteroids	0–1/y [‡]	<div>≥2/y[‡]</div> <div>←————→</div> <div>Consider severity and interval since last exacerbation.</div> <div>Frequency and severity may fluctuate over time for patients in any severity category.</div> <div>Relative annual risk of exacerbation may be related to FEV₁.</div>		
Recommended Steps for Initiating Treatment [§]				
Initiation	Step 1	Step 2	Step 3	Step 4 or 5
Follow-up	In 2–6 wk, evaluate level of asthma control and adjust therapy accordingly.			

Abbreviations: EIB = exercise-induced bronchospasm; FEV₁ = forced expiratory volume in one second; FVC = forced vital capacity; ICU = intensive care unit.

Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

*Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and spirometry.

Assign severity to the most severe category in which any feature occurs.

[†]See Table 3 for normal FEV₁/FVC.

[‡]At present, there are inadequate data to correlate frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

[§]See Table 6 for treatment steps. The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

^{||}And consider short course of oral systemic corticosteroids.

appropriately initiate or change therapy. It is particularly important to determine if the patient is taking long-term control medications, such as inhaled corticosteroids, long-acting β-agonists, leukotriene modifiers, theophylline, or long-acting muscarinic antagonists. If the patient is not taking controllers, severity should be assessed, as described in Table 1, based on symptom frequency, nocturnal awakenings, rescue therapy use, activity limitation, spirometry, and exacerbation history. If the patient is already taking controllers, control should be assessed (Table 2). Normal FEV₁/FVC (forced vital capacity) by age is shown in Table 3.

Long-Term Management

The goals of long-term management are to achieve and maintain well-controlled asthma. Both nonpharmacologic and pharmacologic therapy must be considered.

Nonpharmacologic Therapy

The first tenet of nonpharmacologic therapy in the long-term management of asthma is education. Patients need to understand the inflammatory pathophysiology of asthma and the relationships among airway inflammation, bronchospasm, and symptoms. Patients should be informed that the cause of asthma is unknown and there is no cure, but that triggers can be identified and asthma can be controlled. They should receive education regarding self-assessment, either based on symptoms or peak flow monitoring,

and regarding the recognition of early signs of an impending exacerbation.

The next step is to discuss and agree on the goals of therapy. The NAEPP has defined the following goals:

- Prevent chronic and troublesome daytime and nighttime symptoms.
- Maintain optimal pulmonary function for that patient.
- Maintain normal activity, including work, school, leisure activity, and exercise.
- Prevent recurrent exacerbations, especially those requiring urgent medical visits.
- Provide pharmacotherapy with minimal or no adverse effects.
- Achieve patient and family satisfaction with asthma care.

The physician should let the patient know that these are the expectations of optimal management and confirm that those are the patient's goals as well.

A very important component of nonpharmacologic therapy is reduction of relevant environmental triggers. Information should be given regarding environmental control of pollen, mite, mold, animal dander, and cockroach antigens (Box 1) that appear to be relevant based on the history and results of skin or in vitro specific IgE tests. Inhalant allergen immunotherapy should be considered for patients who have persistent asthma when there is clear evidence of a relationship between symptoms and exposure to an allergen to which the patient is sensitive.

TABLE 2 Assessing Asthma Control and Adjusting Therapy in Patients 12 Years and Older

COMPONENTS OF CONTROL	CLASSIFICATION OF CONTROL*		
	WELL CONTROLLED	NOT WELL CONTROLLED	VERY POORLY CONTROLLED
Impairment			
Symptoms	≤2 d/wk	>2 d/wk	Throughout the d
Nighttime awakenings	≤2 ×/mo	1–3 ×/wk	≥4 ×/wk
Short-acting β ₂ -agonist use for symptom control (not prevention of EIB)	≤2 d/wk	>2 d/wk	Several times per d
Interference with normal activity	None	Some limitation	Extremely limited
FEV ₁ or peak flow	>80% predicted or personal best	60%–80% predicted or personal best	<60% predicted or personal best
Validated Questionnaires†			
ACQ	≤0.75‡	≥1.5	N/A
ACT	≥20	16–19	≤15
ATAQ	0	1–2	3–4
Risk			
Exacerbations requiring oral systemic corticosteroids	0–1/y	≥2/y§	
Progressive loss of lung function	Evaluation requires long-term follow-up care.		
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control, but it should be considered in the overall assessment of risk.		
Recommended action for treatment	Maintain current step	Step up 1 step and reevaluate in 2–6 wk	Consider short course of systemic oral corticosteroids
	Regular follow-up at every 1–6 mo to maintain control	For side effects, consider alternative treatment options	Step up 1–2 steps and reevaluate in 2 wk
	Consider step down if well controlled for ≥3 mo		For side effects, consider alternative treatment options

Abbreviations: ACQ = Asthma Control Questionnaire; ACT = Asthma Control Test; ATAQ = Asthma Therapy Assessment Questionnaire; EIB = exercise-induced bronchospasm; FEV₁ = forced expiratory volume in one second; N/A = not applicable.

Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

*The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

[†]Validated questionnaires for the impairment domain (the questionnaires do not assess the risk domain). Minimal important difference: 0.5 for the ACQ, 1.0 for the ATAQ and 3.0 for the ACT.

[‡]ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

[§]At present, there are inadequate data to correlate frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

^{||}See Table 6 for treatment steps. The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs. Before a step up in therapy, review adherence, inhaler technique, environmental control, and comorbid conditions. If an alternative treatment option was used in a step, discontinue it and use the preferred treatment for that step.

TABLE 3 Normal FEV₁/FVC by Age

AGE RANGE (y)	NORMAL FEV ₁ /FVC (%)
8–19	85
20–39	80
40–59	75
60–80	70

Abbreviations: FEV₁ = forced expiratory volume in one second; FVC = forced vital capacity.

Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

Finally, psychosocial issues should be considered and addressed. For many patients, the education and therapeutic alliance described earlier adequately addresses psychosocial concerns. For other patients, poor past adherence requires identifying the barriers to adherence and finding solutions together. Resources

for patients with poor social support should be identified. Clinically significant anxiety or depression that can make asthma harder to control should be treated.

Pharmacologic Step Therapy

The main principle of asthma pharmacologic step therapy is to add therapy in steps until control is achieved (step up) and decrease therapy in reverse steps (step down) to establish the lowest effective dose necessary to maintain control.

There are two types of asthma medications: quick-relief medications (Table 4) and long-term control medications (Table 5). Systemic corticosteroids can be used either short-term to treat an exacerbation (see Table 4) or as long-term maintenance therapy for patients with severe disease (see Table 5). The generally recommended steps of pharmacologic therapy are shown in Table 6. Definitions of low-, medium-, and high-dose inhaled corticosteroids for each of the available preparations are given in Table 7. At each therapeutic step level, the NAEPP Expert Panel has indicated preferred medications, which generally identify medications with the best balance of efficacy and safety in clinical trials for patients at

Allergens

Reduce or eliminate exposure to the allergen(s) the patient is sensitive to:

Animal Dander

- Remove animal from house or, at a minimum, keep animal out of the patient's bedroom and keep the bedroom door closed.

Dust Mites

- Recommended
 - Encase mattress in a special dust-proof cover
 - Encase pillow in a special dust-proof cover or wash it weekly in hot water.
 - Wash sheets and blankets on the patient's bed in hot water weekly. Water must be hotter than 130°F to kill the mites. Cooler water used with detergent and bleach can also be effective.
- Desirable
 - Reduce indoor humidity to 60% or less.
 - Remove carpets from the bedroom.
 - Avoid sleeping or lying on cloth-covered cushions or furniture.
 - Remove carpets that are laid on concrete.

Cockroaches

- Keep all food out of the bedroom.
- Keep food and garbage in closed containers.
- Use poison baits, powders, gels, or paste (e.g., boric acid). Traps can also be used.
- If a spray is used to kill cockroaches, stay out of the room until the odor goes away.

Pollens (from Trees, Grass, or Weeds) and Outdoor**Molds**

- Try to keep windows closed
- If possible, stay indoors, with windows closed, during periods of peak pollen exposure, which are usually during the midday and afternoon.

Indoor Mold

- Fix all leaks and eliminate water sources associated with mold growth.
- Clean moldy surfaces.
- Dehumidify basements if possible.

Tobacco smoke

- Advise patients and others in the home who smoke to stop smoking or to smoke outside the home.
- Discuss ways to reduce exposure to other sources of tobacco smoke, such as from daycare providers and the workplace.

Indoor and Outdoor Pollutants and Irritants

- If possible, do not use a wood-burning stove, kerosene heater, fireplace, unvented gas stove, or heater.
- Try to stay away from strong odors and sprays, such as perfume, talcum powder, hair spray, paints, new carpet, or particle board.

Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

that level of severity. However, these recommendations are based on population data and must be tailored to individual patient needs, circumstances, and responsiveness to therapy.

All patients with asthma should have an action plan that describes their pharmacologic self-management. Aspects of pharmacologic self-management include the maintenance medication schedule, rescue therapy doses for increased symptoms, when and how to increase controller medication therapy, when and how to use prednisone, how to recognize a severe exacerbation,

and when and how to seek urgent or emergency care. Controller medications should be increased with an upper respiratory infection or with symptoms requiring more than two doses of rescue therapy in 12 hours. Although doubling the dose of inhaled corticosteroids does not appear to generally be sufficient to provide clinical benefit under these circumstances, greater increases may be effective (e.g., fourfold increases). The increased dose of controller medications should be maintained at least until increased symptoms resolve. Prednisone is usually needed for patients with incomplete or temporary responses to adequate doses of β -agonists (4 puffs with a spacer, waiting at least 1 minute between puffs), substantial interference with sleep every night, requirement for 12 or more puffs of β -agonist in a 24-hour period, or a peak flow less than 60% predicted. Home treatment of exacerbations is further discussed later.

For patients not on long-term control medications, assess severity and select the level of treatment that corresponds to the patient's level of severity (see Table 1). Persistent asthma is most effectively controlled with daily long-term control medications, specifically antiinflammatory therapy. For patients receiving long-term control medications, identify their current step of therapy, based on what they are actually taking (see Table 6), and their level of control (see Table 2). In general, step up one step for patients whose asthma is not well controlled. For patients with very poorly controlled asthma, consider increasing by two steps, a course of oral corticosteroids, or both. Before increasing pharmacologic therapy, consider adverse environmental exposures, poor adherence, poor inhaler technique, or comorbidities as targets for intervention. For patients with troublesome or debilitating side effects from asthma therapy, explore a change in therapy.

Follow-up

Patients whose asthma is not controlled should be seen every 2 to 6 weeks (depending on their initial level of severity or control) until control is achieved. Once control is achieved, follow-up contact at 1- to 6-month intervals is recommended. These checkups should ensure continued control, identify other changes in the patient's status, and update the patient's action plan.

When well-controlled asthma has been maintained for at least 3 months, a step down in therapy can be considered to determine the minimum amount of medication required to maintain control or reduce the risk of side effects. Reduction in therapy should be gradual because asthma can deteriorate at a highly variable rate and intensity. Doses of inhaled corticosteroids may be reduced about 25% to 50% every 3 months to the lowest dose possible to maintain control. Many patients with persistent asthma relapse if inhaled corticosteroids are totally discontinued.

Patients should be encouraged to contact their asthma physician for signs of loss of asthma control, such as nocturnal symptoms, increasing β -agonist use, or activity limitation. Consultation with an asthma specialist is recommended if the patient has difficulties achieving or maintaining control of asthma, immunotherapy or an asthma biologic is being considered, the patient requires step 4 care or higher, or the patient has had an exacerbation requiring hospitalization.

Treatment of Exacerbations

Asthma exacerbations are acute or subacute episodes of progressively worsening shortness of breath, cough, wheezing, or chest tightness associated with decreases in expiratory airflow.

Home Management

Patients' action plans should direct their home therapy of asthma exacerbations according to the following recommendations.

Initial therapy should be with inhaled short-acting β -agonists (2–6 puffs by metered-dose inhaler [MDI] or nebulizer). This may be repeated in 20 minutes. With a good response (minimal or no symptoms and peak expiratory flow (PEF) $\geq 80\%$ predicted or personal best), the patient may continue β -agonists every 3 to 4 hours for 24 to 48 hours. If repeated β -agonists are needed, a short course of oral corticosteroids should be considered.

TABLE 4 Usual Dosages for Quick-Relief Medications for Patients 12 Years and Older

MEDICATION	DOSAGE FORM	ADULT DOSE	COMMENTS
Inhaled Short-Acting β_2-Agonists (SABA)			
<i>Metered-Dose Inhaler</i>		<i>Applies to all three SABAs</i>	
Albuterol HFA (Proventil, Ventolin, ProAir)	90 μ g/puff, 200 puffs/canister	2 puffs 5 min before exercise	An increasing use or lack of expected effect indicates diminished control of asthma.
Albuterol RespiClick (ProAir)	90 μ g/puff, 200 puffs/canister	or 2 puffs q4–6h prn	Not recommended for long-term daily treatment. Regular use exceeding 2 d/wk for symptom control (not prevention of EIB) indicates the need for additional long-term control therapy.
Levalbuterol HFA (Xopenex)	45 μ g/puff, 200 puffs/canister		Differences in potencies exist, but all products are essentially comparable on a per-puff basis. May double usual dose for mild exacerbations. For levalbuterol, should prime the inhaler by releasing 4 actuations prior to use. For HFA, periodically clean HFA activator, as drug may block/plug orifice. Nonselective agents (epinephrine [Primatene Mist], isoproterenol [Isopro Aerometer], metaproterenol [Alupent]) are not recommended due to their potential for excessive cardiac stimulation, especially in high doses.
<i>Nebulizer Solutions</i>			
Albuterol (Accuneb, Proventil)	0.63 mg/3 mL 1.25 mg/3 mL 2.5 mg/3 mL 5 mg/mL (0.5%)	1.25–5 mg in 3 mL saline q4–8h prn	May mix with budesonide (Pulmicort) inhalant suspension, cromolyn (Intal) or ipratropium (Atrovent) nebulizer solutions. May double the dose for severe exacerbation.
Levalbuterol (R-albuterol) (Xopenex)	0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/0.5 mL 1.25 mg/3 mL	0.63 mg–1.25 mg q8h prn	Compatible with budesonide (Pulmicort) inhalant suspension. The product is a sterile-filled, preservative-free, unit-dose vial.
Anticholinergics			
<i>Metered-Dose Inhalers</i>			
Ipratropium HFA (Atrovent)	17 μ g/puff, 200 puffs/canister	2–3 puffs q6h	Multiple doses in the emergency department (not hospital) setting provide additive benefit to short-acting beta agonists. Treatment of choice for bronchospasm due to β -blocker. Does not block EIB. Reverses only cholinergically mediated bronchospasm; does not modify reaction to antigen. May be alternative for patients who do not tolerate short-acting beta-agonist. Evidence is lacking for ipratropium producing added benefit to β_2 agonists in long-term control asthma therapy.
Ipratropium with albuterol (Combivent) ¹	18 μ g/puff of ipratropium bromide and 90 μ g/puff of albuterol, 200 puffs/canister	2–3 puffs q6h	
<i>Nebulizer Solutions</i>			
Ipratropium bromide	0.2 mg/mL (0.2%)	0.5 mg q6h	
Ipratropium bromide with albuterol (DuoNeb) ¹	0.5 mg/3 mL ipratropium bromide and 2.5 mg/3 mL albuterol	3 mL q4–6h	Contains EDTA to prevent discoloration of the solution. This additive does not induce bronchospasm.
Systemic Corticosteroids			
Methylprednisolone (Medrol)	2, 4, 6, 8, 16, 32 mg tab	Short course (burst): 40–60 mg/d as single or 2 divided doses for 3–10 d	Short courses (bursts) are effective for establishing control when initiating therapy or during a period of gradual deterioration. Action may be begun within an hour. The burst should be continued until symptoms resolve. This usually requires 3–10 d but can require longer. There is no evidence that tapering the dose following improvement prevents relapse in asthma exacerbations.
Prednisolone (Delta-Cortef, Prelone)	5 mg tabs; 5 mg/5 mL, 15 mg/5 mL		
Prednisone (Deltasone, Orasone)	1, 2.5, 5, 10, 20, 50 mg tabs; 5 mg/mL, 5 mg/5 mL		
<i>Repository Injection</i>			
Methylprednisolone acetate (Depo-Medrol)	40 mg/mL 80 mg/mL	240 mg ^{3,*} IM once	May be used in place of a short burst of oral steroids in patients who are vomiting or if adherence is a problem.

Abbreviations: CFC = chlorofluorocarbon; EDTA = edetic acid; EIB = exercise-induced bronchospasm; HFA = hydrofluoroalkane; PEF = peak expiratory flow; tab = tablet. Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

*80–120 mg per package insert.

TABLE 5 Usual Dosages for Long-Term Control Medications for Patients 12 Years and Older

MEDICATION	DOSAGE FORM*	ADULT DOSE	COMMENTS
Systemic Corticosteroids			
Methylprednisolone (Medrol)	2, 4, 8, 16, 32 mg tab	7.5–60 mg qd in a single dose in AM or qod as needed for control	For long-term treatment of severe persistent asthma, administer single dose in AM either daily or on alternate days (alternate-day therapy may produce less adrenal suppression).
Prednisolone (Delta-Cortef, Prelone)	5 mg tab 5 mg/5 mL, 15 mg/5 mL	Short-course (burst) to achieve control, 40–60 mg/d as single or 2 divided doses for 3–10 d	Short courses (bursts) are effective for establishing control when initiating therapy or during a period of gradual deterioration. There is no evidence that tapering the dose following improvement in symptom control and pulmonary function prevents relapse.
Prednisone (Deltasone, Orasone)	1, 2.5, 5, 10, 20, 50 mg tab 5 mg/mL, 5 mg/5 mL		
Inhaled Long-Acting β_2-Agonists			Should not be used for relief of acute symptoms or exacerbations. Use only with ICS.
Salmeterol (Serevent)	DPI 50 μ g/inhalation	1 inhalation q12h	Decreased duration of protection against EIB may occur with regular use.
Inhaled Combined Medications			
Fluticasone and salmeterol (Advair)	DPI 100 μ g/50 μ g, 250 μ g/50 μ g, or 500 μ g/50 μ g HFA 45 μ g/21 μ g 115 μ g/21 μ g 230 μ g/21 μ g	1 inhalation bid [†]	100/50 DPI or 45/21 HFA for patients not controlled on low-to-medium dose ICS.
		2 puffs bid [†]	250/50 DPI or 115/21 HFA for patients not controlled on medium-to-high dose ICS.
Fluticasone and salmeterol (AirDuo and generic)	Respiclick 55 μ g/14 μ g 113 μ g/14 μ g 232 μ g/14 μ g	1 inhalation bid	
Budesonide and formoterol (Symbicort)	HFA MDI 80 μ g/4.5 μ g 160 μ g/4.5 μ g	2 inhalations bid [†]	80/4.5 for patients not controlled on low-to-medium dose ICS.
			160/4.5 for patients not controlled on medium-to-high dose ICS.
Mometasone and formoterol (Dulera)	100 μ g/5 μ g 200 μ g/5 μ g	2 inhalations bid [†]	100/5 for patients not controlled on low-to-medium dose ICS 200/5 for patients not controlled on medium-to-high dose ICS
Fluticasone furoate/vilanterol trifenate (Breo Elipta)	100 μ g/25 μ g 200 μ g/25 μ g	1 inhalation daily	
Inhaled Long-acting Anticholinergic			
Tiotropium (Spiriva Respimat)	12.5 μ g/actuation	2 puffs daily	May be as effective as LABA as add-on therapy to ICS.
Leukotriene Modifiers			
Leukotriene Receptor Antagonists			
Montelukast (Singulair)	4 mg or 5 mg chewable tab 10 mg tab	10 mg qhs	Montelukast exhibits a flat dose-response curve. Doses >10 mg do not produce a greater response in adults.
Zafirlukast (Accolate)	10 or 20 mg tab	40 mg/d (20 mg tab bid)	For zafirlukast: Administration with meals decreases bioavailability; take at least 1 h before or 2 h after meals. Zafirlukast is a microsomal p450 enzyme inhibitor that can inhibit the metabolism of warfarin. Doses of this drug should be monitored accordingly. Monitor for signs and symptoms of hepatic dysfunction.
5-Lipoxygenase Inhibitor			
Zileuton (Zyflo)	600 mg tab	2400 mg daily (600 mg qid)	Monitor hepatic enzymes (ALT). Zileuton is a microsomal p450 enzyme inhibitor that can inhibit the metabolism of warfarin and theophylline. Doses of these drugs should be monitored accordingly.

Continued

TABLE 5 Usual Dosages for Long-Term Control Medications for Patients 12 Years and Older—cont'd

MEDICATION	DOSAGE FORM	ADULT DOSE	COMMENTS
Methylxanthines			
Theophylline (Slophyllin, Theobid, TheoDur)	Liquids, sustained-release tab, cap	Starting dose 10 mg/kg/d up to 300 mg max Usual max 800 mg/d	Adjust dosage to achieve serum concentration of 5–15 µg/mL at steady-state (≥48 h on same dosage). Due to wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is essential. Patient should be told to discontinue if they experience symptoms of toxicity. Various factors (diet, food, febrile illness, age, smoking, and other medications) can affect serum concentration.
Asthma biologics			
Omalizumab (Xolair)	Subcutaneous (SQ) injection 150 mg/1.2 mL following reconstitution with 1.4 mL sterile water for injection	150–375 mg SQ every 2–4 wk, depending on body weight and pretreatment serum IgE level	Do not administer more than 150 mg per injection site. Monitor patient following injections; be prepared and equipped to identify and treat anaphylaxis that may occur. Whether patients will develop significant antibody titers to the drug with long-term administration is unknown.
Benralizumab (Fasenra)	Solution 30 mg/1 mL	30 mg SQ every 4 weeks for first 3 doses, then every 8 weeks	For 12 years and older with eosinophilic asthma
Mepolizumab (Nucala)	Subcutaneous powder for solution: 100 mg	100 mg SQ every 4 weeks	For 12 years and older with eosinophilic asthma Monitor patient following injections; be prepared and equipped to identify and treat anaphylaxis that may occur.
Reslizumab (Cinqair)	Intravenous solution 10 mg/1 mL	3 mg/kg over 20–50 minutes every 4 weeks	For adults with eosinophilic asthma

Abbreviations: ALT = alanine aminotransferase; amp = ampule; cap = capsule; DPI = dry powder inhaler; EIB = exercise-induced bronchospasm; HFA = hydrofluoroalkane; ICS = inhaled corticosteroid; LABA = long-acting β₂-agonist; max = maximum; MDI = metered-dose inhaler; SABA = short-acting β₂-agonist; tab = tablet.

Data from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

*See Table 7 for estimated comparative daily dosages for inhaled corticosteroids.

†Dose depends on level of severity or control.

TABLE 6 Stepwise Approach for Managing Asthma in Patients 12 Years and Older*

STEP	PREFERRED THERAPY	ALTERNATIVE THERAPY
1	Short-acting β-agonist prn	—
2	Low-dose ICS	LTRA, theophylline
3	Low-dose ICS <i>plus</i> LABA or Medium-dose ICS	Low-dose ICS <i>plus</i> LTRA <i>or</i> theophylline <i>or</i> zileuton (Zyflo) <i>or</i> tiotropium (Spiriva) ¹
4	Medium-dose ICS <i>plus</i> LABA	Medium-dose ICS <i>plus</i> LTRA <i>or</i> theophylline <i>or</i> zileuton (Zyflo) <i>or</i> tiotropium (Spiriva Respimat)
5	High-dose ICS <i>plus</i> LABA Consider omalizumab (Xolair) for patients who have allergies and benralizumab (Fasenra), mepolizumab (Nucala), or reslizumab (Cinqair) for patients who have eosinophilic asthma	—
6	High-dose ICS <i>plus</i> LABA <i>plus</i> oral corticosteroid [†] Consider omalizumab for patients who have allergies and benralizumab (Fasenra), mepolizumab (Nucala), or reslizumab (Cinqair) for patients who have eosinophilic asthma	—

Abbreviations: ICS = inhaled corticosteroid; LABA = long-acting β agonist; LTRA = leukotriene receptor antagonist.

Data updated from the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3: Guidelines for the Management of Asthma.

¹Not FDA approved for this indication.

*The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.

[†]In step 6, before oral corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, zileuton, or tiotropium may be considered, although this approach has not been studied in clinical trials.

With an incomplete response to initial therapy (persistent wheezing and dyspnea and PEF 50% to 79% predicted or personal best), oral corticosteroids should be added, β-agonists should be repeated, and the clinician should be contacted that day.

With a poor response (marked wheezing and dyspnea at rest, PEF <50% predicted or personal best), oral corticosteroids should

be added, the β-agonist should be repeated immediately, and the patient should call the clinician and usually proceed to the emergency department. For signs of severe distress (e.g., difficulty talking in full sentences, diaphoresis, drowsiness, confusion, or cyanosis), 911 should be called. Patients with histories of rapid-onset severe exacerbations should have self-injectable epinephrine

TABLE 7 Estimated Comparative Daily Dosages for Inhaled Corticosteroids for Patients 12 Years and Older

DRUG	DOSAGE FORM	DAILY DOSE		
		LOW (µg)	MEDIUM (µg)	HIGH (µg)
Beclomethasone HFA (QVAR)	40 or 80 µg/puff	80–240	>240–480	>480
Budesonide DPI (Pulmicort)	90 or 180 µg/inhalation	180–540	>540–1080	>1080
Ciclesonide (Alvesco)	80 or 160 µg/actuation	160–320	>320–640	>640
Flunisolide HFA (AeroSpan)	80 µg/puff	320	>320–640	>640

(Adrenaclick, Auvi-Q, EpiPen)¹ at home to use at the onset of increased symptoms.

Emergency Department and Hospital Management

Assessment should rapidly determine the severity of the exacerbation based on intensity of symptoms, signs (heart rate, respiratory rate, use of accessory muscles, chest auscultation), peak flow (unless the patient is too dyspneic to perform), and pulse oximetry. Treatment should begin immediately following recognition of an exacerbation severe enough to cause dyspnea at rest, peak flow less than 70% predicted or personal best, or pulse oximetry oxygen saturation less than 95%. While treatment is being given, a brief, focused history and physical examination pertinent to the exacerbation can be obtained.

In patients with mild to moderate exacerbations (PEF >40% predicted), initial therapy is oxygen to achieve oxygen saturation greater than 90% and inhaled short-acting β -agonist by nebulizer or MDI (4–8 puffs) with holding chamber, which may be repeated up to three times in the first hour. Oral corticosteroids (prednisone 40–80 mg) are recommended if there is no immediate response to therapy or if the patient had been recently treated with oral corticosteroids.

In patients with severe exacerbations (PEF <40% predicted), initial therapy is oxygen as above, inhaled high-dose short-acting β -agonist (e.g., albuterol 5 mg) and ipratropium (0.5 mg) by nebulizer, and oral or intravenous corticosteroids (prednisone or methylprednisolone 80 mg). The albuterol may be repeated every 20 minutes or used continuously for 1 hour.

Repeated assessments of symptoms, signs, PEF, and oxygen saturation determine the responsiveness of the exacerbation to therapy. Such assessments should be made in patients presenting with severe exacerbations after the initial bronchodilator treatment and in all patients after three doses of bronchodilator therapy (60–90 min after initial treatment). In patients who are improving, short-acting β -agonists may be repeated every hour until a good response is achieved (no distress, PEF >70%). When this response is sustained at least 60 minutes after the last treatment, the patient may usually be discharged on a course of oral corticosteroids (generally prednisone 40–60 mg for 5–10 days), initiation or continuation of medium-dose inhaled corticosteroids, and arrangement for outpatient follow-up.

In patients who are not improving with the above therapy, adjunctive therapy, such as with intravenous magnesium sulfate¹ (2 g) or heliox, may be considered. Intubation and mechanical ventilation may be required for patients with respiratory failure in spite of treatment.

Summary

Asthma is a very common problem with the potential to cause substantial interference with quality of life. Although there is no cure

for asthma, asthma can be well controlled in the majority of patients with proper management and an effective patient-physician relationship. I hope that the method described herein for assessing and managing asthma will help physicians help their patients achieve well-controlled asthma.

ATELECTASIS

Method of

Alykhan S. Nagji, MD; Joshua S. Jolissaint, MD; and Christine L. Lau, MD

CURRENT DIAGNOSIS

- Hypoxia
- Tachypnea
- Diminished breath sounds
- Wheezing
- Radiologic signs of atelectasis

CURRENT THERAPY

- Chest percussion or vibration
- Nasotracheal or bronchoscopic suctioning
- Incentive spirometry
- Positive-pressure ventilation
- Ambulation
- Postoperative pain control

Atelectasis refers to the collapse of alveoli that affects segmental or lobar regions of the lung or the entire lung and results in hypoventilation. However, recent studies have suggested that the alveoli are not collapsed but are filled with fluid and foam. These hypotheses are not mutually exclusive; collapsed alveoli and fluid- and foam-filled alveoli may be present concurrently in an atelectatic lung. Although atelectasis is considered a benign condition, early treatment, reversal, and prevention are essential to an overall improved outcome.

Etiology

Compression Atelectasis

Compression atelectasis occurs when the transmural pressure distending the alveolus is reduced to a level that allows the alveolus to collapse. To best illustrate this mechanism, consider the patient

(Adrenaclick, Auvi-Q, EpiPen)¹ at home to use at the onset of increased symptoms.

Emergency Department and Hospital Management

Assessment should rapidly determine the severity of the exacerbation based on intensity of symptoms, signs (heart rate, respiratory rate, use of accessory muscles, chest auscultation), peak flow (unless the patient is too dyspneic to perform), and pulse oximetry. Treatment should begin immediately following recognition of an exacerbation severe enough to cause dyspnea at rest, peak flow less than 70% predicted or personal best, or pulse oximetry oxygen saturation less than 95%. While treatment is being given, a brief, focused history and physical examination pertinent to the exacerbation can be obtained.

In patients with mild to moderate exacerbations (PEF >40% predicted), initial therapy is oxygen to achieve oxygen saturation greater than 90% and inhaled short-acting β -agonist by nebulizer or MDI (4–8 puffs) with holding chamber, which may be repeated up to three times in the first hour. Oral corticosteroids (prednisone 40–80 mg) are recommended if there is no immediate response to therapy or if the patient had been recently treated with oral corticosteroids.

In patients with severe exacerbations (PEF <40% predicted), initial therapy is oxygen as above, inhaled high-dose short-acting β -agonist (e.g., albuterol 5 mg) and ipratropium (0.5 mg) by nebulizer, and oral or intravenous corticosteroids (prednisone or methylprednisolone 80 mg). The albuterol may be repeated every 20 minutes or used continuously for 1 hour.

Repeated assessments of symptoms, signs, PEF, and oxygen saturation determine the responsiveness of the exacerbation to therapy. Such assessments should be made in patients presenting with severe exacerbations after the initial bronchodilator treatment and in all patients after three doses of bronchodilator therapy (60–90 min after initial treatment). In patients who are improving, short-acting β -agonists may be repeated every hour until a good response is achieved (no distress, PEF >70%). When this response is sustained at least 60 minutes after the last treatment, the patient may usually be discharged on a course of oral corticosteroids (generally prednisone 40–60 mg for 5–10 days), initiation or continuation of medium-dose inhaled corticosteroids, and arrangement for outpatient follow-up.

In patients who are not improving with the above therapy, adjunctive therapy, such as with intravenous magnesium sulfate¹ (2 g) or heliox, may be considered. Intubation and mechanical ventilation may be required for patients with respiratory failure in spite of treatment.

Summary

Asthma is a very common problem with the potential to cause substantial interference with quality of life. Although there is no cure

for asthma, asthma can be well controlled in the majority of patients with proper management and an effective patient-physician relationship. I hope that the method described herein for assessing and managing asthma will help physicians help their patients achieve well-controlled asthma.

ATELECTASIS

Method of

Alykhan S. Nagji, MD; Joshua S. Jolissaint, MD; and Christine L. Lau, MD

CURRENT DIAGNOSIS

- Hypoxia
- Tachypnea
- Diminished breath sounds
- Wheezing
- Radiologic signs of atelectasis

CURRENT THERAPY

- Chest percussion or vibration
- Nasotracheal or bronchoscopic suctioning
- Incentive spirometry
- Positive-pressure ventilation
- Ambulation
- Postoperative pain control

Atelectasis refers to the collapse of alveoli that affects segmental or lobar regions of the lung or the entire lung and results in hypoventilation. However, recent studies have suggested that the alveoli are not collapsed but are filled with fluid and foam. These hypotheses are not mutually exclusive; collapsed alveoli and fluid- and foam-filled alveoli may be present concurrently in an atelectatic lung. Although atelectasis is considered a benign condition, early treatment, reversal, and prevention are essential to an overall improved outcome.

Etiology

Compression Atelectasis

Compression atelectasis occurs when the transmural pressure distending the alveolus is reduced to a level that allows the alveolus to collapse. To best illustrate this mechanism, consider the patient

¹Not FDA approved for this indication.

who has undergone induction of anesthesia. The diaphragm is relaxed and is displaced cephalad. In the supine position, the pleural pressures increase to the greatest extent in the dependent lung regions and can compress the adjacent lung tissue.

Surfactant Impairment

Surfactant serves to reduce the alveolar surface tension, thereby stabilizing the alveoli and preventing collapse. Reduction in surfactant occurs with certain types of anesthesia. Studies have shown that hyperinflation by means of increased tidal volume, sequential air inflations to the total lung capacity, or even a single cycle of increased tidal volume can increase the release of surfactant, aiding in recruitment and stabilization of alveoli.

Gas Resorption

One mechanism by which gas resorption results in atelectasis involves the patent airway. In regions of the lung with increased ventilation compared to perfusion, which produces a ventilation/perfusion (V/Q) mismatch, there is low alveolar oxygen tension. Increasing the fraction of inspired oxygen (F_{IO_2}) initiates a cascade of events that increases alveolar oxygen tension (PAO_2) and decreases alveolar nitrogen tension (PAN_2), which results in loss of alveolar volume secondary to increased absorption of oxygen.

Another mechanism by which gas resorption leads to atelectasis occurs after complete airway occlusion. In such cases, gas is trapped distal to the obstruction. Gas uptake by the proximal blood flow continues without additional gas inflow. This causes the alveoli to collapse.

Pathophysiology

The trapping of air and hyperinflation of the alveoli are produced from the aforementioned mechanisms. The gases that are trapped are absorbed by the blood perfusing through that region of the lung, which eventually causes collapse of the alveoli. The atelectasis produces alveolar hypoxia and pulmonary vasoconstriction to prevent V/Q mismatching and to minimize arterial hypoxia. This vascular response is effective only if a large part of the lung is not collapsed; otherwise, intrapulmonary shunting occurs.

Clinical Presentation

The signs and symptoms of atelectasis are often nonspecific. The natural course of atelectasis may lead to fever, cough, tachypnea, wheezing, rhonchi, and chest pain. On physical examination, atelectasis may manifest as an area of localized reduced breath sounds with constant wheeze or reduced chest wall expansion or both.

Diagnosis

Chest radiographs aid in the diagnosis of atelectasis. They provide both direct and indirect signs that may indicate an atelectatic etiology for the patient's symptoms.

Direct signs include:

- Displaced pulmonary vessels
- Air bronchograms
- Displacement of intralobar fissures (most reliable sign)

Indirect signs include:

- Pulmonary opacification
- Diaphragmatic elevation
- Hyperexpansion of unaffected lung
- Tracheal, heart, and mediastinal shift toward atelectatic side
- Shift of the hilum toward the collapsed lobe
- Segmental ipsilateral rib approximation

Treatment

Treatment of atelectasis is geared toward the underlying cause. It is important to recognize respiratory distress and to intubate the patient if appropriate.

If the etiology is that of an obstructive atelectasis, chest percussion or vibration and nasotracheal or bronchoscopic suctioning

may help in the clearing of secretions. With regard to lung re-expansion, incentive spirometry, continuous or intermittent positive-pressure ventilation, and early ambulation may be used.

Those patients who have a nonobstructive atelectasis caused by a pneumothorax or pleural effusion benefit from tube thoracostomy or thoracentesis. Additionally, appropriate pain management in the postoperative setting allows for proper ventilation.

BACTERIAL PNEUMONIA

Method of

Alison N. Huffstetler, MD, Arjun Muthusubramanian, MD, MPH; and Katharine C. DeGeorge, MD, MS

CURRENT DIAGNOSIS

- Diagnosis of community-acquired pneumonia requires symptoms plus radiographic findings consistent with pneumonia.
- Hospital-acquired pneumonia may be diagnosed in hospitalized patients who develop a pulmonary infection ≥ 48 hours after hospital admission in the absence of mechanical ventilation.
- Blood and sputum cultures are not necessary for all patients hospitalized with pneumonia.
- Biomarkers, such as procalcitonin and C-reactive protein, are not routinely recommended for the diagnosis of pneumonia.
- When determining the appropriate treatment setting, use a validated scoring system such as the pneumonia severity index (PSI) or CURB-65 to predict disease severity and risk of death.

CURRENT THERAPY

- Treat outpatients with uncomplicated bacterial pneumonia empirically with either a macrolide (azithromycin [Zithromax]) or doxycycline (Vibramycin).
- Patients hospitalized with pneumonia should be treated with a respiratory fluoroquinolone (levofloxacin [Levaquin] or moxifloxacin [Avelox]) or a select β -lactam (ceftriaxone [Rocephin] or ampicillin) PLUS a macrolide.
- Use broad-spectrum antibiotics to treat patients with hospital-acquired pneumonia; antibiotic selection should be based on local antibiograms, with consideration for coverage for *Pseudomonas aeruginosa* or methicillin-resistant *Staphylococcus aureus* (MRSA).
- Narrow antimicrobial therapy as soon as possible, based on culture results and sensitivities.
- Whenever MRSA is suspected, treatment with vancomycin (Vancocin) or linezolid (Zyvox) should be initiated; daptomycin (Cubicin)¹ should not be used to treat pulmonary MRSA infection.

¹Not FDA approved for this indication.

who has undergone induction of anesthesia. The diaphragm is relaxed and is displaced cephalad. In the supine position, the pleural pressures increase to the greatest extent in the dependent lung regions and can compress the adjacent lung tissue.

Surfactant Impairment

Pneumonia is a leading cause of death in the United States and accounts for more than 400,000 emergency department (ED) visits annually. Pneumonia often presents with shortness of breath, fever, productive cough, with leukocytosis and radiographic findings of lobar infiltrate.

Diagnosis and treatment should be based on underlying characteristics of the patient and their risk factors. The most common cause of community-acquired pneumonia (CAP) is *Streptococcus pneumoniae*, whereas hospital-acquired pneumonia (HAP) is more frequently caused by gram-negative bacteria and places patients at a risk for multidrug-resistant organisms.

This chapter discusses diagnosis and treatment of community-acquired pneumonia (CAP) and HAP in adults. Although previous guidelines approached health care-associated pneumonia (HCAP) and HAP separately, these are now diagnosed and treated as a single disease process (HAP).

Epidemiology

Community-acquired pneumonia (CAP) affects approximately 5 to 6 people per 1000 persons per year, with seasonal variance resulting in higher incidence during winter. The associated morbidity and mortality rates are high; in 2015, 16.1 deaths per 100,000 people in the US population were attributed to pneumonia. Treating these patients comes at a cost of \$10.6 to \$17 billion in the United States annually. Men are affected more frequently than women, and African Americans more frequently than Caucasians. The very young and elderly (aged ≥ 65 years) are affected more often than younger adults. Despite our best efforts, advances in medical therapies have not significantly decreased the mortality rate associated with pneumonia since the advent of penicillin in 1928.

The incidence of HAP is approximately 1.6 to 3.6 cases per 1000 hospital admissions. HAP is a leading cause of hospital-acquired infections (HAI); 22% of HAIs are accounted for by HAP. HAP most frequently occurs in patients outside of the intensive care unit (ICU); however, those in the ICU and on mechanical ventilation are at high risk of ventilator-associated pneumonia (VAP). HAP is associated with complications including respiratory compromise, septic shock, acute renal failure, and empyema.

Etiology

Risk Factors

Predisposing factors for development of pneumonia include several prescription medications (angiotensin-converting enzyme inhibitors, antipsychotic medications, glucocorticoids, H_2 blockers, proton pump inhibitors, and sedatives), tobacco use, alcohol use, malnutrition, use of dentures at night, bronchial obstruction due to foreign body, altered mental status due to reversible causes, and pulmonary edema. Nonmodifiable risk factors include immobile cilia, cystic fibrosis, chronic obstructive pulmonary disease (COPD), Kartagener's syndrome, human immunodeficiency virus (HIV), lung cancer, and Young's syndrome.

Community-Acquired Pneumonia (CAP) Pathogens

Worldwide, *S pneumoniae* is the leading cause of pneumonia. In the United States, however, rates of streptococcal pneumonia have declined after implementation of the pneumococcal vaccine in both adults and children. "Typical" organisms that cause pneumonia in the United States include *Haemophilus influenza* (although less common after development of the *H influenza* vaccine in 1987), *S aureus*, group A streptococcus, *Moraxella catarrhalis*, anaerobes, and aerobic gram negative bacteria. "Atypical" organisms include *Mycoplasma pneumoniae*, *Legionella* spp, *Chlamydia pneumoniae*, and *Chlamydia psittaci*.

Existing pulmonary infection with influenza, RSV, human metapneumovirus, adenovirus, and rhinovirus increase the risk of developing a secondary bacterial pneumonia. Patients admitted to the ICU requiring invasive diagnostic testing frequently become infected with *S pneumoniae* but have a disproportionate incidence of *Legionella*, *S aureus*, *H influenza*, and enteric gram-negative bacilli (*Klebsiella pneumoniae*, *Pseudomonas aeruginosa*,

Acinetobacter spp, *M catarrhalis*). Identification of the organism responsible for CAP is only established in approximately 40% of cases.

Specific patient risk factors should be considered to identify involved pathogens in CAP. Consider local trends and outbreaks for diagnosis of *Legionella*, *M pneumoniae*, and *C pneumoniae*. Alcoholism is frequently linked to anaerobic bacterial pneumonia, *K pneumoniae*, *Mycobacterium tuberculosis*, and *S pneumoniae*. Patients with high risk of aspiration also have higher rates of anaerobic oral flora underlying pneumonia. Patients with COPD frequently have pneumonia caused by *Chlamydophila pneumoniae*, *H influenza*, *Legionella* species, *M catarrhalis*, *P aeruginosa*, and *S pneumoniae*. Exposure to animals such as bats, birds, or farm animals increases risk of *Histoplasma capsulatum* and *Coxiella burnetii* (Q fever) infections. HIV is a risk factor for *H influenza*, *M tuberculosis*, and *S pneumoniae* in the early stages and a risk factor for *Pneumocystis jiroveci* in late stages with decreased CD4 count. Travel increases risk for *Blastomyces dermatitidis* and *Coccidioides* species. Severe infections that do not respond to initial therapy should raise concern for possible MRSA infection. When clinical management would be altered by confirmed diagnosis of microbial infection, effort should be made for more extensive diagnostic testing; Table 1 lists the conditions that should prompt more extensive testing to identify specific pathogen involvement and antibiotic sensitivities.

Hospital-Acquired Pneumonia

Acutely ill, hospitalized patients have a higher risk of aspirating, which accounts for many of the differences in involved pathogens in HAP as compared with CAP. Oropharyngeal colonization with microorganisms that are commonly found in hospitals may occur within 48 hours of admission. Aerobic gram-negative bacilli such as *Escherichia coli*, *K pneumoniae*, *Enterobacter* spp, and *P aeruginosa* are more commonly identified in patients with HAP, but gram-positive cocci are also identified. HAP, distinct from CAP, places patients at higher risk for multidrug-resistant (MDR) pathogens. Prior intravenous (IV) antibiotic use is a strong risk factor for MDR HAP. MRSA is also more common in patients with HAP, primarily because of prior IV antibiotic use as well. MDR *P aeruginosa* is identified most frequently in patients who have received IV antibiotics, previously on mechanical ventilation, and with a history of COPD, cystic fibrosis, and bronchiectasis.

Diagnosis

Symptoms of pneumonia most often include fever, cough, shortness of breath, purulent sputum, and chest pain. Physical examination may demonstrate bronchial breath sounds and crackles, although breath sounds may also be entirely normal, especially in the elderly. Oxygen saturation is often reduced, and chest radiography may demonstrate lobar consolidation, pleural effusion, or cavitory lesions. Depending on the severity of illness, patients may be treated in the outpatient or inpatient acute care settings or may require intensive care for ventilatory or vasopressor support.

Community-Acquired Pneumonia (CAP)

Diagnosis of CAP requires the presence of symptoms (fever, cough, purulent sputum, pleuritis, and/or shortness of breath) plus chest radiographic findings consistent with pneumonia such as lobar consolidation, pleural effusion, or cavitory lesions. Blood oxygen saturation is frequently low and white blood cell counts may be elevated, often with a neutrophilic predominance. Presentation in the elderly may be more subtle, with atypical or absent symptoms, blunted febrile response, and lack of leukocytosis.

Patients diagnosed with bacterial pneumonia treated in the outpatient setting do not require specific microbial identification; neither noninvasive nor invasive testing is recommended for this population (including blood cultures, endotracheal aspirates, and urine antigen testing).

TABLE 1 Patient-Specific Indicators for More-Extensive Diagnostic Testing in CAP

INDICATION	BLOOD CULTURE	SPUTUM CULTURE	LEGIONELLA UAT	PNEUMOCOCCAL UAT	OTHER
Intensive care unit admission	X	X	X	X	X*
Active alcohol abuse	X	X	X	X	
Asplenia	X			X

Positive pneumococcal UAT result	X	X		NA	
Recent travel			X		X‡
Severe obstructive lung disease		X			

Abbreviations: CAP = community-acquired pneumonia; NA = not applicable; UAT = urinary antigen test.

*Endotracheal aspirate (intubated) or bronchoscopy or nonbronchoscopic bronchoalveolar lavage.

†Fungal and tuberculosis cultures.

‡Thoracentesis and pleural fluid cultures.

Expectorated sputum samples for gram stain and culture are optional for most patients with pneumonia but should be collected from those hospitalized requiring intensive care or with any of the risk factors listed in Table 1, ideally before treatment is initiated. Early gram staining can direct initial empiric therapy, especially with findings of less common pathogens. Sputum samples become lower yield as the time between treatment initiation and collection of the sample increases. Inadequate samples (<10 inflammatory cells per epithelial cell) should not be sent for gram stain or culture. Nebulized hypertonic saline may be used to induce sputum sample when necessary.

Blood cultures are optional for most patients with pneumonia but, similarly to sputum culture, should be obtained for those hospitalized requiring intensive care or with any factors listed in Table 1. In the general population of patients hospitalized with pneumonia, false-positive blood cultures are common and can increase the duration of hospital stay and potentially misinform treatment decisions. Additionally, false-positive blood cultures frequently lead to use of broad spectrum antibiotics, increasing microbial resistance patterns.

Biomarkers such as procalcitonin (PCT), soluble triggering receptor expressed on myeloid cells-1, and CRP are not routinely recommended for use in the diagnosis of pneumonia, although there is emerging evidence for their use in distinguishing bacterial pneumonia from other causes of pulmonary symptoms. These markers are better used in assessing response to treatment, discussed below in the treatment section.

Hospital-Acquired Pneumonia

The diagnosis of HAP can be made in hospitalized patients who develop pulmonary infection ≥ 48 hours after hospital admission. Criteria for HAP requires new or progressive findings on chest radiography, fever, leukopenia or leukocytosis, or altered mental status (for patients aged ≥ 70 years), and new or worsening clinical symptoms or signs consistent with bacterial pneumonia in the absence of mechanical ventilation. Similarly to CAP, sputum and blood cultures should be obtained only when clinically indicated (Table 1), and biomarkers for diagnostic purposes are not routinely recommended.

Treatment Setting

Determination of appropriate treatment setting is important for both patient outcomes and health care costs. Inpatient care of pneumonia can be 25 times as costly as outpatient management

and also increases risk of thromboembolic events and superinfection with drug-resistant or virulent organisms. However, inappropriate outpatient management of patients at higher risk of death can lead to potentially avoidable morbidity and death.

Several scoring systems have been developed to help predict short-term mortality and need for hospital or ICU admission in patients with bacterial pneumonia. The following clinical decision aids are the most commonly used:

Pneumonia Severity Index (PSI)

Commonly used, well-validated scoring system that evaluates 20 items with emphasis on the age of the patient. Higher PSI scores indicate higher risk of requiring ICU level care or short-term mortality. See Table 2 for details of PSI scoring. Patients classified as risk classes I and II should be managed as outpatients; those with risk class III should be treated in an observation unit or with short-stay hospitalization; risk classes IV and V should be admitted to the hospital.

CURB-65

Severity-of-illness score which incorporates confusion, uremia, respiratory rate, low blood pressure, and age ≥ 65 years into a prognostic model to determine a patient's candidacy for outpatient therapy. A CURB-65 score of ≥ 2 is indicative of likely need for hospitalization, with consideration for ICU care for those with scores 3 or greater. This shorter scoring system may be less cumbersome in a busy setting, but the effect on hospital admission rates and patient outcomes have been studied less extensively than the PSI score.

SMART-COP

Assists the physician in determining whether the patient requires ICU level care. The algorithm takes into account systolic blood pressure, multilobar chest x-ray findings of infiltrate, albumin, respiratory rate, tachycardia, confusion, oxygenation, and pH and stratifies patients into risk groups that estimate risk of requiring intensive respiratory or vasopressor support.

Patients with septic shock requiring vasopressor therapy in the setting of CAP should be admitted to the ICU. If there is clinical concern for impending airway compromise, the patient should be intubated and admitted to the intensive care unit. In several clinical studies, patients who were critically ill and were not initially admitted to the ICU had higher rates of morbidity and mortality.

TABLE 2 Pneumonia Severity Index

RISK FACTORS	POINTS
Demographics	
Age, men	Age in years
Age, women	Age in years - 10
Nursing home resident	+10
Comorbid conditions	
Active neoplasm	+30
Liver disease	+20
History of CVA	+10
Chronic heart failure	+10
Chronic renal failure	+10
Physical examination	
Altered mental status	+20
Respiratory rate elevated >30	+20
Hypotension, SBP <90 mm Hg	+20
Temperature <95° or >40° C	+15
Tachycardia, pulse > 125 beats/min	+10
Laboratory and imaging findings	
Acidosis, arterial pH < 7.35	+30
Hyponatremia, Na <130 mmol/L	+20
BUN ≥ 30 mg/dL	+20
Glucose ≥ 250 mg/dL	+10
Hematocrit < 30%	+10
PaO ₂ < 60 mm Hg	+10
Pleural effusion	+10
Total points	

Abbreviations: BUN= blood urea nitrogen; CVA= cerebrovascular disease; Na = sodium; PaO₂ = partial pressure of arterial oxygen; SBP= systolic blood pressure. Total points < 51 indicates low incidence of death from CAP. Patients with increased total points have higher risk of death; the greatest risk for those > 130 total points with rate of death for adults diagnosed with CAP of 24.9%.

Treatment

General recommendations for empiric treatment of both CAP and HAP are detailed in Table 3. Treatment of a nonsevere case of pneumonia in an outpatient should be empiric and include a macrolide (such as azithromycin [Zithromax]) or doxycycline (Vibramycin). Therapy for inpatients may rely on sputum cultures with targeted antibiotic regimens to reduce cost and complications of therapy. Common treatment regimens for CAP requiring hospitalization include a respiratory fluoroquinolone (such as moxifloxacin [Avelox]) or a beta-lactam (ceftriaxone [Rocephin]) plus a macrolide. Empiric treatment regimens for HAP should be broad and based on local antibiograms, with consideration for coverage for *P. aeruginosa* or MRSA. Prevention of pneumonia is essential, and pneumococcal vaccines should be provided to children and adults over 65 years of age and those with risk factors for developing pneumonia at a younger age. These antibiotics and supportive care (oxygen, IV fluids, and ventilatory or vasopressor support when necessary) are the mainstay of treatment for both community and hospital-acquired bacterial pneumonia. Antibiotic selection is guided by several factors:

- age
- severity of illness

- risk of infection by multidrug-resistant pathogen (see Table 4 for risk factors)

- setting (both timing and location) of pneumonia onset

Initiation of initial treatment should also be guided by geographic antibiograms, which should be available through local hospitals. The Centers for Disease Control and Prevention's Antibiotic Resistance Patient Safety Atlas provides similar information for the aggregate of hospital-acquired infections. Antibiotic therapy should be narrowed as soon as possible based on culture and subsequent sensitivity results, if culture was obtained.

PCT may be used as an indicator of response to therapy after diagnosis of CAP and HAP based on recent trial data. If procalcitonin measurements decrease to <0.1 µg/L, a provider may consider discontinuation of antibiotics.

In addition to antimicrobial therapy for those who require hospitalization, care should be taken to maintain appropriate oral hygiene and to maintain head of bed at 30° to 45° in efforts to minimize risk of aspiration. Serum glucose goal should be <180 mg/dL. A few additional considerations exist for patients who require an intensive care unit stay during hospitalization. These individuals should all receive dual antibiotic therapy, as noted in Table 3. For those who remain hypotensive despite adequate fluid resuscitation, consider screening for occult adrenal insufficiency. Those with hypoxemia or respiratory distress may receive a closely monitored trial of noninvasive ventilation followed by intubation as indicated. Low-tidal volume ventilation (6 mL/kg of ideal body weight) should be used.

Community-Acquired Pneumonia (CAP)

Patients with suspected CAP should first be risk stratified using one of the pneumonia severity scoring indices discussed above and in Table 2. If being admitted to the hospital, the first dose of empiric antibiotic (see Table 3) should be administered in the emergency department as soon as the diagnosis of pneumonia is made. Patients may be transitioned from intravenous to oral antibiotics when they are hemodynamically stable, able to tolerate oral medications, and are able to absorb these medications enterally. When possible, an oral antibiotic should be chosen from the same or similar antibiotic class as the intravenous antibiotic used. Observation of inpatients after transition to oral antibiotics is not necessary as long as the patient is clinically stable and has a safe disposition plan. The recommended duration of antibiotic therapy is at least 5 days, with discontinuation only after the patient has been afebrile for at least 48 to 72 hours and remains clinically stable. Concern for a coexisting extrapulmonary infection may affect antibiotic selection and extend duration of therapy.

Hospital-Acquired Pneumonia

All patients with suspected HAP should be treated with broad spectrum antibiotics (Table 3). Antibiotic choice should be governed by local antibiograms. As described in more detail in the diagnosis section, Table 1 details the circumstances that guide further diagnostic testing, including cultures and PCR testing. Also, as described in Table 3, if symptoms have a late onset or if risk factors for a multidrug resistant pathogen are present, then dual therapy is indicated. However, in selecting antimicrobial coverage, clinicians must weigh the benefit of initiating adequate coverage as soon as possible against the harms of uniform broad spectrum coverage, such as increased resistance rates, risk of *Clostridium difficile* infection, and adverse drug effects. Whenever MRSA is suspected, treatment with vancomycin (Vancocin) or linezolid (Zyvox) should be initiated; daptomycin (Cubicin)¹ should not be used to treat pulmonary MRSA infection.

¹Not FDA approved for this indication.

TABLE 3 Empiric Antibiotic Therapy for Pneumonia for Adults

TYPE OF PNEUMONIA	SETTING	ANTIMICROBIAL THERAPY
Community-acquired pneumonia	Outpatient, healthy patient	Macrolide (azithromycin [Zithromax] or clarithromycin [Biaxin]) OR Doxycycline (Vibramycin) OR
	Outpatient, patient with risk factors*	Respiratory fluoroquinolone [†] if failure with above therapy OR Macrolide PLUS β -lactam [‡]
	Inpatient, patient not in ICU	Respiratory fluoroquinolone [†] OR Select β -lactam (ceftriaxone [Rocephin], cefotaxime [Claforan], ertapenem [Invanz], or ampicillin) PLUS macrolide
	Inpatient, patient in ICU	Select β -lactam (ceftriaxone, cefotaxime, or ampicillin/sulbactam [Unasyn]) PLUS either a respiratory fluoroquinolone [†] or azithromycin
	Concern for <i>P. aeruginosa</i>	Antipseudomonal β -lactam [§] PLUS either ciprofloxacin (Cipro) or levofloxacin (Levaquin) OR Antipseudomonal β -lactam [§] PLUS aminoglycoside PLUS azithromycin
Aspiration pneumonia	Outpatient	Amoxicillin/clavulanate (Augmentin) OR clindamycin (Cleocin) β -Lactam/ β -lactamase inhibitor (ampicillin/sulbactam [Unasyn], ¹ piperacillin/tazobactam [Zosyn], ticarcillin/clavulanate [Timentin]) OR 3rd or 4th generation cephalosporin PLUS either metronidazole (Flagyl) or clindamycin (Cleocin) OR fluoroquinolone PLUS either metronidazole or clindamycin OR Meropenem (Merrem), ¹ ertapenem (Invanz), doripenem (Doribax), ¹ or imipenem/cilastatin (Primaxin)
	Inpatient	
Hospital-acquired pneumonia	Early-onset AND No risk factors for MDR organisms	Ceftriaxone, cefotaxime, respiratory fluoroquinolone, [†] ampicillin/sulbactam, piperacillin/tazobactam, ticarcillin/clavulanate, or ertapenem
	Late-onset OR Risk factors for MDR organisms	Select β -lactam (cefepime, ceftazidime, imipenem, meropenem, ¹ doripenem, ¹ or piperacillin/tazobactam) PLUS one of ciprofloxacin, levofloxacin, or an aminoglycoside
MRSA suspected	Either community- or hospital-acquired	ADD vancomycin (Vancocin) or linezolid (Zyvox) to regimen

*Presence of comorbid conditions (chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies, asplenia, immunosuppression [iatrogenic or pathologic]), use of antimicrobials within the past 3 months, high-rate (>25%) of macrolide-resistant *S pneumoniae*

[†]Respiratory fluoroquinolones include levofloxacin (Levaquin), moxifloxacin (Avelox), or Gemifloxacin (Factive).

[‡]High-dose amoxicillin, amoxicillin/clavulanate (Augmentin), ceftriaxone (Rocephin), cefuroxime (Ceftin), cefpodoxime (Vantin)

[§]Antipseudomonal β -lactams include piperacillin/tazobactam (Zosyn), cefepime (Maxipime), ceftazidime (Fortaz), imipenem/cilastatin (Primaxin), doripenem (Doribax),¹ and meropenem (Merrem).

¹Not FDA approved for this indication.

TABLE 4 Risk Factors for Multidrug Resistant Pathogens in Hospital-Acquired Pneumonia

Antimicrobial therapy in preceding 90 days
Current hospitalization greater than or equal to 5 days
High frequency of antibiotic resistance in the community or specific hospital unit
Presence of risk factors for health care-associated pneumonia
Hospitalization for 2 or more days in preceding 90 days
Residence in nursing home or extended-care facility
Home infusion therapy (including antibiotics)
Chronic dialysis in preceding 30 days
Home wound care
Family member with MDR pathogen
Immunosuppressive disease or therapy

MDR, multidrug-resistant.

Prevention

Immunization against influenza, *S pneumoniae*, and *H influenza* is the best protection against bacterial pneumonia in adults and children. Recommended vaccine schedules are described in Table 5. In general, everyone should receive an annual influenza vaccine and individuals should receive *H influenza* and pneumococcal immunization on a schedule based on age and risk factors. The pneumococcal vaccines have a 44%–75% efficacy against invasive disease from *S pneumoniae* for persons 65 years and older and have been shown to be cost effective in populations aged 50 years and older. A systematic review demonstrated that the influenza vaccine effectively reduces pneumonia, hospital admission, and death. Annual influenza immunization is recommended, as neuraminidase and hemagglutinin evolve rapidly, and new formulations targeting predicted strains are needed.

TABLE 5 Recommended Vaccinations for the Prevention of Pneumonia

VACCINE	POPULATION	RECOMMENDATIONS
Influenza	All persons older than 6 months	Annually If first lifetime dose of influenza vaccine, 2nd dose should be given 4 weeks after 1st dose
Pneumococcal	All adults	Should receive 1 dose of PCV13 (Pneumovax 23). See below for guidance regarding the number and timing of vaccine doses.
	Immunocompetent adults 19–64 years who smoke tobacco or who have chronic heart disease (excluding hypertension), chronic lung disease, chronic liver disease, alcoholism, or diabetes mellitus	1 dose of PPSV23. At age 65 or older, they should receive 1 dose of PCV13 and 1 dose of PPSV23 at least 1 year after dose of PCV13 AND at least 5 years after previous dose of PPSV23.
	All immunocompetent adults 65 years and older	At 65 years or older they should receive 1 dose of PCV13, followed by PPSV23 at least 1 year after PCV13. If they received dose of PPSV23 before age 65, dose of PCV13 should be given at least 1 year after 1st dose of PPSV23 and dose of PPSV23 should be given at least 5 years after 1st dose of PPSV23.
	Adults 19 and older with immunocompromising conditions*	Administer 1 dose of PCV13 first and then dose of PPSV23 at least 8 weeks after dose of PCV13 and a second dose of PPSV23 5 years after 1st dose of PPSV23. At age 65 and older, administer one final dose of PPSV23 at least 5 years after previous dose of PPSV23 and at least 8 weeks after dose of PCV13.
	Adults 19 and older with cerebrospinal fluid leak or cochlear implant	Administer 1 dose of PCV13 first and then a dose of PPSV23 at least 8 weeks after the dose of PCV13. At age 65 and older, administer 1 final dose of PPSV23 at least 5 years after previous dose of PPSV23 and at least 8 weeks after dose of PCV13.
<i>Haemophilus influenza</i> type B	All children younger than 5 years old, unvaccinated older children and adults with certain medical conditions,* people who receive bone marrow transplant	Administer 1 dose of HiB at age 2, 4, 6 (per product) and 12–15 months with minimum of age 6 weeks. Children with 1 dose at age >15 months need no further doses. For high-risk conditions, children age 12–59 months who previously received 1 or no doses should receive 2 additional doses of HiB, 8 weeks apart. For children who received 2 doses before 12 months of age should receive 1 additional dose. Hib may be given to high-risk adults.

HiB, *Haemophilus influenza* type B; PCV, pneumococcal conjugate vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine.

*B- or T-lymphocyte deficiency, complement deficiencies, phagocytic disorders (excluding chronic granulomatous disease), HIV infection, chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, multiple myeloma, solid organ transplant, iatrogenic immunosuppression, anatomic, or functional asplenia.

BLASTOMYCOSIS

Method of

John M. Embil, MD; and Donald C. Vinh, MD

CURRENT DIAGNOSIS

- Blastomycosis is caused by the thermally dimorphic fungus *Blastomyces dermatitidis*.
- *B. dermatitidis* is endemic to the United States (southeastern and south central states bordering Mississippi and Ohio rivers; upper Midwestern states bordering the Great Lakes) and to Canada (Manitoba and Ontario bordering the Great Lakes; Quebec adjacent to St. Lawrence River).

CURRENT THERAPY

- Treatment varies with the severity of disease.
- Long-term suppressive therapy may be required for those who are immunosuppressed.

Blastomyces dermatitidis, and the recently identified *B. gilchristii*, are the thermally dimorphic fungi that causes blastomycosis. These fungi exist in mycelial form in the environment but grow as yeast forms at body temperature. Although *Blastomyces* spp. are endemic to certain specific regions within North America, numerous cases have been reported from areas where they are not

considered endemic. It is presumed that those patients acquired infection in the endemic areas and subsequently presented outside of these geographic locations. The clinical manifestations of blastomycosis can be diverse, and therefore this infection should be suspected within the appropriate clinical context in persons with a history of residence or travel to such endemic areas.

Epidemiology

Our knowledge of the exact geographic distribution of *B. dermatitidis*, and of the newer *B. gilchristii*, is limited by the fact that the fungus cannot be readily recovered from nature; thus, identification of the endemic area has been largely derived from outbreak investigations and small case series. Most epidemiologic studies have depended upon recovery of *B. dermatitidis* in culture from clinical specimens or histologic visualization to establish the diagnosis. In addition, the incidence and prevalence of blastomycosis has been difficult to establish because suitable serologic or skin-prick assays (demonstrating acceptable sensitivity and/or specificity) to confirm infection are lacking. The geographic niche of *Blastomyces* spp. may therefore be greater than is currently believed.

The currently known areas of endemicity for *B. dermatitidis/gilchristii* are the south central and upper midwestern United States, including areas surrounding the Great Lakes. *B. dermatitidis* is also endemic in Wisconsin (1.3 cases per 100,000 population) and Mississippi (1.4 cases per 100,000 population), as well as parts of Missouri, Kentucky, Tennessee, Arkansas, and Alabama. In Canada, the major areas of endemicity include the province of Manitoba (0.62 cases per 100,000 population), the southern region of Québec (0.46–0.79 cases per 100,000 population), and the Kenora region of the province of Ontario (7.11 cases per 100,000 population). Although most cases of blastomycosis are concentrated in these regions, it should be remembered that persons can acquire infection with *Blastomyces* spp. in these areas but present at a later time to health care providers in locations where blastomycosis is not usually observed. Inquiring about residence or travel to these areas is important to help establish the diagnosis.

Risk factors for acquiring blastomycosis have been defined by case reports, case series, and a small number of case-control studies and have not been conclusively established. Exposure while in endemic regions to soil, decaying wood, or to dust clouds generated by soil disruption is important; however, specific outdoor occupations or activities have not been confirmed. The fungus may also be associated with exposure to river waterways.

Race may be a contributing factor to disease. In one study from Mississippi, African-American race and prior history of pneumonia were independent risk factors for blastomycosis; however, neither environmental nor socioeconomic risk factors were detected. These findings were in contrast to previously noted studies where race and gender were not identified as specific risk factors for acquisition of blastomycosis. One study in Canada noted an increased incidence among the aboriginal population of Manitoba. Thus, it remains unclear if certain ethnic groups are at increased risk for disease or simply reflect differences in exposure.

Immunosuppression may also be an important risk factor, particularly for the tendency to develop severe disease. Blastomycosis has been reported in pregnant women, persons with diabetes mellitus, organ transplant recipients, and persons infected with HIV.

Dogs and humans are the species most commonly affected by *B. dermatitidis*. Anecdotally, dogs can serve as a sentinel marker for human disease (i.e., dogs present with systemic infection before their owners), leading to early suspicion of human infections by astute veterinarians. In such cases, it is speculated that humans and their pet dogs have a simultaneous exposure to the same source of fungus and therefore develop synchronous infection. This hypothesis, however, remains to be confirmed, and in a more recent study, canine blastomycosis was not deemed to predict human disease among the human owners. Additional studies are required to establish the relationship between blastomycosis in humans and disease in their pet dogs.

The most common mode of transmission is presumed to be by inhalation of aerosolized conidia from the environment. There are, however, reports of cutaneous blastomycosis occurring after accidental cutaneous inoculation, for example in the laboratory setting during autopsy or after dog bites. The median incubation period, established by reviewing the results of point-source outbreaks, ranges from 30 to 45 days.

Pathophysiology

Following inhalation of conidia into the lungs, the fungus is phagocytosed by alveolar macrophages. The human body temperature allows the fungus to transform to the yeast phase. It is speculated that a process similar to infection with *Mycobacterium tuberculosis* then occurs. The fungus might spread to other organs via the bloodstream and lymphatics. The primary defense against *B. dermatitidis* is through a suppurative response initially with neutrophils, followed by influx of monocytes with establishment of cell mediated immunity, resulting in noncaseating granuloma. The patient with intact immunologic responses can contain the process without progression to clinical disease. Alternatively, the patient can develop a symptomatic pneumonia and then mount a suitable immunologic response and recover. Impaired immunity favors the development of progressive pulmonary disease with or without extrapulmonary manifestations. It has also been suggested that reactivation of disease can occur at pulmonary or extrapulmonary sites. The pathophysiology of *B. gilchristii* is thought to be similar to that of *B. dermatitidis*. A vaccine that protects humans against infection with *Blastomyces* spp. is unavailable.

Clinical Manifestations

After inhalation of the conidia, an initial infection can occur. Most primary infections (at least 50%) are asymptomatic or mild and usually go unrecognized, resolving spontaneously. In others, a symptomatic pneumonia can develop; recovery can occur either spontaneously or with therapy, without further progression. Some persons develop progressive pneumonia or extrapulmonary manifestations. The type of clinical manifestations (localized, extrapulmonary or disseminated disease) can have a seasonal variation: Persons with manifestations occurring early after exposure (1–6 months) developed localized pneumonia, whereas those who presented later after exposure (4–9 months) tended to have isolated extrapulmonary or disseminated disease. Blastomycosis has been termed “the great mimic,” because its clinical manifestations are nonspecific and can be similar to those of many different clinical entities. The most common organ systems involved in blastomycosis, in descending order of frequency, include lung, skin, bone, genitourinary, and central nervous systems (CNS). [Box 1](#) summarizes the key clinical manifestations of blastomycosis.

Blastomycosis in Special Populations

Children account for a small percentage of the cases of blastomycosis, ranging from 2% to 11%. Children demonstrate a similar spectrum of manifestations as in adults (excluding prostatic disease). The most common symptoms include cough, headache, chest pain, weight loss, fever, abdominal pain, and night sweats. It is postulated that children experience disseminated infection more frequently than do adults.

Although there are few published reports of blastomycosis in pregnancy, disease has been observed in pregnant women, with presumed subsequent intrauterine and perinatal transmission.

Blastomycosis has been reported in persons with advanced HIV and among those who have undergone solid organ transplants. In immunocompromised hosts, it appears that a significant percentage developed rapidly progressive pulmonary disease, leading to respiratory failure and death. For those who are immunocompromised, the reported mortality rate range is 30% to 40%, with death occurring within the first few weeks of disease onset.

Diagnosis

The most reliable technique for confirming the diagnosis of blastomycosis is recovery of the fungus in culture. Alternatively, direct

Lung**Acute Pneumonia**

Acute pneumonia is clinically indistinguishable from bacterial pneumonia.

Patients may present with fevers, chills, dyspnea, and cough, which initially might not be productive but, with time, may be accompanied by sputum production.

Radiographic findings can also be difficult to discern from those due to a bacterial pneumonia.

The radiographic pattern of pulmonary blastomycosis includes the following:

- Lobar infiltrates that mimic bacterial pneumonias
- Cavitory lung lesions and miliary patterns, which can mimic tuberculosis
- Mass lesions that may be mistaken for neoplasms
- Cystic lesions that resemble abscesses

There is no definitive plain radiograph or computed tomographic scan findings characteristic of pulmonary blastomycosis.

The spectrum of clinical pulmonary disease ranges from spontaneous resolution to pneumonia, with or without the acute respiratory distress syndrome; the latter is accompanied by high (50%–89%) mortality rates.

Chronic Pneumonia

A nonresolving pneumonia is one of the hallmarks of pulmonary blastomycosis.

Chronic pneumonia may be associated with fever, chills, weight loss, sputum-producing cough, and hemoptysis.

There is no characteristic radiographic appearance to help establish the diagnosis.

Skin

Cutaneous lesions are the most common extrapulmonary manifestations of blastomycosis. Lesions usually result from dissemination of a primary pulmonary lesion or rarely from direct inoculation.

Lesions can have a number of different appearances, with verrucae (wartlike lesions) and ulcers being the most common

manifestations. The verrucous lesions have a heaped-up appearance with a raw excoriated center. These lesions can mimic squamous cell carcinomas. Cutaneous abscesses may be associated with these lesions.

Ulcerative lesions initially manifest as pustules that eventually erode, producing a bed of granulation tissue that is friable and bleeds when traumatized. Other skin lesions include subcutaneous nodules and isolated abscesses.

Bone and Joint

The most common manifestation of extrapulmonary blastomycosis, after cutaneous disease, is involvement of bones and joints.

Any bone may be involved, although the long bones and axial skeleton are the most commonly affected.

The radiographic findings are indistinguishable from bacterial osteomyelitis and arthritis.

Genitourinary Tract

In the genitourinary tract, the prostate has been reported to be commonly affected by blastomycosis.

Symptoms can mimic prostatitis, and patients can present with obstructive uropathy.

Central Nervous System

The CNS is infrequently affected by *B. dermatitidis*. Infection may occur in isolation or with concomitant non-CNS infection.

CNS blastomycosis can occur in immunocompromised patients (e.g., HIV, solid organ transplant), as well as in patients with little/no risk factors (e.g., diabetes mellitus alone; persons with no underlying co-morbidities).

Clinical manifestations depend on the area of involvement and range from focal neurologic findings (e.g., due to mass lesions in the brain parenchyma) to symptoms of meningitis due to involvement of the meninges.

Radiographically, the findings may be indistinguishable from bacterial processes. Other sites of involvement have been described but are infrequent compared to those summarized above.

observation of the pathogen by light microscopy or with calcofluor white stain or in histopathologic examination of tissue establishes a presumptive diagnosis. *Blastomyces* spp. are characteristically observed as a thick-walled, broad-based budding yeast. Because colonization does not occur, identification of *B. dermatitidis/gilchristii* should never be considered a contaminant. Serologic assays are extremely variable in their sensitivity and specificity and do not play a role in confirming or excluding the diagnosis, thus limiting their value in therapeutic decision making. A reliable skin test is unavailable, but a urinary antigen detection assay exists that may aid in diagnosis and may be of benefit to follow the efficacy of treatment in established infections. Box 2 summarizes techniques for establishing the diagnosis of blastomycosis.

Treatment

The treatment recommendations for blastomycosis from the Infectious Diseases Society of America (IDSA) are summarized in Table 1. Amphotericin B deoxycholate (Fungizone) is the agent with which there is the greatest experience, particularly for the treatment of patients with severe blastomycosis or for those who have CNS involvement. Lipid preparations of amphotericin B (Abelect, Amphotec, AmBisome)¹ have been shown to be effective in animal models, although clinical trial data are unavailable for these agents in humans. Clinical experience suggests that the lipid formulations are as effective but less toxic than the deoxycholate preparation.

It is generally accepted that in patients with severe disease or CNS involvement, amphotericin B-based products should be used to initiate therapy until the patient is stable, followed by step-down to an azole, specifically itraconazole (Sporanox), to complete the total duration of therapy. Patients on itraconazole should have serum levels of the antifungal drug measured after at least 2 weeks of therapy, targeting a level >1.0 mcg/mL and <10.0 mcg/mL. Ketoconazole (Nizoral), although once recommended as the agent of choice, is less effective and more toxic than itraconazole. Experience with fluconazole (Diflucan)¹ for the treatment of blastomycosis is limited, although *in vitro* studies have demonstrated that fluconazole is effective against *B. dermatitidis*. Fluconazole does, however, have excellent penetration into the CNS; therefore, fluconazole may be considered as an alternative treatment of CNS blastomycosis. There are also a number of reports of voriconazole (Vfend)¹ being used for the successful treatment of CNS blastomycosis, as well as in persons with refractory blastomycosis. A case series of patients with CNS blastomycosis suggested that voriconazole may be the most desirable azole for the management of CNS disease. The echinocandins (caspo-fungin [Cancidas],¹ micafungin [Mycamine],¹ and anidulafungin [Eraxis]¹) have limited activity against *B. dermatitidis* and are not considered appropriate choices.

Box 2 summarizes the therapeutic options for treatment of various types of blastomycosis. Amphotericin B-based therapy is usually the treatment option of choice in persons who have severe

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

BOX 2

Establishing the Diagnosis of Blastomycosis

Direct Examination

A wet preparation of respiratory secretions or a touch preparation of tissues examined under high magnification by light microscopy can reveal the characteristic thick-walled, broad-based budding yeast form. However, this method has a low diagnostic yield: 36% for a single specimen and 46% for multiple specimens.

Calcofluor white stains can help in identifying the pathogen but require fluorescence microscopy.

Histopathologic Examination

The fungus may be difficult to identify with hematoxylin and eosin stain.

If there is a high index of suspicion, the Gomori methenamine-silver stain should be used to optimize detection of thick-walled, broad-based budding yeast forms compatible with *B. dermatitidis*.

Culture

Diagnostic yield ranges from approximately 86% from sputum to 92% from specimens obtained by bronchoscopy.

Culture is the gold standard for diagnosis. However, the fungus can take several weeks to be isolated in culture.

Confirmation of identity traditionally requires demonstration of thermal-dimorphism (mycelial-to-yeast conversion), which can further delay diagnosis.

Isolation of *B. dermatitidis* should not be considered a contaminant.

Serology

Current serologic assays are neither sensitive nor specific, and they should not be used to establish or refute a diagnosis or in therapeutic decision making.

Nucleic Acid Detection

This method permits genetic-based identification of *B. dermatitidis* from culture of clinical specimens, rather than relying on thermal-dimorphism to confirm identity of the fungus, thus reducing the time required for its identification.

Antigen Detection

The only currently available antigen detection assay has its greatest sensitivity in urine, although antigens can be detected in serum and other body fluids.

Cross reaction with antigens from other fungi (e.g., *Histoplasma* spp.) can occur.

The greatest benefit of the antigen detection assay may be to follow efficacy of treatment in patients with established disease (antigen levels decrease with successful treatment or rise with recurrence).

Skin Testing

A commercially available standardized reagent for skin testing is not available.

Modified from Chapman SW, Bradsher RW, Campbell GD, et al: Practice guidelines for the management of patients with blastomycosis. *Clin Infect Dis* 2000;30:679–683; and Martynowicz MA, Prakash UBS: Pulmonary blastomycosis: An appraisal of diagnostic techniques. *Chest* 2002;121:768–773.

disease. Whenever the patient is clinically stable, it is desirable to switch from the potentially toxic amphotericin B to a less-toxic agent (usually an azole). It is important to note that amphotericin B in cumulative doses of 1.5 to 2.5 grams for persons with disseminated blastomycosis, with life-threatening disease, or in those who

are immunocompromised or pregnant, can lead to cure without relapses.

In patients with overwhelming pulmonary disease, amphotericin B-based products are the therapeutic agents of choice. Although acute respiratory distress syndrome (ARDS) can

TABLE 1 Treatment Suggestions for Infections Caused by *Blastomycosis dermatitidis*

TREATMENT RECOMMENDATIONS

MANIFESTATION	PRIMARY RECOMMENDATION	ALTERNATIVE RECOMMENDATION	COMMENTS
Pulmonary Infection			
Mild to moderate	Itraconazole (Sporanox) 200 mg PO tid × 3 days, then qd or bid × 6–12 mo	Fluconazole (Diflucan) ¹ 400–800 ³ mg/day or ketoconazole (Nizoral) 400–800 mg/kg × 6–12 mo	For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0 mcg/mL and <10.0 mcg/mL
Moderate to severe	Lipid formulation of amphotericin B (AmBisome, Abelect, Amphotec) ¹ 3–5 mg/kg/day OR Amphotericin B deoxycholate (Fungizone) 0.7–1 mg/kg/d for 1–2 wk or until improvement, followed by itraconazole 200 mg PO tid × 3 days then 200 mg PO bid × 6–12 mo		Amphotericin B toxicity can be attenuated by minimizing the duration of therapy and switching to oral therapy when the patient is stable. For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0 mcg/mL and <10.0 mcg/mL
Disseminated Infection Not Involving the Central Nervous System			
Mild to moderate	Itraconazole 200 mg PO tid × 3 days then qd or bid × 6–12 mo		
Moderate to severe	Lipid formulation of amphotericin B 3–5 mg/kg/d OR Amphotericin B deoxycholate 0.7–1 mg/kg/d for 1–2 wk or until improvement, followed by Itraconazole 200 mg PO tid × 3 days then 200 mg PO bid to complete at least 12 mo		To minimize toxicity, switching to oral therapy once the patient is stable should be considered. Bone and joint infections are usually treated for at least 12 mo with itraconazole. For Itraconazole, measure serum levels after at least 2 weeks, to ensure adequate drug exposure. Target level: >1.0 mcg/mL and <10.0 mcg/mL

MANIFESTATION	PRIMARY RECOMMENDATION	ALTERNATIVE RECOMMENDATION	COMMENTS
Central Nervous System Involvement (with or without other manifestations)			
	Lipid preparations of amphotericin B ¹ 5 mg/kg/d × 4–6 wk followed by an oral azole for ≥12 mo		It has been suggested that liposomal amphotericin B achieves higher CNS levels than other lipid formulations When switching to oral azole, options include fluconazole ¹ 800 mg PO qd, ³ itraconazole 200 mg PO bid or tid, ³ or voriconazole (Vfend) ¹ 200–400 ³ mg PO bid Longer durations of therapy may be necessary in the immunocompromised host
Special Populations			
Immunocompromised	Lipid formulation of amphotericin B 3–5 mg/kg/d OR Amphotericin B deoxycholate 0.7–1 mg/kg/d for 1–2 wk or until improvement, followed by Itraconazole 200 mg PO tid × 3 days then 200 mg PO bid to complete at least 12 mo		Lifelong suppression with itraconazole 200 mg PO qd may be required for those in whom immunosuppression cannot be reversed
Pregnant patients	Lipid formulation of amphotericin B 3–5 mg/kg/d		No duration of lipid formulation amphotericin B treatment provided; continue until clinical cure During pregnancy, azoles should be avoided because of potential teratogenicity If the placenta or newborn demonstrates evidence of infection, give amphotericin B deoxycholate 1.0 mg/kg/d
Children: mild to moderate	Itraconazole ¹ 10 mg/kg/d for 6–12 mo		Maximum dose of itraconazole should be 400 mg/d
Children: moderate to severe	Amphotericin B deoxycholate 0.7–10.0 mg/kg/d OR Lipid formulation amphotericin B 3–5 mg/kg/d × 1–2 wk followed by itraconazole 10 mg/kg/d × 12 mo

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

complicate the management of these patients, data on the beneficial role of corticosteroids in the management of patients with overwhelming pulmonary disease or ARDS are limited to few case reports. For patients with less-severe pulmonary disease, an alternative to amphotericin B is a 6- to 12-month course of oral itraconazole. A similarly prolonged course of oral itraconazole is also appropriate for persons with bone and joint disease. The precise duration of therapy, however, is unknown and should be individualized. The same is true for cutaneous blastomycosis. For persons with CNS blastomycosis, an initial treatment course of 4 to 6 weeks with intravenous lipid formulation of amphotericin B should be followed with an oral azole to complete at least 12 months of therapy. For those who are immunocompromised, prolonged therapy is also necessary. Patients who are immunosuppressed and in whom the immunosuppression cannot be reversed can require lifelong suppressive itraconazole therapy at 200 mg per day. Additional details for the management of the various stages of blastomycosis should be sought from the most current version of the IDSA guidelines.

BRONCHITIS AND VIRAL RESPIRATORY INFECTIONS

Method of

Tomoko Sairenji, MD

CURRENT DIAGNOSIS

- Most cases of acute bronchitis are caused by viruses and diagnosed clinically.
- Predominant symptom is acute cough, with or without sputum.
- Other diseases such as asthma, pneumonia, chronic obstructive pulmonary disease exacerbation, and heart failure should be ruled out.

CURRENT THERAPY

- Antibiotics are not recommended for most cases of acute bronchitis.
- Dextromethorphan, guaifenesin, and honey may be considered to relieve cough symptoms.
- Patient education: Cough can last 3 weeks or more.

Epidemiology

Acute cough is the most common reason for ambulatory care visits. Acute bronchitis, which is characterized by an acute cough, is most commonly caused by viruses such as rhinovirus, enterovirus, influenza A and B, parainfluenza, coronavirus, coxsackie, and respiratory syncytial virus. Bacterial causes such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Bordetella pertussis* are much less common.

Pathophysiology

Acute bronchitis is caused by an acute inflammatory process in the mucosa of the trachea and bronchi with resultant injury to epithelium of the mucosa.

Clinical Manifestations

Cough is the primary symptom of acute bronchitis, but it can cause other symptoms such as nasal congestion, wheezing, dyspnea, fever, and nonspecific constitutional symptoms.

Diagnosis

Acute bronchitis is diagnosed clinically, characterized by an acute cough with or without sputum production. It is often a diagnosis of exclusion, in which other diseases such as asthma, pneumonia, chronic obstructive pulmonary disease exacerbation, and heart failure are ruled out. Initially, manifestations of acute bronchitis can be identical to the common cold and difficult to distinguish. Fever is less common in bronchitis after the first few days, and patients may have a mildly ill appearance. On auscultation, there may be wheezing or rhonchi that improve with coughing. A patient with a high temperature, otherwise abnormal vital signs, and a more toxic appearance should raise concern for pneumonia or influenza.

Laboratory testing is usually not necessary for the typical patient in the outpatient setting, but testing for influenza and pertussis can be done when there is greater suspicion for these diseases.

Imaging such as chest x-rays are not necessary in most cases for patients who have normal vital signs, no bloody sputum, and have a normal lung examination result, because there are typically no findings in acute bronchitis. However, it is recommended in those older than 75 years of age, because pneumonia does not always mount a fever or cause tachycardia.

Differential Diagnosis

Common Cold/Upper Respiratory Infections (URI)

The common cold can be difficult to differentiate from acute bronchitis. On average, adults have 2 to 4, and young children as many as 6 to 10 episodes annually. It is most commonly caused by rhinoviruses but can also be caused by other respiratory viruses such as coronavirus, influenza, and respiratory syncytial virus and parainfluenza viruses. The symptomatic trajectory of the common cold is sore throat, malaise, and low-grade fever for 1 to 2 days, followed by nasal congestion, rhinorrhea, and cough. Cough can occur in 30% to 40% of cases, and fluid can accumulate in middle ear or sinus cavities. Symptoms generally are the worst on day 3 to 4 and start to improve by day 7. Symptoms that would warrant consideration for more serious disease are respiratory distress, difficulty swallowing, altered mental status, signs suggesting dehydration, stiff neck, rash, or sore throat for more than 5 days. Influenza (high fever with general myalgias), acute bacterial sinusitis (symptoms for more than 10 days without improvement, severe symptoms including fever $\geq 39^{\circ}\text{C}$, and purulent nasal discharge lasting more than 3 consecutive days), streptococcal pharyngitis (absence of cough with tender lymphadenopathy and tonsillar exudates), asthma exacerbations triggered by URI, and infectious mononucleosis (fatigue, fever, sore throat, and adenopathy more severe than typical URI) are other conditions on the differential. Testing is not warranted for the diagnosis of a common cold unless one of these diseases is suspected and needs to be ruled out.

Similar to acute bronchitis, antibiotics are strongly discouraged for the common cold because they provide no benefit in terms of reducing symptom severity or duration. If symptoms are severe, treatment focuses mostly on symptomatic management, of which most can be done using over-the-counter therapies. Rest as well as adequate hydration and nutrition are encouraged but not studied in trials. Acetaminophen and nonsteroidal antiinflammatory drugs can help with fever and discomfort. The combination of antihistamines and decongestants may be more beneficial than either component alone for nasal symptoms. When needed, dextromethorphan may provide symptom relief with cough suppression. Intranasal or inhaled cromolyn sodium¹ may help with rhinorrhea, throat pain, or cough. Various formulations of intranasal cromolyn sodium (NasalCrom) are available over the counter, and oral inhaled cromolyn sodium (Intal) is available by a prescription. Regular use of vitamin C supplements^{1,7} (at least 200 mg/d) may decrease duration of cold symptoms but is not effective if started after cold symptoms start. Oral zinc sulfate^{1,7} may decrease URI symptom duration and severity, but it is not routinely recommended because of adverse effects (bad taste and nausea).

Croup

Croup affects children with a peak incidence between 6 and 36 months of age, annually affecting 3% of those in this age range. Parainfluenza virus types 1 to 3 constitute 75% of all cases, but infection with many different viruses can produce this illness. Although some cases of croup can be caused by bacteria, it does not change how it is managed.

Croup is diagnosed clinically. Initially, patients experience cold-like symptoms: low-grade fevers and coryza. Inspiratory stridor, hoarseness, and a barking cough are typical findings that follow, peaking between 24 to 48 hours after onset. These symptoms are caused by mucosal inflammatory swelling of the larynx, trachea, and bronchi. Symptoms are often worse at night and can be exacerbated by emotional distress. Most (85%) cases are considered mild, but nasal flaring and retractions, increased respiratory rate, hypoxia, and tachycardia are indicators of more severe croup. Routine radiologic imaging is not encouraged,

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

because the steeple sign that is often associated with croup is actually nonspecific and can be seen in other causes of glottic and subglottic narrowing such as epiglottitis and bacterial tracheitis.

Management of croup is dependent on the severity of the disease. Administration of corticosteroids (single dose of dexamethasone [Decadron]¹ 0.6 mg/kg) are recommended for croup of any severity because it reduces return visits and hospitalization rates. Oxygen should be given to children with hypoxia or respiratory distress. Nebulized epinephrine¹ (0.05 mL/kg of racemic epinephrine 2.25% [max dose = 0.5 mL] or 0.5 mL per kg of L-epinephrine 1:1,000 via nebulizer [max dose = 5 mL]) is recommended for moderate or severe croup. It takes effect by vasoconstriction of the upper airway mucosa, leading to decreased edema. It has a quick onset of action, but efficacy wanes after 1 to 2 hours, so monitoring patients beyond 2 hours is recommended.

Humidified air has been commonly used for croup, but it has not been shown to be effective in decreasing croup symptoms or hospital admissions in moderate croup.

Pertussis

Pertussis should be suspected when patients have a persistent cough of more than 2 weeks with a characteristic paroxysmal cough, whooping cough, and post-tussive emesis or recent pertussis exposure. Most pertussis is caused by *B pertussis*. The number of outbreaks and pertussis incidence has increased in recent years. In the early catarrhal stage (1–2 weeks), it is difficult to discern from a common cold. The cough becomes more frequent, and severe bouts characterize the following paroxysmal stage (1–6 weeks, maximum of 10 weeks). Paroxysms of cough can be debilitating and cause post-tussive emesis, weight loss, and other conditions related to severe cough, but there are few symptoms otherwise. After this stage, the cough gradually improves over the course of a few weeks.

Atypical presentations are not uncommon, because those who have acquired immunity can present with a lesser degree of paroxysm. Thus pertussis should be suspected if cough symptoms last more than 3 weeks. Infants may also have atypical presentation of cough without paroxysmal whooping.

Diagnosis should be confirmed with either culture, polymerase chain reaction (both better for early stages), or serology (accurate in later stage). Efficacy of antibiotics is questionable because treatment does not improve symptoms. However, antibiotics (Azithromycin [Zithromax]¹ is first line—Children: 10 mg/kg/d for 3 days, or 10 mg/kg on day 1, then 5 mg/kg/d on days 2–5; Adults: 500 mg/d for 3 days, or 500 mg on day 1, then 250 mg/d on days 2–5) are still recommended because they eradicate *B pertussis* from the nasopharynx and may decrease transmission. Immunization is critical to prevent further outbreaks of pertussis.

Bronchiolitis

Bronchiolitis is the most common cause for infant hospitalization of infants. Respiratory syncytial virus is the most common cause of bronchiolitis. Bronchioles become plugged with detached epithelium and inflammatory cells. Onset of upper respiratory symptoms is often soon followed by rapid development of wheezing and labored breathing. Infants with bronchiolitis typically do not have a marked response to asthma treatment with bronchodilators and corticosteroids, despite similar presenting symptoms. Treatment primarily consists of supplemental oxygen and intravenous fluids as needed to prevent dehydration. Palivizumab (Synagis) is used to prevent hospitalization rate for high-risk infants, such as those with premature birth, chronic lung disease, and hemodynamically significant congenital heart disease.

Therapy (or Treatment)

Decreasing Antibiotic Use

Antibiotic use in the treatment of bronchitis is strongly discouraged in all major guidelines, but they are often prescribed

regardless of the recommendations. The strongest predictor of whether a patient will receive antibiotics is whether the clinician perceives the patient desires them. Patient education such as setting the expectation that cough from acute bronchitis can last 3 weeks, that antibiotics would not effectively aid in shortening the duration of symptoms, and explaining the undesired consequences of inappropriate antibiotic use such as antibiotic resistance and adverse effects is important. One in five patients treated with antibiotics will experience side effects such as headache, nausea, skin rash, diarrhea, and vaginitis. Patients are more likely to respond to this sort of education if they feel their concerns have been heard and addressed. In some cases, using a delayed prescription strategy wherein patients would need to call for a prescription or agree to pick up antibiotics after a certain number of days may be effective in decreasing antibiotic use. Providing methods for symptomatic management is also important for patients who desire treatment.

Recommended Cough Treatment

Dextromethorphan, guaifenesin, and honey may be considered to relieve cough symptoms. Dextromethorphan (30 mg orally every 6 to 8 hours) is a central-acting antitussive that reduces the cough reflex. In placebo-controlled studies, it was shown to decrease coughs by 19% to 36% (8 to 10 fewer coughs per 30 minutes) compared with placebo. Guaifenesin (immediate-release) 200 to 400 mg orally every 4 hours is an expectorant that increases respiratory tract secretions, hence decreasing mucus thickness. Study results vary, but it has been shown to decrease cough frequency and severity compared with placebo. Honey (2.5–10 mL [0.5–2 teaspoons]) has been compared with dextromethorphan, diphenhydramine, and no treatment in children. It was found to be better than no treatment in its effectiveness in decreasing cough severity and frequency and improving sleep quality. Honey would be an option for children older than 1 year, because antitussive use is not recommended in small children.

Cough Treatments that are not Recommended

There is no evidence that centrally acting antitussive codeine¹ has any effect to decrease cough symptoms, and benzonatate (Tessalon Perles), a peripherally acting antitussive has only been shown to be effective in conjunction with guaifenesin. Unfortunately, many over-the-counter therapies do not significantly impact acute bronchitis symptoms. Clinical trials have shown that ibuprofen (Motrin)¹ and antihistamines are not effective in reducing symptoms of cough. The FDA warns against using cough medications that have antihistamines and antitussives because of the high risk for potential harm in children younger than 4 years of age. Use of beta-agonists is also not recommended, unless the patient presents with wheezing at the time of presentation.

¹Not FDA approved for this indication.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Method of

Michael L. Corriveau, MD; and J. Barry Fagan, MD

CURRENT DIAGNOSIS

- Chronic obstructive pulmonary disease (COPD) is a treatable though not curable disease.
- Smoking is the most common risk factor for COPD worldwide.
- Eleven million Americans are diagnosed with COPD.
- As many as an additional 11 million Americans have COPD but have not been diagnosed.
- Alpha-1 antitrypsin deficiency occurs in 1 in every 1500 to 3000 individuals of European ancestry and is treatable by alpha-1 antitrypsin augmentation.
- Dyspnea, cough, and sputum production are common presenting complaints.
- Examination may reveal use of accessory muscles of ventilation, increased anteroposterior diameter, diminished breath sounds, wheezing, rhonchi, or crackles.
- Spirometry is the cornerstone of the diagnosis of COPD.
- COPD is defined by a reduction in the forced expiratory volume in 1 second/forced vital capacity (FEV_1/FVC).
- The severity of COPD is defined by the FEV_1 percent of predicted: mild (stage 1): FEV_1 greater than 79%; moderate (stage 2) FEV_1 : 50% to 79%; severe (stage 3): FEV_1 30% to 49%; very severe (stage 4): FEV_1 less than 30%.

CURRENT THERAPY

- Smoking cessation is the cornerstone of COPD management. Counseling and pharmacotherapy improve quit rates.
- Patients with COPD should receive the pneumococcal and influenza vaccines.
- Pulmonary rehabilitation improves activity capacity and quality of life and decreases dyspnea and hospitalization.
- Supplemental oxygen is used for resting, nocturnal, or exertional hypoxemia.
- Supplemental oxygen use prolongs life in those with resting hypoxemia, $PaO_2 < 89\%$.
- Pharmacotherapy can improve symptoms and decrease exacerbation rate.
- Proper inhaler technique is necessary for maximal benefit from inhaled medications.
- Short-acting beta-agonists are appropriate for mild, intermittent symptoms.
- A long-acting beta-agonist (LABA), a long-acting antimuscarinic (LAMA), or both may be added in patients with more frequent or severe dyspnea.
- Inhaled corticosteroids can decrease exacerbation frequency.
- Attention should be paid to management of retained secretions.
- Noninvasive ventilation can decrease hypercapnia and dyspnea in patients with chronic hypercapnic respiratory failure.
- A selected group of patients with severe disease may benefit from endobronchial valve treatment or surgical interventions, such as lung volume reduction surgery or lung transplantation.
- Exacerbations of COPD in outpatients may be managed with increased frequency of short-acting bronchodilators, systemic corticosteroids, and antibiotics.
- Palliative care is appropriate for patients with severe, refractory symptoms.

Epidemiology

Over 11 million Americans have chronic obstructive pulmonary disease, but including those undiagnosed, the number may be as high as 24 million. Prevalence varies state by state, from as low as 4% in Wisconsin and South Dakota to 10.4% in Kentucky. The global incidence in 2010 was estimated to be 384 million, with a global prevalence of 11.7%. The medical cost of COPD was estimated to be \$32 billion per year in 2010, with an additional loss of \$3.9 billion from absenteeism. These combined costs are estimated to increase to \$49 billion annually by 2020. COPD is the third-leading cause of death in the United States, accounting for more than 480,000 deaths per year, and is the fourth-leading cause of death worldwide. Although the death rate from COPD in men in the United States has been dropping, the death rate in women is stable to rising.

Risk Factors

Smoking is the leading risk factor for COPD in the United States and around the world. Of American adults over age 18, 15.1% are smokers (16.7% of men and 13.6% of women), which is approximately 36.5 million people. Globally, some 8 million people use the burning of biomass fuels or coal as their main source of energy for both cooking and heating. This indoor pollution is a significant risk factor for COPD in nonsmoking women and children in the Middle East, Africa, and Asia, and it is estimated to kill 2 million women and children each year. Occupational dusts and chemicals are additional risk factors. Alpha-1 antitrypsin (A1A) deficiency is an important genetic risk factor for COPD. A1A occurs in 1 in every 1500 to 3000 individuals of European ancestry, but is less common in Asian and black populations. The metalloproteinase 12 gene is associated with decline in lung function; the relationship between other genes and reduction in lung function is less well understood. It appears that women are more susceptible to the effects of cigarette smoke than men. Other factors possibly playing a role in COPD development include childhood respiratory infections, asthma, and low socioeconomic status.

Pathophysiology

COPD is an inflammatory lung disease, caused by an imbalance between proinflammatory cytokines, enzymes, and effector cells and the pulmonary defense mechanisms. An increase is seen in the number of proinflammatory cells, including circulating neutrophils and CD8 T lymphocytes, as well as the number of macrophages in bronchial mucosa. CD8⁺ cells have the potential to release tumor necrosis factor- α , perforins, and granzymes, though the exact role of T lymphocytes in COPD remains unclear. Neutrophils produce proteases that have the potential to cause alveolar destruction, elastase destruction, and mucus hypersecretion. Macrophages produce proteases and a variety of inflammatory mediators. Cigarette smoke promotes the release of these proinflammatory mediators and also inactivates several antiproteases, causing an inflammation/antiinflammation imbalance. This imbalance causes a cycle of injury and repair, which results in permanent damage to airways, lung parenchyma, and vasculature. The airways become narrowed by increased numbers of goblet cells, increased size of submucosal glands, mucosal thickening, collagen deposition, ciliary dysfunction (promoting retention of secretions within the airway), and destruction of alveolar walls and alveolar support. Loss of pulmonary vascular bed, vascular remodeling, and arterial vasoconstriction lead to hypoxemia from ventilation-perfusion mismatch and pulmonary hypertension.

Airways obstruction results in air trapping, hyperinflation, and flattening of the diaphragms. As the diaphragms flatten, the patient requires the use of accessory muscles of ventilation to move air. Airway narrowing or collapse increases the resistance to airflow, increasing the work of breathing and resulting in dyspnea. Lung compliance is decreased at high lung volumes, so breathing at high lung volumes owing to hyperinflation also results in dyspnea. Work of breathing is increased at rest in COPD and increases exponentially with activity. Dyspnea often leads to the vicious cycle of decreased activity, deconditioning, and progressive disability.

Diagnosis

Most patients with COPD present to their provider with complaints of dyspnea, cough and sputum production, or decreased activity capacity. This presentation may be relatively late in the disease course. Many smokers accept their cough as a “smoker’s cough.” Nonsmokers have a large ventilatory reserve; we breathe about 5 L/min at rest, but our maximum ventilatory volume is approximately 180 L/min. Because of this, especially if the patient is sedentary, he or she may not notice dyspnea until there has been considerable loss of pulmonary function.

The diagnosis of COPD should be considered in all patients with dyspnea, cough, sputum production, or exposure to risk factors. A careful history should include questions regarding quantity and duration of smoking and exposure to passive smoking or other occupational or environmental exposures. The patient should be asked about activity capacity; activities resulting in dyspnea, cough, or mucus production; and ease or difficulty clearing secretions. The input from a family member or friend is valuable, in that the patient may have become desensitized to dyspnea. On observation, the patient may be found in the “tripod” position, resting his or her arms on a surface and elevating the clavicles, which places the accessory muscles of ventilation at better mechanical advantage. This is why patients will often relate that they can walk farther while using a shopping cart and “tripoding” on the cart’s handles. Patients may be observed to be pursed-lip breathing, exhaling through pursed lips, elevating the pressure in the airways, stenting them open and allowing a fuller expiration, and decreasing air trapping and hyperinflation. Percussion may reveal evidence of hyperinflation. Auscultation may reveal wheezing or prolonged expiration resulting from airway obstruction, as well as rhonchi from retained secretions in the airways. Normal breath sounds originate in the terminal airways, and emphysematous destruction of these airways results in diminished breath sounds. Emphysema results in increased compliance of the lung, which raises the closing volume (the volume of air within the lung at which airways close). The closing volume may rise above functional residual capacity (the normal end-expiratory volume), causing inspiratory crackles.

Spirometry is the cornerstone of the diagnosis of COPD. Airway obstruction is defined by an FEV₁/FVC of less than 70%. Patients with airway obstruction may be able to exhale much of their vital capacity (VC), but because of airway narrowing, they cannot do it very quickly, resulting in the low ratio. The degree of obstruction is defined by the FEV₁ percent of predicted value (Figure 1). It is recommended that an A1A level be obtained in all patients diagnosed with COPD. It is important to note that A1A is an acute-phase reactant and can be elevated during an exacerbation of COPD; it is therefore best to obtain the A1A level when the patient is clinically stable.

Differential Diagnosis

COPD may be confused with other obstructive airway diseases, most notably asthma. Asthma will most often present at a younger age,

though it may be diagnosed during any decade of life. People with asthma generally have more reversibility and less fixed obstruction, but overlap is seen. Both COPD and asthma may cause hyperinflation and reduction in forced expiratory flows on pulmonary function testing, but a reduction in diffusing capacity would be more characteristic of COPD. Exhaled nitric oxide will more often be elevated in asthma. Eosinophils are characteristically elevated in the sputum, blood and bronchoalveolar lavage (BAL) fluid in patients with asthma, whereas neutrophils are more commonly elevated in patients with COPD. Considerable overlap occurs in each of these areas. There is a small percentage of patients in whom COPD and asthma cannot be differentiated; this is called the “overlap syndrome.”

Treatment of Stable COPD

The goals of treatment of COPD include improving quality of life, decreasing dyspnea, increasing activity capacity, preventing and treating complications and exacerbations, and prolonging life.

Smoking Cessation

Smoking cessation is the cornerstone of management of COPD. Smoking cessation and supplemental oxygen in patients with severe chronic hypoxemia are the only two interventions that prolong life in patients with COPD. During each clinical interaction with a patient who smokes, it is appropriate to *ask* about their smoking status, *advise* all smokers to quit, *assess* the willingness of the patient to quit, *assist* the patient in quitting, and *arrange* a follow-up visit. Brief counseling alone can improve the quit rate. In those patients who express a willingness to attempt to quit, adding pharmacotherapy to counseling is appropriate. Considerations for pharmacotherapy include nicotine replacement therapy, bupropion (Zyban), and varenicline (Chantix) (Figure 2). E-cigarettes are not currently recommended to assist with smoking cessation.

Pulmonary Rehabilitation

Pulmonary rehabilitation programs are widely available and can be defined as multidisciplinary programs that seek to improve the quality of life for patients with COPD or other lung diseases. Programs vary in content but will always include an exercise and an educational component, supervised by a respiratory therapist. They often meet two or three times weekly and last about 6 to 8 weeks. The educational component includes information on the disease state; medications used to manage COPD; energy-conserving techniques, such as pacing activities; breathing techniques, such as pursed-lip breathing; and what steps to take during an exacerbation. Programs may include nutritional advice, smoking cessation education, or psychosocial counseling. The exercise component is tailored to the individual patient and often includes treadmill or stationary bicycle exercise, light weights, arm ergometry, and stretching. Programs stress the importance of maintaining exercise following completion of the program and may offer a phase 3 component for continued exercise. Pulmonary rehabilitation has many proven benefits, including decreased dyspnea, improved quality of life, improved activity capacity, and decreased hospitalization. Pulmonary rehabilitation may be offered to any patient with COPD with symptoms or high risk of exacerbation.

Vaccinations

Annual influenza vaccines are recommended for all patients with COPD. Polysaccharide Pneumococcal vaccines (PPSV23) are recommended for all patients who smoke and/or have COPD with a repeat dose given 5 years after the first dose. At age 65, PCV13 is given, since it is more important for those that are immunocompromised which happens with more advanced age.

Medications

Commonly used medications for the treatment of stable COPD are listed in Figure 3. The beta-agonists stimulate beta-2 receptors on airway smooth muscle, causing muscle relaxation and bronchodilation. The short-acting beta-agonists have an onset of action of 1 to 3 minutes and duration of action of 4 to 6 hours. Because of their

SEVERITY	SPIROMETRY
Stage I: mild	FEV ₁ /FVC <70% FEV ₁ ≥80%
Stage II: moderate	FEV ₁ /FVC <70% 50% ≤FEV ₁ <80%
Stage III: severe	FEV ₁ /FVC <70% 30% ≤FEV ₁ <50%
Stage IV: very severe	FEV ₁ /FVC <70% FEV ₁ <30%

Abbreviations: FEV₁ = forced expiratory volume in 1 second; FVC = forced vital capacity

Medication**Dosage and Administration****Figure 2** Smoking cessation medications.

Nicotine Transdermal (NicoDerm CQ)	21 mg/24 hours, 14 mg/24 hours, 7 mg/24 hours If >10 cigarettes/D, then use 21 mg/D for 6 weeks, then 14 mg/D for 2 weeks, then 7 mg/D for 2 weeks, If <10 cigarettes/D, then use 14 mg/D for 6 weeks, then 7 mg/D for 2 weeks
Nicotine lozenges (Nicorette)	4 mg, 2 mg weeks 1–6, 1 lozenge every 1–2 hours, weeks 7–9 1 lozenge every 2–4 hours, weeks 10–12, 1 lozenge every 4–8 hours
Nicotine gum (Nicorelief, Thrive)	4 mg, 2 mg weeks 1–6, 1 gum every 1–2 hours, weeks 7–9 1 gum every 2–4 hours, weeks 10–12, 1 gum every 4–8 hours
Nicotine inhaler (Nicotrol)	10 mg/cartridge up to 12 weeks, 6–16 cartridges/day up to 12 weeks (if necessary), gradual reduction
Nicotine nasal spray (Nicotrol NS)	0.5 mg/spray each nostril, beginning 1–2/hour, maximum 5 doses/hour, maximum 40 doses/day up to 8 weeks, then taper up to 6 weeks
Bupropion hydrochloride SR (Zyban)	150 mg per day, first 3 days, then 150 mg bid
Varenicline (Chantix)	Day 1–3, 0.5 mg q day, day 4–7, 0.5 mg bid, day 8–end of treatment, 1 mg bid. Patients who quit at 12 weeks may be treated an additional 12 weeks.

Medication**Dosage****Figure 3** Commonly used inhaled medications for stable chronic obstructive pulmonary disease (COPD).

Short-acting beta agonists: Albuterol (multiple brands) Levalbuterol (Xopenex) Ipratropium (Atrovent) Albuterol/ipratropium (Combivent Respimat)	2 puffs q 4–6 hours, prn 1–2 puffs q 4–6 hours prn 2 inhalations 4 times a day 1 inhalation 4 times a day
Long-acting beta agonists: Formoterol (Foradil) Salmeterol (Serevent) Indacaterol (Arcapta) Olodaterol (Striverdi)	inhale contents of one capsule q 12 hrs one inhalation twice daily inhale contents of one capsule q day 2 puffs once day, same time of day
Long-acting antimuscarinics: Tiotropium (Spiriva Handihaler, Spiriva Respimat) Aclidinium (Tudorza)	2 inhalations of the powder contents of a single Spiriva capsule once daily 2 inhalations once daily 1 inhalation twice daily
Combination medications: Umeclidinium/vilanterol (Anoro) Budesonide/formoterol (Symbicort 160/4.5, 80/4.5) Fluticasone/salmeterol (Advair Diskus ¹ 100/50, 250/50, 500/50) (Advair HFA 45/21, 115/21, 230/21) Mometasone/formoterol (Dulera ¹ 100/5, 200/5) Olodaterol/tiotropium (Stiolto) Fluticasone/vilanterol (Breo 100/25, 200/25)	1 inhalation once daily 2 puffs twice daily 1 inhalation twice daily 2 puffs twice daily 2 inhalations twice daily 2 inhalations once daily 1 inhalation once daily

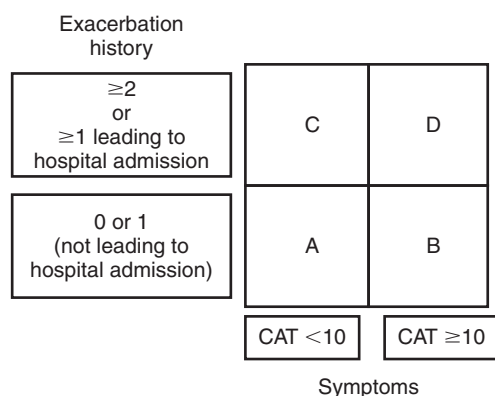

(Advair Diskus 100/50¹, 250/50, 500/50¹) (Advair HFA¹ 45/21, 115/21, 230/21)

quick onset and short duration of action, they are used as “rescue” or as-needed medications. Some long-acting beta-agonists also have rapid onset of action, but the duration of action is 12 to 24 hours. Potential side effects of beta-agonists include tremor, tachycardia, and uncommonly hypokalemia.

The antimuscarinic bronchodilators bind to muscarinic receptors, which are found on smooth muscle and submucosal glands. Two of these receptors, the M1 and M3 receptors, facilitate acetylcholine transmission, which results in bronchoconstriction. Potential side effects of the antimuscarinics include dry mouth and urinary hesitancy. The beta-agonists and antimuscarinics have additive effects on bronchial smooth muscle. Inhaled corticosteroids decrease airway inflammation and have been shown to decrease the frequency of exacerbation of COPD. Unlike in asthma, inhaled corticosteroids are not used as the sole maintenance therapy in COPD. Potential side effects of the inhaled corticosteroids include a small increase in risk of pneumonia and oral candidiasis. There are now many varieties of inhaler devices. Instruction in the use of the devices and observation of proper technique are necessary to ensure maximal benefit.

In the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines, medication recommendations are dictated by a classification system based on symptom score and exacerbation history (Figure 4). Patients are categorized as having either zero or one exacerbation, not requiring hospitalization, or two or more exacerbations or at least one exacerbation requiring hospitalization. Symptom severity is based on a symptom scoring scale, such as the COPD Assessment Test (Figure 5). On the COPD Assessment Test, the patient is asked a series of eight questions, grading severity as 0 to 5. The sum of the scores is used to categorize the patient in the GOLD classification grid.

Patients in group A are given a trial of short- or long-acting bronchodilators. The medication is continued if the patient is determined to have benefited from the intervention. Group B patients should be started on a long-acting bronchodilator, either a LABA or LAMA. If the patient has continued dyspnea, LAMA and LABA may be used together. For patients with severe dyspnea, treatment may begin with both agents. Initial therapy for group C patients is a LAMA. For patients with persisting exacerbations, adding a LABA is the primary choice. Adding an inhaled corticosteroid (ICS) would be a secondary choice. Recommended initial treatment for group D patients is a LABA/LAMA combination. Consideration could be given to initiating treatment with an LABA/ICS combination in patients with prominent asthmatic symptoms. Patients with continuing exacerbations may be switched to a LABA/LAMA/ICS combination. In patients with persisting exacerbations on this treatment, the phosphodiesterase-4 inhibitor roflumilast (Daliresp)

500 mcg/day or prophylactic azithromycin (Zithromax)¹ 250 mg/day or 500 mg on Monday, Wednesday, and Friday have been shown to decrease the frequency of exacerbations.

Sustained-release theophylline preparations have a mild bronchodilator effect and may be added to an otherwise maximized regimen or used when cost considerations prohibit the use of long-acting bronchodilators.

Retained secretions may increase dyspnea and hypoxemia. Management may include use of guaifenesin¹ 200 to 400 mg orally every 4 hours as needed, not to exceed 2.4 g/day; potassium iodide (SSKI) 0.3 mL (300 mg) or 0.6 mL (600 mg) diluted in one glassful of water, fruit juice, or milk three to four times daily; and positive expiratory pressure devices, such as the Acapella.

Noninvasive Ventilation

Bilevel ventilation has been used in patients with chronic hypercapnic respiratory failure. Regular use of noninvasive ventilation in this population has shown improvement in walk distance, dyspnea, and hypercapnia by increasing minute ventilation and decreasing work of breathing. Medicare guidelines for prescribing require documented hypercapnia ($P_{aCO_2} > 51$) and a nocturnal oximetry showing desaturation to SaO_2 less than 89% for at least 5 consecutive minutes during sleep. Initial settings are somewhat empiric, often beginning at inspiratory positive airway pressure (IPAP) of 12 cm H_2O and expiratory positive airway pressure (EPAP) of 5 cm H_2O . These settings may be adjusted based on comfort and degree of hypercapnia.

Surgical Remedies

Lung volume reduction surgery is a consideration for patients with severe disease meeting certain criteria. The rationale is that removing the most diseased portions of lung in patients with emphysema will decrease hyperinflation, improve ventilation/perfusion matching, and decrease lung compliance. This elevates the diaphragm, placing it at better mechanical advantage, and stents open the airways. Selection criteria come from the National Emphysema Therapy Trial (NETT) and include patients with emphysema who are

¹Not FDA approved for this indication.

younger than 75 years old, ex-smokers, and on no more than 20 mg/day of prednisone with functional limitation and good compliance. Laboratory evaluation must demonstrate upper lobe–predominant emphysema on chest computed tomography, hyperinflation, low FEV₁ ($\leq 45\%$ predicted, and $\geq 15\%$ predicted if age over 70), and postrehabilitation 6-minute walk greater than 140 m. Exclusionary criteria include morbid obesity, significant comorbidities, previous chest surgery or chest wall deformity that might interfere with the procedure, resting pulmonary hypertension, well-preserved exercise capacity, and significant pleural or interstitial disease.

Lung transplantation may be considered in patients younger than 65 years old (younger than 60 years old for double lung transplant), with FEV₁ less than 25% predicted and/or PaCO₂ greater than 55 mm Hg and/or pulmonary hypertension, especially in patients with progressive disease requiring supplemental oxygen. Exclusionary criteria include other major organ dysfunction, recent malignancy, HIV-positive status, and hepatitis B or C.

An emerging therapy is endobronchial valve therapy, in which one-way valves are placed in some airways endoscopically to produce a nonsurgical lung volume reduction. This treatment has been shown to result in improved pulmonary function, exercise capacity, and quality of life in some patients with emphysema.

Supplemental Oxygen

The use of supplemental oxygen in patients with COPD is based on the fact that its use in severely hypoxemic patients helps prevent pulmonary hypertension, cor pulmonale, and premature death. Indications for continuous supplemental oxygen are resting PaO₂ less than or equal to 55 mm Hg or PaO₂ 56 to 59 mm Hg with evidence of complications, such as pulmonary hypertension or polycythemia. Supplemental oxygen may be prescribed during activity for SaO₂ less than 89% during activity, and may be prescribed during sleep for patients with SaO₂ less than 89% for at least 5 minutes during sleep.

Treatment of Exacerbations of COPD

COPD exacerbations are defined as an acute increase in symptoms requiring an adjustment in medication. They are defined as mild (requiring only bronchodilator adjustment), moderate (requiring antibiotics and/or oral corticosteroids), or severe (requiring hospitalization or emergency department management). Some factors that help determine the need for hospitalization include severity of symptoms, failure to respond to initial management, increasing hypoxemia or hypercapnia, or mental status changes. Underlying comorbidities or lack of support at home may also contribute to the need for hospitalization. Exacerbations may be triggered by viral or bacterial infections or environmental factors. Thirty percent cannot be attributed to a specific cause.

An increase in the frequency of use of as-needed short-acting beta-agonists is initial management for exacerbations. Systemic corticosteroids improve pulmonary function measurement and shorten recovery time. Prednisone 40 mg/day for 5 days is effective and has been shown to have a similar effect to intravenous steroid administration. The addition of an antibiotic course for 5 to 7 days has been shown to improve outcomes in outpatients with either increased dyspnea or increased sputum production plus increased sputum purulence. Antibiotics have been shown to decrease mortality and the incidence of nosocomial infection in patients with exacerbation who require invasive or noninvasive mechanical ventilation.

COCCIDIOIDOMYCOSIS

Method of

Gregory M. Anstead, MD, PhD

CURRENT DIAGNOSIS

- Maintain a high index of suspicion in patients from endemic areas and travelers
- Diagnostic tests include:
 - Serologic detection of immunoglobulin M and immunoglobulin G antibodies by immunodiffusion, complement fixation, and enzyme immunoassay
 - Culture of sputum, exudates, cerebrospinal fluid, and tissue
 - Direct observation of *Coccidioides* spherules in histopathologic and cytologic specimens
 - Urine antigen enzyme immunoassay

CURRENT THERAPY

Pulmonary Infection

- No risk factors for dissemination; not severe disease—observe
- Risk factors; prolonged symptoms—fluconazole (Diflucan)¹ 400 mg/day or itraconazole (Sporanox)¹ 200 mg twice a day for 3 to 6 months
- Diffuse or severe pneumonia—amphotericin B (Fungizone) 1 mg/kg/day or lipid formulation of amphotericin (Abelcet, AmBisome)¹ 5 mg/kg/day; after improvement, switch to azole; treat for 1 year
- Chronic fibrocavitary disease—azole therapy for at least 1 year; resection in selected cases

Disseminated Disease

- Nonmeningeal, severe disease—amphotericin B 1 mg/kg/day or lipid formulation of amphotericin¹ 5 mg/kg/day; after improvement, switch to azole for 1 to 2 years; consider posaconazole (Noxafil)¹ suspension 200 mg four times daily or voriconazole (Vfend)¹ 400–600 mg/day daily in refractory cases
- Nonmeningeal, slowly progressive—azole therapy for 1 to 2 years; itraconazole¹ preferred for bony involvement; consider posaconazole¹ or voriconazole¹ (as above) in refractory cases
- Meningeal, central nervous system involvement—fluconazole¹ 800 to 2000 mg/day³; intrathecal amphotericin B¹ or voriconazole (Vfend)¹ 200 mg twice daily in refractory cases¹; shunting for hydrocephalus; consider corticosteroids if vasculitis is present

¹Not FDA approved for this indication.

Coccidioidomycosis is caused by soil fungi of the genus *Coccidioides*, divided genetically into *Coccidioides immitis* (California isolates) and *Coccidioides posadasii* (isolates outside California). There are no distinct clinical differences between the two species. *Coccidioides* occurs only in the Western hemisphere, primarily in the southwestern United States (Arizona and parts of California, New Mexico, Utah, Nevada, and Texas) and in northern Mexico, areas characterized by arid to semiarid climates, hot summers, low altitude, alkaline soil, and sparse vegetation. Hyperendemic areas include the San Joaquin Valley of California and Pima, Pinal, and Maricopa Counties in Arizona. *Coccidioides* is also found in parts of Latin America (Guatemala, Honduras, Nicaragua, Argentina, Paraguay, Venezuela, and Colombia). Cases may be observed in nonendemic areas because of travel or reactivation of prior infection. In the United States, an estimated 150,000 cases of coccidioidomycosis occur annually, with the clinical presentation ranging from a self-limited respiratory infection to devastating disseminated disease. The incidence of coccidioidomycosis is increasing in the USA due to rising populations and the resulting construction in the endemic areas. Risk factors for increased severity of coccidioidomycosis include: receiving immunosuppressive medications (corticosteroids, transplant drugs, and tumor necrosis factor- α antagonists); pregnancy (esp. the third trimester); genetic factors (i.e., defects in the IL-12/interferon- γ axis and STAT3 pathways, certain ABO blood group and HLA types); and specific races/ethnicities (African Americans, Asian-Pacific Islanders, and Native Americans). Outbreaks may occur after dust storms, earthquakes, droughts, and activities causing soil disruption, such as construction and archeological digs. Persons with occupations involving exposure to soil are also at risk for acquiring coccidioidomycosis.

Coccidioides is dimorphic; in the soil, the organism exists in its mycelial form, which produces barrel-shaped arthroconidia. The usual means of infection is the inhalation of arthroconidia; uncommon routes include direct cutaneous inoculation and organ transplantation. Arthroconidia germinate to produce spherules filled with endospores, the characteristic tissue phase. Spherules rupture to release endospores, which form additional spherules. The spherules become surrounded by neutrophils and macrophages, which leads to granuloma formation. Both B and T lymphocytes are essential for host defense against this pathogen.

Clinical Manifestations

Coccidioidomycosis is asymptomatic in 60% of infected individuals. In the remaining 40% a self-limited, flu-like illness, with dry cough, pleuritic chest pain, myalgias, arthralgia, fever, sweats, anorexia, and weakness, develops 1 to 3 weeks after exposure. Primary infection may be accompanied by immune complex-mediated complications, including an erythematous macular rash, erythema multiforme, and erythema nodosum. Acute infection usually resolves without therapy, although symptoms may persist for weeks. In 5% of these patients, asymptomatic pulmonary residua persist, including pulmonary nodules and cavitation. Immunocompromised patients may develop chronic progressive pulmonary infection, with the evolution of thin-walled cavities that may rupture, leading to bronchopleural fistula and empyema formation.

Extrapulmonary disease develops in 1 of every 200 patients and can involve the skin, soft tissues, bones, joints, and meninges. The most common cutaneous lesions are verrucous papules, ulcers, or plaques. The spine is the most frequent site of osseous dissemination, although the typical lytic lesions may also occur in the skull, hands, feet, and tibia. Joint involvement is usually monoarticular and most commonly involves the ankle and knee. Fungemia may occur in immunocompromised patients and carries a poor prognosis.

In coccidioidal meningitis, the basilar meninges are usually affected. Cerebrospinal fluid findings include lymphocytic pleocytosis (often with eosinophilia), hypoglycorrachia, and elevated protein levels. The mortality rate is greater than 90% at 1 year without therapy, and chronic infection is the rule. Hydrocephalus or

hydrocephalus coexisting with brain infarction is associated with a higher mortality rate.

Coccidioidomycosis is a great imitator and has many diverse clinical presentations, including immune thrombocytopenia, ocular involvement, massive cervical lymphadenopathy, laryngeal and retropharyngeal abscesses, endocarditis, pericarditis, peritonitis, hepatitis, and lesions of the male and female genitals and urogenital tracts.

Diagnosis

Coccidioidomycosis may be diagnosed by direct observation of spherules in tissues or in wet mounts of sputa or exudates. The growth of *Coccidioides* in culture usually occurs in 3 to 5 days, with sporulation after 5 to 10 days. Definitive identification is made by DNA probe or exoantigen testing. Laboratory personnel should exercise extreme caution when handling cultures of *Coccidioides*.

Serologic methods are quite useful in establishing the diagnosis and for monitoring the course of the infection. Immunoglobulin M (IgM) antibodies are present soon after infection or relapse but then wane; quantification does not correlate with disease severity. The IgG antibody appears later and remains positive for months. Rising titers of IgG are associated with progressive disease, and declining titers are associated with resolution. The IgG antibodies are able to fix complement when combined with coccidioidal antigen, and can be detected by immunodiffusion for complement fixation (IDCF); titers of 1:16 or greater suggest disseminated disease. In the cerebrospinal fluid, a positive IDCF of any titer is considered diagnostic of meningitis and is much more sensitive than culture in making the diagnosis. An enzyme immunoassay is also available, but it is less specific. Recently, a specific urinary antigen test became available for the diagnosis of coccidioidomycosis; this assay has a sensitivity of 71% in moderate-to-severe disease, compared with 84% for culture, 29% for histopathologic examination, and 75% for serologic testing.

Treatment

In most patients, primary pulmonary infection resolves spontaneously without treatment. However, all patients require observation for at least 2 years to document resolution of infection and to identify any complications as soon as possible. For patients who have risk factors for disseminated disease (listed earlier), treatment is necessary. Other indications for treatment are severe disease (infiltrates involving both lungs or more than half of one lung; significant hilar or mediastinal lymphadenopathy; complement fixation titers >1:16) and highly symptomatic disease (weight loss >10%; night sweats present for >3 weeks; symptoms present for >2 months).

For diffuse or severe pneumonia, therapy with amphotericin B deoxycholate (Fungizone) 0.5 to 1.5 mg/kg/day, or a lipid formulation of amphotericin B (Abelcet or AmBisome)¹ 2 to 5 mg/kg/day should be given for several weeks, followed by an oral azole, such as itraconazole (Sporanox)¹ 200 mg twice daily or fluconazole (Diflucan)¹ 400 to 800 mg/day. The total duration of therapy should be at least 1 year; for immunosuppressed patients, oral azole therapy should be maintained as secondary prophylaxis. In HIV patients with CD4-positive T-cell counts greater than 250 cells/mm³ who had focal pneumonias that responded to azoles, antifungals may be discontinued. Azole therapy may be used initially for less severe disease. During pregnancy, amphotericin B is the preferred drug, because of the teratogenicity of azoles.

An asymptomatic patient with a solitary nodule or pulmonary cavitation due to *C. immitis* does not require specific antifungal therapy or resection. However, the development of complications from the cavitation, such as hemoptysis or bacterial or fungal superinfection, necessitates initiation of azole therapy. Resection of the cavities is an alternative to antifungal therapy. Rupture of a cavity into the pleural space requires surgical intervention with

¹Not FDA approved for this indication.

closure by lobectomy with decortication, in addition to antifungal therapy. For chronic pneumonia, the initial treatment should be an oral azole for at least 1 year. If the disease persists, one may switch to another oral azole, increase the dose if fluconazole was initially selected, or switch to amphotericin B. Resection should be performed for patients with refractory focal lesions or severe hemoptysis.

The treatment of disseminated infection without central nervous system involvement is based on oral azole therapy, such as itraconazole¹ or fluconazole¹ (400 mg/day, or higher in case of fluconazole). If there is little or no improvement or if there is vertebral involvement, treatment with amphotericin B is recommended (dosage as for diffuse pneumonia). Concomitant surgical débridement or stabilization is also recommended. In patients with refractory coccidioidomycosis that has failed to respond to fluconazole, itraconazole, and amphotericin B and its lipid formulations, treatment with posaconazole (Noxafil)¹ suspension 200 mg four times daily with a fatty meal or voriconazole (Vfend)¹, at doses of 400–600 mg/day, has been successful. A posaconazole tablet with improved oral bioavailability and an intravenous preparation are now available and likely these new forms of posaconazole are more efficacious. Clinical experience with voriconazole is limited.

For coccidioid meningitis, lifetime treatment with azoles is indicated. Fluconazole¹, at doses of 800 mg/day or higher³, is recommended. There have been a few reports of successful treatment of coccidioid meningitis with voriconazole (Vfend)¹ 200 mg orally twice daily after a loading dose. Itraconazole is not recommended because of its irregular oral absorption. For patients with increased intracranial pressure at the time of meningitis diagnosis, repeated lumbar punctures are recommended. Obstructive hydrocephalus requires shunting. Intrathecal amphotericin B¹ is now strictly reserved for meningitis refractory to high-dose azoles or coccidioid meningitis in the first trimester of pregnancy. In patients with CNS vasculitis with cerebrovascular accident due to coccidioidomycosis, those that received corticosteroids were less likely to develop additional infarcts compared to those who did not.

Reduction of immunosuppression is an important adjunct to antifungal therapy, including the initiation of antiretroviral therapy if the patient has HIV infection. In patients with AIDS and non-meningeal coccidioidomycosis, antifungal therapy can be discontinued when the CD4 count exceeds 250 cells/mm³.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

CYSTIC FIBROSIS

Method of

Robert Giusti, MD

CURRENT DIAGNOSIS

- Sweat testing remains the standard for making the diagnosis of CF.
- Genetic testing is also available to detect gene mutations.

CURRENT THERAPY

- Nationwide newborn screening improves outcomes.
- With appropriate treatment, median survival has improved to age 47 years.
- Ivacaftor (Kalydeco), a CFTR potentiator, is the first treatment to the underlying cause of CF in patients with the G551D mutation that improves function of the chloride channel.

Cystic fibrosis (CF), an autosomal recessive disease, is the most common lethal inherited disease in the white population. In this population the carrier rate is approximately 1 in 30, with an incidence of 1 in 3200 births. CF also occurs in African Americans (1 in 15,000), Hispanic Americans (1 in 8000) and Asian Americans (1 in 31,000), but diagnosis may be delayed because of a low index of suspicion in these ethnic groups. Lung disease is the primary cause of morbidity and mortality in CF. Progressive fibrosis and destruction of lung tissue from chronic cycles of infection and inflammation lead to respiratory failure. The median predicted age of survival for people with CF has risen steadily over the last 25 years. Since 2002, the median predicted survival age has increased almost 10 years from age 31.3 in 2002 to 47 in 2016.

Pathophysiology

The defect that results in CF is an abnormal gene located on the long arm of chromosome 7 that codes for a protein known as the cystic fibrosis transmembrane regulator (CFTR). This protein becomes incorporated into the lipid bilayer of the epithelial surface of the cell and functions as a chloride channel. Defective cyclic adenosine monophosphate (cAMP)-regulated chloride secretion through a mutated CFTR protein results in dehydrated airway surface fluid, which impedes the normal ciliary function, resulting in chronic infection and atelectasis. In addition, CFTR also down-regulates an epithelial sodium channel (ENaC). When CFTR is defective, this down-regulation is diminished, resulting in increased sodium reabsorption and a further reduction in airway surface fluid. The CFTR gene is expressed in the biliary ducts, vas deferens, pancreatic ducts, sweat glands, and the mucous glands of the lung.

Researchers have identified more than 2,000 mutations in the cystic fibrosis (CF) gene (<http://www.genet.sickkids.on.ca/Home.html>). The functional consequences of mutations at the cellular level have been classified based on the way the mutations affect the CFTR protein production (<http://www.CFTR2.org>). These genetic changes can be grouped into different types, based on how confident scientists are that the change actually causes the CF disease:

closure by lobectomy with decortication, in addition to antifungal therapy. For chronic pneumonia, the initial treatment should be an oral azole for at least 1 year. CYSTIC FIBROSIS

Method of

Robert Giusti, MD

CURRENT DIAGNOSIS

- Sweat testing remains the standard for making the diagnosis of CF.
- Genetic testing is also available to detect gene mutations.

CURRENT THERAPY

- Nationwide newborn screening improves outcomes.
- With appropriate treatment, median survival has improved to age 47 years.
- Ivacaftor (Kalydeco), a CFTR potentiator, is the first treatment to the underlying cause of CF in patients with the G551D mutation that improves function of the chloride channel.

Cystic fibrosis (CF), an autosomal recessive disease, is the most common lethal inherited disease in the white population. In this population the carrier rate is approximately 1 in 30, with an incidence of 1 in 3200 births. CF also occurs in African Americans (1 in 15,000), Hispanic Americans (1 in 8000) and Asian Americans (1 in 31,000), but diagnosis may be delayed because of a low index of suspicion in these ethnic groups. Lung disease is the primary cause of morbidity and mortality in CF. Progressive fibrosis and destruction of lung tissue from chronic cycles of infection and inflammation lead to respiratory failure. The median predicted age of survival for people with CF has risen steadily over the last 25 years. Since 2002, the median predicted survival age has increased almost 10 years from age 31.3 in 2002 to 47 in 2016.

Pathophysiology

The defect that results in CF is an abnormal gene located on the long arm of chromosome 7 that codes for a protein known as the cystic fibrosis transmembrane regulator (CFTR). This protein becomes incorporated into the lipid bilayer of the epithelial surface of the cell and functions as a chloride channel. Defective cyclic adenosine monophosphate (cAMP)-regulated chloride secretion through a mutated CFTR protein results in dehydrated airway surface fluid, which impedes the normal ciliary function, resulting in chronic infection and atelectasis. In addition, CFTR also down-regulates an epithelial sodium channel (ENaC). When CFTR is defective, this down-regulation is diminished, resulting in increased sodium reabsorption and a further reduction in airway surface fluid. The CFTR gene is expressed in the biliary ducts, vas deferens, pancreatic ducts, sweat glands, and the mucous glands of the lung.

Researchers have identified more than 2,000 mutations in the cystic fibrosis (CF) gene (<http://www.genet.sickkids.on.ca/Home.html>). The functional consequences of mutations at the cellular level have been classified based on the way the mutations affect the CFTR protein production (<http://www.CFTR2.org>). These genetic changes can be grouped into different types, based on how confident scientists are that the change actually causes the CF disease:

- **Confirmed CF-causing mutations.** These mutations are seen in people with CF. When a person inherits two of these mutations (one from each parent), that person will always have CF.
- **Suspected CF-causing mutations.** These are mutations that have been reported in people with CF but have not been confirmed to always cause CF.
- **Variants of uncertain clinical impact.** We do not know if these mutations cause CF.
 - Mutations that sometimes cause CF, but sometimes do not.
 - Mutations that have not been found often enough through genetic testing to know for sure if they do or do not cause CF.
- **Neutral variants.** These are genetic changes that do not cause CF.

There are three medications known as CFTR modulators approved by the FDA to treat the underlying defect, which is reduced CFTR function. Ivacaftor (Kalydeco), which functions as a potentiator of CFTR chloride ion movement across epithelial membranes, is approved for the G551D mutation and other mutations in which chloride channel conductance is defective. The combination drug lumacaftor/ivacaftor (Orkambi), which combines a corrector with a potentiator, is approved for patient with homozygous Delta 508 mutations. This year, a new combination potentiator and corrector, ivacaftor/tezacaftor (Symdeko), has also been approved with improvement in FEV₁ compared to the previous approved therapies. CFTR correctors facilitate the intracellular processing of misfolded mutant proteins increasing the amount of CFTR protein that reaches the epithelial cell surface.

In Classes IV and V mutations, CFTR is present on the apical surface but chloride channel conduction is defective, resulting in 5% residual CFTR activity and the pancreatic sufficient (PS) phenotype. In the PS phenotype, respiratory symptoms might not present until adulthood, and sufficient pancreatic function is maintained to prevent malabsorption. Because PS patients have residual pancreatic function, there is adequate pancreatic tissue to become inflamed, and these patients might present with recurrent pancreatitis. Residual CFTR function is also manifested in the sweat gland, with sweat tests in the borderline range (40–60 mmol/L). The presence of a class IV or V mutation with a Δ508 mutation results in a PS phenotype.

There is another polymorphism found on intron 8, a noncoding region of the CFTR gene, which affects the amount of normal CFTR transcripts produced. The length of the poly T sequence (5T, 7T, or 9T) is significant in the presence of variable mutation R117H. A lower number of thymidine units results in less efficient splicing of CFTR transcripts and therefore a lower amount of functional CFTR protein. The 5T allele has been classified as a mutation causing mild disease with partial penetrance. The 5T polymorphism is found on about 21% of the CFTR genes derived from patients with congenital bilateral absence of the vas deferens (CBAVD). In CBAVD there is 10% CFTR activity, which is sufficient to have obstructive azoospermia as the only clinical manifestation (Box 1).

Diagnosis

Sweat testing remains the standard for making the diagnosis of CF. The elevation of the chloride results from CFTR chloride channel dysfunction in the sweat ducts, where reabsorption of chloride occurs. Pilocarpine is iontophoresized into the skin to stimulate sweating. A chloride level greater than 60 mmol/L is consistent with the diagnosis of CF, but the result must be interpreted in the context of the clinical picture. The borderline range for sweat chloride is 30 to 60 mmol/L. Additional testing is necessary to confirm the diagnosis when the sweat test is in the borderline range. False-positive sweat test results can occur with malnutrition, Addison's disease, and ectodermal dysplasia, so it is essential to confirm the diagnosis with a confirmatory sweat test or a genetic analysis, or both. Sweat tests can be performed after 2 weeks of age, at which time a sufficient quantity of sweat can be collected to ensure a proper analysis.

Genetic analysis for mutations known to cause CF symptoms is an alternative diagnostic approach. The presence of two abnormal

BOX 1

Differentiating Between Criteria of CFTR Genotypes

Pancreatic Insufficient

Class I, II, or III mutation

1% CFTR activity

Absent or minimal chloride channel function

Elevated sweat chloride >60 mmol/L

Classic early presentation (50% diagnosed by 6 months of age)

Median survival is 37.4 years

Patients require pancreatic enzymes

Fecal pancreatic elastase-1 <100 µg/g

Atrophic scarred pancreas

Risk of diabetes mellitus increases with age

Pancreatic Sufficient

Class IV or V mutation

5% CFTR activity

Some chloride channel function

Borderline or mildly elevated sweat chloride (40–60 mmol/L)

Atypical late presentation (sometimes in adulthood)

Survival to 50 years is not uncommon

No pancreatic enzyme supplement required

Fecal pancreatic elastase-1 >250 µg/g

Adequate functional pancreatic tissue to develop recurrent pancreatitis

Lower risk of diabetes mellitus

Abbreviations: CFTR = cystic fibrosis transmembrane regulator (protein).

Class I, II and III mutations result from abnormal protein production, trafficking through the cell and regulation at the cell surface. These mutations result in 1% CFTR activity and are associated with more severe disease, worse pulmonary function, and pancreatic insufficient phenotype.

CFTR mutations known to cause CF disease predicts with a high degree of certainty that a patient has CF. Prenatal screening is recommended by the American College of Obstetrics and Gynecology for pregnant women. When both parents are found to be carriers, amniocentesis and chorionic villous sampling can be used to assess the 25% chance of having an infant affected by CF.

The active transport of ions generates a transepithelial electrical potential difference (PD). Abnormalities of chloride ion transport in patients with CF are associated with a different pattern of PD compared with normal epithelium. This assay thus provides a direct view of the physiology at the ion channel level. Nasal PD measurements help resolve diagnostic dilemmas in atypical patients and a change of PD measurement toward normal is an outcome measure of therapeutic interventions that correct the chloride channel dysfunction.

Three features distinguish the nasal PD in a patient with CF. A high basal PD reflects enhanced sodium transport across a relatively chloride impermeable membrane. A larger inhibition of PD after nasal perfusion with the sodium channel inhibitor amiloride reflects inhibition of accelerated sodium transport. Little or no change in PD in response to perfusion of the nasal epithelial surface with a chloride-free solution in conjunction with isoproterenol reflects an absence of CFTR-mediated chloride secretion.

Newborn screening for CF has been shown to improve nutritional and neurodevelopmental outcomes. Trypsinogen, a precursor of trypsin, is commonly elevated in the serum of newborns with CF. Infants with CF have elevated immunoreactive trypsinogen (IRT) levels for 2 to 3 weeks after birth. When the IRT is elevated in a blood specimen collected shortly after birth, then an analysis for the presence of CF mutations on the same blood specimen or a persistent elevation of IRT at 2 to 3 weeks of age in a repeat blood specimen are two different methods to determine which infants should be referred for sweat testing. Mutation analysis performed during newborn screening detects carriers of CF mutations, and genetic counseling for these families is warranted to permit informed decisions concerning future pregnancies.

Clinical Presentation With Specific Therapy

Gastrointestinal

About 15% of infants present with meconium ileus, obstruction of the distal ileum with thickened viscid meconium. Prenatal ultrasound might detect echogenic bowel, which suggests CF. Infants present shortly after birth with feeding intolerance and a distended abdomen that requires surgical intervention. Colostomies are placed to permit irrigation to dilate the underdeveloped micro colon, and resection of the terminal ileum is sometimes required. In utero perforation of the bowel can occur, manifesting with calcifications on abdominal x-ray.

The distal intestinal obstruction syndrome (DIOS) is an intestinal obstruction seen in older CF patients. It manifests with abdominal pain, constipation, and a palpable mass in the right lower quadrant consisting of viscous mucus and undigested fecal material that causes obstruction at the ileocecal valve. This can predispose to intussusception. The obstruction is treated by oral or nasogastric administration of polyethylene glycol and electrolytes (GoLYTELY),¹ an osmotic agent, which causes water to be retained in the intestine, inducing diarrhea. If the obstruction persists, a therapeutic gastrografin enema with reflux past the ileocecal valve may be necessary. Rectal prolapse and the meconium plug syndrome, in which there is delayed passage of meconium in the newborn period, are additional reasons for referring a child for a sweat test.

Infants might also present with prolonged obstructive jaundice, which can progress to hepatic steatosis, complete biliary obstruction, and acholic stools. In the biliary tree, sludging of bile due to inadequate chloride and fluid transfer into the bile canaliculus can result in focal biliary cirrhosis and cholethiasis. Approximately 2% of patients progress to multilobular cirrhosis with portal hypertension, hypersplenism, and esophageal varices. Progression to liver failure and the need for transplantation is a possibility. Ursodeoxycholic acid (Actigall),¹ a cholorectic bile acid that increases the flow of bile, has been shown to lower hepatic enzymes and delay the progression of liver disease.

Chloride channel dysfunction in the pancreas results in thickened secretions within the pancreatic ducts and obstruction to the flow of pancreatic chyle. Approximately 85% of patients with CF develop exocrine pancreatic insufficiency. The inadequate production of pancreatic lipase and amylase results in fat and protein malabsorption, steatorrhea, failure to thrive, hypoalbuminemia, and edema. The buffering capacity of pancreatic chyle is diminished, resulting in decreased effectiveness of pancreatic enzyme replacement therapy, which is optimally effective at a neutral pH.

The 72-hour recording of dietary intake and stool collection for quantitative determination of fecal fat content is inconvenient and prone to collection errors in the nonresearch setting. The pancreatic enzyme elastase-1 is stable during intestinal transit and is not affected by porcine pancreatic replacement therapy. The measurement of fecal elastase-1 in stool has been found to be a less cumbersome and a sensitive assay to assess pancreatic function. This can be performed on a small specimen and does not require a timed collection.

Treatment with pancreatic enzyme replacement (pancrelipase [Creon, Pancrease]) improves linear growth and weight gain. The recommended dose per meal is 1000 to 2500 U/kg/dose. A high-fat diet is recommended to increase caloric intake to 150 kcal/kg of body weight, which is necessary to ensure optimal growth. The report of the Cystic Fibrosis Foundation Patient Registry indicates that 14% of CF patients are below the 5th percentile for height and 22% are below the 10th percentile for weight. Because nutritional failure as measured by body mass index (BMI), this parameter has been shown to be a predictor of progressive pulmonary deterioration. Aggressive use of nutritional supplementation and nighttime gastrostomy feeds are advocated to improve the quality of life and lung function. Supplementation of fat-soluble vitamins is necessary to prevent nutritional deficiency.

Because CF patients are living longer, progressive fibrosis of the pancreas results in an increased incidence of diabetes, which is seen in 15% of CF patients. Annual glucose tolerance testing has become the standard of care in adolescents and adults to diagnose glucose intolerance before the onset of diabetes, which has been found to result in deterioration of lung function. Respiratory infection and steroid therapy can result in hyperglycemia, leading to a need for insulin before the patient develops frank diabetes. Because there are reductions of both insulin and glucagon, ketoacidosis is rare.

Infants with CF lose a great deal of salt in their sweat and can develop hyponatremic dehydration, heat prostration, and hypochloremic alkalosis. Salt supplementation is the norm, especially during warm summer months.

Pulmonary

The lungs in CF are normal at birth. In young CF patients *Staphylococcus aureus* and *Haemophilus influenzae* are common early colonizers, but as patients age, *Pseudomonas aeruginosa* becomes the predominant organism and is present in the sputum of 65% of adults. *P. aeruginosa* undergoes a mucoid transformation, which interferes with the effectiveness of antibiotic therapy. Because the acquisition of *P. aeruginosa* has been correlated with a more rapid deterioration of lung function and decreased survival, aggressive antibiotic therapy is initiated when this organism is isolated to prevent chronic colonization of the airway.

Burkholderia cepacia, an organism that is intrinsically resistant to a broad range of antibiotics, has been associated with poorer lung function. Nine genetically distinct species, known as genomovars, make up the *B. cepacia* complex. *Burkholderia cenocepacia* and *Burkholderia multivorans* are most commonly isolated from CF patients. The transmission of these organisms and other multiply resistant gram-negative bacteria from person to person in CF clinics and summer camps has resulted in strict infection-control guidelines.

A chronic cough, recurrent chest infections, purulent sputum, digital clubbing, chronic sinusitis, and nasal polyps are common presenting symptoms in CF. The incidence of recurrent pneumothorax is increased in CF, and chemical pleurodesis or pleurectomy are often required. Massive hemoptysis and recurrent episodes of hemoptysis are often a result of collateral bronchial arteries that can require embolization. CF patients often have opacification of the sinuses and nasal polyposis (Box 2).

BOX 2 Clinical Presentation of Cystic Fibrosis

¹Not FDA approved for this indication.

Figure 1 Therapeutic interventions for cystic fibrosis lung disease.

Treatment

Therapeutic interventions are shown in Figure 1.

Gene Therapy

The goal of gene therapy is to correct the basic defect by inserting a normal functioning gene into the ciliated cells in the submucous glands that express abnormal CFTR function. Initial attempts using the adenovirus as the vehicle for transporting the gene into the cells lining the airway appeared promising; however, the host immune response to the virus has limited the effectiveness of this approach. The ideal vector would efficiently deliver the gene to the appropriate target cell without causing toxicity or an inflammatory response. Although gene therapy offers the potential to correct the basic defect of CF, many technical barriers to effective gene therapy need to be addressed to permit this form of therapy to become an effective treatment. Liposomes are being evaluated as an alternate delivery system for administering the normal gene into epithelial cells.

CFTR Potentiator

Ivacaftor (Kalydeco), a CFTR potentiator, is the first treatment to the underlying cause of CF in patients with the G551D mutation (approximately 4% of CF patients in U.S. Cystic Fibrosis Foundation Registry). Ivacaftor facilitates increased chloride transport by potentiating the channel-open probability (or gating) of the G551D-CFTR protein. It improves lung function, reduces pulmonary exacerbations, decreases the length of time needed to treat a pulmonary exacerbation with intravenous antibiotics, and improves weight gain. In clinical trials in patients with the G551D mutation, ivacaftor led to statistically significant reductions in sweat chloride concentration. FDA approval has also been provided for 33 additional class III and IV CF mutations.

Hydration of Airway Surface Fluid

Hypertonic saline (HyperSal), at a 7% concentration, has been shown to increase the hydration of the airway surface fluid and reduce the frequency of pulmonary exacerbations. This recent addition to the therapeutic treatment regimen has been shown to facilitate the clearance of airway mucus, resulting in improved pulmonary function, and to decrease the frequency of pulmonary exacerbations. Hypertonic saline induces coughing and bronchospasm and is administered following bronchodilator therapy. An inhaled dry powder preparation of mannitol (Bronchitol)⁵ has also been developed to increase hydration of the airway surface fluid.

Physical Therapy

Airway clearance can be performed using various techniques, including conventional percussion therapy, pneumatically inflated chest vest percussion device, oscillating positive pressure devices such as the Flutter or Acapella, autogenic drainage, and exercise. These techniques are recommended on a daily basis to help mobilize secretions and prevent the complications related to persistent accumulation of airway mucus.

Bronchodilators

Airway hyper-reactivity is present in 50% to 60% of CF patients. β -Agonists keep airways open and facilitate airway clearance by increasing ciliary beat frequency and smooth muscle relaxation. The spirometry response to β -agonists should be monitored because with worsening bronchiectasis and the development of floppy airways, airflow may be impaired. Because anticholinergics alter viscosity of mucus and can have an adverse effect on gastrointestinal motility, this class of bronchodilator has not been recommended for routine use in CF by a consensus conference of the Cystic Fibrosis Foundation.

Antibiotics

Aggressive use of antibiotics for the chronic *Pseudomonas aeruginosa* bacterial colonization of the airways in CF has resulted in improving longevity and quality of life. Prophylactic inhaled antibiotics have been effective in CF patients to decrease the bacterial burden in the CF airway. Alternate-month therapy with a 300-mg aerosol preparation of tobramycin (TOBI) in a nebulized or powder preparation used with a podhaler device improves lung function, delays the time to the onset of pulmonary exacerbation, and decreases the need for hospitalization. A nebulized formulation of aztreonam (Cayston), which is administered by a very efficient portable nebulizer (Altera nebulizer system), is also approved by the FDA.

Pulmonary exacerbations are characterized by an increased cough, copious purulent sputum, decreased appetite, weight loss, and decreased exercise tolerance. Quinolone antibiotics are effective for treating *P. aeruginosa* in an oral preparation, but the development of resistance to this class of drug is a limiting factor. Ciprofloxacin (Cipro) is not approved by the FDA for use in children, but there is considerable experience with this drug in children with CF. When oral and inhaled antibiotics are not effective, hospitalization for aggressive airway clearance and a 10- to 14-day course of IV antibiotics is indicated. A combination of two drugs (usually an aminoglycoside and β -lactam semisynthetic penicillin or a cephalosporin) is selected based on susceptibility of the organism recovered by culture of sputum or a deep throat swab. In young children who are not able to produce sputum, bronchoscopy may be performed to obtain a specimen for culture and sensitivity and to assess the amount of airway inflammation.

Mucolytic Therapy

DNase (Pulmozyme) is a nebulized mucolytic agent that cleaves neutrophil-derived DNA that contributes to the thick airway secretions that clog the CF airways. Daily inhalation therapy (2.5 mg) reduces sputum viscosity, facilitating airway clearance and resulting in a 5% improvement in lung function. This therapy has largely replaced treatment with N-acetylcysteine (Mucomyst),¹ which causes bronchial irritation.

Antiinflammatory Therapy

There has been growing awareness of the role of the host inflammatory responses in the progression of CF lung disease. Chronic endobronchial colonization with bacteria results in the release of proinflammatory mediators interleukin (IL)-8 and nuclear factor (NF)- κ B. These mediators recruit neutrophils into the airway; the neutrophils release elastase, protease, superoxide ions, and

⁵Investigational drug in the United States.

¹Not FDA approved for this indication.

hydroxyl radicals, which damage lung tissue and contribute to the development of bronchiectasis.

Corticosteroids

Alternate-day systemic steroids were studied in a multicenter placebo-controlled study as a therapeutic intervention to decrease the inflammatory response in the CF airway. Significant risks of growth impairment, diabetes, and cataracts were found. Although inhaled steroids are commonly prescribed for CF patients, there is no double-blind study to demonstrate the benefit of long-term therapy in CF patients who do not have a component of asthma.

Nonsteroidal Antiinflammatory Drugs

Oral administration of twice-daily high-dose ibuprofen¹ (20–30 mg/kg)³ to achieve peak plasma concentration of 50 to 100 µg/mL interferes with neutrophil migration and inhibits the activation of NF-κB. Konstan studied 85 CF patients and found that ibuprofen therapy results in less decline in lung function, fewer hospitalizations, and improved weight gain. This effect is most pronounced in patients who are younger than 13 years and have minimal lung disease. Although prolonged use of this therapy has been shown to have ongoing benefit, the risk of GI side effects has limited the implementation of this therapy by most CF patients.

Macrolide antibiotics (azithromycin [Zithromax])¹ are not considered effective in the treatment of infection with *P. aeruginosa*, but a number of clinical trials have demonstrated a modest improvement in lung function and a decrease in the frequency of infectious exacerbations and need for antibiotic therapy in CF patients chronically colonized with *P. aeruginosa*. The mechanisms of action are not well understood but are believed to be related to a number of antiinflammatory and immunomodulatory effects of this class of antibiotic. The expression of *P. aeruginosa* pathogenicity factors and neutrophil recruitment appear to be altered by chronic macrolide therapy.

Oxygen therapy to correct alveolar hypoxia is effective to prevent pulmonary hypertension in CF patients with severe lung disease. Pulmonary hypertension results from pulmonary vascular remodeling, which results in increased pulmonary vascular resistance. Cor pulmonale contributes to the morbidity of CF with right heart failure, progressive exercise intolerance, and risk of syncope.

Lung Transplantation

Approximately 250 patients receive bilateral cadaveric lung transplants per year. Evaluation at a lung transplant center is considered when progressive deterioration in lung function results in a forced expiratory volume in one second (FEV₁) less than 30% predicted. Survival rates in CF lung-transplant recipients are comparable with other groups of patients. The availability of donor organs continues to be a limiting factor, and the disparity between donor availability and a growing recipient pool has progressively lengthened the waiting time for organs and has increased the mortality for patients awaiting lung transplantation. Living-donor lobar transplantation, which involves removal of both diseased lungs from the recipient and the implantation of two lower lobes donated by two donors, is an alternative for CF patients awaiting lung transplantation.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

HISTOPLASMOSIS

Method of

David van Duin, MD, PhD

CURRENT DIAGNOSIS

- The most common symptomatic manifestation of histoplasmosis is acute pulmonary histoplasmosis, which is generally characterized by nonspecific symptoms including fevers, chills, malaise, a nonproductive cough, and chest pain.
- Other presentations of histoplasmosis include chronic pulmonary histoplasmosis, disseminated histoplasmosis in immunocompromised hosts, and extrapulmonary disease such as mediastinal histoplasmosis.
- A multimodality approach to diagnosis, which may include serology, histopathology, antigen testing, and culture, should be considered in the appropriate setting.

CURRENT THERAPY

- Oral itraconazole is the treatment of choice for most forms of histoplasmosis.
- Serum levels of itraconazole are unpredictable and should be monitored during treatment.
- Depending on localization and severity of disease, induction with amphotericin B formulations may be required.
- Careful monitoring of patients during and after treatment is recommended, because relapses are observed in a subset of patients.

Mycology and Pathogenesis

Histoplasma capsulatum var. *capsulatum* and *H. capsulatum* var. *duboisii* are the two varieties of *H. capsulatum* that cause human histoplasmosis. *H. capsulatum* var. *duboisii* is the causative agent of African histoplasmosis, which is characterized by skin, bone, lymph node, and subcutaneous tissue involvement. This chapter focuses solely on the manifestations and treatment of *H. capsulatum* var. *capsulatum*, hereafter referred to as *H. capsulatum*.

H. capsulatum is a thermally dimorphic fungal pathogen, which grows as a mold in the environment, and converts to a yeast at 37°C during infection. During mold growth, *H. capsulatum* forms macroconidia, which are 8 to 15 µm and have thick walls and protuberances, as well as microconidia, which are 2 to 4 µm and have a smooth surface.

Disruption of soil containing *H. capsulatum*, such as during a construction project, results in the aerosolization of microconidia, which are the infectious particles. Inhaled microconidia are phagocytized but are able to survive and convert to yeast phase inside pulmonary macrophages. The resulting dissemination through the reticuloendothelial system is usually quickly contained in immunocompetent hosts, but it can lead to severe disease in the absence of normal immunity. Microconidia can be carried for several miles by air currents. Therefore, persons who are not in the direct vicinity of the disrupted soil are also at risk for developing histoplasmosis.

In tissues, *H. capsulatum* is recognized as 2- to 4-µm oval yeast forms with narrow-based budding. *H. capsulatum* does not have a capsule; the name is derived from the erroneous interpretation by Samuel Darling of an apparent clearing surrounding these yeasts in tissues as a capsule.

Epidemiology

Histoplasmosis is most common in North and Central America, but cases occur worldwide, some in microfoci of infection. Areas of high prevalence include the Mississippi and Ohio River valleys

hydroxyl radicals, which damage lung tissue and contribute to the development of bronchiectasis.

Mycology and Pathogenesis

Histoplasma capsulatum var. *capsulatum* and *H. capsulatum* var. *duboisii* are the two varieties of *H. capsulatum* that cause human histoplasmosis. *H. capsulatum* var. *duboisii* is the causative agent of African histoplasmosis, which is characterized by skin, bone, lymph node, and subcutaneous tissue involvement. This chapter focuses solely on the manifestations and treatment of *H. capsulatum* var. *capsulatum*, hereafter referred to as *H. capsulatum*.

H. capsulatum is a thermally dimorphic fungal pathogen, which grows as a mold in the environment, and converts to a yeast at 37°C during infection. During mold growth, *H. capsulatum* forms macroconidia, which are 8 to 15 µm and have thick walls and protuberances, as well as microconidia, which are 2 to 4 µm and have a smooth surface.

Disruption of soil containing *H. capsulatum*, such as during a construction project, results in the aerosolization of microconidia, which are the infectious particles. Inhaled microconidia are phagocytized but are able to survive and convert to yeast phase inside pulmonary macrophages. The resulting dissemination through the reticuloendothelial system is usually quickly contained in immunocompetent hosts, but it can lead to severe disease in the absence of normal immunity. Microconidia can be carried for several miles by air currents. Therefore, persons who are not in the direct vicinity of the disrupted soil are also at risk for developing histoplasmosis.

In tissues, *H. capsulatum* is recognized as 2- to 4-µm oval yeast forms with narrow-based budding. *H. capsulatum* does not have a capsule; the name is derived from the erroneous interpretation by Samuel Darling of an apparent clearing surrounding these yeasts in tissues as a capsule.

Epidemiology

Histoplasmosis is most common in North and Central America, but cases occur worldwide, some in microfoci of infection. Areas of high prevalence include the Mississippi and Ohio River valleys

in the United States and Rio de Janeiro State in Brazil. *H. capsulatum* thrives in soil that is enriched with bird or bat guano, and it can be found in high quantities near bird roosts, chicken coops, abandoned old buildings, and bat-infested caves. Because *H. capsulatum* can enter a state of latency and reactivate years later, cases have been described in patients who have a remote history of living in or visiting endemic areas. A complete geographic history and a high index of suspicion are required for the correct diagnosis of such cases in nonendemic areas.

Clinical Manifestations

Most *H. capsulatum* infections are asymptomatic; it is estimated that less than 5% of infections lead to clinical symptoms. The occurrence and severity of a clinical syndrome are thought to be related to the immune status of the host, as well as the size of the infectious inoculum. The most common clinical scenario is acute pulmonary histoplasmosis, but a variety of other symptomatic histoplasmosis syndromes have been described. Also, a substantial number of cases come to clinical attention years after the initial infection during the course of a pulmonary nodule work-up, when malignancy is suspected. Although they are asymptomatic, these cases can lead to anxiety, as well as the morbidity and health care costs associated with radiographic exposures and biopsy procedures.

Acute Pulmonary Histoplasmosis

Most commonly, acute pulmonary histoplasmosis is a self-limited flulike illness. Symptoms are generally nonspecific and include fevers, chills, malaise, a nonproductive cough, and chest pain. Chest radiographs can show diffuse infiltrates in one or more lobes, often with hilar lymphadenopathy. The differential diagnosis includes more common infections such as bacterial and viral pneumonias. Symptoms usually resolve without treatment in 2 to 3 weeks. However, more-severe cases do occur, even in seemingly immunocompetent hosts. In these cases, severe respiratory distress, prolonged symptoms, and even death can occur in the absence of adequate treatment. This highlights the importance of timely diagnosis and treatment when indicated.

Chronic Pulmonary Histoplasmosis

Some patients with acute pulmonary histoplasmosis fail to clear their infection and go on to develop a chronic pulmonary infection. A subset of these patients has chronic cavitary disease.

Chronic pulmonary histoplasmosis may be arbitrarily defined when the duration of symptoms from pulmonary histoplasmosis exceeds 6 weeks. The classic patient is a white middle-aged to elderly man with chronic obstructive pulmonary disease (COPD). Although these are clearly risk factors for the development of chronic disease, case series have illustrated that even never-smokers without preexisting lung disease are at risk for developing this complication.

A combination of systemic and pulmonary signs and symptoms is usually found in chronic pulmonary histoplasmosis. Fevers, night sweats, weight loss, lack of appetite, subjective loss of energy, and malaise are common systemic symptoms, and pulmonary symptoms include cough, sometimes with minimal hemoptysis, dyspnea, and sputum production. In patients with preexisting lung disease it may be difficult to distinguish these symptoms from baseline symptomatology. Radiology studies classically show cavitary disease without hilar lymphadenopathy. However, nodules, infiltrates, and lymphadenopathy are also seen, especially in nonsmoking women.

Untreated, this form of histoplasmosis can lead to death secondary to respiratory failure. With treatment, prognosis depends on coexisting pulmonary disease, and is generally favorable with regard to microbiological cure. However, relapses occur in up to 20% of cases even after prolonged treatment.

Disseminated Histoplasmosis

Most, if not all, episodes of histoplasmosis have a period of dissemination, during which infected macrophages spread throughout the

body via the reticuloendothelial system. In the majority of cases this is a self-limited event, which is quickly contained upon activation of the immune system. However, about 1 in 2000 infections results in progressive disseminated disease. Almost invariably, these cases occur in immunocompromised hosts. Patients at risk for progressive disseminated disease include those with advanced HIV infection, solid organ transplant recipients, patients with hematologic malignancies, and those treated with immunomodulating agents, most notably corticosteroids or tumor necrosis factor α (TNF- α) inhibitors. Infants are also at risk.

Recognition of disseminated histoplasmosis can be challenging. Symptoms include fevers, malaise, anorexia, respiratory symptoms, and weight loss. Laboratory investigations often reveal elevated acute phase reactants, abnormal liver function tests, and pancytopenia. Hepatosplenomegaly and lymphadenopathy occur in about half of cases. Severe cases can be clinically indistinguishable from bacterial sepsis, and patients present with hypotension and multiorgan failure. A potential diagnostic clue to the diagnosis is the presence of mucosal ulcerations, which are generally painful and can occur anywhere in the oral, pharyngeal, or laryngeal mucosa. Various morphologies may be seen, ranging from superficial to verrucous. Adrenal involvement resulting in adrenal insufficiency can occur. These patients present with enlarged adrenals on imaging and clinical symptoms of Addison disease.

Although survival without antifungal therapy has been described, disseminated histoplasmosis is generally fatal if left untreated.

Mediastinal Manifestations of Histoplasmosis

Mediastinal disease can manifest itself as mediastinal fibrosis or granulomatous mediastinitis. Mediastinal fibrosis or fibrosing mediastinitis is an uncommon complication of pulmonary disease, in which extensive fibrotic tissue develops in the mediastinum in response to infection. Men between the ages of 20 and 40 years are at the highest risk for this complication. The fibrosis consists of mature collagen, rather than granulomatous tissue, which encases the structures of the mediastinum and can have a progressive course eventually leading to death. The prognosis depends on the extent of involvement of mediastinal structures. Bilateral disease in which the pulmonary veins are involved is especially associated with poor outcomes. No satisfactory treatment is available.

In contrast, granulomatous mediastinitis, also known as mediastinal granuloma, is characterized by a caseous inflammatory mass of mediastinal lymph nodes. Most patients remain asymptomatic, and cases are often recognized only as an incidental imaging finding. However, a subset of patients develops symptoms related to compromise of mediastinal structures. The prognosis is more benign; usually the process resolves and the involved lymph nodes calcify. The role of treatment in this entity remains unclear.

Central Nervous System Histoplasmosis

Central nervous system (CNS) involvement during *H. capsulatum* infection occurs infrequently. Like other extrapulmonary disease, CNS disease may be seen as a part of progressive disseminated histoplasmosis in about 5% to 10% of disseminated histoplasmosis cases. Additionally, isolated cases in which no other signs of dissemination are found have been reported. CNS histoplasmosis typically results in chronic lymphocytic meningitis, but parenchymal lesions can also be found. Symptoms are similar to those of other chronic infectious meningitides. The typical presentation is a combination of systemic symptoms including fevers, weight loss, and night sweats and localizing symptoms of headache, focal neurologic deficits, or behavioral changes. Treatment failures and relapses are common. Prognosis in the context of adequate treatment is dependent on the degree and the reversibility of immunosuppression.

Other Manifestations of Histoplasmosis

Involvement of all organ systems with *H. capsulatum* has been reported, either in the setting of clinical disseminated histoplasmosis or as an isolated extrapulmonary site of infection.

H. capsulatum as a cause of endovascular and cardiac infections is well established. In endocarditis cases, native and prosthetic valves may be involved. Pericarditis is found in around 5% of patients with pulmonary histoplasmosis, and it appears to represent an immunologic reaction. Consistent with this, symptoms usually resolve with nonsteroidal antiinflammatory drugs (NSAIDs) or corticosteroids. Bone, joint, and skin infections can also occur and can present diagnostic difficulty.

Urogenital involvement is often documented in autopsy series, but it infrequently results in clinical symptoms. Few cases of *H. capsulatum* causing symptomatic prostatitis, nephritis, epididymitis, vaginal and penile ulcers, and ovarian involvement have been reported. Similarly, although autopsy series report gastrointestinal involvement in disseminated histoplasmosis in up to 70% to 90% of cases, specific symptoms attributable to the gastrointestinal tract are much less common. Diarrhea, gastrointestinal bleeding, bowel perforation, or bowel obstruction can result from gastrointestinal histoplasmosis.

Diagnosis

Diagnosing histoplasmosis can be complicated, and the available specific diagnostic tests each have their limitations. If the diagnosis is suspected, using available modalities in combination is generally the right approach. Turn-around time can vary depending on circumstances, and in severe or disseminated cases, empiric therapy may be warranted. Obtaining tissue, when it is feasible to do so, is essential for a pathologic diagnosis.

Histopathology

One of the most useful modalities in reaching a diagnosis is histopathology. Necrotizing or non-necrotizing granulomas are often seen. An experienced pathologist can recognize the specific pattern of yeast forms, mostly inside but also outside of macrophages. The yeast forms are best visualized by a methamine silver stain, such as the Gomori-Grocott methenamine silver stain (GMS). Alternatively, periodic acid-Schiff (PAS) staining may be used. Confusion with other pathogens or, more commonly, staining artifacts can occur, and expert consultation is required in such cases. Obtaining tissue for histopathology is usually the real challenge, and a careful evaluation of the risk-to-benefit ratio for each individual patient needs to be made.

Cultures

Culture confirmation of histoplasmosis is desirable, but often the yield of cultures is limited. In addition, cultures may be subject to a substantial time delay of several weeks. In disseminated histoplasmosis, cultures are often positive from several sites, including blood and bone marrow. In acute pulmonary histoplasmosis, the yield of respiratory cultures is estimated to be between 9% and 40%, depending on the degree of lung involvement. In mild to moderate cases, cultures are rarely positive. In chronic cavitary lung disease, the yield of culture improves, probably as a reflection of the increased fungal burden in these patients, and cultures can grow *H. capsulatum* in as many as 85% of cases. A positive fungal culture, with microscopic characteristics suggesting *H. capsulatum*, should be confirmed by specific testing. This is usually accomplished by DNA probing.

Serology

Antibody testing can be helpful when used in conjunction with the clinical scenario and other specific testing. The presence of antibodies to *H. capsulatum* may be determined by complement fixation (CF) or immunodiffusion (ID). Immunodiffusion methods evaluate the presence of M and H precipitin bands. Mild acute infections may be characterized by presence of an M band in isolation. Presence of an H band generally indicates more severe or chronic infection and is usually found in combination with an M band. Complement fixation determines the level of antibodies directed against mycelial and yeast antigens separately. For diagnosis, a fourfold rise in either mycelial or yeast CF antibody titer is required.

The incidence of detectable antibodies in persons in endemic areas is much lower than the incidence of positive skin testing, which suggests that detectable antibodies probably wane after exposure to undetectable levels. Therefore, although an isolated antibody titer of 1:32 or greater is not diagnostic, it is very suggestive of histoplasmosis in a patient with a consistent clinical presentation. In addition, any positive titer should lead to additional work-up because a substantial number of patients with confirmed histoplasmosis have antibody titers that are in the low positive range. Antibodies take 2 to 6 weeks to appear, which limits their use in acute cases. Immunosuppressed states clearly diminish the sensitivity of serology, but positive serologies are found in around 50% of disseminated histoplasmosis in immunocompromised patients. Antibody testing may be particularly helpful in CNS histoplasmosis, where cerebrospinal fluid (CSF) cultures are often negative. The finding of detectable anti-*H. capsulatum* antibodies in the CSF is diagnostic in the right clinical setting.

Antigen Detection

A commercial assay is available to determine the presence of polysaccharide antigens shed by *H. capsulatum* in urine or serum. Previously, urine assays appeared to outperform serum assays, but the most recent generation of antigen assays seems to be equivalent in urine and serum. Measuring antigen shedding in bronchoalveolar lavage (BAL) fluid is a new and promising development. Preliminary data indicate that yields from BAL may be increased in pulmonary disease. In general, antigen detection assays are a valuable adjunct to diagnosis and should be obtained in any case in which histoplasmosis is suspected. Because direct shedding is measured, the yield of this test is not diminished in immunocompromised hosts. In limited disease with a minimal fungal burden, antigens are unlikely to be detected.

Treatment

In 2007, the Infectious Diseases Society of America (IDSA) published updated management guidelines for the treatment of histoplasmosis (Table 1). The IDSA emphasizes that all of its guidelines “cannot always account for individual variation among patients. They are not intended to supplant physician judgment with respect to particular patients or special clinical situations.” Regarding acute pulmonary histoplasmosis, no evidence from clinical trials is available to guide treatment decisions, and the IDSA guidelines are relatively conservative, reserving treatment only for “moderately severe to severe” cases. No explicit definition of severity is provided. Also, when mild to moderate symptoms persist, treatment is not recommended until the patient has been symptomatic for more than 4 weeks. Here, careful clinical judgment is warranted. Although poor long-term outcomes are uncommon in these patients, symptom resolution upon antifungal treatment is the rule. Therefore, some experts treat even mild to moderate acute pulmonary disease with a symptom duration of less than 4 weeks, in contrast to IDSA guideline recommendations.

Recommended induction treatment for the first 1 to 2 weeks in moderately severe to severe acute pulmonary histoplasmosis is a lipid formulation of amphotericin B (AmBisome, Abelcet)¹ 3 to 5 mg/kg IV daily. During induction therapy, methylprednisolone (Solu-Medrol) may be used as needed for respiratory complications. After that, oral itraconazole (Sporanox) can be used (200 mg three times daily for 3 days and then 200 mg twice daily) for a total duration of treatment of 12 weeks. Oral itraconazole for 6 to 12 weeks is the treatment of choice when the decision is made to treat mild to moderate acute pulmonary histoplasmosis.

When itraconazole is used, careful instructions should be given to ensure optimal oral absorption. Using the solution results generally in higher blood levels, but the unpleasant taste can be an issue for patients. To optimize absorption of the capsules, encourage patients to take them with a cola beverage. Because of substantial

¹Not FDA approved for this indication.

TABLE 1 2007 IDSA Guidelines for Treating Histoplasmosis

CLINICAL MANIFESTATION	INDUCTION	DURATION	MAINTENANCE	TOTAL DURATION
Acute Pulmonary				
Mild to moderate <4 weeks	None			
Mild to moderate >4 weeks	None		Itra*	6–12 wk
Moderately severe to severe	AmB [†]	1–2 wk	Itra*	12 wk
Chronic Pulmonary				
	Itra*	3 day	Itra*	1–2 yr
Disseminated				
Mild to moderate	Itra*	3 day	Itra*	1 yr
Moderately severe to severe	AmB [†]	1–2 wk	Itra*	1 yr
Granulomatous mediastinitis	Itra*	3 day	Itra*	6–12 wk
CNS	AmB [†]	4–6 wk	Itra*	1 yr

Abbreviations: AmB = amphotericin B; CNS = central nervous system; IDSA = Infectious Diseases Society of America; Itra = itraconazole.

[†]Not FDA approved for this indication.

*Itraconazole (Sporanox) dosing for mild to moderate disease is 200 mg qd or bid; for all other indications a loading dose of 200 mg tid × 3 d is recommended followed by 200 mg qd or bid, guided by blood levels.

[†]Amphotericin B, in general liposomal (AmBisome)¹ or lipid formulations (Abelcet)¹ are preferred, but deoxycholate formulation of amphotericin B (Fungizone) may be used as an alternative in the treatment of acute pulmonary histoplasmosis. In CNS histoplasmosis, liposomal amphotericin B¹ is preferred.

interpersonal variability in itraconazole metabolism, blood levels remain unpredictable. As a result, levels should be monitored on all patients whose treatment exceeds 2 weeks. In general, blood levels between 1.0 and 10.0 µg/mL are recommended, even though strong evidence for these cutoffs is lacking.

Chronic pulmonary histoplasmosis requires oral itraconazole therapy for 1 to 2 years. As noted earlier, relapses can occur even with prolonged therapy, and some patients require lifelong suppressive therapy. When an asymptomatic pulmonary nodule is found to be a histoplasma in the course of a malignancy work-up, no treatment is generally indicated.

In disseminated histoplasmosis with moderately severe to severe symptoms, induction treatment with liposomal amphotericin B¹ (3 mg/kg IV daily) is recommended for the first 1 to 2 weeks. This is followed by oral itraconazole for a total of at least 1 year. When symptoms of disseminated histoplasmosis are mild to moderate, the induction phase can be omitted, and treatment with oral itraconazole for 1 year should suffice. The role of treatment in mediastinal complications of histoplasmosis depends on the etiology. If symptomatic and inflammatory findings predominate, as in granulomatous mediastinitis, treatment with oral itraconazole is warranted. In mediastinal fibrosis, antifungal treatment generally does not improve the prognosis. CNS histoplasmosis should be aggressively treated with liposomal amphotericin B (5 mg/kg daily intravenously) for 4 to 6 weeks, followed by oral itraconazole for at least 1 year.

¹Not FDA approved for this indication.

HYPERSENSITIVITY PNEUMONITIS

Method of

David I. Bernstein, MD; and Haejin Kim, MD

CURRENT DIAGNOSIS

- Objective evidence of parenchymal and/or interstitial infiltrative disease by physical examination, spirometry, and radiography associated with exposure to a causative agent
- Improvement in symptoms, lung function, and radiographic abnormalities with avoidance of the causative agent

TABLE 1 2007 IDSA Guidelines for Treating Histoplasmosis

CLINICAL MANIFESTATION	INDUCTION	DURATION	MAINTENANCE	TOTAL DURATION
Acute Pulmonary				
Mild to moderate <4 weeks	None			
Mild to moderate >4 weeks	None		Itra*	6–12 wk
Moderately severe to severe	AmB [†]	1–2 wk	Itra*	12 wk
Chronic Pulmonary				
	Itra*	3 day	Itra*	1–2 yr
Disseminated				
Mild to moderate	Itra*	3 day	Itra*	1 yr
Moderately severe to severe	AmB [†]	1–2 wk	Itra*	1 yr
Granulomatous mediastinitis	Itra*	3 day	Itra*	6–12 wk
CNS	AmB [†]	4–6 wk	Itra*	1 yr

Abbreviations: AmB = amphotericin B; CNS = central nervous system; IDSA = Infectious Diseases Society of America; Itra = itraconazole.

[†]Not FDA approved for this indication.

*Itraconazole (Sporanox) dosing for mild to moderate disease is 200 mg qd or bid; for all other indications a loading dose of 200 mg tid × 3 d is recommended followed by 200 mg qd or bid, guided by blood levels.

[†]Amphotericin B, in general liposomal (AmBisome)¹ or lipid formulations (Abelcet)¹ are preferred, but deoxycholate formulation of amphotericin B (Fungizone) may be used as an alternative in the treatment of acute pulmonary histoplasmosis. In CNS histoplasmosis, liposomal amphotericin B¹ is preferred.

interpersonal variability in itraconazole metabolism, blood levels remain unpredictable. As a result, levels should be monitored on all patients whose treatment exceeds 2 weeks. In general, blood levels between 1.0 and 10.0 µg/mL are recommended, even though strong evidence for these cutoffs is lacking.

Chronic pulmonary histoplasmosis requires oral itraconazole therapy for 1 to 2 years. As noted earlier, relapses can occur even with prolonged therapy, and some patients require lifelong suppressive therapy. When an asymptomatic pulmonary nodule is found to be a histoplasma in the course of a malignancy work-up, no treatment is generally indicated.

In disseminated histoplasmosis with moderately severe to severe symptoms, induction treatment with liposomal amphotericin B¹ (3 mg/kg IV daily) is recommended for the first 1 to 2 weeks. This is followed by oral itraconazole for a total of at least 1 year. When symptoms of disseminated histoplasmosis are mild to moderate, the induction phase can be omitted, and treatment with oral itraconazole for 1 year should suffice. The role of treatment in mediastinal complications of histoplasmosis depends on the etiology. If symptomatic and inflammatory findings predominate, as in granulomatous mediastinitis, treatment with oral itraconazole is warranted. In mediastinal fibrosis, antifungal treatment generally does not improve the prognosis. CNS histoplasmosis should be aggressively treated with liposomal amphotericin B (5 mg/kg daily intravenously) for 4 to 6 weeks, followed by oral itraconazole for at least 1 year.

¹Not FDA approved for this indication.

HYPERSENSITIVITY PNEUMONITIS

Method of

David I. Bernstein, MD; and Haejin Kim, MD

CURRENT DIAGNOSIS

- Objective evidence of parenchymal and/or interstitial infiltrative disease by physical examination, spirometry, and radiography associated with exposure to a causative agent
- Improvement in symptoms, lung function, and radiographic abnormalities with avoidance of the causative agent

CURRENT THERAPY

- Avoidance of contact with the offending antigen is essential and is often curative if performed early in the course of the disease.
- Systemic corticosteroids are often required during the acute phase of hypersensitivity pneumonitis.

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is an inflammatory disorder of the lungs that is mediated by immunologic hypersensitivity to a specific antigen, usually organic in nature. Table 1 lists causative agents in hypersensitivity pneumonitis.

Pathophysiology

Hypersensitivity pneumonitis is thought to involve primarily type IV (cell-mediated) hypersensitivity. Bronchoalveolar fluid obtained from patients with hypersensitivity pneumonitis shows a predominant CD8⁺ lymphocytosis supporting T cell-mediated disease. Viruses are thought to play a role in the development of hypersensitivity pneumonitis through upregulation of costimulatory molecules on alveolar macrophages and dendritic cells, leading to

increased activation of type 1 helper T cells. Adoptive transfer models in animals have shown that CD4⁺ T cells and cytotoxic T cells are the most important effector cells in experimental hypersensitivity pneumonitis, rather than cytokines, antibodies, or complement alone. Genetic susceptibility to this disorder could be associated with presence of specific MHC class II alleles.

Clinical Presentation and Diagnosis

The main clinical features for hypersensitivity pneumonitis are listed in Table 2. Hypersensitivity pneumonitis is most likely to be diagnosed if the history, physical findings, high-resolution chest CT, and pulmonary function tests indicate infiltrative and restrictive lung disease; exposure is documented to a recognized or new causative agent; and there is significant improvement in symptoms, lung function, and radiographic findings with avoidance of the offending cause. Antibody to the offending antigen may be demonstrated but is not required for diagnosis. These are the most widely accepted criteria, but evidence-based diagnostic guidelines have not been established. A careful home, environmental, and occupational history is essential to identify one or more causative antigens.

Treatment

The primary treatment is cessation of exposure to the sources of offending antigens at home or in the workplace. Effective environmental control measures may include modification of work habits,

TABLE 1 Hypersensitivity Pneumonitis: Representative Sources and Causative Agents

CONDITION OR PERSONS AT RISK	SOURCE	CAUSATIVE ANTIGENS
Dairy farmers	Hay, grains, silage	Thermophilic actinomycetes
Bird fancier's or pigeon breeder's disease	Avian droppings or feathers	Avian proteins
Humidifier lung	Contaminated water	Thermophilic actinomycetes or other microorganisms
Chemical workers	Polyurethane foam, varnishes, lacquers	Isocyanates
Machine workers	Metalworking fluid	<i>Pseudomonas fluorescens</i> , <i>Aspergillus niger</i> , <i>Staphylococcus capitis</i> , <i>Rhodococcus</i> spp., <i>Bacillus pumilus</i>
Familial hypersensitivity pneumonitis	Contaminated wood dust in walls	<i>Bacillus subtilis</i>
Hot tub lung	Mold on ceiling	<i>Cladosporium</i> spp., <i>Mycobacterium avium</i>

Modified from Richerson HB, Bernstein IL, Fink JN, et al: Guidelines for the clinical evaluation of hypersensitivity pneumonitis: Report of the subcommittee on hypersensitivity pneumonitis. *J Allergy Clin Immunol* 1989;84:839–844; and Hanak V, Golbin JM, Hartman TE, et al: High-resolution CT findings of parenchymal fibrosis correlate with prognosis in hypersensitivity pneumonitis. *Chest* 2008;134:133–138.

TABLE 2 Clinical Features of Hypersensitivity Pneumonitis

FEATURE	ACUTE	SUBACUTE	CHRONIC
Exposure to antigen	Hours to days	Days to weeks	Months
Symptoms	Influenza-like illness ± cough/dyspnea	Cough and dyspnea with severe cyanosis	Increasing cough and exertional dyspnea; fatigue, weight loss
Physical findings	Fever; lungs normal or bibasilar crackles	Cyanosis; lungs normal or bibasilar crackles	Cyanosis; right-sided heart failure; lungs normal or bibasilar crackles
High-resolution computed tomography	Diffuse ground-glass infiltrates	Reticulation; small centrilobular nodules; air trapping on expiration	Honeycombing, traction bronchiectasis
Pulmonary function testing	↓ FEV ₁ and FVC (restrictive pattern); ↓ TLC; ↓ PaO ₂ on exercise challenge; ↓ D _{LCO}		
Other findings supportive of a diagnosis of HP	<ul style="list-style-type: none"> • Positive natural challenge or increase in signs and symptoms on reexposure • Positive precipitating antibodies to HP antigens or antigens cultured directly from the causative environment • Improvement with avoidance • Surgical lung biopsy: interstitial lymphocytic or plasma cell infiltrates and/or noncaseating granulomas; pulmonary fibrosis in advanced cases • BAL lymphocytosis with reduced CD4/CD8 ratio 		

Abbreviations: BAL = bronchoalveolar lavage; D_{LCO} = carbon monoxide diffusion in the lungs; FEV₁ = forced expiratory volume in 1 second; FVC = forced vital capacity; HP = hypersensitivity pneumonitis; PaO₂ = arterial partial pressure of oxygen; TLC = total lung capacity.

LEGIONELLOSIS (LEGIONNAIRES' DISEASE AND PONTIAC FEVER)

Method of

Julio A. Ramirez, MD

In the summer of 1976, an outbreak of approximately 182 cases of pneumonia occurred in persons attending the American Legion convention in Philadelphia. One year later, Dr. McDade reported the identification of *Legionella pneumophila*, the bacterium responsible for the infection. Today, the family of Legionellaceae is composed of more than 40 species, with some species having different serogroups. *L. pneumophila* causes approximately 85% of all *Legionella* infections. *L. pneumophila* serogroup 1 is the single most common member of the family causing clinical infections.

Epidemiology

Legionella is an intracellular organism that lives in natural water. In the aquatic environment, the bacteria live and multiply within freshwater amoebae. The number of *Legionella* organisms in the water can increase significantly with appropriate local conditions such as warm temperature, lack of biocides, stagnant water, and presence of amoebae and other nutrients. These special conditions can be present in artificial water systems such as cooling towers, whirlpools, decorative fountains, and respiratory therapy devices.

The susceptible host acquires the bacteria from water containing the organism. Infection can be acquired by inhaling aerosols containing *Legionella* organisms or by microaspiration of water contaminated with *Legionella*. The hospitalized patient with *Legionella* pneumonia does not require respiratory isolation because legionellosis is not transmitted from person to person.

Clinical Features

Once *Legionella* organisms reach the respiratory tract, based on the interactions of the organism with the host immune system, the patient can have four possible clinical outcomes: asymptomatic infection, Pontiac fever, Legionnaires' disease, or extrapulmonary disease involving the liver, heart, brain, or other organs. Pontiac fever is a nonpneumonic form of disease characterized by fever, headaches, myalgias, and malaise. The patient has an influenza-like illness, with resolution of disease in a few days without specific antimicrobial therapy. Patients with Legionnaires' disease present with community-acquired pneumonia associated with high fever, gastrointestinal complaints such as diarrhea, and central nervous system complaints such as headaches or mental status changes.

Hospital-acquired pneumonia can occur if *Legionella* is present in the hospital water supply.

Diagnosis

The currently available laboratory tests for diagnosis of *Legionella* infections include the direct fluorescent antibody stain (DFA), culture, antigen detection in the urine, antibody detection in serum by indirect fluorescent antibody testing (IFA), and DNA amplification using the polymerase chain reaction (PCR). The DFA stain can detect all *L. pneumophila* serogroups, but a large number of bacteria need to be present in sputum for a positive result. *Legionella* can be cultured from respiratory specimens on selective media composed of buffered charcoal–yeast extract agar. The urinary antigen detection has a specificity greater than 95%; the disadvantage is that the test detects only the antigen of *L. pneumophila* serogroup 1. Clinical specimens that have been used to detect *Legionella* by PCR include throat swabs, sputum, tracheal suction, bronchoalveolar lavage fluid, pleural fluid, and lung tissue.

Treatment

In the pulmonary parenchyma, *Legionella* can infect and multiply inside alveolar macrophages, alveolar epithelial cells, and capillary endothelial cells. The poor clinical outcome with β -lactam antibiotics is due to their lack of penetration into cells. Antibiotics with good intracellular penetration that can be used as monotherapy for *Legionella* infections include macrolides, ketolides, tetracyclines, and quinolones (Table 1). Rifampin (Rifadin)¹ is not used as monotherapy because resistance can rapidly emerge when it is used alone.

Therapy of the patient with severe disease is initiated with intravenous antibiotics. Once the patient reaches clinical stability, the intravenous therapy can be switched to oral therapy. Doses for the most common antibiotics for intravenous and oral therapy are depicted in Table 1. In the nonimmunocompromised patient, the recommended duration of therapy is 7 to 10 days. In immunocompromised patients, because they are at risk for relapsing infection, the recommended duration of therapy is 14 to 21 days.

Several antibiotics have demonstrated clinical efficacy in Legionnaires' disease. Data with several in vitro and animal studies comparing different anti-*Legionella* antibiotics indicate that erythromycin (Ery-Tab) is a weak anti-*Legionella* agent. If erythromycin is selected for therapy, it is important to add rifampin to the

regimen to increase intracellular killing. From the family of macrolides, azithromycin (Zithromax)¹ is the most active. The best bactericidal activity in the laboratory is achieved with quinolones. Retrospective observational studies indicate that patients treated with levofloxacin (Levaquin) have a shorter time to reach clinical stability and shorter duration of hospital stay. These antibiotics are considered primary anti-*Legionella* agents.

In clinical practice, I treat immunocompromised patients who have severe Legionnaires' disease with a combination of an intravenous quinolone plus an intravenous macrolide (e.g., levofloxacin plus azithromycin). This regimen is based only on the theoretical consideration that synergistic killing may be obtained using a quinolone to alter DNA synthesis and a macrolide to alter protein synthesis.

¹Not FDA approved for this indication.

OBSTRUCTIVE SLEEP APNEA

Method of

Daniel P. Fox, MD; and Masayoshi Takashima, MD

CURRENT DIAGNOSIS

Symptoms

- Excessive daytime fatigue and somnolence
- Morning headaches
- Loud snoring and gasping for air
- Witnessed apneic episodes following loud snoring
- Frequent nocturia with no other underlying etiology
- Hypertension

Clinical Signs and Risk Factors

- Central obesity with body mass index (BMI) $>30 \text{ kg/m}^2$
- Large neck circumference (>17 inches in men, >16 inches in women)
- Being male or a postmenopausal woman
- Use of sedatives or alcohol before going to bed
- Family history of sleep apnea
- Craniofacial abnormalities: retrognathia, micrognathia, congenital malformations

CURRENT THERAPY

- Gold standard for treatment is positive airway pressure
- Weight loss, smoking cessation, avoidance of sedatives
- Improvement of sleep hygiene and sleep schedule
- Minimally invasive procedures (oral appliances, palatal stents, radiofrequency turbinate reductions) may be beneficial for a select patient population
- Surgical therapy is usually reserved for patients not tolerating or unable to use CPAP or BiPAP
- Initial procedures are focused on decreasing upper airway resistance to improve compliance with CPAP or BiPAP
- Identification of anatomic sites of obstruction is critical to successful surgical outcomes

Abbreviation: BiPAP = bilevel positive airway pressure; CPAP = continuous positive airway pressure.

Sleep-disordered breathing encompasses the spectrum from upper airway resistance syndrome to obstructive sleep apnea (OSA). OSA is characterized by episodes of partial or complete upper airway collapse leading to cessation or reduction of airflow. Such events lead to oxygen desaturation and sleep fragmentation, causing excessive daytime sleepiness, morning headaches, depression, memory loss,

impaired alertness, decreased libido, and reduced cognitive function. Nighttime symptoms are often more telling, and obtaining a sleep history from a bed partner is exceptionally helpful. The most common symptoms include loud snoring, restless sleep, choking or gasping episodes, and awakenings during sleep. Nocturnal perspiration, nocturia, and symptoms of nocturnal gastroesophageal reflux are also commonly associated with severe OSA.

As the severity of OSA typically increases with age, nightly hypoventilation and activation of the sympathetic nervous system lead to pathophysiologic derangements, such as hypertension, ischemic heart disease, myocardial infarction, stroke, arrhythmia, and premature death. An apnea-hypopnea index (AHI) of greater than 5 has been shown to be associated with increased risk of cerebrovascular accident. An AHI greater than 20 is associated with increased mortality. Patients with oxygen desaturation below 90% have an elevated incidence of cardiac arrhythmias. These potentially severe consequences, along with a patient's decreased quality of life, substantiate the need for early recognition and treatment.

Definitions of terms related to sleep apnea are listed in [Box 1](#).

Epidemiology

Based on available population-based studies, the prevalence of OSA among adults between 30 and 60 years of age is estimated to be 6% for women and 13% for men. This represents relative increases over the last two decades of 14–55% amongst subgroups divided by age, gender, and BMI. OSA remains undiagnosed in 70% to 80% of patients because their symptoms are often vague, and OSA must be diagnosed with polysomnography.

Risk Factors

When controlling for gender and BMI, patients over age 50 have an increased prevalence of obstructive sleep apnea secondary to decreased muscle tone.

Obesity (body mass index [BMI] greater than 30 kg/m^2) is a risk factor for OSA. A 10% increase in weight is associated with a six-fold increase in risk for development of OSA, and a 10% weight loss is associated with 26% decrease in AHI. Patients undergoing bariatric surgery on average have post-surgical reductions in AHI

BOX 1 Definitions of Sleep Medicine Terms

Apnea-hypopnea index (AHI): Sum of apneas and hypopneas per hour of sleep.

Obstructive apnea: Cessation of airflow for ≥ 10 seconds associated with ongoing ventilatory effort.

Obstructive hypopnea: 1. Decreased airflow by $\geq 30\%$ which is ≥ 10 seconds and a $\geq 3\%$ oxygen desaturation and or associated with an arousal. 2. Decreased airflow $\geq 30\%$ which is ≥ 10 seconds which is associated with a $\geq 4\%$ oxygen desaturation

Obstructive sleep apnea (OSA): AHI >5 events per hour of sleep, often associated with oxygen desaturation $<90\%$. Mild OSA is defined by an AHI of 5 to 15. Moderate OSA is an AHI 15 to 30, and severe OSA is an AHI >30 .

Obstructive sleep apnea syndrome: OSA in association with daytime symptoms of excessive sleepiness or other neurobehavioral symptoms.

Primary snoring: Snoring with an AHI <5 and no complaints of excessive daytime sleepiness.

Respiratory effort-related arousals: Sleep fragmentation that is caused by arousals from increasing respiratory effort but that does not meet criteria for an apnea or hypopnea. The event lasts longer than 10 seconds.

Respiratory disturbance index: Sum of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep.

Upper airway resistance syndrome (UARS): Snoring in association with AHI <5 , frequent arousals, and abnormally negative midesophageal pressure (less than $-10 \text{ cm H}_2\text{O}$) or increased diaphragmatic electromyogram activity.

regimen to increase intracellular killing. From the family of macrolides, azithromycin (Zithromax)¹ is the most active. The best bactericidal activity in the laboratory is achieved with quinolones. Retrospective observational studies indicate that patients treated with levofloxacin (Levaquin) have a shorter time to reach clinical stability and shorter duration of hospital stay. These antibiotics are considered primary anti-*Legionella* agents.

In clinical practice, I treat immunocompromised patients who have severe Legionnaires' disease with a combination of an intravenous quinolone plus an intravenous macrolide (e.g., levofloxacin plus azithromycin). This regimen is based only on the theoretical consideration that synergistic killing may be obtained using a quinolone to alter DNA synthesis and a macrolide to alter protein synthesis.

¹Not FDA approved for this indication.

OBSTRUCTIVE SLEEP APNEA

Method of

Daniel P. Fox, MD; and Masayoshi Takashima, MD

CURRENT DIAGNOSIS

Symptoms

- Excessive daytime fatigue and somnolence
- Morning headaches
- Loud snoring and gasping for air
- Witnessed apneic episodes following loud snoring
- Frequent nocturia with no other underlying etiology
- Hypertension

Clinical Signs and Risk Factors

- Central obesity with body mass index (BMI) $>30 \text{ kg/m}^2$
- Large neck circumference (>17 inches in men, >16 inches in women)
- Being male or a postmenopausal woman
- Use of sedatives or alcohol before going to bed
- Family history of sleep apnea
- Craniofacial abnormalities: retrognathia, micrognathia, congenital malformations

CURRENT THERAPY

- Gold standard for treatment is positive airway pressure
- Weight loss, smoking cessation, avoidance of sedatives
- Improvement of sleep hygiene and sleep schedule
- Minimally invasive procedures (oral appliances, palatal stents, radiofrequency turbinate reductions) may be beneficial for a select patient population
- Surgical therapy is usually reserved for patients not tolerating or unable to use CPAP or BiPAP
- Initial procedures are focused on decreasing upper airway resistance to improve compliance with CPAP or BiPAP
- Identification of anatomic sites of obstruction is critical to successful surgical outcomes

Abbreviation: BiPAP = bilevel positive airway pressure; CPAP = continuous positive airway pressure.

Sleep-disordered breathing encompasses the spectrum from upper airway resistance syndrome to obstructive sleep apnea (OSA). OSA is characterized by episodes of partial or complete upper airway collapse leading to cessation or reduction of airflow. Such events lead to oxygen desaturation and sleep fragmentation, causing excessive daytime sleepiness, morning headaches, depression, memory loss,

impaired alertness, decreased libido, and reduced cognitive function. Nighttime symptoms are often more telling, and obtaining a sleep history from a bed partner is exceptionally helpful. The most common symptoms include loud snoring, restless sleep, choking or gasping episodes, and awakenings during sleep. Nocturnal perspiration, nocturia, and symptoms of nocturnal gastroesophageal reflux are also commonly associated with severe OSA.

As the severity of OSA typically increases with age, nightly hypoventilation and activation of the sympathetic nervous system lead to pathophysiologic derangements, such as hypertension, ischemic heart disease, myocardial infarction, stroke, arrhythmia, and premature death. An apnea-hypopnea index (AHI) of greater than 5 has been shown to be associated with increased risk of cerebrovascular accident. An AHI greater than 20 is associated with increased mortality. Patients with oxygen desaturation below 90% have an elevated incidence of cardiac arrhythmias. These potentially severe consequences, along with a patient's decreased quality of life, substantiate the need for early recognition and treatment.

Definitions of terms related to sleep apnea are listed in [Box 1](#).

Epidemiology

Based on available population-based studies, the prevalence of OSA among adults between 30 and 60 years of age is estimated to be 6% for women and 13% for men. This represents relative increases over the last two decades of 14–55% amongst subgroups divided by age, gender, and BMI. OSA remains undiagnosed in 70% to 80% of patients because their symptoms are often vague, and OSA must be diagnosed with polysomnography.

Risk Factors

When controlling for gender and BMI, patients over age 50 have an increased prevalence of obstructive sleep apnea secondary to decreased muscle tone.

Obesity (body mass index [BMI] greater than 30 kg/m^2) is a risk factor for OSA. A 10% increase in weight is associated with a six-fold increase in risk for development of OSA, and a 10% weight loss is associated with 26% decrease in AHI. Patients undergoing bariatric surgery on average have post-surgical reductions in AHI

BOX 1 Definitions of Sleep Medicine Terms

Apnea-hypopnea index (AHI): Sum of apneas and hypopneas per hour of sleep.

Obstructive apnea: Cessation of airflow for ≥ 10 seconds associated with ongoing ventilatory effort.

Obstructive hypopnea: 1. Decreased airflow by $\geq 30\%$ which is ≥ 10 seconds and a $\geq 3\%$ oxygen desaturation and or associated with an arousal. 2. Decreased airflow $\geq 30\%$ which is ≥ 10 seconds which is associated with a $\geq 4\%$ oxygen desaturation

Obstructive sleep apnea (OSA): AHI >5 events per hour of sleep, often associated with oxygen desaturation $<90\%$. Mild OSA is defined by an AHI of 5 to 15. Moderate OSA is an AHI 15 to 30, and severe OSA is an AHI >30 .

Obstructive sleep apnea syndrome: OSA in association with daytime symptoms of excessive sleepiness or other neurobehavioral symptoms.

Primary snoring: Snoring with an AHI <5 and no complaints of excessive daytime sleepiness.

Respiratory effort-related arousals: Sleep fragmentation that is caused by arousals from increasing respiratory effort but that does not meet criteria for an apnea or hypopnea. The event lasts longer than 10 seconds.

Respiratory disturbance index: Sum of apneas, hypopneas, and respiratory effort-related arousals per hour of sleep.

Upper airway resistance syndrome (UARS): Snoring in association with AHI <5 , frequent arousals, and abnormally negative midesophageal pressure (less than $-10 \text{ cm H}_2\text{O}$) or increased diaphragmatic electromyogram activity.

of 29 events per hour. There is evidence of a potential link between OSA and insulin resistance.

Approximately 30% of hypertensive persons have OSA and up to 50% of OSA patients have hypertension. Resistant hypertension, which is defined as blood pressure $>140/90$ mmHg despite therapy with at least 3 different anti-hypertensive classes, is especially prevalent in the OSA population. It is estimated that 90% of male patients and 77% of female patients with resistant hypertension have OSA. A dose-effect relationship between OSA severity and severity of hypertension has been established. Mechanisms for hypertension center around hypoxemia and hypercapnia leading to increased oxidative stress, decreased nitric oxide secretion, and increased catecholamine, angiotensin II, aldosterone, renin, and endothelin-1 secretion.

Male patients are nearly twice as likely to have OSA as female patients. Estrogen and progesterone might have a protective role because population-based studies have demonstrated that postmenopausal women have a two- to threefold increased risk of OSA compared to premenopausal women.

African Americans and Asians are at greater risk for OSA than Caucasians. Being African American is an independent risk factor for severe sleep-disordered breathing, with an odds ratio of 2.55 compared with whites. Asians have a narrower cranial base, a higher Mallampati score, smaller thyromental distance, and steeper thyromental plane than whites, which might account for their increased risk.

Pathophysiology

Airway obstruction leading to OSA can occur anywhere along the pathway from the nostrils, soft palate, base of tongue, hypopharynx, and the epiglottis. The airway lacks skeletal structure and is vulnerable to influences such as muscle tone, fat deposition, and tissue redundancy.

Prevention

Lifestyle modification can prevent OSA. Patients should adopt a healthy and athletic lifestyle to develop good muscle tone and weight loss, avoid sedatives and alcohol at bedtime, establish regular sleeping patterns, avoid the supine sleeping position, and elevate the head when sleeping.

Diagnosis

Definitive diagnosis of OSA is made by polysomnography. Mild OSA is defined as an AHI of 5 to 15 per hour, moderate OSA is an AHI of 15 to 30 per hour, and severe OSA is an AHI greater than 30 per hour. Patients spend the night in a sleep laboratory during which multiple physiologic variables are continuously monitored. These include electroencephalogram (EEG), electrooculogram (EOG), electromyogram (EMG), oronasal airflow, chest wall effort, body position, snore volume, electrocardiogram (ECG), and oxyhemoglobin saturation. Laboratory testing also includes a complete accounting of sleep variables, monitoring of cardiac rhythm, and assessment of possible restless legs syndrome (RLS) or periodic limb movements (PLMs) during sleep. This information enables the clinician to determine the severity of the condition and identifies potentially relevant comorbidities.

A thorough diagnostic study requires at least 6 hours of sleep, allowing assessment of variability related to sleep stages. If there are sufficient apneas or hypopneas during the first half of the study (ideally 4 hours of diagnostic testing, with a minimum of 2 hours if an AHI >40 is confirmed), a split-night study may be performed, in which the second half of the night (minimum of 3 hours of sleep) is devoted to titration of continuous positive airway pressure (CPAP) therapy. If the criteria for a split-night sleep study are not achieved during the night, a second night for titration study is ordered. The split-night protocol is a cost-effective use of laboratory resources that is particularly well suited for patients with severe OSA.

According to the Institute for Clinical Systems Improvement (ICSI), polysomnography should be performed in patients with symptoms of OSA and one or more of the following: cardiovascular disease, hypertension, coronary artery disease, obesity, sleep

complaint, type 2 diabetes mellitus, recurrent atrial fibrillation, and large neck circumference.

Treatment

Initially, patients should be counseled to avoid practices that can potentially worsen the severity of OSA. CNS depressants taken before sleep (alcohol, sleep medications, pain medications) can worsen upper airway collapse during sleep and should be discouraged. Weight loss and maintenance should always play a role in the treatment of these patients. Myofunctional Therapy, which is a series of isometric and isotonic exercises of the oral cavity and pharyngeal muscles, is designed to increase upper airway tone. Oral Pressure Therapy uses a mouthpiece to generate negative pressure to gently pull the palate forward, opening the retropalatal airway. End Positive Airway Pressure (EPAP) Therapy uses nasal appliances to increase expiratory resistance and prevent pharyngeal collapse.

In patients with positional OSA, defined as >2 -fold difference in AHI between supine and non-supine positions, avoiding the supine position during sleep may suffice to normalize ventilation during sleep. There are several commercial devices worn around the neck or back that gently vibrate when a patient is supine. Nightly compliance rates are 75–96%.

Continuous Positive Airway Pressure Therapy

CPAP remains the therapeutic mainstay for primary treatment of OSA. It serves as a pneumatic stent for the upper airway and is effective in reducing the physiologic abnormalities measured on polysomnography. Additionally, CPAP is thought to augment lung volumes and elicit a reflex that increases tone in the upper airway musculature. Overall, it has been shown to reduce AHI, improve quality of life, and reduce cardiovascular risk.

There are many manufacturers of CPAP devices and many interfaces that help maximize comfort with treatment. Expiratory pressure release (EPR) is available through several CPAP manufacturers. EPR does not seem to compromise the effectiveness of CPAP therapy and improves the patient's sense of comfort with therapy, but it does not seem to systematically improve the level of adherence. Automatically-adjusting Positive Airway Pressure (APAP), is similar to CPAP but instead of delivering a constant pressure adjusts delivered pressure breath-to-breath.

Bi-level respiratory-assist devices deliver alternating levels of positive airway pressure and might be considered an alternative therapeutic option when standard CPAP is not tolerated or when oxygen saturation is not raised sufficiently with standard CPAP. In some cases of severe OSA (in particular among patients with underlying pulmonary conditions), supplemental oxygen can be used in conjunction with CPAP therapy.

The main disadvantage with positive airway pressure treatment is poor compliance. Multicenter trials show that CPAP adherence rates defined as at least 4 hours per night 70% of nights are between only 39–50% overall CPAP compliance. Treatment is effective as long as the patient uses the device for the entire night, every night. APAP, CPAP desensitization, and the use of integrated heated humidifiers helped improve adherence to therapy.

Oral Appliances

Oral appliances worn in the mouth during sleep can help maintain a patent airway, especially in patients with significant positional sleep apnea who sleep supine and experience airway collapse secondary to the tongue falling posteriorly. In general, there are two types of appliances, mandibular-advancement appliances and tongue-retaining devices. The mandibular-advancement appliances are currently used more often and have been more widely studied. They require viable dentition for retention and they are fitted to the maxillary and mandibular dentition to enable the protrusion of the mandible and therefore increase oropharyngeal patency. The most common side effect is drooling. Temporomandibular joint pain might limit the viability of this therapy, and chronic use of the appliance can result in a change of the dental occlusion. A dentist with expertise in sleep medicine should ideally implement and monitor this type of treatment.

BOX 2 Treatments for Obstructive Sleep Apnea**Nasal Obstruction**

Septoplasty
Rhinoplasty or nasal valve surgery
Turbinates reduction
Adenoidectomy

Retropalatal Obstruction

Tonsillectomy
Uvulopalatopharyngoplasty
Z-palatoplasty
Lateral pharyngoplasty
Palatal stents
Radiofrequency soft palate surgery

Retrolingual Obstruction

Transoral robotic-assisted base of tongue reduction
Lingual tonsillectomy
Genioglossus advancement
Hyoid suspension
Tongue base suspension
Maxillomandibular advancement

Surgical Procedures

If patients are not tolerating CPAP and a significant upper airway anatomic obstruction is identified, surgery should be considered. A variety of procedures help stabilize the retropalatal region, and others are intended to stabilize the retrolingual airway (Box 2). Sleep surgery has been shown to be most effective when addressing multiple levels of obstruction. Procedures are often combined for maximum effectiveness, such as septoplasty, turbinate reduction, tonsillectomy, uvulopalatopharyngoplasty and genial tubercle advancement. With the advent of transoral robotic surgery, surgeons are now able to access the posterior oropharynx, base of tongue, and hypopharynx more easily, and procedures to address these areas are more common. A substantially more invasive procedure, the maxillomandibular advancement, has been shown very effective in a number of case series. However, the only definitive surgical cure is tracheostomy, which completely bypasses the upper airway but is not without its comorbidities.

It is challenging to predict which patients are likely to have a successful surgical outcome. Much of this difficulty is associated with accurately identifying the site(s) of obstruction. The current gold standard is drug-induced sleep endoscopy (DISE), a procedure that examines the upper airway while the patient is in a drug-induced (propofol [Diprivan]¹ or dexmedetomidine [Precedex]) sleep-resembling state. As the patient snores and obstructs, a flexible fiberoptic scope is passed through the nose to evaluate the upper airway for the site of obstruction.

Monitoring

The patient's response to therapy needs to be monitored. In the case of CPAP therapy, monitoring of CPAP adherence is critical, because subjective reports are inaccurate. Resolution of excessive sleepiness is the desired outcome for patients who are symptomatic at baseline. If excessive sleepiness remains problematic despite documentation of desirable CPAP adherence, treatment with modafinil (Provigil) 100 to 400 mg in the morning might be considered. Other potential conditions affecting sleep need to be monitored and, if necessary, treated. Often, other conditions such as poor sleep hygiene, restless legs syndrome, periodic limb movements, or psychophysiological insomnia interfere with adequate response to therapy.

For patients who undergo surgery, retesting is indicated. The interval at which retesting should be done depends on the type of surgery that was performed. Retesting 3 months following the surgical intervention is adequate in most cases.

¹Not FDA approved for this indication.

PLEURAL EFFUSIONS AND EMPYEMA THORACIS

Method of

David J. Finley, MD; and Raja Flores, MD

Pleural effusions have multiple etiologies, making the diagnosis and management a common clinical issue. Though the amount of fluid produced varies significantly, an average 0.1 to 0.2 mL/kg is maintained within the pleural space. Production of fluid is matched with removal during normal physiologic states, but aberrations of this homeostasis with local or systemic diseases lead to the formation of an effusion. Symptoms are related to the volume of fluid and the etiology of the fluid accumulation, including both benign and malignant processes. Secondary infection of a pleural effusion, known as an empyema, is a significant complication necessitating aggressive treatment of both the underlying cause and the empyema itself.

Symptoms are variable and include dyspnea, shortness of breath, cough, and chest discomfort, though patients can be asymptomatic, even with very large effusions. Dullness to percussion and decreased breath sounds are often hallmarks of effusions, but these signs are also seen with lung masses and consolidative pneumonias. A clinical history, physical examination, and imaging studies are often needed in combination to diagnose an effusion.

Etiology

Many local and systemic illnesses are associated with the formation of a pleural effusion. Systemic symptoms can indicate the most common cause of the effusion, but diagnostic procedures are often necessary to delineate the etiology. Determination of an exudative or transudative effusion can point out possible disease that may be the cause (Box 1).

PLEURAL EFFUSIONS AND EMPYEMA THORACIS

Method of

David J. Finley, MD; and Raja Flores, MD

Pleural effusions have multiple etiologies, making the diagnosis and management a common clinical issue. Though the amount of fluid produced varies significantly, an average 0.1 to 0.2 mL/kg is maintained within the pleural space. Production of fluid is matched with removal during normal physiologic states, but aberrations of this homeostasis with local or systemic diseases lead to the formation of an effusion. Symptoms are related to the volume of fluid and the etiology of the fluid accumulation, including both benign and malignant processes. Secondary infection of a pleural effusion, known as an empyema, is a significant complication necessitating aggressive treatment of both the underlying cause and the empyema itself.

Symptoms are variable and include dyspnea, shortness of breath, cough, and chest discomfort, though patients can be asymptomatic, even with very large effusions. Dullness to percussion and decreased breath sounds are often hallmarks of effusions, but these signs are also seen with lung masses and consolidative pneumonias. A clinical history, physical examination, and imaging studies are often needed in combination to diagnose an effusion.

Etiology

Many local and systemic illnesses are associated with the formation of a pleural effusion. Systemic symptoms can indicate the most common cause of the effusion, but diagnostic procedures are often necessary to delineate the etiology. Determination of an exudative or transudative effusion can point out possible disease that may be the cause (Box 1).

Transudative

Congestive heart failure
Cirrhosis
Pulmonary emboli
Peritoneal dialysis
Renal disorders
Myxedema
Sarcoidosis

Exudative

Malignancy
Infection
Drugs (e.g., nitrofurantoin [Marcodantin, Macrobid], methotrexate [Trexall])
Chylothorax
Pulmonary emboli
Gastrointestinal diseases (e.g., pancreatitis)
Collagen vascular disease (e.g., rheumatoid arthritis)
Asbestos exposure
Trauma (e.g., hemothorax, chest surgery)
Postpericardiectomy or postmyocardial infarction syndrome
Pleuropericarditis

Fluid that is low in total protein is a transudative effusion, which is most commonly caused by decreased oncotic pressure or increased capillary hydrostatic pressure. Transudative effusions can also be caused by fluid traversing the diaphragm, as seen in patients with ascites.

Exudative effusions are high in total protein (pleural fluid-to-serum ratio >0.5) and often have an elevated cell count. Increased capillary permeability and decreased lymphatic clearance, usually due to a local or systemic inflammatory illness, produce exudative effusions. The causes are varied, but the most common causes are malignancy, infection, and pulmonary emboli.

Diagnosis**Imaging**

Approximately 200 to 500 mL of pleural fluid is necessary before it can be visualized on a posteroanterior upright chest x-ray, usually as blunting of the costophrenic angle. A lateral chest x-ray is more sensitive, often discerning fluid with as little as 100 mL present; layering of the fluid confirms that it is free flowing. Loculations can be seen on x-ray but may be mistaken for lung or pleural masses. Large effusion can completely opacify the hemithorax where the effusion is located. Ultrasound is useful in defining the location and extent of an effusion and can also identify loculated effusions, pleural thickening, and masses. When used to help guide thoracentesis, it can increase diagnostic accuracy and yield and decrease complications.

Chest computed tomography (CT) has distinct advantages over x-ray and ultrasound, though its utility is significantly decreased when there is a large effusion. Imaging with CT after initial drainage of a large effusion is recommended to obtain the most information regarding the possible etiologies of the effusion and aid in operative planning for treatment of an empyema. It also delineates pleural masses and helps differentiate pleural disease from lung pathology (e.g., loculated effusion vs. lung abscess).

Thoracentesis

Often it is difficult to discern the cause of an effusion solely based on the patient's clinical presentation and image studies. Also, when concerned about a malignant process or an infected effusion, these studies do not give enough information to make a definitive diagnosis. Thoracentesis is the diagnostic procedure of choice, allowing drainage of the fluid to relieve symptoms for the patient and provide a specimen for evaluation. Ultrasound should be employed to help guide thoracentesis, especially if the effusion is small or loculated.

Care must be taken when draining a large amount of fluid in one setting due to the risk of reexpansion pulmonary edema. If a patient becomes symptomatic during the procedure (persistent cough, significant pleuritic pain, or shortness of breath) no more fluid should be removed at that time. Coagulopathy is a contraindication to thoracentesis due to the risk of intrathoracic bleeding.

Pleural Fluid

The initial evaluation of pleural fluid is done at the bedside by determining the nature of the fluid: clear, cloudy, bloody, or milky. One should also evaluate the fluid for odor and cellularity. These simple steps can point the clinician toward the correct diagnosis. In addition to bedside evaluation, the fluid should be sent for the following laboratory studies: pH, glucose, lactate dehydrogenase (LDH), protein, cytology, Gram stain, and culture (including fungal and viral). Serum pH, protein, LDH and glucose should be sent at the same time.

Light's criteria are helpful in differentiating between an exudative and transudative effusion (Box 2). The sensitivity and specificity of Light's criteria is 82% to 90%.

Transudative effusions rarely need any further intervention, and the goal of treatment is directed at the underlying condition (see Box 1). For exudative effusions, the cause of the effusion dictates the treatment. Incorporating the clinical picture and radiographs with the pleural fluid chemistry studies, cytology, and cultures, the diagnosis is often obtained. Malignant effusions can have positive cytology, but they are more likely to have a pleural fluid glucose level less than 60 mg/dL and to be bloody. An elevated amylase level is seen in esophageal perforation, pancreatitis, and malignant effusions. Chylothorax can be definitively diagnosed if the triglyceride level is more than 110 mg/dL within the pleural fluid. Finally, pH, glucose, and cultures are useful in the treatment of patients with a presumed infected pleural effusion (empyema).

Up to 25% of patients will not have a definitive diagnosis based on the clinical scenario and pleural fluid evaluation. These patients can require further diagnostic testing, including repeat thoracentesis or evaluation of the chest cavity via video-assisted thoracoscopic surgery (VATS) with pleural biopsies.

Treatment

After initial evacuation of the effusion, treatment is directed at controlling the underlying disease that caused the effusion. Malignant effusions are best managed with pleurodesis, usually employing talc (Sterile Talc), if lung re-expansion can be obtained. This is best performed via VATS, which allows biopsies to be performed, confirming the diagnosis and visually confirming lung re-expansion. Though it can be done via tube thoracostomy at the bedside, VATS pleurodesis has been shown to reduce hospital stay and the risk of recurrence. If the lung cannot expand fully, then the fluid is often best managed with an indwelling long-term silicone-elastic catheter for palliation. In patients with benign disease, pleurodesis is rarely done because of the high complication and failure rates.

Infected Pleural Space and Empyema

A parapneumonic effusion (exudative effusion in the setting of pulmonary infection) is seen in 20% to 40% of patients admitted for pneumonia, of whom 10% to 20% will develop a complicated parapneumonic effusion or empyema (pus in the pleural space). Progression to empyema is most often due to delay in treatment and leads to longer hospital stays and increased morbidity and

BOX 2**Light's Criteria for an Exudative Effusion**

Pleural fluid-to-serum ratio of protein >0.5
Pleural fluid-to-serum ratio of LDH >0.6
Absolute pleural fluid LDH $>2/3$ of upper limit of normal serum levels

Abbreviation: LDH = lactate dehydrogenase.

mortality. Other causes of infected effusions are trauma, thoracic surgical procedures, perforated esophagus, systemic infection, and transdiaphragmatic spread.

Parapneumonic effusions can be separated into three stages: exudative (stage I), fibropurulent (stage II), and organizational (stage III). Though thoracentesis is indicated in each stage, it is usually sufficient for stage I effusions when coupled with appropriate antibiotics. These effusions are free flowing, have negative cultures, and often do not reaccumulate.

Complicated parapneumonic, or stage II, effusions require drainage beyond the initial thoracentesis. The fluid is more viscous and has positive bacterial cultures, a low glucose level, and low pH. Progression to frank pus, or empyema, occurs in this stage, with the formation of loculations as fibrin deposition increases. Complete evacuation of the effusion is required, and initial tube thoracostomy is indicated. If the patient does not improve over the next 24 hours or the space is not completely drained (residual loculations), then surgery is recommended. Randomized, placebo-controlled trials showed no improved outcomes with the use of fibrinolytics as compared to standard tube thoracostomy drainage. The introduction of DNase (Pulmozyme)¹ may be of benefit, but data are insufficient to recommend this treatment. We strongly recommend early intervention with VATS, which has been shown to reduce hospital stay and offers definitive treatment as compared to tube thoracostomy with fibrinolytic therapy.

Delayed or inadequate treatment causes the patient to progress to the organizational stage. This is characterized by heavy fibrin deposit with the formation of a thick peel throughout the pleura with loculations, trapping, and retarding lung re-expansion. Classic CT findings include thickened pleura with multiple loculations and inability of the lung to expand after tube thoracostomy. Decortication, either via VATS or thoracotomy, is required to completely remove the peel off the parietal and visceral pleura. Without obliteration of the empyema space it is very unlikely that the infection can be cleared. In these situations an open thoracostomy, or Eloesser flap, may be required to eradicate the infection.

¹Not FDA approved for this indication.

PNEUMOCONIOSIS: ASBESTOSIS AND SILICOSIS

Method of

David N. Weissman, MD

CURRENT DIAGNOSIS

- History of inhalation of mineral or metal dust
- Respiratory symptoms such as cough and dyspnea

- Spirometry and lung volumes show restriction in advanced disease
- Interstitial lung disease can usually be demonstrated by chest imaging. Biopsy is usually unnecessary.
- No other likely cause of interstitial lung disease is present

CURRENT THERAPY

- Treatment is symptomatic and similar to that for other patients with chronic lung disease
- Give pneumococcal and influenza vaccinations.
- Provide empiric treatment with short- and long-acting inhaled bronchodilators and inhaled corticosteroids when they are found to provide symptomatic relief.
- Give supplemental oxygen therapy if pulmonary hypertension is present or to prevent pulmonary hypertension if O₂ saturation is less than 88% at rest, with exercise, or with sleep.
- Consider lung transplantation in the setting of end-stage lung disease.

The pneumoconioses are a group of interstitial fibrotic lung diseases predominantly associated with occupational exposures. They are caused by inhalation of mineral or metallic dust particles small enough to penetrate into the deep lung (respirable size range) (Table 1). These agents interact with pulmonary target cells, including alveolar macrophages and alveolar epithelial cells, to activate a cascade of inflammatory mediators including growth factors. Although exposure to these dusts can induce other types of respiratory disease as well, the final common pathway leading to pneumoconiosis is alveolar epithelial cell damage and interstitial fibrosis. This chapter focuses on silicosis and asbestosis, two common forms of pneumoconiosis.

Asbestosis

Asbestos is composed of strong, heat-resistant fibers of hydrated magnesium silicate classified morphologically as serpentine (chrysotile) or amphibole (crocidolite [riebeckite asbestos], amosite [cummingtonite-grunerite asbestos], anthophyllite asbestos, actinolite asbestos, and tremolite asbestos). In addition, certain asbestiform fibers (winchite, richterite, erionite) can cause adverse health effects identical to those of asbestos. Fiber dimensions and persistence in tissues are key determinants of toxicity. There is a dose-response effect between the quantity of asbestos inhaled and the severity of fibrotic lung disease. Asbestos is also a carcinogen, and increasing exposure is associated with increased risk for lung cancer, mesothelioma, ovarian cancer, and laryngeal cancer.

Although asbestos is no longer mined in the United States, importation of asbestos-containing products continues. Exposures also continue to occur, especially in construction and renovation (due to reservoirs of asbestos that are still present in many older buildings), the heating trades (where asbestos is often encountered), and with exposure to older or imported asbestos-containing automotive friction products such as brake linings and clutch facings. Workers exposed to asbestos can carry it home on their clothing, resulting in exposure of family members. Living near geological formations prone to asbestos formation in California has been implicated as a risk factor for mesothelioma.

The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for asbestos is 0.1 fiber per cc air. This limit was based in part on the limits of the analytical methodology used in exposure assessment. Exposure to the PEL every day over a 45-year working lifetime has been estimated to be associated with an increased risk of cancer (lung, mesothelioma, and gastrointestinal) of 336 cases per 100,000 exposed persons and an increased risk of asbestosis of 250 cases per 100,000 exposed persons.

Asbestosis causes symptoms of dyspnea and cough. Latency between initial exposure and disease onset is related to exposure

mortality. Other causes of infected effusions are trauma, thoracic surgical procedures, perforated esophagus, systemic infection, and transdiaphragmatic spread.

Parapneumonic effusions can be separated into three stages: exudative (stage I), fibropurulent (stage II), and organizational (stage III). Though thoracentesis is indicated in each stage, it is usually sufficient for stage I effusions when coupled with appropriate antibiotics. These effusions are free flowing, have negative cultures, and often do not reaccumulate.

- No other likely cause of interstitial lung disease is present

CURRENT THERAPY

- Treatment is symptomatic and similar to that for other patients with chronic lung disease
- Give pneumococcal and influenza vaccinations.
- Provide empiric treatment with short- and long-acting inhaled bronchodilators and inhaled corticosteroids when they are found to provide symptomatic relief.
- Give supplemental oxygen therapy if pulmonary hypertension is present or to prevent pulmonary hypertension if O₂ saturation is less than 88% at rest, with exercise, or with sleep.
- Consider lung transplantation in the setting of end-stage lung disease.

The pneumoconioses are a group of interstitial fibrotic lung diseases predominantly associated with occupational exposures. They are caused by inhalation of mineral or metallic dust particles small enough to penetrate into the deep lung (respirable size range) (Table 1). These agents interact with pulmonary target cells, including alveolar macrophages and alveolar epithelial cells, to activate a cascade of inflammatory mediators including growth factors. Although exposure to these dusts can induce other types of respiratory disease as well, the final common pathway leading to pneumoconiosis is alveolar epithelial cell damage and interstitial fibrosis. This chapter focuses on silicosis and asbestosis, two common forms of pneumoconiosis.

Asbestosis

Asbestos is composed of strong, heat-resistant fibers of hydrated magnesium silicate classified morphologically as serpentine (chrysotile) or amphibole (crocidolite [riebeckite asbestos], amosite [cummingtonite-grunerite asbestos], anthophyllite asbestos, actinolite asbestos, and tremolite asbestos). In addition, certain asbestiform fibers (winchite, richterite, erionite) can cause adverse health effects identical to those of asbestos. Fiber dimensions and persistence in tissues are key determinants of toxicity. There is a dose-response effect between the quantity of asbestos inhaled and the severity of fibrotic lung disease. Asbestos is also a carcinogen, and increasing exposure is associated with increased risk for lung cancer, mesothelioma, ovarian cancer, and laryngeal cancer.

Although asbestos is no longer mined in the United States, importation of asbestos-containing products continues. Exposures also continue to occur, especially in construction and renovation (due to reservoirs of asbestos that are still present in many older buildings), the heating trades (where asbestos is often encountered), and with exposure to older or imported asbestos-containing automotive friction products such as brake linings and clutch facings. Workers exposed to asbestos can carry it home on their clothing, resulting in exposure of family members. Living near geological formations prone to asbestos formation in California has been implicated as a risk factor for mesothelioma.

The Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for asbestos is 0.1 fiber per cc air. This limit was based in part on the limits of the analytical methodology used in exposure assessment. Exposure to the PEL every day over a 45-year working lifetime has been estimated to be associated with an increased risk of cancer (lung, mesothelioma, and gastrointestinal) of 336 cases per 100,000 exposed persons and an increased risk of asbestosis of 250 cases per 100,000 exposed persons.

Asbestosis causes symptoms of dyspnea and cough. Latency between initial exposure and disease onset is related to exposure

TABLE 1 Representative Pneumoconioses

SOURCE	MAIN CLINICAL FEATURES	OCCUPATION	DUST
Crystalline silica	Silicosis, increased susceptibility to TB, airways obstruction, lung cancer	Mining, stone cutting, pottery, foundry work	Free crystalline silica (SiO ₂)
Asbestiform fibers	Asbestosis, bronchogenic carcinoma, mesothelioma, various forms of benign pleural disease	Insulation, shipbuilding, construction, some mining (e.g., vermiculite mining in Libby, MT)	Various asbestiform fibers
Coal	Coal workers' pneumoconiosis, COPD	Coal mining	Coal mine dust
Hard metal	Hard metal lung disease (cobalt lung), asthma	Machinists, metal workers	Hard metal, composed primarily of tungsten carbide and cobalt

Abbreviations: COPD = chronic obstructive pulmonary disease; TB = tuberculosis.

intensity. In the United States, this period is generally about two or more decades. The disease can lead to chronic respiratory failure. Effects of smoking add to the severity of the disease and can cause obstructive findings in addition to the expected decreased lung volume and diffusion capacity associated with fibrotic lung diseases. Bibasilar inspiratory crackles on auscultation, finger clubbing, and bibasilar small, irregular parenchymal opacities on chest x-ray with extension to mid- and upper-zones with advancing disease are characteristic.

The International Labour Organization (ILO) has established a system for classification (grading) of radiographs for the presence of radiographic abnormalities in lung parenchyma and pleura that are associated with pneumoconiosis, as well as their severity. The ILO classification system is widely used in epidemiology, surveillance, administrative, and legal settings. The small opacity profusion grades of 0/1 and 1/0 are often considered as defining the boundary between normal and abnormal lung parenchyma.

High-resolution computed tomography (CT) is the most sensitive imaging method for suspected asbestosis. Findings associated with asbestos exposure include lower lobe or diffuse irregular opacities, bronchial wall thickening, rounded atelectasis, and pleural abnormalities such as pleural plaques and diffuse pleural thickening. The presence of pleural plaques on radiography (particularly bilateral calcified pleural plaques); or uncoated asbestos fibers or fibers coated with an iron-rich proteinaceous material (asbestos bodies) in sputum, bronchoalveolar lavage, or lung biopsy help differentiate asbestosis from idiopathic pulmonary fibrosis.

Criteria for Diagnosis

Diagnosis is supported by radiographic chest imaging or lung biopsy findings of interstitial lung disease compatible with asbestosis; documentation of exposure to asbestos by history, the presence of pleural plaques (bilateral pleural plaques are essentially pathognomonic for asbestos exposure), or the presence of asbestos bodies or an excessive burden of uncoated asbestos fibers in lung biopsy tissue or possibly via bronchoalveolar lavage or sputum; and no other likely explanation for the diffuse fibrotic lung disease.

Asbestos-Related Benign Pleural Disease

Pleural plaques are characteristic forms of localized parietal pleural thickening that are usually bilateral and asymmetrical, involve the lower lung fields or the diaphragm, and spare the costophrenic angles and apices. Pleural plaques are a marker for exposure to asbestos and are often associated with other asbestos-related conditions. Pleural plaques generally result in minimal reductions in forced vital capacity and do not degenerate into malignant lesions.

In contrast, diffuse visceral pleural thickening can result in adhesions between the visceral and parietal pleura with major decreases in forced vital capacity and respiratory insufficiency sufficient for consideration of decortication.

Benign pleural effusions can occur in the first decade after asbestos exposure and contain erythrocytes and a mixed inflammatory cell infiltrate of lymphocytes, neutrophils, and eosinophils. The thickened visceral pleura and adjacent atelectatic lung tissue can result in a pleural-based area of rounded atelectasis, simulating a lung mass

on chest radiography. CT can reveal the comet sign, a pleural band connecting the apparent mass to an area of thickened pleura.

Lung Cancer and Malignant Mesothelioma

Exposure to all forms of asbestos increases the risk of lung cancer. The peak risk occurs at about 30 to 35 years after the onset of exposure. Tobacco smoking increases this risk in a supra-additive fashion, increasing risk to a level greater than for asbestos or smoking alone. In contrast, smoking does not further increase the asbestos-associated risk for malignant mesothelioma. Asbestos-associated malignant mesothelioma can also affect the peritoneum (and sometimes the pericardium), but when it affects the pleura, this disease manifests with dyspnea, chest pain, and bloody pleural effusion (most often unilateral). A latency period of 30 years or longer after initial exposure is common. Special immunochemical stains and electron microscopy of pleural fluid or pleural biopsies may be necessary to differentiate mesothelioma from adenocarcinoma. It is currently unclear when to screen asbestos-exposed individuals at increased risk for lung cancer with low-dose chest computed tomography.

Treatment

Treatment of asbestosis is symptomatic and similar to that for other patients with chronic lung disease (Box 1). Lung transplantation should be considered in the setting of end-stage lung disease.

BOX 1

Recommendations for Managing Patients With Silicosis or Asbestos-Related Lung Disease

Patients

Stop further exposure to silica or asbestos.
Stop smoking, avoid exposure to tobacco products.

Physicians

Provide early treatment of respiratory infections with antibiotics.
Give pneumococcal and influenza vaccinations.
Maintain a high index of suspicion and provide early evaluation of symptoms for lung, laryngeal, and ovarian cancers and mesothelioma in asbestos-exposed patients.
Maintain a high index of suspicion for pulmonary infection with *Mycobacterium tuberculosis*, nontuberculous mycobacteria, and fungi in silica-exposed patients.
Screen silica-exposed patients for latent tuberculosis infection.
Treat latent infections with one of the currently-approved drug protocols.
Provide empiric treatment with short- and long-acting inhaled bronchodilators and inhaled corticosteroids when they are found to provide symptomatic relief.
Give supplemental oxygen therapy if pulmonary hypertension is present or to prevent pulmonary hypertension if O₂ saturation is less than 88% at rest, with exercise, or with sleep.
Consider lung transplantation in the setting of end-stage lung disease.

Treatment of benign pleural disease is also symptomatic; as already noted, decortication is an option for managing severe cases of diffuse visceral pleural thickening. Depending on extent of disease, mesothelioma may be treated with surgery, radiation, chemotherapy, or some combination of these. In general, prognosis is poor. Mesothelioma-associated malignant pleural effusion can require palliation through procedures such as pleurodesis, pleurectomy, and decortication. Asbestos-associated lung cancer is managed in the same fashion as lung cancer occurring without a history of exposure to asbestos.

Silicosis

Silicosis is a fibrosing interstitial lung disease resulting from the inhalation of crystalline silicon dioxide (silica) in dust of respirable size. The commonest form of crystalline silica is quartz, which is the main component of sand and is present in most rocks. Noncrystalline (amorphous) silica, like that in diatomaceous earth or glass, does not cause silicosis. However, heating amorphous silica, as occurs in foundries when molten metal is poured into clay castings, can convert amorphous silica into cristobalite, a hazardous form of crystalline silica. Mining, stone cutting, sandblasting, and foundry work are all examples of trades associated with exposure to respirable dust containing crystalline silica. The International Agency for Research on Cancer (IARC) has designated crystalline silica as a Group 1 human lung carcinogen.

In 2016, OSHA established a new PEL for respirable crystalline silica of 0.05 mg/m^3 . It also established requirements for engineering and administrative controls, personal protective equipment, and medical surveillance including periodic chest radiography and spirometry obtained at least every 3 years. Reporting of silicosis cases to public health authorities is required in some states.

Radiographic Patterns of Silicosis

Three main radiographic patterns of silicosis have been described. Two are nodular interstitial patterns and one is an alveolar-filling pattern. The *simple* pattern is associated with nodules that are smaller than 10 mm and that are predominantly rounded and in the upper lung zones. *Progressive massive fibrosis* (PMF) is found in more advanced interstitial disease. It is associated with multiple coalescent larger nodules, upper lobe fibrosis, upward retraction of the hila, and compensatory hyperinflation of the lower lobes. The large upper-zone opacities can cavitate, sometimes in the setting of superimposed mycobacterial infection. Hilar adenopathy can occur in association with either pattern, sometimes with an egg-shell pattern of hilar node calcification. A third radiographic pattern is an alveolar-filling process. Overwhelming silica exposure over a short period can cause a pathologic response called *silico-proteinosis*, in which alveoli become flooded with proteinaceous fluid. The condition resembles idiopathic pulmonary alveolar proteinosis. The radiographic alveolar filling pattern favors the lower lung zones and is not associated with the changes of simple silicosis or PMF.

Silicosis Syndromes

Three syndromes of silicosis can be defined based on clinical course and radiographic pattern. Chronic silicosis develops slowly, usually 10 to 30 years after first exposure. It most often has the simple radiographic pattern, but it can be associated with PMF.

Accelerated silicosis develops more rapidly, within 10 years after first exposure. It is associated with higher intensity exposures and can be associated with either the simple or PMF radiographic patterns. Accelerated silicosis is differentiated from chronic silicosis by its more rapid course. Patients with accelerated courses are at greater risk for developing PMF. The clinical presentations of chronic and accelerated silicosis are variable but include cough, dyspnea, and a variety of chest findings ranging from a normal chest examination to crackles, rhonchi, or wheezing. PMF is associated with more severe symptoms and respiratory impairment. Findings compatible with both restrictive and obstructive lung

disease (decreased forced vital capacity [FVC], forced expiratory volume at 1 sec [FEV₁], FEV₁/FVC, diffusion capacity) can occur, potentially leading to cor pulmonale and respiratory failure.

Acute silicosis is associated with very intense exposures to silica, leading to symptoms within a few weeks to a few years after exposure. Intense exposure results in lung injury caused by flooding of alveoli with proteinaceous material, or silicoproteinosis. As already noted, the radiographic appearance is that of an alveolar-filling pattern favoring the lower lung zones. Patients present weeks to a few years after exposure with cough, weight loss, fatigue, and occasional pleuritic chest pain, crackles on auscultation, and progression to respiratory failure often complicated by mycobacterial infection.

Criteria for Diagnosis

The diagnosis of silicosis is predicated on a history of exposure to respirable crystalline silica, typical chest x-ray findings, and the lack of a more likely diagnosis. High-resolution CT detects changes of silicosis with greater sensitivity than chest radiography. Lung biopsy is seldom required for diagnosis.

Treatment

Treatment is symptomatic and similar to that for other patients with chronic lung disease (see [Box 1](#)). Experimental therapies such as oral corticosteroid therapy and whole-lung lavage have been reported, but clinical benefit is unclear. Lung transplantation should be considered for patients with end-stage lung disease.

All forms of silicosis, as well as substantial exposure to crystalline silica in the absence of silicosis, are associated with an increased risk of pulmonary tuberculosis and fungal infections. Patients should be evaluated for latent tuberculosis infection by tuberculin skin testing or with an interferon gamma release assay. A positive tuberculin skin test in a patient with a history of substantial silica exposure of at least 10 mm of induration should be considered evidence of tuberculosis infection, regardless of previous immunization with bacille Calmette-Guérin. If testing for latent tuberculosis infection is positive, an evaluation for active tuberculosis should be performed and active disease treated. If active tuberculosis is not present, treat for latent infection. As in other settings, treatment for active or latent infection should be provided using one of the drug treatment protocols recommended by the Centers for Disease Control and Prevention. Vaccination for influenza should be provided annually. In addition, adults with silicosis should be vaccinated with 13-valent pneumococcal conjugate vaccine (PCV13, Prevnar 13) and 23-valent pneumococcal polysaccharide vaccine (PPSV23, Pneumovax 23) according to current Centers for Disease Control and Prevention recommendations.

PRIMARY LUNG ABSCESS

Method of
Dan Schuller, MD

CURRENT DIAGNOSIS

- Lung abscess is usually a complication of aspiration in patients with gingivitis or periodontal disease.
- Mixed aerobic-anaerobic copathogens are common, but sputum cultures are not reliable.
- Lung abscesses are rare in edentulous patients and should prompt evaluation for bronchial obstruction.
- CT scan of the chest is very useful in the diagnostic evaluation.

CURRENT THERAPY

- Prolonged antimicrobial therapy (6–8 weeks) and postural drainage are the cornerstones of therapy.
- Clindamycin (Cleocin) or alternative anaerobic coverage is required even if sputum cultures grow only aerobic bacteria (colonizers or copathogens).
- Percutaneous or bronchoscopic drainage is reserved for selected cases refractory to medical management or at a high risk for complications.
- Surgical resection is seldom needed because of the success of medical therapy.
- Evaluation and management of underlying predisposing conditions should not be neglected.

Definition and Classification

Lung abscess is defined as a focal area of necrosis of the lung parenchyma resulting from microbial infection and usually measuring more than 2 cm in diameter. Smaller or multiple areas of necrosis in contiguous areas are referred to as *necrotizing pneumonia*. Primary lung abscess (80%) is due to direct infection or aspiration. Secondary lung abscess (20%) is secondary to bronchial obstruction, immunodeficiency, pulmonary infarction, trauma, or complications from surgery. Lung abscesses can also be classified according to pathogen (e.g., mixed anaerobic, *Pseudomonas*, mycobacterial, fungal) or duration of symptoms (e.g., chronic with symptoms for more than a month before presentation).

Epidemiology and Risk Factors

Most lung abscesses result from aspiration of oral secretions in patients who harbor high bacterial concentrations in the gingival crevices. Periodontal disease, especially gingivitis, is a major predisposing condition, particularly in hosts impaired by altered sensorium due to alcoholism, anesthesia, coma, drug overdose, seizures, or stroke. Because edentulous persons rarely develop lung abscesses, other causes such as malignancy should be carefully sought. Patients with dysphagia, esophageal disease, poor airway protection, or weak cough and respiratory clearance mechanisms are also at risk for developing lung abscess.

Patients whose immune systems are compromised by malignancy, HIV infection, malnutrition, diabetes, chronic use of corticosteroids, or previous organ transplantation are more likely to be infected with aerobic bacteria, mycobacterial or fungal pathogens. These patients are more likely to have multiple abscesses, less response to treatment, and a worse prognosis.

In children, consider secondary causes including foreign body aspiration, congenital cystic adenomatoid malformation, pulmonary sequestration, cystic fibrosis, bronchiectasis, bronchogenic cyst, congenital immunodeficiency, or severe underlying neurologic abnormality.

Lemierre's disease or jugular vein suppurative thrombophlebitis, usually caused by *Fusobacterium necrophorum*, is a rare infection that begins in the pharynx as a tonsillar or peritonsillar abscess and spreads to involve the internal jugular vein, with septic emboli to the lung with secondary cavitations.

Pathophysiology

The development of a lung abscess usually starts when an insult (e.g., inoculum of highly contaminated oral secretions) overcomes the pulmonary mechanisms of defense and begins a process of pneumonitis in the dependent areas affected by aspiration. Depending on the microbiology and the intensity of the inflammatory response, the acute pneumonitis evolves to tissue necrosis after 7 to 14 days and subsequent cavitation. At first, the enclosing wall is poorly defined, but with time and progressive fibrosis it becomes more discrete. When a communication with the airway exists, the suppurative debris from the abscess can partially drain, leaving an air-containing cavity with a radiographic air-fluid level. Occasionally, abscesses rupture into the pleural cavity yielding an empyema or a bronchopleural fistula (Figure 1). Primary abscesses due to aspiration are much more common on the right side than the left and are most often single. The most common locations include the superior segments of the lower lobes and the posterior segment of the right upper lobe.

Clinical Manifestations

Most patients present with insidious symptoms that evolve over a period of weeks to months. Cough productive of copious amounts of putrid, foul-smelling sputum that occurs in paroxysms after changing position are characteristic. Fevers, chills, night sweats, chest pain, dyspnea, general malaise, and fatigue are common. Hemoptysis can vary from blood-streaked sputum to life-threatening hemorrhage. Physical findings can include fever, tachycardia, periodontal disease, halitosis, signs of lung consolidation or pleural effusion, amphoric breath sounds, and occasionally clubbing of the fingers and toes can appear within a few weeks after the onset of an abscess.

Diagnosis

Lung abscess is easily diagnosed when there is a classic clinical presentation with indolent symptoms lasting more than 2 weeks in a host with predisposing risk factors and a chest radiograph revealing a cavitary infiltrate or an air-fluid level. However, numerous pathogens are associated with this syndrome, and attempts to establish microbiological diagnosis and exclude other conditions are warranted.

Computed tomography (CT) scans can be useful for better anatomic definition, to evaluate possible associated conditions such as

Figure 1 Primary lung abscess in the right lower lobe with rupture into the pleural space causing an empyema.

malignancy, and to rule out pleural involvement. Distinguishing between a lung abscess and an empyema with an associated bronchopleural fistula leading to an air-fluid level can sometimes be challenging, but it is crucial because the management of these conditions is very different. Features that suggest empyema include a lenticular shape or a larger diameter of the air-fluid level on the lateral view of the chest film, an obtuse angle of the cavity with the chest wall, and a split pleural sign with contrast enhancement of the pleura.

Most lung abscesses are caused by anaerobic or mixed aerobic and anaerobic infections. Anaerobic bacteria include *Peptostreptococcus*, *Prevotella*, *Bacteroides* spp., and *Fusobacterium* spp. and are difficult to isolate owing to technical issues and contamination by upper airway flora. Other pathogens, including *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas*, *Burkholderia pseudomallei*, *Nocardia*, *Actinomyces*, and mycobacterial or fungal organisms, are more likely to occur in secondary lung abscesses.

Sputum Gram stains and culture should be performed in all patients but interpreted with caution because prior antimicrobial therapy can inhibit growth, and contaminant strains can be misleading. Even when there is abundant growth of a species of aerobic bacteria, treatment should still be directed at covering anaerobes.

In the absence of positive blood or pleural fluid cultures, microbiological confirmation of a lung abscess requires other invasive methods such as a transthoracic needle aspirates (TTNA) or bronchoscopy with bronchoalveolar lavage (BAL) or protected specimen brush (PSB). The best timing for bronchoscopy is controversial because early intervention has the highest diagnostic yield but at the risk of provoking spillage of a relatively contained abscess into additional lobes or the contralateral lung. In patients who are edentulous or in whom there is a high suspicion for malignancy, the indication for bronchoscopic evaluation is almost universal but should be scheduled when the risk for clinical deterioration (e.g., spillage with resultant respiratory failure) has been minimized.

Differential Diagnosis

In addition to the multiple necrotizing infections or an empyema with a bronchopleural fistula (see earlier), there are many noninfectious diseases that can cause cavitary lung lesions and mimic a lung abscess. The differential diagnosis includes neoplasm (primary or metastatic), bullae or cyst with air-fluid level, bronchiectasis, necrotizing vasculitis, or pulmonary infarction. In patients with multiple cavitary lesions, consider septic emboli.

Treatment

Lung abscess is best treated with a prolonged course of adequate antimicrobials and postural drainage. Percutaneous or bronchoscopic drainage and surgery are considered only for selected patients whose disease is refractory to standard care.

Initial empiric antibiotic treatment for a typical community-acquired lung abscess should consist of intravenous clindamycin (Cleocin) 600 to 900 mg every 6 to 8 hours, which has been shown to be superior to penicillin. For patients with a nosocomial or health care-associated lung abscess, additional coverage for enteric gram-negative pathogens including *Pseudomonas aeruginosa* and *Staphylococcus aureus* is appropriate.

Alternative antimicrobial options include ampicillin-sulbactam (Unasyn)¹ 1.5 to 3.0 g IV every 6 hours, piperacillin-tazobactam (Zosyn)¹ 3.35 g IV every 6 hours, cefoxitin (Mefoxin) 2 to 3 g every 6 to 8 hours, or a combination of moxifloxacin (Avelox)¹ 400 mg IV daily and metronidazole (Flagyl) 500 mg IV every 6 to 8 hours. The use of metronidazole as single agent has been associated with a high therapeutic failure rate.

After defervescence and radiographic improvement, parenteral antibiotics can be switched to oral bioequivalent therapy for 6 to 8 weeks or longer depending on the course. Shorter antimicrobial courses are associated with a high rate of relapse. Most experts

suggest continuing therapy until there is radiographic resolution or a small stable lesion.

Indications for percutaneous or bronchoscopic drainage include persistent sepsis after 5 to 7 days of antimicrobial therapy, abscesses larger than 4 cm that are under tension or enlarging, and need for mechanical ventilator support. Percutaneous drainage should only be considered when there is a reasonable abscess-pleura symphysis and no associated coagulopathy.

Postural drainage and chest physiotherapy facilitate removal of pus, relieving symptoms and improving gas exchange. Surgical resection is required in less than 10% of patients whose disease is refractory to medical management.

Finally, evaluation and management of the predisposing conditions leading to aspiration should take place after the patient is stabilized. This can include swallowing assessment, dental work, or oral surgery.

Prognosis

Primary lung abscesses in nonimmunocompromised hosts have cure rates of 90% to 95% with antimicrobial therapy and postural drainage alone. However, in immunocompromised patients and those with bronchial obstruction due to cancer, the mortality has been reported between 20% and 75%.

PRIMARY LUNG CANCER

Method of

Rober A. Kratzke, MD; and Manish R. Patel, DO

CURRENT DIAGNOSIS

- Cigarette smoking history is greatest risk factor.
- Cough, dyspnea, and chest pain are the most common presenting symptoms.
- Diagnosis is made by needle biopsy or pleural fluid cytology.
- Initial staging evaluation should include:
 - Positron emission tomography (PET)/computed tomography (CT) to evaluate for distant metastasis
 - Magnetic resonance imaging (MRI) of the brain
- Potentially resectable patients should have additional evaluation of mediastinum prior to resection (i.e., mediastinoscopy or endoscopic ultrasonography).

Lung cancer is the leading cause of cancer-related death worldwide for men and women. Though it is not the most common cancer, most patients with lung cancer are diagnosed at a late stage, accounting for the excess mortality. Lung cancer accounts for only 13% of new cancer cases but accounts for almost one third of cancer-related deaths. Even accounting for the approximately one third of patients diagnosed at an early stage, the rate of 5-year survival for all patients with lung cancer is less than 20% overall.

Lung cancer is broadly divided into two groups, small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). Approximately 80% of lung cancers are NSCLC, of which the vast majorities are adenocarcinomas, squamous cell carcinomas, and mucinous adenocarcinoma. Carcinoid tumors and other neuroendocrine tumors are less common, and adenoid cystic carcinomas are rare. Owing to differences in biology and the efficacy of therapeutic agents, the histologic classification of non-small cell lung cancer is now of critical importance when considering a therapeutic approach.

Epidemiology

Lung cancer occurs most commonly among middle-aged and elderly people. The peak incidence is in those aged 65 to 85 years old. It is extremely rare in people under the age of 30, and the incidence decreases above age 85. Prior to the 1960s, lung cancer was rare among women; however, the current rate is nearly equal between men and women. The incidence is decreasing among men and has leveled off in women over the past decade. Lung cancer incidence is highest in African-Americans. This most likely reflects socioeconomic status more than genetic risk as cigarette smoking is higher among African-Americans; however, there is some evidence that African-Americans are more vulnerable to the effects of tobacco-related carcinogens.

Etiology

Cigarette smoking is the established cause of the vast majority of lung cancer and virtually all patients with SCLC. Eighty percent of newly diagnosed lung cancers are in patients who are current or former smokers. Ninety-five percent of those diagnosed with SCLC have a significant smoking history. Current smokers with a greater than 20-pack-year smoking history have a 2000-fold greater risk of developing lung cancer compared with nonsmokers. Smoking cessation does decrease the risk of developing lung cancer but does not eliminate it. The risk of developing lung cancer in

former smokers remains increased by ninefold over nonsmokers. There is also clearly a dose-response relationship in tobacco smoke-induced lung cancer in that the risk is highest among those with the most prior cigarette exposure. Pipe and cigar smoke also increase the risk of developing lung cancer. Among nonsmokers, the risk of developing lung cancer is now clearly associated with inhalation of second-hand smoke.

Other environmental factors have been associated with the development of lung cancer as well. Up to 20% of lung cancer occurs in nonsmokers, and this population of patients appears to be rising. Certainly, some of this increase is the result of second-hand exposure to cigarette smoke; however, this is difficult to quantify. Asbestos exposure has been associated with development of lung cancer, and the risk is particularly accentuated by combination with cigarette smoke. Exposure to radon is perhaps the strongest known environmental risk for developing lung cancer, particularly in uranium mine workers, who have a risk that is about 10 times the risk of the general population. Several other environmental exposures such as chromium, arsenic, and polyvinyl chloride have been implicated in the development of lung cancer; however, a clear causal link has not been established.

Finally, while a patient with a family history of lung cancer has an approximate twofold higher risk of developing lung cancer, the genetic basis of this is not well understood.

Clinical Presentation

The location of tumors and the appearance of paraneoplastic syndromes determine the clinical presentation of most patients with lung cancer (Table 1). Many patients with early-stage disease may be asymptomatic and have a mass discovered incidentally on chest x-ray or CT scans done for some other reason. Centrally located tumors will often cause symptoms associated with local effects of the tumor such as cough, hemoptysis, wheezing, or stridor. Obstruction of the bronchi can lead to postobstructive pneumonia as the presenting sign, and obstruction of the superior vena cava (SVC) can lead to the SVC syndrome with facial edema, bluish discoloration of the upper chest, and shortness of breath. Mediastinal lymph node involvement can cause disruption of the recurrent laryngeal nerve, leading to hoarseness. Tumors arising in the superior sulcus, so-called Pancoast tumors, can lead to a lower brachial plexopathy and Horner syndrome. Peripheral tumors tend to present later as pain when involving the chest wall or pleura. Pleural effusion may also be the presenting sign for lung cancer.

TABLE 1 Clinical Manifestations

TUMOR LOCAL EFFECTS	DISTANT METASTASES	PARANEOPLASTIC SYNDROMES
Cough	Bone pain	Hypercalcemia
Dyspnea	Neurologic symptoms	SIADH
Hemoptysis	Headache	Lambert-Eaton syndrome
Chest pain	Nausea and vomiting	Cerebellar ataxia
Hoarseness	Weight loss	Encephalitis
Horner syndrome	Fatigue	Cachexia/anorexia
SVC syndrome	Abdominal pain	Cushing syndrome
Postobstructive pneumonia	Spinal cord compression	
Pericardial effusion	Pathologic fracture	
Pleural effusion		

Abbreviations: SIADH = syndrome of inappropriate antidiuretic hormone secretion; SVC = superior vena cava.

Lung cancer frequently metastasizes early and symptoms from metastatic lesions may be the first sign of malignancy. Brain metastases are a common presentation particularly in patients with SCLC, but also in NSCLC. Symptoms such as seizures, nausea and vomiting, headache, and focal neurologic signs may be the initial presentation of such patients. Bony metastases are common in all types of lung cancer and can present with pain, pathologic fracture, or spinal cord compression. Liver metastases can cause biliary obstruction and jaundice; however, this is not particularly common.

Lung cancers are notable for ectopic production of hormones leading to several paraneoplastic syndromes. These are most commonly described in SCLC; however, several occur in NSCLC as well. Probably the most common paraneoplastic syndromes in NSCLC are tumor cachexia and hypercalcemia. While the causes of tumor cachexia are not well characterized, hypercalcemia is mediated by the production of parathyroid hormone–related peptide (PTHrP). This leads to release of calcium from bones and elevation of calcium in the blood. This syndrome is effectively treated with bisphosphonate therapy. Hypertrophic pulmonary arthropathy can occur with NSCLC or SCLC and is characterized by digital clubbing and periostitis of the long bones that are demonstrable on plain x-rays. SCLC commonly presents with paraneoplastic syndromes, the most common being the Lambert-Eaton myasthenic syndrome (LEMS). Approximately 50% of patients who present with this syndrome have an underlying malignancy and 95% of those are SCLC. Other paraneoplastic syndromes related to SCLC are the syndrome of inappropriate antidiuretic hormone (SIADH), Cushing syndrome due to ectopic production of adrenocorticotrophic hormone (ACTH), and cerebellar degeneration associated with the elaboration of anti-Yo autoantibodies.

Screening

Since the vast majority of patients present with lung cancer with advanced disease and curative approaches are limited to patients with limited disease, screening at-risk patients for lung cancer has been undertaken to identify patients with early-stage disease to prevent excess mortality from lung cancer. While chest x-ray has been proven to be ineffective as a screening tool, recent data has shown that low-dose computed tomography (LDCT) is an effective tool to identify patients with early-stage lung cancer. The National Lung Cancer Screening trial randomized 53,464 patients with a 30-pack-year smoking history to three yearly LDCT scans or yearly chest x-ray. For the patients undergoing LDCT screening, there was a 20% relative decrease in lung cancer–specific mortality compared with screening with chest x-ray. Fifty percent of tumors identified by LDCT were stage I lung cancer versus only 31% with x-ray. One drawback of LDCT screening is the number of false positives. Ninety-five percent of positive scans were later determined to be false positives by biopsies or long-term follow-up of nodules. It is now widely recommended to incorporate lung cancer screening in patients with a heavy smoking history; however, decisions regarding management of positive screening scans need to be managed in a multidisciplinary fashion to avoid unnecessary diagnostic procedures.

Diagnosis and Evaluation

Once lung cancer is suspected, tissue biopsy is required to make a definitive diagnosis. Several methods can be used to obtain tissue depending on the location of the tumor. Mediastinal involvement can be accessed by mediastinoscopy or increasingly endoscopic ultrasound (EUS). Transbronchial biopsy can be performed for centrally located tumors and the yield may be increased by using endobronchial ultrasound (EBUS) techniques. For peripheral lesions, CT-guided needle biopsy is usually recommended. If equivocal results are obtained, open procedures using video-assisted thoracoscopic surgery (VATS) are occasionally required. For patients presenting with pleural effusion, cytologic examination of pleural fluid can establish the diagnosis. The choice of method for diagnosis should be individualized according to the resources that are available at the treating institution. Whatever method is

chosen, it is increasingly important that enough tissue be obtained to ascertain the histologic subtype of lung cancer and to ensure that there is sufficient DNA in the specimen to allow for molecular testing (see later). If sufficient tissue is not obtained to further classify the subtype of lung cancer, additional procedures to obtain sufficient tissue are warranted.

Once the diagnosis is confirmed, accurate staging of disease is important to determine the prognosis and appropriate therapy. The first step is to rule out metastatic disease. For NSCLC, fusion PET/CT scans are the best test to do this. While SCLCs are PET-avid tumors, the added benefit of the PET/CT scan over CT scan is not clear for this disease. For most patients, MRI of the brain is recommended to complete the staging workup and is mandatory for patients with SCLC. For patients with clinical stage I NSCLC, MRI of the brain may be omitted if there are no concerning symptoms. PET/CT is sufficient to rule out bony metastasis; however, where PET/CT scan is not available, a bone scan is recommended for evaluation.

In patients who are potentially resectable, accurate staging of the mediastinum becomes paramount. Abnormal lymphadenopathy by CT scan is not adequate to determine lymph node involvement for NSCLC. PET/CT scans have higher sensitivity and specificity; however, these tests do not replace direct sampling of the lymph nodes by mediastinoscopy. EUS and EBUS are less invasive techniques that can be combined with lymph node sampling and are emerging as appropriate methods of staging the mediastinum in experienced hands.

All patients should be evaluated with baseline bloodwork to include a complete blood count, liver function tests, and assessment of renal function. Assessment of the patient's performance status has important prognostic and therapeutic implications and should be documented for all patients. Furthermore, for patients who are considered surgically resectable, it is important to assess the tolerability of lobectomy or pneumonectomy. A forced expiratory volume in 1 second (FEV₁) greater than 2 L generally predicts the ability to tolerate pneumonectomy, while FEV₁ of less than 1 L predicts worse outcome with lobectomy. The diffusion capacity of carbon monoxide (DL_{CO}) can also be a useful measurement in borderline cases.

Treatment

Non–Small Cell Lung Cancer

For NSCLC, the stage at diagnosis is the best predictor of overall survival and the most appropriate therapy (Tables 2 and 3).

Stage I: This group includes T1 (Stage IA) or T2 (Stage IB) tumors that do not have any nodal involvement (N0) and no evidence of distant metastasis (M0). The primary mode of therapy for these patients is surgical resection, which results in 5-year survival of approximately 70%. Wherever possible, lobectomy with complete mediastinal lymph node dissection is recommended for accurate pathologic staging. Occasionally, pneumonectomy is required based on the location of the primary tumor; however, the morbidity and mortality of this procedure are much higher than lobectomy. Video-assisted thoracoscopic approaches are desirable whenever possible and result in lower surgical morbidity. Surgical resection may not be feasible for all patients, particularly those with poor pulmonary function or performance status. In these patients, primary radiotherapy can be considered. Traditional external-beam radiation therapy results in much poorer outcomes than surgery; however, newer techniques such as stereotactic radiosurgery are emerging as an effective method of providing local control for stage I tumors and are now offered routinely to patients with stage I disease who are not candidates for surgical resection.

Several studies have evaluated the role of adjuvant chemotherapy in this group of patients; however, no clear survival benefit has emerged. The Cancer and Leukemia Group B (CALGB) 9633 randomized 344 patients with stage Ib tumors to surgery alone or surgery followed by carboplatin (Paraplatin)¹ and

paclitaxel (Taxol). A survival benefit was only demonstrated in patients with tumors greater than 4 cm. The JBR.10 study conducted by the National Cancer Institute of Canada showed a survival benefit for carboplatin (Paraplatin) and vinorelbine (Navelbine) adjuvant therapy; however, both stage Ib and II patients were included in this study. Furthermore, another study comparing adjuvant carboplatin (Paraplatin) and vinorelbine (Navelbine) with surgery alone in stage Ib, II, and IIIa patients showed an overall survival benefit of 8% for adjuvant therapy; however, this was limited to the stage II and IIIa patients. Finally, the LACE metaanalysis incorporated data from five large randomized trials and found no significant benefit of adjuvant chemotherapy in stage I patients. Therefore, adjuvant therapy for stage I NSCLC is not routinely recommended except as part of a clinical trial.

There does not appear to be any added benefit to using radiation therapy after surgical resection of stage I tumors. In cases in which the surgical margins are positive, adjuvant radiation therapy is routinely recommended; however, this is infrequent. As will be discussed later, some patients with clinical stage I NSCLC will be upstaged by the finding of malignant disease in the mediastinum, and in this group postoperative XRT improves local control and potentially survival when combined with adjuvant chemotherapy.

Stage II: The approach to treating stage II NSCLC is largely the same as stage I, with surgical resection as the primary modality of treatment. Again, lobectomy using a minimally invasive

video-assisted thoracoscopic approach is preferred whenever possible. Adjuvant chemotherapy offers a more clear survival advantage in patients with stage II disease. All three of the aforementioned studies and the metaanalysis showed a benefit of adjuvant chemotherapy in stage II patients, and four cycles of adjuvant platinum doublet chemotherapy is routinely offered in this group of patients.

Stage III: Stage III NSCLC denotes metastasis to mediastinal lymph nodes. The treatment of stage III patients is hallmarked by a multimodal approach in which surgery, radiation, and chemotherapy all may play a significant role. The division of this stage into IIIA and IIIB denotes ipsilateral and contralateral nodal involvement, respectively. While the overall prognosis of this group of patients is poor, treatment with curative intent results in long-term survival of 10% to 30%. This also represents the stage with the most heterogeneity; therefore the approach should be individualized taking into consideration the patient's performance status, resectability, and extent of disease.

Whether or not patients with stage III should undergo resection of the tumor is still open to some debate. The Intergroup 0139 trial randomized stage IIIA and selected stage IIIB patients to receive concurrent chemoradiation with cisplatin (Platinol)¹ and etoposide (VePesid)¹ and 45 Gy of radiation followed by surgical resection or the same chemoradiation with 61 Gy of XRT. Patients in the surgical arm who progressed on the chemotherapy were given additional XRT to 61 Gy. There was no difference in the overall survival between the two groups (23.6 months vs. 22.2 months for trimodality vs. chemoradiation groups). Recurrence rates and progression-free survival were much more favorable for the surgery arm. Much of the excess mortality in the surgery arm was for those patients requiring a pneumonectomy for complete resection. Finally, 46% of patients were downstaged by induction chemotherapy to have N0 disease at the time of resection. Among those patients, the 5-year survival was 40%, suggesting that good response to induction chemoradiotherapy may predict a benefit to surgical resection. Therefore at this time, patients with stage IIIA who have resectable tumors at the outset could be offered two cycles of induction chemotherapy with or without irradiation followed by surgical resection with mediastinal lymph node dissection. Radiation therapy to the mediastinum should be offered to patients who have residual mediastinal disease at the time of resection. Stage III patients who would require a pneumonectomy or where surgical resectability at the time of diagnosis is unclear should be treated with definitive chemoradiation. Even with appropriate staging procedures, some patients will be found to have mediastinal lymph node

¹Not FDA approved for this indication.

involvement on pathologic examination postoperatively. In those patients, radiation therapy to the mediastinum is typically offered either in combination with or sequential to adjuvant chemotherapy. Given the complexities of treatment of stage IIIa disease, the preferred treatment approach should be individualized for each patient, with decisions made in a multidisciplinary fashion.

Stage IIIB disease is inoperable. Satellite tumors within the same lobe may be considered resectable provided patients do not have disease in the mediastinum and can be resected with no more than a lobectomy. For patients with inoperable stage III disease, chemotherapy with radiation is clearly superior to radiation alone and can lead to long-term survival with a 3-year survival as high as 30%. The optimal strategy is not known; however, a common regimen is the combination of cisplatin (Platinol)¹ and etoposide (VePesid)¹ concurrently with XRT to 66 Gy for 6 weeks. Recently, the combination of cisplatin and pemetrexed (Alimta) with 66 Gy of XRT was found to be equivalent to the platinum/etoposide regimen with a better toxicity profile. Therefore a cisplatin/pemetrexed regimen could be considered for patients with stage III adenocarcinoma. The use of induction chemotherapy followed by chemoradiation has been evaluated, as has the use of consolidation chemotherapy; however, no regimen has clearly proven to be superior. For patients with poor performance status, using sequential chemotherapy followed by radiation might be preferred, or for those deemed unfit for chemotherapy, palliative radiation could be the most appropriate therapy.

¹Not FDA approved for this indication.

Stage IV: For most patients with metastatic NSCLC, the treatment is palliative; however, prolongation of survival is a reasonable goal. While platinum doublet chemotherapy remains the standard of care for many patients with NSCLC, the choice of initial treatment depends on the molecular and histologic subclassification of tumors (Figure 1). It is now well recognized that some patients, particularly those with NSCLC who are light smokers or have never smoked, harbor activating mutations in oncogenes (e.g., epidermal growth factor receptor [EGFR], echinodermal mitochondrial-like 4-anaplastic lymphoma kinase [EML4-ALK], or ROS1) that are highly responsive to oncogene-targeted oral tyrosine kinase inhibitors (TKIs). Thus use of gefitinib (Iressa) or erlotinib (Tarceva) in patients with activating mutations in EGFR results in improved progression-free survival compared with chemotherapy in a first-line setting. Furthermore, the second-generation EGFR tyrosine kinase inhibitor afatinib (Gilotrif) improves overall survival compared with chemotherapy in these patients. Likewise, crizotinib (Xalkori) results in dramatically improved progression-free survival and overall survival in patients with EML4-ALK and ROS1 alterations. Thus identification of these patients with molecular testing is now the standard of care to determine the most appropriate first-line therapy for patients with lung adenocarcinoma. Resistance to TKIs invariably occurs after some time, and there are now effective second- and third-generation targeted agents for acquired resistance to EGFR and ALK TKIs. For EGFR mutation-positive patients, the most common resistance mechanism is a secondary mutation in EGFR, T790M. For those patients, osimertinib (Tagrisso) is a third-generation TKI that results in marked treatment response in patients who have failed prior

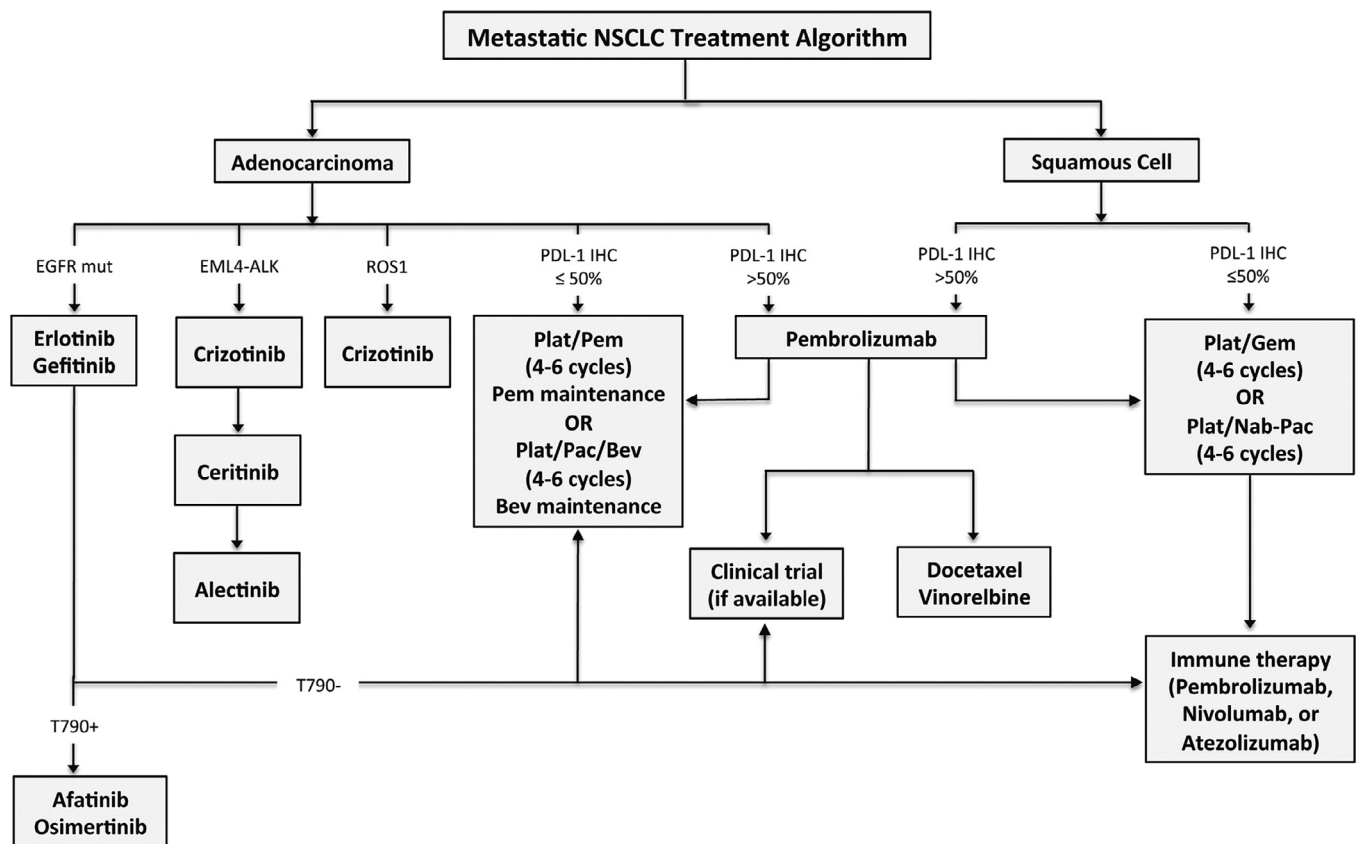

Figure 1 Treatment algorithm for metastatic non-small cell lung cancer (NSCLC). For patients with NSCLC, histology is of key importance. For patients with adenocarcinoma, all patients should undergo molecular testing of the tumor for the presence of key mutational drivers, EGFR, EML4-ALK, and ROS1. If any of those mutations are present, then patients should be treated with a molecularly targeted agent. All patients with NSCLC should undergo PD-L1 testing by immunohistochemistry. In patients whose tumor stains positive for PD-L1 in greater than 50% of tumor cells, pembrolizumab (Keytrada) should be offered as first-line therapy. For all others, platinum doublet chemotherapy remains the standard of care. For adenocarcinoma, platinum doublet with either pemetrexed±bevacizumab (Avastin) could be offered, but neither of those is effective for squamous cell tumors. Second-line treatment results in a survival benefit and therefore should be offered to patients with acceptable functional status. Options include chemotherapy with platinum doublets if patients did not receive this in the first line, immune therapy if not received in the first line, and single-agent chemotherapy.

EGFR TKIs. For EML4-ALK-positive patients who have failed crizotinib, ceritinib (Zykadia) and alectinib (Alecensa) are now FDA approved based on a robust response rate and median progression-free survival of about 2 years. Of note, alectinib has excellent penetration into the central nervous system (CNS) and would be the treatment of choice for EML4-ALK-positive patients with active CNS disease. Thus for about 20% of NSCLC patients with a molecular driver mutation, these novel treatments have resulted in a median survival that exceeds 2 years, more than double the results with conventional chemotherapy.

In the absence of these molecular driver mutations, immune therapy is now the standard of care for approximately 30% of patients with NSCLC. Programmed death 1 (PD-1) and its ligand PD-L1 are so-called immune checkpoint proteins that serve to send an off signal to T lymphocytes in the tumor microenvironment. Therapeutic response to drugs targeting PD-1 can be dramatic and is most notable for a prolonged duration of response. Pembrolizumab (Keytruda), an anti-PD-1 monoclonal antibody, was tested compared with standard chemotherapy in the first-line setting for patients with NSCLC with greater than 50% of tumor cells staining positive for PD-L1. Pembrolizumab was associated with an improved overall survival and improved quality of life compared with chemotherapy, with approximately 20% of patients treated experiencing a prolonged disease remission of greater than 2 years. Thus pembrolizumab is now standard first-line therapy for NSCLC of any histology expressing a high level of PD-L1 on tumor cells.

For the remaining patients who do not have a molecular driver mutation or high expression of PD-L1, doublet chemotherapy with platinum as a backbone remains the standard of care. However, the FDA approval of pemetrexed (Alimta) and bevacizumab (Avastin) in only patients with adenocarcinoma again highlights the importance of histology in defining the treatment. While both carboplatin¹/pemetrexed and carboplatin¹/paclitaxel/bevacizumab regimens are acceptable choices for adenocarcinoma, the tolerability of carboplatin/pemetrexed makes this the preferred regimen for most patients with metastatic adenocarcinoma without a molecular driver mutation. For squamous cell carcinoma, the carboplatin partner is often a taxane (paclitaxel [Taxol], nab-paclitaxel [Abraxane], or docetaxel [Taxotere]) or gemcitabine (Gemzar). All have roughly equivalent response rates and survival outcomes, and therefore the choice of regimen is largely based on perceived tolerability for the individual patient. It is typical to evaluate for treatment response with a CT scan after two to three cycles of treatment. In stable or responding patients, platinum doublet chemotherapy should be continued for no more than six cycles. For adenocarcinoma, maintenance therapy is the standard of care based on improved survival in patients receiving maintenance pemetrexed every 3 weeks until disease progression. If bevacizumab is chosen as a part of first-line treatment, maintenance bevacizumab until disease progression is also the standard of care.

At the time of disease progression, for those patients treated with chemotherapy in the first-line setting, immunotherapy with antibodies against PD-1 or PD-L1 is now the standard of care. Nivolumab (Opdivo) and pembrolizumab (Keytruda), PD-1 inhibitors, and atezolizumab (Tecentriq) are FDA approved in the second line for NSCLC regardless of histology, based on a survival benefit compared with the previous standard of care of docetaxel. Tumor PD-L1 staining greater than 1% was mandated for treatment with pembrolizumab, whereas nivolumab and atezolizumab were approved regardless of PD-L1 staining. Response rates to immunotherapy are in the range of 20% to 25%, and in those patients, the response may be quite durable, with 15% to 20% having response for greater than 1 year. For patients with molecular driver mutations, response to immune therapy is generally low (<10%), and therefore it is generally preferable to treat with molecularly targeted agents if possible. For those patients failing immunotherapy and who have an acceptable functional status, treatment options include single-agent chemotherapy with docetaxel (Taxotere), gemcitabine (Gemzar),

or vinorelbine (Navelbine). Of those, only docetaxel has demonstrated a survival benefit in the second- or third-line setting. Erlotinib (Tarceva) has been shown to modestly improve survival in molecularly unselected patients in the second- or third-line setting and can be a treatment option for those patients who will not tolerate single-agent chemotherapy.

In summary, the last several years have seen a dramatic shift in the treatment paradigm for metastatic NSCLC with the introduction of molecularly directed therapy and, more recently, immunotherapy into the standard of care. Though the treatment algorithm is more complex, the identification of safer and more effective therapy has resulted in improvement in outcomes for many patients with NSCLC (Figure 1).

Small Cell Lung Cancer

Small cell lung cancer is hallmarked by aggressive growth and early metastasis. If left untreated, median survival is only 2 to 4 months. However, these tumors are highly sensitive to chemotherapy and response rates of 60% to 80% are expected. These tumors are also highly radiosensitive; however, radiation is limited by the extent of metastatic disease. While the TNM staging system for NSCLC applies, in practical terms, SCLC is generally referred to as being limited or extensive based on whether the disease is limited to one radiation field or not, respectively. Surgery is not usually a viable treatment option except in those with very small tumors and no evidence of metastasis to the mediastinum or distant sites.

Limited-stage patients should be treated with four cycles of cisplatin (Platinol)¹ and etoposide (VePesid) with concurrent involved-field radiotherapy. With this approach, approximately 20% are disease free at 3 years. For extensive-stage patients, the disease is incurable; however, median survival is in the 8- to 12-month range and chemotherapy can result in dramatic improvements in patients' performance status, and this represents one of the few cases in which chemotherapy should be offered even to very moribund patients. The standard of care is carboplatin (Paraplatin)¹ and etoposide (VePesid). Despite numerous trials of multiagent chemotherapy and novel targeted agents, none have surpassed the results of the standard of care. The combination of carboplatin (Paraplatin) and irinotecan (Camptosar)¹ has been shown to be superior to the standard of care in a large randomized phase III trial in Japan; however, an American trial showed no benefit to this approach. At this time, cisplatin (Platinol) and irinotecan (Camptosar) could be considered an acceptable alternative to the standard of care. The toxicity profile is similar, with the irinotecan (Camptosar) regimen causing significant gastrointestinal toxicity and the etoposide (VePesid) having mainly hematologic toxicity. For patients failing first-line therapy, topotecan (Hycamtin) has been shown to improve quality of life and overall survival when used as second-line therapy. There are no other second- or third-line agents with proven survival or palliative benefit, and given the dismal prognosis, patients should be considered for a clinical trial whenever possible.

For both limited- and extensive-stage patients, the risk of relapse in the brain is a significant cause of morbidity and mortality. This has prompted the use of prophylactic cranial irradiation (PCI). This approach has consistently proven to be of benefit for patients having a good response to primary therapy. The benefit has been seen to not only prevent symptomatic brain metastasis but also improve overall survival. Cognitive dysfunction after PCI can be seen particularly when given concurrently with chemotherapy. Therefore wherever possible, PCI should be given only after chemotherapy is completed.

SARCOIDOSIS

Method of

Marc A. Judson, MD

CURRENT DIAGNOSIS

- The diagnosis of sarcoidosis is one of exclusion.
- Tissue biopsy, confirming noncaseating granulomatous inflammation, is required in most cases.
- Efforts should be made to search for the least invasive biopsy site.

CURRENT THERAPY

- Many cases of sarcoidosis do not require treatment.
- All patients should be evaluated for possible pulmonary, eye, and cardiac disease.
- When therapy is indicated, corticosteroids are most commonly used.
- Topical corticosteroids should be given whenever possible.

Sarcoidosis is a multisystem granulomatous disease of unknown cause. The lung is most commonly affected, but any organ may be involved. The natural course of sarcoidosis is variable, ranging from an asymptomatic state to a progressive disease causing significant organ dysfunction that may be life-threatening. This variability in organ involvement and disease presentation often makes the diagnosis of sarcoidosis problematic.

Epidemiology

Sarcoidosis occurs worldwide and affects all races and ages. Although the disease has been thought to be most common between ages 20 and 40, analyses from large databases have revealed that the incidence and prevalence of the disease is greatest between ages 45 and 65. There is an earlier onset of disease in blacks and males. A large analysis from an American national health care database found an incidence of 17.8 per 100,000 in African Americans and 8.1 per 100,000 in American whites, a prevalence of 141 per 100,000 in African Americans and 50 per 100,000 in American whites. Incidence and prevalence rates were lower in American Hispanics than whites and lower still in

American Asians. The highest prevalence of sarcoidosis is found in whites in Scandinavia and in persons of African descent in the United States. The relative risk for having sarcoidosis increases significantly if a family member has it as well. In the United States, nearly 20% of African Americans with sarcoidosis have an affected first-degree relative, compared with 5% in whites.

The clinical presentation and severity of sarcoidosis vary among racial and ethnic groups. The disease tends to be more severe in African Americans, whereas whites are more likely to be asymptomatic at presentation. Extrathoracic manifestations are more common in certain populations, such as ocular and cardiac sarcoidosis in Japanese populations, chronic uveitis in African Americans, and erythema nodosum in Europeans. There is increasing evidence that genetic polymorphisms affect the risks and manifestations of the disease. This is consistent with the current theory that sarcoidosis does not have a single cause but is the result of an abnormal host (granulomatous) response to one of many potential antigens in a genetically susceptible person.

Immunopathogenesis

The exact immunopathogenesis of sarcoidosis is unknown, but it is thought to be similar to that of other granulomatous diseases. That is, antigen-presenting cells (APCs), usually either macrophages or dendritic cells, process and present an antigen via a human leukocyte antigen (HLA) class II molecule to T lymphocytes and their receptors. These T lymphocytes are usually of the CD4 T-helper 1 (T_H1) class. The antigen involved in this reaction is unknown, and there may be many antigens that are each associated with a specific HLA class II molecule and T-cell receptor. This could explain the inability to determine one specific cause of sarcoidosis and the varied phenotypic expressions of the disease.

The interaction of APCs and T lymphocytes activates the APCs to produce tumor necrosis factor α (TNF- α) and other cytokines. A proliferation of CD4 T_H1 lymphocytes also ensues, which results in the secretion of interferon- γ (IFN- γ), interleukin (IL)-2, IL-12, and other cytokines. These cytokines activate and recruit monocytes and macrophages and transform them into giant cells, which are important building blocks of the granuloma. Recent evidence suggests that an additional factor leading to this series of immunologic events is persistence of antigen, possibly related to production of soluble AA amyloid fibrils, that prevents antigen degradation.

The typical sarcoidosis lesion is a noncaseating (non-necrotic) granuloma. The sarcoid granuloma consists of a compact core of macrophage-derived epithelioid and multinucleated giant cells surrounded by a perimeter of monocytes, lymphocytes, and fibroblasts. Granulomas can resolve spontaneously or with therapy; however, they can also persist and lead to persistent hyalinization and fibrosis. The development of such fibrosis can cause permanent organ damage and in large part determines the prognosis.

Clinical Features and Clinical Course

Pulmonary Sarcoidosis

Between 30% and 60% of patients with pulmonary sarcoidosis are asymptomatic, and the disease is detected incidentally on chest x-ray. Some patients present with nonspecific pulmonary symptoms, such as dyspnea, cough, wheezing, and chest pain. Respiratory failure from sarcoidosis is extremely rare at presentation. Unlike in many other interstitial lung diseases, crackles are rarely heard on chest auscultation. Abnormalities on the chest radiograph occur in more than 90% of patients with pulmonary sarcoidosis. Bilateral hilar adenopathy occurs in 50% to 85% at disease presentation, and 25% to 50% have parenchymal infiltrates. Sarcoid granulomas have a predilection for the bronchovascular bundles, subpleural locations, intralobular septa, and the airways.

A radiographic staging system was developed several decades ago (Table 1). Groups of patients with higher radiographic stages have more-severe pulmonary dysfunction, lower remission rates, and greater mortality. However, there is significant overlap among these groups, and predictions concerning individual patients based on stage are highly inaccurate. (See Fig. 1.)

Adapted from Judson MA, Baughman RP: Sarcoidosis. In Baughman RP, du Bois RM, Lynch JP, Wells AU (eds): *Diffuse Lung Disease: A Practical Approach*. London, Arnold, 2004, p 109–29.

Advanced pulmonary stage IV (fibrocystic) sarcoidosis displays destruction of the lung architecture, with upward traction of the hila, lung distortion, upper-lobe volume loss, fibrocystic disease, honeycombed cysts, and decreased lung volumes. Aspergillomas can develop in these large cystic lesions and may be associated with life-threatening hemoptysis. Bronchiectasis from airway distortion also can occur and is an additional potential cause of hemoptysis.

The majority of patients with pulmonary sarcoidosis have a vital capacity of greater than 70% of predicted at diagnosis. Pulmonary function and the chest radiographic findings are often discordant. In pulmonary sarcoidosis patients with a normal lung parenchyma (stage I), the vital capacity, diffusing capacity, partial pressure of arterial oxygen (P_{aO_2}) at rest, P_{aO_2} with exercise, and lung compliance are abnormal in 20% to 40% of cases. Patients with abnormal lung parenchyma have abnormal pulmonary function tests 50% to 70% of the time. Patients with stage IV fibrocystic sarcoidosis tend to have the most severe pulmonary dysfunction.

Sarcoidosis is an interstitial lung disease with a restrictive ventilatory defect often found on spirometry. It is underappreciated, however, that endobronchial involvement is common in sarcoidosis, and therefore airflow obstruction may be the major abnormality found on pulmonary function testing. Wheezing may be the prominent presenting symptom of sarcoidosis, and many cases of sarcoidosis are misdiagnosed as asthma. Airflow obstruction is also common in chronic pulmonary sarcoidosis, where it is caused by airway distortion from fibrosis. The cause of dyspnea in pulmonary sarcoidosis is multifactorial. It may be the result of abnormalities of gas exchange or lung mechanics, weakness of the respiratory muscles, obesity from corticosteroid therapy, pulmonary hypertension, or sarcoidosis involvement of the heart.

Only 3% to 5% of patients die of sarcoidosis. In the United States, 75% of these deaths are the result of pulmonary involvement. Death from pulmonary involvement is rarely acute but normally is an insidious process that develops over 5 to 25 years with

the development of progressive pulmonary fibrosis. Several studies have suggested that pulmonary hypertension is a major risk factor for death from pulmonary sarcoidosis. Patients with aspergillomas are also at risk for death from episodes of life-threatening hemoptysis. Both pulmonary hypertension and aspergillosis are most commonly found in the sarcoidosis patients with stage IV fibrocystic disease. Other organs that result in fatalities from sarcoidosis are the heart and the central nervous system. In Japan, death from sarcoidosis is more commonly caused by cardiac than pulmonary involvement.

Extrapulmonary Sarcoidosis

The extrapulmonary manifestations of sarcoidosis can predominate in many patients. Extrapulmonary disease can affect the prognosis and treatment options for sarcoidosis.

The eyes and skin are the most common extrapulmonary organs involved with sarcoidosis. Ocular manifestations occur in 25% to 50% of patients; anterior uveitis is the most common manifestation. Symptoms of anterior uveitis include red eyes, painful eyes, and photophobia. However, in one-third of patients with anterior uveitis from sarcoidosis have no ocular symptoms. In addition, an intermediate or posterior uveitis can cause vision problems or can be asymptomatic. For these reasons, all patients with sarcoidosis should undergo an eye examination by an ophthalmologist. Other ocular manifestations of sarcoidosis include conjunctivitis, keratoconjunctivitis sicca (dry eyes), scleritis, and optic neuritis.

Skin lesions in sarcoidosis can be classified into two categories: specific lesions that demonstrate noncaseating granulomas on biopsy and nonspecific lesions that do not. The specific skin lesions are often papular and have a predilection for areas of previous scars and tattoos. Lupus pernio is a type of specific skin lesion causing disfiguring lesions on the face, often with erythema and significant induration. These lesions have a predilection for the nose, cheeks, medial and lateral sides of the eyes, and lateral sides of the mouth. Lupus pernio lesions are relatively recalcitrant to therapy and often respond only partially to corticosteroids. The most common nonspecific skin lesion is erythema nodosum, which is often seen with an acute sarcoidosis presentation of fever, arthritis (especially in the ankles), pulmonary symptoms, and bilateral hilar adenopathy on chest radiograph. This syndrome is known as *Löfgren's syndrome* and tends to have a good long-term prognosis.

Cardiac and neurologic sarcoidosis can be life threatening and are therefore important to recognize. Cardiac involvement is detected clinically in 5% of sarcoidosis patients during life but in 25% at autopsy. Cardiac sarcoidosis can cause left ventricular dysfunction and cardiac arrhythmias, possibly resulting in sudden death. All patients with sarcoidosis should be screened for cardiac sarcoidosis. Such screenings should include eliciting symptoms of left ventricular dysfunction (e.g., orthopnea, peripheral edema)

Figure 1 Skin lesions of sarcoidosis. A, Sarcoid lesions may occur at any site, and they may take nodular, papular, or plaque forms. Biopsy is often necessary for diagnosis. B, *Lupus pernio* is the term used to describe a dusky-purple infiltration of the skin of the nose, cheeks, or ears in chronic sarcoidosis. (From Forbes CD, Jackson WF: *Color Atlas and Text of Clinical Medicine*, 3rd ed. London, Mosby, 2003, with permission.)

and cardiac arrhythmia (e.g., palpitations, sensation of skipped heartbeats, syncope). Echocardiography and Holter monitoring have been recommended by some as appropriate additional screening tests. The diagnosis of cardiac sarcoidosis is problematic, because the disease is patchy and diagnosed less than 25% of the time by endomyocardial biopsy because of sampling error. Often the diagnosis is made noninvasively, if a typical clinical presentation is coupled with detection of abnormalities on echocardiography, gallium scanning, thallium scanning, cardiac magnetic resonance imaging (MRI), or positron emission tomography (PET).

Clinically apparent neurosarcoidosis occurs in less than 10% of sarcoidosis patients. Palsy of the seventh cranial nerve is the most common manifestation of neurosarcoidosis, and it often predates the diagnosis of the disease. Sarcoidosis can affect any part of the peripheral nervous system and central nervous system and can cause a cranial nerve palsy, mononeuropathy or polyneuropathy, aseptic meningitis, seizures, mass lesions in the brain and spinal cord, and encephalopathy.

Sarcoidosis causes clinically apparent peripheral lymphadenopathy in more than 10% of patients. The spleen may be involved in up to 50% of patients, but it is usually asymptomatic and rarely causes hypersplenism.

Bone involvement is occasional, usually occurring as small cysts or cortical defects found in the small bones of the hands and feet. An acute sarcoid arthritis often is present at disease onset and has a good prognosis. This is commonly found in the ankles of patients who present with Löfgren's syndrome. Chronic sarcoid arthritis is rare. It is usually a nondestructive arthropathy of the shoulders, wrists, knees, ankles, and small joints of the hands and feet.

Sarcoidosis of the sinuses is underappreciated. It can occur in the nasopharynx, hypopharynx, larynx, or any of the sinuses and is known as *sarcoidosis of the upper respiratory tract*. Sarcoidosis of the upper respiratory tract is often relatively recalcitrant to therapy.

Histologic evidence of hepatic sarcoidosis is present in 50% to 80% of sarcoidosis patients, although most of these patients are asymptomatic and have normal liver function tests. Hepatomegaly, abdominal pain, and pruritus are the most common symptoms associated with hepatic sarcoidosis but are present only in 15% to 25% of patients with hepatic involvement. Elevation of the serum alkaline phosphatase is the most common liver function test abnormality.

Hypercalcemia or hypercalciuria leading to nephrolithiasis and renal dysfunction can occur with sarcoidosis. These phenomena are the result of the enzyme 1α -hydroxylase in activated macrophages that convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active form of the vitamin. This results in increased gut absorption and increased renal excretion of calcium that can cause nephrolithiasis.

Sarcoidosis rarely involves the thyroid, kidney, breast, renal parenchyma, GU tract, and GI tract.

Patients can have constitutional symptoms such as fever, night sweats, weight loss, malaise, and fatigue at presentation. These symptoms occasionally are associated with hepatic sarcoid involvement but may be a sign of the systemic nature of the disease, presumably from cytokine release, rather than specific organ involvement. A small fiber neuropathy may occur with sarcoidosis and cause pain or autonomic dysfunction. Patients who present with Löfgren's syndrome or with asymptomatic bilateral hilar adenopathy on chest radiograph have a good prognosis. African Americans tend to have a worse prognosis than whites, with lower forced vital capacity and more new organ involvement within 2 years of diagnosis. **Box 1** lists risk factors associated with a poor prognosis.

Diagnosis and Initial Workup

The diagnosis of sarcoidosis requires a compatible clinical picture, histologic demonstration of noncaseating granulomas, and exclusion of other diseases capable of producing a similar histologic and clinical picture. It is prudent to bear a healthy degree of skepticism in the diagnosis and evaluate the patient closely for additional clues

BOX 1

Factors Associated With a Poor Prognosis in Sarcoidosis

African-American race
Extrathoracic disease
Stage II to III versus stage I on chest x-ray
Age >40 years
Splenic involvement
Lupus pernio
Disease duration >2 years
Forced vital capacity <1.5 L
Stage IV chest x-ray or aspergilloma
Pulmonary hypertension

Data from Judson MA, Baughman RP: Sarcoidosis. In Baughman RP, du Bois RM, Lynch JP, Wells AU (eds): *Diffuse Lung Disease: A Practical Approach*. London, Arnold, 2004, p 109–29.

supporting an alternative diagnosis. Mycobacterial and fungal diseases must always be considered as alternative causes of granulomatous inflammation. Therefore stains and cultures of tissue specimens for mycobacteria and fungi always should be obtained when the diagnosis of sarcoidosis is considered. Hypersensitivity pneumonitis, a granulomatous lung disease from inhalation of bioaerosols, is another disease that may mimic sarcoidosis. Bioaerosols from hot tubs and birds are the most common causes of hypersensitivity pneumonitis, and clinicians should specifically inquire about these two exposures in individuals who are being evaluated for sarcoidosis. Sarcoidosis is a systemic disease, so signs or symptoms of extrathoracic disease such as uveitis, skin lesions, or an elevated serum alkaline phosphatase concentration should be sought. Because of the varied clinical presentation of sarcoidosis, there is no single diagnostic algorithm.

It is prudent to select a biopsy site associated with less morbidity, such as the skin if a lesion is present. Transbronchial lung biopsy has a diagnostic yield of 40% to more than 90% in pulmonary sarcoidosis. Endobronchial biopsy has a 40% to 60% sensitivity and adds to the yield of transbronchial biopsy. Although granulomas are almost universally obtained via mediastinoscopy when mediastinal lymphadenopathy is present, transthoracic needle aspiration under ultrasound guidance (EBUS-TBNA) of mediastinal lymph nodes via bronchoscopy has a high yield for the diagnosis of sarcoidosis and has supplanted mediastinoscopy at many centers.

Bronchoalveolar lavage (BAL) with examination of lymphocyte populations has been used in the evaluation of possible pulmonary sarcoidosis. In sarcoidosis, there is an increased number of BAL lymphocytes, and these are predominantly CD4⁺. It has been proposed that an increase in BAL lymphocytes and a BAL CD4/CD8 ratio greater than 3.5 makes the diagnosis of sarcoidosis highly likely.

Although serum angiotensin-converting enzyme (ACE) often is elevated in active sarcoidosis, the specificity and sensitivity of this test are inadequate for it to be used diagnostically. Serum ACE may be used as supportive evidence for the diagnosis, and it also may be used in some instances to follow disease activity.

Gallium-67 (⁶⁷Ga) scanning is cumbersome because it takes several days to complete and is infrequently used as a diagnostic test. However, bilateral hilar uptake and right paratracheal uptake (lambda sign) coupled with lacrimal and parotid uptake (panda sign) with ⁶⁷Ga strongly suggest a diagnosis of sarcoidosis.

Gadolinium enhancement on MRI and fluorodeoxyglucose PET scanning may replace ⁶⁷Ga scanning for detecting sarcoidosis activity, because evidence suggests that they may be more sensitive in detecting sarcoidosis activity and they can be performed in one sitting.

Ideally, the diagnosis of sarcoidosis requires demonstration of noncaseating granulomas in at least one organ. However, certain clinical presentations are so specific for the diagnosis of sarcoidosis that the diagnosis may be accepted without tissue biopsy. Extreme

caution must be used in these situations to ensure that there is no clinical information that would suggest an alternative diagnosis that should prompt a tissue biopsy. Clinical or laboratory findings that strongly support the diagnosis of sarcoidosis without a tissue biopsy are listed in [Box 2](#).

Treatment

Therapy is not mandated for sarcoidosis because the disease can remit spontaneously. Therapy is indicated for potentially dangerous disease that includes neurosarcoidosis, cardiac sarcoidosis, hypercalcemia that does not respond to dietary measures, ocular sarcoidosis that does not respond to topical (eyedrop) therapy, and other life- or organ-threatening disease. Therapy also should be considered when the disease is progressive. Relative indications for therapy include arthritis that fails to respond to nonsteroidal antiinflammatory drugs (NSAIDs); a systemic inflammatory response syndrome of fever, night sweats, fatigue, and arthralgias; and symptomatic hepatic disease. In general, treatment is discouraged for asymptomatic elevations of serum liver function tests, specific levels of ACE, or asymptomatic uptake on ⁶⁷Ga scan (with the possible exceptions of the heart or brain).

The decision to treat sarcoidosis can be problematic, because the disease has a variable prognosis that must be weighed against the potential side effects of therapy. It is often most prudent to monitor patients without therapy if they are asymptomatic or have only mild organ dysfunction. For pulmonary sarcoidosis, asymptomatic patients and those with mild disease that might spontaneously remit usually are not treated. For patients with clinical findings that predict spontaneous remission (e.g., erythema nodosum), the benefits of treatment often are offset by the toxicity of therapy. Often these patients can be managed with palliative therapy such as NSAIDs for arthralgias and fever and bronchodilators and inhaled corticosteroids for wheezing and cough.

It is recommended that patients with mild to moderate pulmonary sarcoidosis be observed for 2 to 6 months, if possible. Patients who improve will have avoided the toxicity of corticosteroids, and patients who deteriorate over this period should be considered for treatment. Patients with pulmonary dysfunction who neither improve nor deteriorate during the observation period may be given a corticosteroid trial, or they may be observed further. Patients with severe pulmonary dysfunction or pulmonary symptoms causing significant impairment should be treated.

Corticosteroids often are used to treat sarcoidosis, but the dose, duration of therapy, and method by which one can assess effectiveness have not been standardized. Topical corticosteroid therapy should be used whenever possible in an attempt to minimize systemic complications. This includes corticosteroid eye drops for anterior sarcoid uveitis and corticosteroid creams and injections for localized skin lesions. Pulmonary sarcoidosis usually is treated initially with 20 to 40 mg/day of prednisone or its equivalent. Higher doses may be required for neurosarcoidosis and cardiac sarcoidosis. The patient usually is evaluated within 2 to 12 weeks for a response. Patients failing to respond to therapy within 3 months are unlikely to respond to a more protracted course of therapy or a higher dose. Among the responders, the corticosteroid dose is tapered to 5 to 10 mg/day of a prednisone equivalent or an every-other-day regimen. Treatment is usually continued for at least 6 months.

The relapse rate after corticosteroid therapy is withdrawn may be as high as 70%, and therefore patients need to be followed closely as the corticosteroid dose is tapered and discontinued. In some patients, there may be recurrent relapses requiring long-term low-dose therapy. On occasion, the chronic prednisone dose needed to prevent relapse is less than 5 mg/day. Patients who relapse after corticosteroids have been withdrawn should be re-treated with corticosteroids. Alternative agents, such as corticosteroid-sparing agents, to control the disease in a patient on a chronic low dose of prednisone should be considered. On occasion, alternative agents may completely replace corticosteroid therapy. In general, corticosteroid-sparing agents should not be considered unless the patient requires more than 7.5 mg/day of prednisone to control the disease.

Methotrexate (Rheumatrex)¹ and hydroxychloroquine (Plaque-nil)¹ are the most-studied alternative sarcoidosis medications. They are usually used as corticosteroid-sparing agents but at times can be used as replacement therapy. Methotrexate is most useful for pulmonary, skin, joint, and eye sarcoidosis. Hydroxychloroquine is often used for sarcoidosis of the skin, joints, and nerves and for hypercalcemia from sarcoidosis. Azathioprine (Imuran)¹ may be useful for sarcoid uveitis, but usually it is added to corticosteroid plus methotrexate in this instance. Minocycline (Minocin)¹ and doxycycline (Vibramycin)¹ may be useful for skin sarcoidosis. Cyclophosphamide (Cytoxan)¹ is used occasionally and seems to have a potential role in neurosarcoidosis. Leflunomide (Arava)¹ has also been shown to be useful in the treatment of pulmonary and extrapulmonary sarcoidosis. Recently anti-TNF- α therapies have shown promise in the treatment of sarcoidosis. Such agents include pentoxifylline (Trental)¹, thalidomide (Thalomid)¹, and monoclonal antibodies against TNF- α , such as infliximab (Remicade)¹ and adalimumab (Humira)¹.

¹Not FDA approved for this indication.

TUBERCULOSIS AND OTHER MYCOBACTERIAL DISEASES*Method of*

Jotam Pasipanodya, MD; Ronald Hall, II, PharmD, MSCS; and Tawanda Gumbo, MD

Mycobacterial diseases are some of the oldest documented infectious diseases in humans, and they still cause significant morbidity and mortality. *Mycobacterium tuberculosis* complex, *Mycobacterium*

avium complex (MAC), and *Mycobacterium leprae* are slow-growing, acid-fast bacilli that belong to the family Mycobacteriaceae of the order Actinomycetales. This chapter deals with management of diseases caused by *M. tuberculosis*, MAC, and *M. leprae*. A summary of diseases caused by other, less common mycobacteria is presented in Table 1.

Recent evidence suggests that the mycobacteria causing tuberculosis (TB) might have co-evolved with humans. Clues attesting to the success of mycobacteria as human pathogens include the prolonged period of latency and the ability to cause extensive disease in only a narrow host range. DNA evidence suggests that the *M. tuberculosis* strains causing the current waves of TB epidemics most likely evolved from a common ancestor. *Mycobacterium canettii* and the other strains that form the *M. tuberculosis* complex (i.e., *Mycobacterium africanum*, *Mycobacterium microti*, and *Mycobacterium bovis* strains) also evolved from the ancestral strain through successive loss of DNA. This is contrary to the belief that the *M. tuberculosis* complex evolved from *M. bovis*.

Tuberculosis

Epidemiology

TB remains a global pandemic, with 9.3 million new cases and 1.4 million deaths reported worldwide in 2007. Approximately 1 of every 7 patients who has TB is co-infected with the human immunodeficiency virus (HIV). Whereas global TB incidence trends are stabilizing after reaching a peak in 2004, rates in countries with a low TB burden have been declining gradually. An explanation could be the similar plateau and declines in HIV prevalence observed in the year 2000. On the other hand, this could merely reflect the natural ebbs and increases inherent to epidemic cycles.

Global estimates show that one third of humankind has been infected with *M. tuberculosis*, the TB disease-causing bacillus. About 80% of global TB is accounted for by the 22 high-burden countries. The top five countries in rank order are India, China, Indonesia, Nigeria, and South Africa. TB program priorities and approaches to combating the disease differ among and within countries. These differences are based on the availability of resources and the prevalence of HIV within communities. For example, program goals in areas of low TB incidence, such as the United States, are aimed at TB elimination. Therefore, in the United States, treatment of latent TB is a priority. Reducing TB transmission through increased diagnosis of patients with active TB disease is the primary goal in high-incidence areas.

In 2007, a total of 13,299 TB cases (case rate, 4.4 per 100,000 population) were reported to the Centers for Disease Control and Prevention (CDC) from the 50 U.S. states and the District of Columbia. Foreign-born persons accounted for 58% of the national case total. This means that a high degree of suspicion is needed for the diagnosis of TB when recent immigrants are seen in the clinic. The top five countries of origin for foreign-born persons with TB in the United States were Mexico, the Philippines, India, Vietnam, and China. Since the 1992 TB resurgence peak, the number of cases reported annually in the United States has decreased by 50%.

Natural History

Susceptibility to *M. tuberculosis* infection and the subsequent progression of that infection to active TB disease is influenced by the complex interaction of host, pathogen, and environmental factors. Between 20% and 30% of people exposed to a person with active TB become infected. Animal models, twin studies, segregation

TABLE 1 Species of Mycobacteria

MICROBE		RESERVOIR	CLINICAL MANIFESTATION
Always Pathogenic in Humans			
<i>M. tuberculosis</i>	Humans		Pulmonary and disseminated tuberculosis
<i>M. bovis</i>	Cattle, humans		TB-like disease
<i>M. africanum</i>	Humans, monkeys		Rarely, TB-like pulmonary disease
<i>M. leprae</i>	Humans		Leprosy
<i>M. canettii</i>	Humans, possibly others		Rarely, TB-like pulmonary disease
Potentially Pathogenic in Humans			
<i>M. avium</i> complex	Soil, water, birds, swine, cattle, environment		Disseminated and pulmonary TB-like disease
<i>M. microti</i>	Rodents, llamas, cats, ferrets, and possibly humans		Rarely, TB-like pulmonary disease
<i>M. kansasii</i>	Water, cattle		TB-like disease
Uncommon or Rarely Pathogenic in Humans			
<i>M. flavescens</i>	Humans, environment		TB-like disease
<i>M. genavense</i>	Humans, birds		Blood-borne disease with AIDS
<i>M. haemophilum</i>	Unknown		Skin, joint, bone, and pulmonary infections in immunocompromised individuals; lymphadenitis in children
<i>M. malmoense</i>	Environment, possibly others		TB-like pulmonary disease in adults; lymphadenitis in children
<i>M. marinum</i>	Fish, water		Skin infections
<i>M. scrofulaceum</i>	Soil, water		Cervical lymphadenitis
<i>M. simiae</i>	Monkeys, water		TB-like pulmonary disease and disseminated disease with AIDS
<i>M. szulgai</i>	Water, environment		TB-like pulmonary disease
<i>M. ulcerans</i>	Humans, environment		Skin infections (Buruli ulcer)
<i>M. xenopi</i>	Water, birds		TB-like pulmonary disease

studies, and candidate gene analysis studies provide insight into the role of host genetic factors in susceptibility to TB.

The immune system contains the infection in more than 90% to 95% of persons infected. Protective immunity mediated by subsets of T lymphocytes produces soluble lymphokines that enable macrophages to kill intracellular bacilli. The bacilli are often not completely eradicated and remain dormant in macrophages or other cells, with the potential to reactivate to active disease when the immune system wanes. This is termed latent TB infection (LTBI). The lifetime risk of reactivation to active TB disease is 5% to 10%. This risk of reactivation increases with several factors, including development of the acquired immunodeficiency syndrome (AIDS), renal failure, immunomodulatory therapy, and poorly controlled diabetes mellitus.

In a small subgroup of patients, *M. tuberculosis* infection is not brought under control during primary infection and quickly progresses to disseminated disease. TB that follows such a course is called progressive primary TB. Primary TB is associated with a higher mortality rate, and death typically occurs within 2 years after infection. The risk of developing TB disease after being infected is higher in males from infancy to 6 years of age. Males older than 45 years of age are also at an increased risk compared to females of the same age.

Diagnosis of Active Tuberculosis

In immunocompetent persons, pulmonary involvement is the most common presentation, followed by isolated extrapulmonary disease. Involvement of only extrapulmonary sites is rare, and most immunocompromised patients present with both pulmonary and extrapulmonary involvement. The presenting signs and symptoms of active TB disease are site specific. However, constitutional symptoms such as fever, night sweats, and fatigue are common and gradually evolve over many weeks. Patients should be specifically asked about constitutional symptoms, because these symptoms raise the index of suspicion. Atypical presentations are common in patients who are immunosuppressed and can delay diagnosis.

Definitive diagnosis is made on the basis of a positive culture. Therefore, all patients with suspected TB must have the appropriate specimens collected for microscopic and, if appropriate, histologic examination. Mycobacterial culture and sensitivity testing should also be performed, if available. Acid-fast bacillus (AFB) staining and microscopy is limited by poor sensitivity (45%–80% with culture-confirmed TB cases) and poor positive predictive value (50%–80%) for TB in settings where nontuberculous mycobacteria are commonly isolated. TB culture results are available only after 2 to 6 weeks. Nucleic acid amplification (NAA) testing can also be used to confirm a TB diagnosis in 24 to 48 hours, even when the specimen sample is limited. NAA tests can detect the presence of *M. tuberculosis* in 50% to 80% of AFB-negative and culture-positive specimens. The CDC now recommends that evaluation of at least the first diagnostic specimen include NAA testing.

Serial radiologic images can be used to exclude active TB and assess clinical improvement.

Principles of Treatment

The goal of anti-TB therapy is cure. A secondary objective is minimizing the transmission of *M. tuberculosis* to others by curing the patient. Treatment outcomes are best when patient-centered treatments and care are offered, regardless of whether the treatment facility is private or public. Patient management and supervision plans should be tailored to the patient's clinical and social circumstances. Directly observed therapy (DOT) is recommended by regulatory bodies to help ensure adherence to treatment and is regarded as central to current case management. However, the efficacy of DOT compared with self-administration has been questioned in recent studies. There are three types of anti-TB therapy: prophylaxis, definitive TB therapy for drug-susceptible infection, and therapy for drug-resistant TB.

Chemoprophylaxis

The confusing terms preventive therapy and chemoprophylaxis are sometimes used to describe treatment of LTBI. Preventive therapy,

in this context, does not actually prevent infection; rather, it prevents development of active TB in those already infected. Therefore, the better descriptive term, treatment of LTBI, is preferred. Treatment of minimal or latent TB infection prevents subsequent evolution to active disease. A series of double-blind, placebo-controlled clinical trials done in the 1950s and 1960s provided evidence demonstrating the effectiveness of treatment of LTBI. Priority is usually given to those patients with the highest risk for reactivation.

Treatment of LTBI, particularly when it is targeted toward persons with higher risks of reactivation, is one of the major strategies for elimination of TB in the United States. Targets include people who have been recently infected and those who were remotely infected but have concurrent disease that puts them at higher risk for developing reactivation disease. There are more than 11 million people with LTBI in the United States, each with a 5% to 10% lifetime risk of developing TB disease.

The Mantoux method of tuberculin skin testing is commonly used to diagnose LTBI as well as active disease. Use of tuberculin skin testing is hampered by low sensitivity in immunocompromised patients, low specificity in persons who have received the bacille Calmette-Guérin (BCG) vaccine, and the requirement to

BOX 1 Interpretation of a Tuberculin Skin Test

Reaction ≥ 5 mm of Induration

HIV-positive persons
Recent contacts of TB case patients
Fibrotic changes on chest radiography consistent with prior TB
Organ transplant recipients and other immunosuppressed patients (receiving the equivalent of ≥ 15 mg/d of prednisone for 1 mo or longer)*

Reaction ≥ 10 mm of Induration

Recent immigrants (i.e., ≤ 5 y) from high-prevalence countries
Injection drug users
Residents and employees† of the following high-risk congregate settings:

- Prisons and jails
- Nursing homes and other long-term facilities for the elderly
- Hospitals and other health care facilities
- Residential facilities for patients with AIDS
- Homeless shelters
- Mycobacteriology laboratory personnel

Persons with the following clinical conditions that place them at high risk:

- Silicosis
- Diabetes mellitus
- Chronic renal failure
- Certain hematologic disorders (e.g., leukemias, lymphomas)
- Other specific malignancies (e.g., carcinoma of the head, neck, or lung)
- Weight loss ($>10\%$ of ideal body weight)
- Gastrectomy and jejunioileal bypass

Children <4 yr of age; infants, children, and adolescents exposed to adults at high risk

Reaction >15 mm of Induration

Persons with no risk factors for TB

Abbreviations: AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency syndrome; TB = tuberculosis.

Adapted from Centers for Disease Control and Prevention: Screening for tuberculosis and tuberculosis infection in high-risk populations: Recommendations of the Advisory Council for the Elimination of Tuberculosis. *Morb Mortal Wkly Rep MMWR* 1995;44 (No. RR-11):19–34.

* Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

† For persons who are otherwise at low risk and are tested at the start of employment, a reaction of >15 mm induration is considered positive.

TABLE 2 CDC-Recommended Treatment for Latent Tuberculosis Infection

DRUG	INTERVAL*	ORAL DOSE (mg/kg)		MONITORING
		CHILDREN	ADULTS	
Isoniazid (INH, Nydrazid)	Daily Twice weekly	10–20 ³ 20–40	5 15	Monthly, LFTs [†] at baseline, repeat in selected patients if initial results are abnormal; hepatitis risk increases with age and alcohol consumption; pyridoxine [‡] 10–25 mg/d may prevent peripheral neuropathy and CNS effects
Rifampin (Rifadin)	Daily Twice weekly	10–20 —	10 10	Weeks 2, 4, and 8 with pyrazinamide; contraindicated in patients receiving antiretroviral drugs; baseline LFTs [†] and CBC and platelets
Rifabutin (Mycobutin) ¹	Daily Twice weekly	— —	5 5	Weeks 2, 4, and 8; baseline LFTs [†] and CBC and platelets; use adjusted daily doses of rifabutin and monitor for decreased antiretroviral activity and rifabutin toxicity if PIs or NNRTIs are taken concurrently; contraindicated with saquinavir (Invirase) or delavirdine (Rescriptor)
Pyrazinamide [‡]	Daily Twice weekly	— —	15–20 50	Weeks 2, 4, and 8; LFTs [†] at baseline; avoid in first trimester of pregnancy
Rifapentine (Priftin) [§]	Weekly	—	10–14 kg: 300 mg 14.1–25 kg: 450 mg 25.1–32.0 kg: 600 mg 32.1–49.9 kg: 750 mg ≥50.0 kg: 900 mg	Monthly, LFTs [†] at baseline, repeat in selected patients if initial results are abnormal; hepatitis risk increases with age and alcohol consumption

Abbreviations: CBC = complete blood count; CDC = Centers for Disease Control and Prevention; CNS = central nervous system; LFT = liver function test; NNRTI = non-nucleoside reverse transcriptase inhibitor; PI = protease inhibitor.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

*All intermittent dosing should be given by directly observed therapy (DOT).

[†]LFTs include aspartate aminotransferase (AST), alanine aminotransferase (ALT), and serum albumin.

[‡]Used with either rifampin or rifabutin in combination therapy for 2–4 mo.

[§]Rifapentine (RPT) is formulated as 150-mg tablets in blister packs that should be kept sealed until usage, as shown above. Combined with INH.

return to a trained person to have the test read after 48 to 72 hours. Results are interpreted based on the patient scenario (Box 1).

Recently, various blood-testing methods that are based on detection of the interferon- γ (IFN- γ) released by T lymphocytes in response to *M. tuberculosis*-specific antigens have become available as an alternative to skin testing. These tests may be more specific than the tuberculin skin test in BCG-vaccinated and immunocompromised populations. However, IFN- γ release assays do not differentiate LTBI from active TB disease. Currently available IFN- γ release assays are QuantiFERON, QuantiFERON-Gold, and ELISPOT. The CDC recommends these tests for LTBI screening of health care workers, recent immigrants, injection drug users, prison and jail inmates and workers, and contacts of TB cases within schools, workplaces, and the military. Prohibitive costs limit the use of these assays in resource-limited places.

Table 2 summarizes the regimens recently recommended by the American Thoracic Society (ATS), CDC, and Infectious Diseases Society of America (IDSA) for treatment of LTBI. Because of high rates of hospitalization and death from liver injury, the ATS and the CDC no longer recommend the 2-month regimen of daily or twice-weekly rifampin (Rifadin) plus pyrazinamide for LTBI. Directly observed 12-dose once-weekly regimen of isoniazid (INH; Nydrazid) and rifapentine (RPT; Priftin) is recommended as an option equal to the standard INH 9-month daily regimen for treating LTBI in otherwise healthy people 12 years of age and older who were recently in contact with infectious TB, or who had tuberculin skin test or blood test for TB infection conversions, or those with radiologic findings consistent with healed pulmonary TB. In recent large clinical trials of mostly adults without HIV, this regimen was associated with fewer serious adverse events, higher completion rates, and equal efficacy, as compared with isoniazid for 9 months. Rifampin or rifabutin (Mycobutin)¹

may be used to treat LTBI in HIV-infected persons exposed to TB that is resistant to isoniazid (INH; Nydrazid) and susceptible to rifampin, with dose adjustments and diligence taken to prevent cytochrome P-450–derived drug interactions with antiretroviral agents.

Definitive Therapy

The decision to initiate therapy is made based on local epidemiologic information; the patient's clinical, pathologic, and radiologic data; and the results of microscopic and culture examination. Therapy may be started immediately if the index of suspicion is high or if the patient is gravely ill. However, in general, clinicians should still collect initial specimens for microscopic evaluation and culture before starting treatment. HIV testing and baseline liver function testing, serum creatinine levels, and platelet counts should be conducted as part of standard medical care for patients with suspected or documented TB disease.

Achieving microbiologic cure by killing all bacilli and preventing emergence of clinically significant drug-resistant mutants are the primary goals of definitive TB therapy. Therapy is prolonged despite sputum conversion and resolution of symptoms, because some organisms persist in some tissues. DOT is generally recommended to ensure compliance with prescribed medications.

The four ATS/CDC/IDSA-recommended regimens used for treating TB caused by drug-susceptible organisms are shown in Table 3. Each regimen has an initial phase of 2 months followed by a choice of several options for the continuation phase of 4 or 7 months. Treatment of previously untreated TB consists of 2 months of an initial phase of four drugs: isoniazid, rifampin, pyrazinamide, and ethambutol (Myambutol) or streptomycin (generally not used in the United States). The newer rifamycins are also first-line drugs used under certain circumstances. Rifabutin¹ is used if rifampin is contraindicated, as in patients taking certain

TABLE 3 Drug Regimen for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

			DOSE (MAXIMUM DOSE IN 24 h OR MAXIMUM DURATION)	
REGIMEN	DRUGS	INTERVAL AND MINIMUM DURATION*	CHILDREN	ADULTS
Initial Phase				
1	Isoniazid (INH, Nydrazid) Rifampin (Rifadin) Pyrazinamide Ethambutol (Myambutol)	Once daily on 7 d/wk for 56 doses (8 wk), or Once daily on 5 d/wk for 40 doses (8 wk)	10–20 mg/kg/d ³ (300 mg) 10–20 mg/kg/d (600 mg) 15–30 mg/kg/d (2000 mg) 15–25 mg/kg/d	5 mg/kg/d (300 mg) 10 mg/kg/d (600 mg) 15–30 mg/kg/d (2000 mg) 15–25 mg/kg/d
2	Isoniazid Rifampin Pyrazinamide Ethambutol	Once daily on 7 d/wk for 14 doses (2 wk), then twice weekly for 12 doses (6 wk), or Once daily on 5 d/wk for 10 doses (2 wk), then twice weekly for 12 doses (6 wk)	20–40 mg/kg/d (900 mg) 10–20 mg/kg/d (600 mg) 50–70 mg/kg/d (4000 mg) 50 mg/kg/d ³	15 mg/kg/d (900 mg) 10 mg/kg/d (900 mg) ³ 50–70 mg/kg/d (4000 mg) 50 mg/kg/d ³
3	Isoniazid Rifampin Pyrazinamide Ethambutol	Three times weekly for 24 doses (8 wk)	20–40 mg/kg/d (900 mg) 10–20 mg/kg/d (600 mg) 50–70 mg/kg/d (3000 mg) 50 mg/kg/d ³	15 mg/kg/d (900 mg) 10 mg/kg/d (900 mg) ³ 50–70 mg/kg/d (3000 mg) 50 mg/kg/d ³
4	Isoniazid Rifampin Ethambutol	Once daily on 7 d/wk for 56 doses (8 wk), or Once daily on 5 d/wk for 40 doses (8 wk)		
Continuation Phase [†]				
1a	Isoniazid Rifampin	Once daily on 7 d/wk for 126 doses (18 wk), or Once daily on 5 d/wk for 90 doses (18 wk)	182–130 doses (max. 26 wk)	
1b [‡]	Isoniazid Rifampin	Twice weekly for 36 doses (18 wk)	92–76 doses (max. 26 wk)	
1c [§]	Isoniazid Rifapentine	Once weekly for 18 doses (18 wk)	74–58 doses (max. 26 wk)	
2a [‡]	Isoniazid Rifampin	Twice weekly for 36 doses (18 wk)	62–58 doses (max. 26 wk)	
2b [§]	Isoniazid Rifapentine (Priftin)	Once weekly for 18 doses (18 wk)	44–40 doses (max. 26 wk)	
3a	Isoniazid Rifampin	Three times weekly for 54 doses (18 wk)	78 doses (max. 26 wk)	
4a	Isoniazid Rifampin	Once daily on 7 d/wk for 217 doses (31 wk), or Once daily on 5 d/wk for 155 doses (31 wk)	273–195 doses (max. 39 wk)	
4b	Isoniazid Rifampin	Twice weekly for 62 doses (31 wk)	118–102 doses (max. 39 wk)	

Adapted from the American Thoracic Society: Treatment of tuberculosis. Am J Respir Crit Care Med 2003;167:603–662.

³Exceeds dosage recommended by the manufacturer.

*When directly observed therapy (DOT) is used, drugs may be given on 5 d/wk, with the necessary number of doses adjusted accordingly; therapy administered on 5 d/wk should always be given by DOT.

[†]Patients with cavitation on initial chest radiography and positive cultures at 2 mo should receive a 7-mo (31-wk) regimen of either 217 (daily) or 62 (twice weekly) doses in the continuation phase.[‡]Not recommended for HIV-infected patients with CD4⁺ T-cell count <100 cells/mm³.[§]Use only in HIV-negative patients who have negative smears at 2 mo and no cavitation on chest radiography.

antiretroviral drugs; rifapentine (Priftin) is used in the once-weekly continuation phase with isoniazid in selected patients (see Table 3). If the organisms are later demonstrated to be susceptible to isoniazid and rifampin, ethambutol is discontinued. The continuation phase is usually 4 months of daily or intermittent isoniazid and rifampin or rifapentine. The 7-month continuation phase is recommended only for those patients with cavitary TB caused by susceptible organisms that remains sputum positive after 2 months of DOT, patients whose initial treatment phase did not include pyrazinamide, and patients on weekly isoniazid and rifapentine whose sputum smear was still positive at the end of the intensive phase. There is evidence from many clinical trials done worldwide that demonstrates the efficacy of supervised intermittent therapy is similar to daily dosing in terms of various clinical outcomes. Routine follow-up to monitor adverse events and adherence to the treatment regimen should occur at least monthly.

Approximately 80% of patients who take the four-drug therapy for susceptible organisms are expected to convert from culture positive to negative after 2 months, and 90% to 95% after 3 months. Failure of treatment is defined by positive culture or, at times, positive smears after 4 months of supervised therapy. Relapse is defined by recurrent TB at any time after completion of treatment or apparent cure. Relapses most commonly occur during the first 6 to 12 months after the end of therapy. Treatment of initially susceptible disease can fail for many reasons, including extensive cavitary disease, drug resistance, malabsorption of drugs, laboratory error, and biologic variation in response. In any case, positive smears or cultures after 2 months of supervised therapy should be carefully evaluated to determine the cause. In addition, a full course of therapy is determined by the number of doses completed. Hence, a 6-month daily regimen (including both initiation and continuation phases) consists of at least 182 doses of isoniazid and rifampin

and 56 doses of pyrazinamide (see Table 3). All missed doses should be taken. Patients interrupting therapy by more than 14 days during the initial phase or more than 3 months during continuation phase should be restarted on therapy from the beginning.

Treatment of Tuberculosis in Resource-Poor Settings

Direct observation of patients taking therapy is just one of five elements of DOTS recommended by the World Health Organization and the International Union Against Tuberculosis and Lung Disease for TB treatment programs in resource-poor settings. The five elements of DOTS are:

- Government commitment to sustained TB control activities
- Case detection by sputum microscopy in symptomatic patients self-reporting to health centers
- Standardized treatment regimen of 6 to 9 months for at least all confirmed sputum smear-positive cases, with DOT for at least the intensive phase
- Regular, uninterrupted supply of essential anti-TB drugs
- Standardized recording and reporting system that allows for patient and program assessments

Smear microscopy for AFB is emphasized because of cost concerns and because access to culture facilities is limited in most countries. Three AFB stains that include early-morning sputum smears are recommended for a diagnosis. However, some recent data refute the need for three sputum samples by suggesting that no significant benefit is derived from the third smear when performed in high-burden countries. A new molecular diagnostic test called Xpert MTB/RIF assay detects *M. tuberculosis* complex within 2 hours with an assay sensitivity that is much higher than that of smear microscopy, and detects multidrug-resistant tuberculosis at the same time. In HIV infected patients, the test has a rate of case detection that is increased by 45%, as compared to smear microscopy.

Susceptibility testing is strongly recommended for patients who fail to convert to smear-negative status after 2 months of treatment. The prevalence of drug resistance in areas of high TB burden is unknown because of limited laboratory capacity.

Individualized TB care in resource-limited areas is difficult to implement because most decisions are made based solely on clinical judgment or limited radiologic findings. These challenges result in the use of standardized treatments that emphasize cost-effectiveness for utilitarian returns. This “one size fits all” approach is likely to worsen the financial and clinical outcomes of some patients.

Treatment of Tuberculosis in Special Circumstances

Multidrug-Resistant Tuberculosis

In resource-poor settings, where susceptibility testing facilities usually are not available, the surrogate terms “retreatment” and “chronic” are used to define various forms of drug-resistant strains. In the United States, about 1.1% of TB cases reported in 2007 had primary multidrug resistance, which is defined as resistance to at least isoniazid and rifampin in a patient with no previous history of TB treatment. Combination therapy including first- and second-line drugs is used to treat multidrug-resistant TB, and at least one of the drugs must be an injectable agent. Some of the second-line TB drugs are levofloxacin (Levaquin),¹ cycloserine (Seromycin), ethionamide (Trecator), *p*-aminosalicylic-acid (Paser), capreomycin (Capastat), kanamycin (Kantrex),¹ and amikacin (Amikin).¹

Therapy takes several years to complete. Treatment failure, costs, and drug-related side-effects are higher with the second-line drugs. Patients with suspected treatment failure should be managed at specialized facilities with necessary expertise where the full range of drug susceptibilities can be performed. As a general rule, single drugs should never be added to failing regimens because this leads to acquired resistance to each new drug. Drug resistance in mycobacteria occurs through random genetic mutations, with minimal lateral transfer of genetic material. Chances of detecting primary

resistance are greater when the bacillary load is high, for example in patients with multiple cavitory disease. In addition, selective pressure can induce the emergence of drug-resistant mutants.

Extrapulmonary and Sputum-Negative Tuberculosis

TB can involve any organ or tissue in the body. Therefore, histologic examination or smear microscopy with AFB staining of specimens from appropriate sites is necessary to confirm extrapulmonary TB. The specimens may include cerebrospinal, pleural, pericardial, or ascitic fluids and lymph node tissue, bone, bone marrow, or brain biopsy specimens. The yield of bacilli in staining or culture from body fluids is usually very low (<50% for pericardial fluid). A diagnosis of extrapulmonary TB can also be made based on clinical and radiologic improvement on empiric therapy if it is not possible to obtain a specimen.

The same four drugs and dosing regimens used to treat pulmonary TB are also used for extrapulmonary disease. Use of adjunct corticosteroids in patients with pericardial or meningeal TB was associated with lower mortality in some prospective and retrospective studies. Bone and joint TB is treated for 6 to 9 months, and central nervous system TB (including meningitis) for 9 to 12 months. Duration of treatment for TB in all other sites is 6 months if pyrazinamide is given during the first 2 months; otherwise, the continuation phase is prolonged to 7 months. The ATS/CDC/IDSA guidelines also recommend intermittent therapy. Once-weekly administration of isoniazid and rifapentine should be avoided in the continuation phase, because data to support the efficacy of this regimen in patients with extrapulmonary TB is lacking. However, recent data report poor long-term outcomes despite adequate therapy in patients successfully treated for pericardial and meningeal TB. These and other studies question the wisdom of using the same drug exposures to target organisms in different physiologic spaces, given that drug penetration, and therefore drug concentrations, in these spaces differs.

A diagnosis of sputum-negative TB is made in patients for whom the clinical and radiologic findings strongly suggest TB but the culture and AFB smears are negative. In addition, there is clinical and/or radiologic improvements at the end of 2 months of therapy. A 2-month continuation phase of isoniazid and rifampin is used for these patients, rather than the 4 months used for sputum-positive patients.

Mycobacterium avium Complex Infection

In patients with advanced AIDS and other causes of severe cell-mediated immune deficiency, MAC causes disseminated infections. In others with ill-defined immunologic disorders, and in those who are immunocompetent, MAC causes chronic pulmonary disease. Therapy for these patients is long and complicated, with many adverse effects. The same regimens are used for all patients regardless of their HIV/AIDS status. Drug resistance is frequent.

Culture from blood or other sites (e.g., lymph node, bone marrow) is required to demonstrate invasive or disseminated disease. Bacteriologic diagnosis should be based on positive cultures or smears (or both) from sputum or bronchial wash specimens. If sputum specimens are used to diagnose pulmonary disease, at least three positive sputum smears are needed for diagnosis. Clinical and radiologic findings must also be consistent with MAC.

Combination therapy is used to prevent selection of drug-resistant mutants and to capitalize on the additive and synergistic effects of antimycobacterial drugs. Clarithromycin (Biaxin) or azithromycin (Zithromax) together with ethambutol is now the cornerstone of MAC therapy. Three- or four-drug combinations that included ethambutol, a rifamycin (rifampin¹ or rifabutin), clofazimine (Lamprène),¹ isoniazid,¹ or ciprofloxacin (Cipro)¹ were shown to clear bacteremia better in some AIDS patients, especially those with a bacillary burden of greater than 2 log₁₀ colony-forming units per milliliter. However, adherence to therapy was poor because of toxicity. Two-way interactions between

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

antiretroviral medications (e.g. protease inhibitors, non-nucleoside reverse transcriptase inhibitors) and the rifamycins as well as clarithromycin and rifabutin can make patient management complicated. AIDS patients with CD4-positive T-cell counts lower than 50 cells/mm³ should be offered prophylactic therapy to protect against disseminated MAC. Azithromycin has greater efficacy, has fewer drug interactions, and can be given once weekly. Resistance has been observed in 16% of patients treated with azithromycin and in 29% to 58% of those treated with clarithromycin. Resistance of MAC to rifamycin is rare.

Mycobacterium leprae

Leprosy is a legendary disease that has been stigmatized throughout many societies and eras of human history. The causative organism is *M. leprae*. The global incidence of this disease has been on the decline. Fewer than 200 cases are diagnosed each year in the United States, almost exclusively in immigrants. Most practitioners in the United States will not encounter patients with this disease.

The important clinical features of leprosy are skin lesions, nerve involvement, disfigurement of the face, and reversal reactions. Skin lesions are hypopigmented anesthetic macules and papules. Peripheral nerve enlargement can also occur, as can disfigurement of parts of the face (e.g., leonine faces). Leprosy has a spectrum of manifestations. Some patients have multibacillary leprosy associated with poor cell-mediated immunity. Others have paucibacillary leprosy resulting in a few skin patches with a robust cell-mediated immunity. Skin reactions encountered in paucibacillary leprosy due to delayed hypersensitivity to *M. leprae* antigens are called reversal reactions. These may also occur when massive numbers of bacilli are killed by chemotherapy.

Diagnosis is established on the basis of a compatible clinical picture and demonstration of *M. leprae* in smears or on histologic analysis of skin and nerve biopsy specimens. The lepromin skin test is nonreactive in multibacillary disease but reactive in paucibacillary disease. Unlike other mycobacteria, *M. leprae* has stringent growth requirements; it can only grow when injected into foot pads of some animals and does not grow on artificial laboratory media.

The aim of leprosy treatment is total cure. As with other slow-growing mycobacteria, multidrug therapy is administered. Therapy consists of rifampin,¹ clofazimine (Lamprene), and dapsone. Recently, fluoroquinolones have been investigated for a role in the treatment of leprosy. In the United States, the therapy for paucibacillary leprosy is oral rifampin 600 mg/day and dapsone 100 mg/day for 6 months, followed by dapsone monotherapy for at least 3 years. The treatment of multibacillary leprosy is similar to that of paucibacillary leprosy, with dual therapy being continued for 3 years. Clofazimine is added for reverse reactions and if there is dapsone resistance. After 3 years of dual or even triple therapy, dapsone monotherapy is continued for 10 years. These regimens differ from those recommended by the World Health Organization, which are utilized elsewhere.

Mycobacteria Other Than Tuberculosis

Mycobacteria other than tuberculosis (MOTT) are mycobacterial species that may cause human disease but do not cause TB (see Table 1). The incidence of infection is reported to be about 2 in 100,000, but this may be an underestimate. The common mycobacteria identified in the United States are *M. avium*, *Mycobacterium gordonae*, *Mycobacterium fortuitum*, *Mycobacterium kansasii*, and *Mycobacterium chelonae*. MOTT infections are not contagious, but some produce signs and symptoms similar to those of TB, whereas others cause suppurative-like disease. MOTT primarily affect the lungs, and disease progression is slow. MOTT cause reportable disease.

Diagnosis is based on clinical presentation, radiologic findings, examination of histologic specimens, culture, and smear staining for microscopy of sputa or bronchial washings. The diagnostic criteria for MOTT in AIDS and non-AIDS patients are

- Chest radiographs showing infiltrates or nodular or cavitary disease or computed tomographic scans consistent with bronchiectasis or small nodules
- Three positive cultures with negative AFB smears or two positive cultures and one positive AFB smear from three sputum or bronchial washing specimens obtained within the previous 12 months
- Positive culture from bronchial wash with AFB smear or growth on solid media greater than 2+
- Transbronchial or lung biopsy consistent with mycobacterium histologic features and sputum or bronchial washings that are nondiagnostic of another disease.
- For mycobacteria other than tuberculosis such as *M. abscessus/chelonae* therapy is more with standard antibiotics like ceftriaxone. However, all these patients should be reported to specialist centers.

VENOUS THROMBOEMBOLISM

Method of

Moniba Nazeeq, MD; and John P. Sheehan, MD

CURRENT DIAGNOSIS

- A good history is the most important diagnostic tool to assess risk factors including recent surgery or bedridden state, trauma, orthopedic procedure, or active cancer. Risk tools such as Wells model may be useful.
- Moderately high-sensitivity D-Dimer assays (>85% sensitivity) can be used to exclude venous thromboembolism (VTE) if there is low clinical probability but should be combined with imaging in all other cases.
- Venous compression ultrasonography (CUS) is a noninvasive, affordable, and widely available test for the diagnosis of deep vein thrombosis (DVT).

CURRENT THERAPY

- The choice of initial therapy is frequently guided by the clinical scenario. Initial therapy includes unfractionated heparin (UFH), low-molecular-weight heparin (LWMH), fondaparinux (Arixtra), or the direct oral anticoagulants (DOACs) rivaroxaban (Xarelto) or apixaban (Eliquis)
- The traditional heparin-warfarin regimen has been increasingly supplanted by the use of direct oral anticoagulants (DOAC).
- Standard treatment for a new episode of DVT or Pulmonary Embolism (PE) has traditionally been 3 to 6 months of therapeutic anticoagulation. The recommended duration of anticoagulation for VTE requires individualized analysis of the clinical presentation and patient specific factors that weigh both recurrence and bleeding risk.

Venous thromboembolism (VTE) is a significant health problem, with surveillance data suggesting that 60,000 to 100,000 people die of VTE each year in the United States. Approximately 50%

to 60% of this disease burden is associated with a recent hospitalization, underscoring the importance of VTE prophylaxis. VTE is comprised of superficial vein thrombosis (SVT), deep venous thrombosis (DVT), and pulmonary embolism (PE). DVT typically starts in the deep veins of the lower extremities and progresses proximally. If untreated, a clot can break off and travel to the lungs where it is trapped in the pulmonary circulation, resulting in PE. DVT confined to the deep veins of the calf is termed *isolated distal DVT*, whereas involvement of the popliteal or more proximal veins is termed *proximal DVT*. SVT represents thrombosis in the superficial veins of the legs or arms and rarely progresses to DVT. The focus of this chapter is to understand the risk factors, diagnosis, treatment, and prevention of DVT and PE.

Pathophysiology/Risk Factors

Venous blood flow is maintained by a delicate homeostatic balance of prothrombotic and antithrombotic factors. Virchow's triad describes the major factors leading to VTE from a pathophysiologic standpoint: (1) intrinsic hypercoagulability, (2) endothelial damage, and (3) venous stasis. Most often, a combination of these factors leads to the development of VTE. Based on the presence or absence of typical clinical risk factors, VTE occurrences can be considered either provoked (e.g., postsurgical) or unprovoked (spontaneous). Furthermore, provoking risk factors may be transient/reversible (e.g., estrogen use) versus nontransient/irreversible (e.g., lower extremity paresis), which has implications for decisions regarding duration of anticoagulant therapy [Table 1](#).

Acquired Risk Factors

Certain clinical conditions shift the balance between procoagulant and anticoagulant factors to promote thrombosis. These conditions include surgery, pregnancy and puerperium, inflammation, active cancer, major trauma, specific medications, and a variety of conditions that lead to immobility. A more comprehensive list is provided in [Table 1](#). Many of these clinical conditions cause multiple changes relevant to VTE risk. For example, surgical interventions may induce endothelial damage, immobilization leading to venous stasis, platelet activation, and trigger inflammatory responses that increase fibrinogen, factor VIII, and von Willebrand factor levels. Orthopedic

TABLE 1 Risk Factors for Venous Thromboembolism

Transient/Reversible

Surgery (esp. lower limb orthopedic surgery)
General anesthesia >30 min
Immobility due to surgical or medical condition
Oral contraceptives/hormone replacement therapy
Pregnancy, puerperium
Major trauma
Acute inflammation
Indwelling venous catheters
Heparin induced thrombocytopenia
Travel-associated thrombosis
Medications- including tamoxifen, L-asparaginase, immunomodulatory agents (lenalidomide), EPO

Permanent/Non-Reversible

Active cancer
Antiphospholipid Syndrome
Myeloproliferative neoplasms
Paroxysmal nocturnal hemoglobinuria (PNH)
Lower extremity paresis from neurologic disease
Sickle Cell Disease
Nephrotic Syndrome
Active autoimmune conditions (SLE, IBD, ITP, TTP)
Chronic infection/inflammation
Morbid obesity (BMI > 40)

EPO, Erythropoietin; SLE, systemic lupus erythematosus; IBD, inflammatory bowel disease; ITP, immune thrombocytopenic purpura; TTP, thrombotic thrombocytopenic purpura.

procedures involving the lower limbs and abdominopelvic surgeries in cancer patients are especially high risk from a VTE standpoint. Active cancer is associated with 20% of all VTE and involves a variety of mechanisms leading to hypercoagulability, including increased tissue factor expression, venous obstruction, indwelling catheters, reduced mobility, and chemotherapy.

Pregnancy and the puerperium, oral contraceptives (OC), and hormone replacement therapy (HRP) are important VTE risk factors in women. OC and HRP are associated with a number of changes in hemostatic protein levels and platelet function that appear globally prothrombotic. Higher estrogen content is associated with increased thrombotic risk and is modulated by a combination with specific progestins. Additionally, there is a higher risk of VTE in OCP users with a positive family history, suggesting an underlying genetic predisposition.

A variety of conditions that involve prolonged immobilization enhance VTE risk. Cast immobilization of the lower extremity, paresis after neurologic events, multiple trauma, orthopedic surgeries, travel-associated immobility (>4–6 hours) or a bedridden state due to a variety of medical or surgical conditions result in stasis that promotes venous thrombosis. Many of these clinical situations are also associated with an inflammatory state that concomitantly increases intrinsic hypercoagulability of the blood. Venous wall injury may occur via a variety of mechanisms, including surgical interventions, indwelling intravenous catheters, trauma, and vasculitis.

Genetics of Venous Thromboembolism

Although acquired clinical risk factors are critical to assessing risk, the genetic contribution to VTE is also substantial, with heritability of VTE estimated at 40% to 47%. Like many complex phenotypes, VTE has a multigenic basis in which most individual alleles make relatively small contributions to overall risk. Factor V Leiden and the prothrombin G20210A polymorphism are examples of such alleles (2- to 4-fold relative risk). At least 17 genes have been identified that harbor VTE-associated variants. Importantly, family history remains an independent risk factor even after excluding known gene variants associated with thrombophilia, suggesting that unidentified genes also contribute to VTE risk. Deficiencies of the coagulation inhibitors antithrombin, protein C, and protein S are rare conditions with a more substantial effect on the relative risk of VTE (10- to 20-fold increase) but tend to be diagnosed erroneously in the setting of acute thrombosis. The multigenic basis of VTE has implications for thrombophilia testing that include: (1) identification of minor alleles (e.g., FV Leiden) is not helpful for prediction of VTE recurrence risk; (2) a careful family history is generally more valuable than a thrombophilia evaluation; and (3) the *absolute* risk for carriers of thrombophilic alleles is generally quite small and does not justify indefinite anticoagulation. A robust estimate of individual genetic risk requires systematic screening of all known VTE risk genes or whole genome/exome sequencing approaches that are not routinely available. Thus current thrombophilia testing rarely contributes to clinical decision making in patients with VTE. Testing should never be pursued for provoked events and is best limited to selected situations such as presentations at a young age (<30 years) or known thrombophilic traits occurring in the context of a family history of VTE. A thorough personal and family history is generally sufficient to determine the likelihood of an underlying inherited hypercoagulable state.

Epidemiology and Natural History

The exact incidence of VTE is unknown, but it is estimated that about 300,000 to 600,000 Americans are affected by VTE each year. VTE incidence appears ~30% higher in African Americans and ~70% lower in Asian and Native American populations relative to Caucasians. Importantly, the incidence of VTE increases with age, particularly after age 50. Whereas overall VTE is slightly more common in men, women have an increased incidence before age 40 based on the impact of pregnancy and contraceptives. In older age groups, the frequency of PE is increased relative to DVT. Finally, the incidence of VTE has been increasing steadily since the mid-1980s, which may, in large part, represent the

increased use and enhanced sensitivity of computed tomography (CT) scans and magnetic resonance imaging (MRI).

The natural history of VTE is impacted by the underlying clinical risk factors, provoked versus unprovoked nature of the event, reversibility of risk factors, and location/nature of the thrombotic event. In general, untreated thrombi tend to extend proximally, break off, and embolize to the pulmonary circulation, where they may result in infarction and pulmonary hypertension. The risk of PE is increased for proximal versus distal involvement with DVT. More than 75% of VTE starts in the calf veins, and 20% to 30% of these cases progress to involve proximal veins in the leg or pelvis. Approximately 50% of patients with untreated symptomatic proximal DVT develop symptomatic PE, whereas the incidence of asymptomatic PE is even higher. Importantly, 10% of symptomatic PE is rapidly fatal, and 30% of patients with untreated symptomatic nonfatal PE will have a fatal recurrence. Thus recognition of PE is of the utmost clinical importance. Anticoagulant therapy inhibits thrombus growth and largely prevents interval recurrence, whereas endogenous thrombolysis may result in partial or complete resolution of the thrombus. Uncommonly, progressive thrombosis in the presence of anticoagulation may occur in high-risk situations such as metastatic malignancy or the antiphospholipid syndrome.

The risk of VTE recurrence after stopping anticoagulation varies significantly based on clinical presentation. About 20% to 40% of VTE episodes are unprovoked in nature, which is associated with a substantially higher recurrence rate. For unprovoked clots, recurrence rate is estimated to be ~10% in one year, ~30% in 5 years, and approaches ~40% in 10 years. In contrast, the recurrence risk of VTE associated with surgery (a transient risk factor) is less than 3% per year. Recurrences tend to occur in a similar site to the initial event, which is particularly important in the case of PE, as 25% of pulmonary embolism presents as sudden death. In contrast, the risk of recurrent VTE is much smaller in isolated distal (calf) DVT compared with proximal DVT and PE.

Long-Term Complications of VTE

Postthrombotic Syndrome (PTS)

About 20% to 50% patients with DVT develop some degree of PTS within the subsequent 1–2 years. Chronic venous obstruction, inflammation, endofibrosis, and valvular dysfunction contribute to the chronic venous insufficiency of PTS. Risk factors for PTS include persistent DVT symptoms after one month, extensive or recurrent DVT, inadequate anticoagulation, and advanced age. Manifestations include chronic leg edema, pain, heaviness, erythema, and venous ulcers that may result in significant disability. PTS is largely non-reversible, emphasizing the importance of DVT prevention. Graduated compression stockings provide symptomatic relief by preventing pooling of blood in the lower extremities, but do not prevent PTS. In the 5% to 10% of patients with severe PTS, active supportive care and consultation with vascular surgery, dermatology, or vein specialists should be sought early to avoid development of debilitating venous ulcers.

Chronic Thromboembolic Pulmonary Hypertension (CTEPH)

CTEPH is a long-term complication of PE affecting 3% to 4% patients despite adequate anticoagulation. CTEPH is characterized by progressive pulmonary hypertension and right-side heart failure due to remodeling of pulmonary vasculature by thrombotic material. Patients with large central or extensive pulmonary emboli, hemodynamic compromise, and right heart dysfunction at diagnosis are at highest risk. Chronic progressive dyspnea with exertion is the most common symptom, and the clinician must have a high clinical suspicion based on patient's history of PE. An echocardiogram revealing elevated pulmonary arterial hypertension should trigger evaluation with a VQ scan. The presence of chronic mismatched segmental perfusion defects on the VQ scan is diagnostic of CTEPH. If anatomically feasible, treatment of choice is pulmonary endarterectomy, which can reverse the hemodynamic and functional abnormalities. Early recognition and referral to a specialized surgical treatment center are critical to patient outcomes. Lifelong anticoagulation is recommended for all patients with CTEPH.

Diagnosis of Deep Venous Thrombosis

The diagnosis of DVT proceeds via determination of clinical probability, D-dimer screening, and confirmatory imaging.

Clinical Features

Diagnosis begins with evaluation of the clinical scenario for VTE risk factors and suspicious physical exam findings. Suggestive features in the patient's recent history include recent surgery or bedridden state, trauma or orthopedic procedure, active cancer, and other typical risk factors (Table 1). Classic symptoms of DVT include limb swelling, pain, and erythema. On exam, unilateral calf swelling, pitting edema, dilated veins, and tenderness on palpation can be seen. The clinical probability becomes stronger when more of these findings are present. Risk stratification systems such as the Wells model (Table 2) use these clinical features to rapidly classify patients as high (~60% thrombosis), moderate (~25%), or low (~5%) risk for DVT. Differential diagnosis of DVT includes trauma, cellulitis, osteomyelitis, chronic venous

insufficiency, arterial ischemia, ruptured Baker's cyst, hematoma, and superficial thrombophlebitis. Because neither history nor physical examination findings are specific for DVT, D-dimer screening and objective imaging must be pursued if sufficient clinical suspicion exists. A simplified algorithm for diagnosis of DVT is provided (Figure 1).

D-Dimer Screening

D-dimer is a specific fibrin degradation product generated by plasmin cleavage of cross-linked fibrin clot, formed by thrombin and Factor XIII activity. D-dimer represents a useful screening tool based on excellent sensitivity and a high negative predictive value for VTE. However, D-dimer lacks specificity, as it is increased in a variety of conditions, including acute inflammation, recent surgery or trauma, pregnancy, DIC, advanced age, or cancer. The level of clinical suspicion also impacts interpretation of D-dimer results. Specific D-dimer assays vary in sensitivity and specificity, although qualitative testing has largely been replaced by enzyme-linked immunosorbent assay–based quantitative assays. More recently, highly sensitive assays (>95% sensitivity) using latex-enhanced immunoturbidimetric immunoassays provide rapid quantitation for use in the diagnosis of VTE. Point-of-care (POC) testing with specified cutoff values are also available. Thus the clinician should be familiar with the type of D-dimer testing available locally. Highly sensitive assays have a good negative predictive value to rule out VTE without further testing. Moderately high-sensitivity assays (>85% sensitivity) can be used to exclude VTE if there is low clinical probability but should be combined with imaging in all other cases. Qualitative or semiquantitative assays are generally not reliable for excluding thrombosis. Finally, if clinical suspicion for DVT or PE is high, a negative D-dimer should not be used to rule out VTE, and appropriate imaging should be pursued to confirm the diagnosis.

Imaging

Ultrasonography

Venous compression ultrasonography (CUS) is a noninvasive, affordable, and widely available test for the diagnosis of DVT. The deep veins are assessed by use of a compression probe with lack of compressibility in a venous segment indicative of thrombus. Duplex technology or color-coded Doppler scanning visualizes blood flow to allow accurate identification of deep veins. Lack of flow plus non-compressibility increases diagnostic accuracy and also facilitates diagnosis in veins that cannot be compressed (e.g., pelvic and subclavian veins). Venous ultrasonography has an excellent sensitivity and specificity (~94%) for diagnosis of proximal limb DVT. The common femoral, femoral, and

TABLE 2 Wells Model for Predicting Pretest Probability of Deep Vein Thrombosis

CLINICAL VARIABLE	POINTS
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Recently bedridden >3 days or major surgery within 4 weeks	1

Dilated superficial veins (non-varicose)	1
Previous documented DVT	1
Paralysis, paresis, or recent plaster immobilization of the 1 lower extremities	1
Localized tenderness along the distribution of the deep 1 venous system	1
Calf swelling 3 cm greater than asymptomatic side measured 10 cm below tibial tuberosity	1
Pitting edema confined to the symptomatic leg	1
Alternative diagnosis at least as likely as DVT	-2

Clinical probability by interpretation of total score: >2 points, high; 1 or 2, moderate; <1, low.

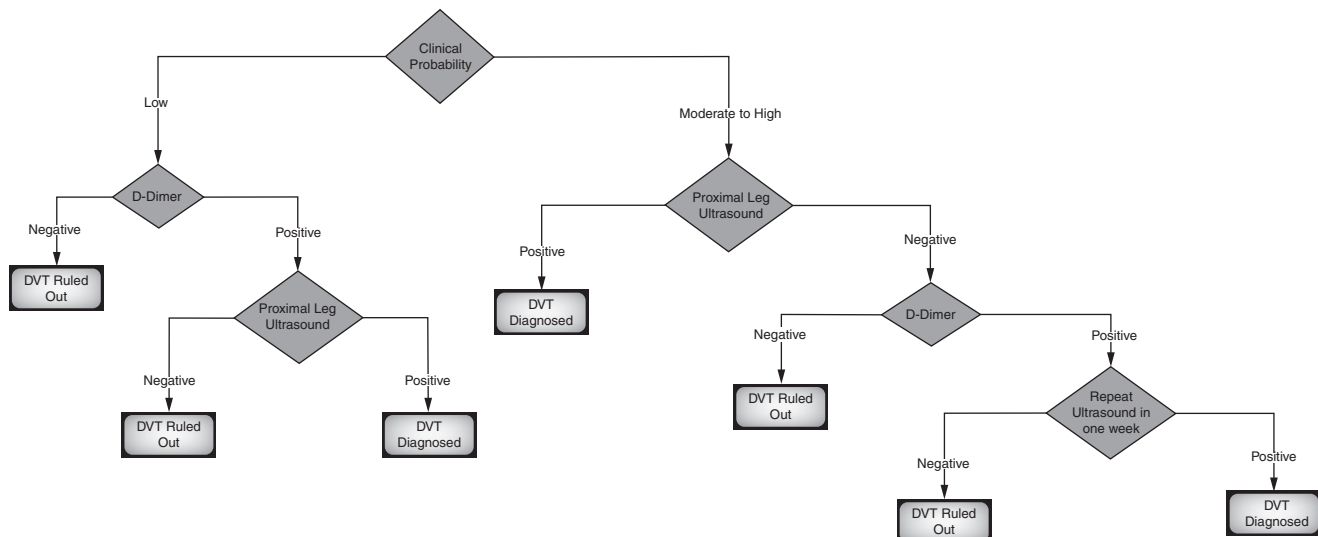

Figure 1 Suggested diagnostic algorithm for diagnosis of deep venous thrombosis (DVT).

trifurcation of calf veins are readily visualized. In most cases, a negative test is sufficient to rule out proximal VTE. Currently two methods for CUS are used: (1) the two point compression technique, which only evaluates the proximal veins in the groin and popliteal fossa; and (2) whole-leg ultrasound scanning evaluating both proximal and distal veins. The sensitivity and specificity of CUS for calf vein DVT is significantly lower and highly operator dependent. Therefore many centers only perform the proximal vein assessment, which is reliable, reproducible, and efficient. If clinical suspicion remains high after a negative proximal vein ultrasound scan, repeat ultrasound scanning should be performed in about a week to assess for proximal extension in the deep venous system. If negative, no further testing is needed. A negative whole-leg CUS test result essentially rules out DVT and does not need follow-up testing. However, this approach is time consuming, may lead to increased diagnosis of calf vein thromboses, and potential overtreatment. The 3-month incidence of symptomatic proximal venous thrombosis in patients with a normal initial test are comparable at ~1% for both approaches. For upper extremities, compression ultrasonography is about 86% sensitive and specific.

Contrast Venography

Previously the gold standard for diagnosis of DVT, contrast venography is rarely used because it is invasive and requires contrast exposure. CT and MR venography have a sensitivity and specificity of >90% for DVT in lower extremities. However, these studies are also not widely used for diagnosis because of increased cost, radiation, and contrast exposure. CT and MR venography are useful to define anatomy in patients with multiple recurrent DVT (evaluation by CUS is problematic), an indeterminate abnormality on ultrasound scanning, or a thrombus diagnosed in the setting of very low clinical suspicion.

Diagnosis of PE

Similar to DVT, the diagnosis of PE requires determination of clinical probability, consideration of D-dimer testing, and confirmatory imaging.

Clinical Features

A patient presenting with risk factors for VTE and antecedent history of DVT should raise the suspicion for pulmonary embolism. The most common symptoms of PE are shortness of breath and chest pain. Pleuritic chest pain is typical, but PE may also present with substernal pressure or be confused with musculoskeletal pain. Other symptoms may include cough and hemoptysis. Clinical signs include tachypnea, tachycardia, and hypoxia. The findings of DVT in the lower extremities increase the probability of PE. The Well's model for PE provides a useful framework to estimate the pretest probability using these variables (Table 3).

TABLE 3 Wells Model for Predicting Pretest Probability of Pulmonary Embolism

CLINICAL VARIABLE	POINTS
Clinical signs and symptoms of DVT (minimum leg swelling and pain with palpation of the deep veins)	3
An alternative diagnosis is less likely than PE	3
Heart rate >100 beats/min	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Hemoptysis	1
Active Cancer (treatment ongoing or within previous 6 months or palliative)	1

Clinical probability by interpretation of total score: >6 points, high; 4 to 6, moderate; <4, low.

Chest X-Ray, Electrocardiography, and Troponin

Chest x-ray should be performed in all suspected cases. The classical "Hampton's hump" or peripheral wedge-shaped opacity corresponding to a large pulmonary infarct is seldom appreciated and not very sensitive or specific. However, a chest x-ray is useful in assessing for other conditions such as pneumonia, pneumothorax, and pulmonary edema that can present in similar fashion. Electrocardiography (EKG) should be performed in anyone presenting with chest pain to rule out myocardial infarction. Evidence of right heart strain on EKG has predictive and prognostic value in assessment of pulmonary embolism. Similarly, a troponin level is usually obtained in evaluation for myocardial ischemia. An elevated troponin level in the absence of EKG evidence of ischemia can be suggestive of myocardial injury in the setting of massive or submassive PE.

Ventilation/Perfusion (V/Q) Scanning

V/Q scans have largely been replaced by computed tomography pulmonary angiography (CTPA). However, V/Q scans remain useful in selected patients with significant renal insufficiency (to avoid contrast dye) and young or pregnant females (to avoid radiation exposure). This technique uses inhaled and intravenous radioisotopes to evaluate ventilation and circulation in the pulmonary parenchyma and vasculature, respectively. A normal perfusion scan in the setting of a normal chest x-ray excludes PE. The addition of a ventilation scan increases specificity by accounting for other pulmonary disorders. A normal chest x-ray and ventilation scan in areas with multiple large perfusion defects that involve >75% of a segment (V/Q mismatch) is associated with >80% probability of PE and considered a high-probability V/Q scan. An intermediate-probability scan usually requires further diagnostic evaluation because it is considered nondiagnostic in most situations. Three-dimensional single-photon emission CT (SPECT) is now used by many centers in place of planar VQ scans. SPECT may be more accurate than planar VQ scanning, resulting in fewer nondiagnostic studies.

Computed Tomography Pulmonary Angiography

Computed tomography pulmonary angiography (CTPA) has become the modality of choice for diagnosis of PE. It is a relatively noninvasive procedure that can provide prompt diagnosis of PE. With recent advancements, the availability of thin-slice scans provides a detailed analysis of pulmonary vasculature that increases the sensitivity for detecting thrombi at the subsegmental and peripheral arterial level. In contrast to V/Q scanning, CTPA provides detailed visualization of the lung parenchyma, which can detect peripheral pulmonary infarctions and alternative diagnoses. When required, the CTPA examination can be extended to include the iliac veins, providing a detailed view with a single contrast exposure. CTPA has excellent sensitivity and specificity for diagnosis of lobar and segmental PE. Diagnostic accuracy is lower at the subsegmental level, and results should be interpreted in the context of clinical probability, proximal lower extremity ultrasound results, and D-dimer level. A simplified algorithmic approach to diagnosis of PE is provided (Figure 2). CTPA use is limited by costs, exposure to potentially nephrotoxic contrast dye, and chest radiation. It should be avoided in younger women because of the associated increased risk of breast cancer.

Pulmonary Angiography

Formerly the gold standard for the diagnosis of PE, pulmonary angiography is an invasive procedure that has been replaced by CTPA and is now very rarely performed.

Magnetic Resonance Angiography

Pulmonary contrast-enhanced magnetic resonance angiography (CE-MRA) is emerging as a useful alternative to CTPA in select patients such as younger females and those with severe iodinated contrast allergy. Currently, CE-MRA has limited availability and usefulness that is dependent on the expertise and experience of the available radiologists.

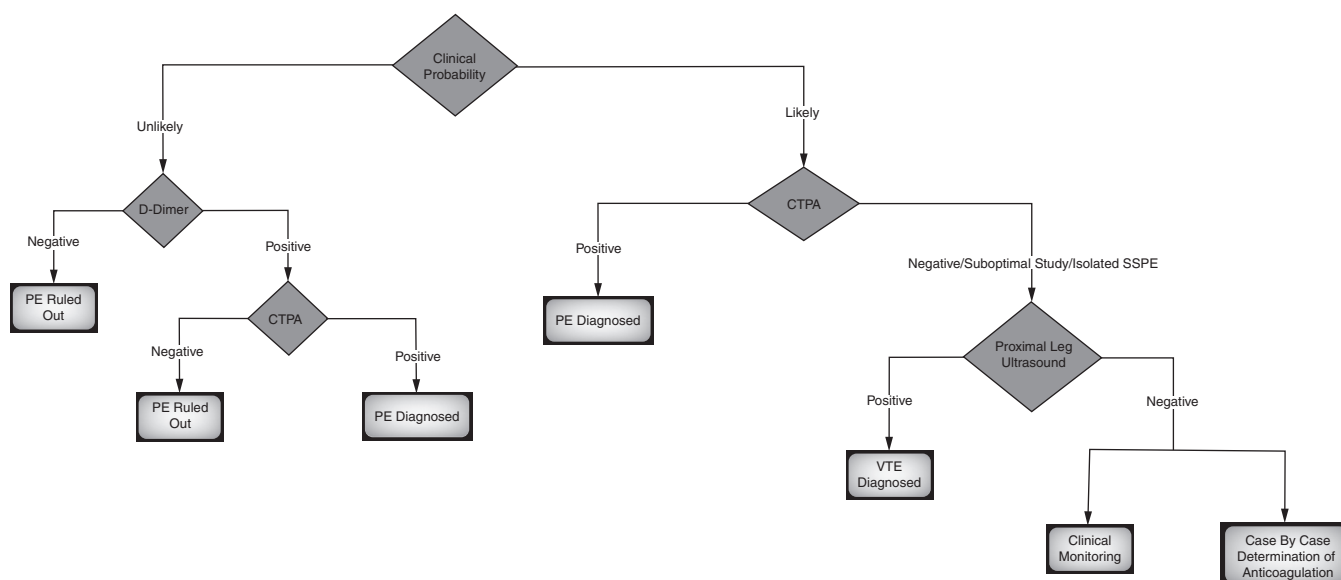

Figure 2 Suggested diagnostic algorithm for diagnosis of pulmonary embolism (PE). CTPA, computed tomography pulmonary angiography.

Diagnosis of Recurrent DVT

The diagnosis of recurrent DVT can be challenging, because signs and symptoms of PTS in the affected extremity can obscure the diagnosis. Clinical assessment of the probability for recurrent DVT is less well standardized than initial episodes; however, many predictive factors are expected to be shared. The clinician should assess for the presence of ongoing clinical risk factors, attempt to discern between chronic and acute signs and symptoms, and consider D-dimer testing. A negative D-dimer test can be used to exclude recurrent DVT, although the accuracy of this approach has not been well studied. If D-dimer testing is positive or has not been done, CUS is performed. The finding of non-compressibility of an ipsilateral femoral or popliteal vein segment, which was previously unaffected, can be considered diagnostic. For diagnosing recurrent DVT in a previously affected vein segment, an increase in thrombus diameter of at least 4 mm on serial CUS in combination with a D-dimer measurement can serve as helpful criteria. This diagnosis requires the expertise of an experienced radiologist with the previous ultrasound available for comparison. In practice, comparison with previous CUS is difficult, given the operator-dependent characteristics of the test. If comparison with the previous examination is equivocal or unavailable, CT or MR venography may be considered. An intraluminal filling defect suggests acute rather than remote thrombosis. Alternatively, a patient with initially equivocal CUS findings can undergo serial repeat examinations to detect DVT extension.

Treatment of Venous Thromboembolism

Anticoagulation Therapy for VTE

Patients with newly diagnosed VTE should be promptly initiated on therapeutic anticoagulation. In the absence of a severely symptomatic lower extremity, high thrombus burden pulmonary embolism with right ventricular dysfunction or significant cardiovascular comorbidity, management is predominantly outpatient. In the presence of PE, a simplified pulmonary embolism severity index (sPESI) is often used to assess appropriateness for outpatient therapy. The sPESI score includes the following factors (1 point each): age >80, history of cancer, chronic cardiopulmonary disease, pulse >110 beats/min, systolic blood pressure <100 mm Hg, arterial oxygen saturation <90%. Patients with a sPESI score ≥ 1 are considered “high risk” and should be considered for initial inpatient management.

Choice of Initial Anticoagulant Therapy

The choice of initial therapy is frequently guided by the clinical scenario. Initial therapy includes unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), fondaparinux (Arixtra), or the direct oral anticoagulants rivaroxaban (Xarelto) or apixaban (Eliquis) (Table 4). Therapeutic UFH is administered intravenously (IV) and demonstrates complex pharmacokinetics (both hepatic and renal clearance) that requires laboratory monitoring of drug effect (aPTT or anti-factor Xa activity). Thus UFH therapy requires hospital admission and has largely been replaced by other

TABLE 4 Drugs for the Treatment of VTE

DRUG	DOSING	ELIMINATION	HALF-LIFE	MONITORING
UFH	80 units/kg IV bolus, then 18 units/kg/hour initial infusion rate	Complex, hepatic/renal metabolism	1–2 hours	APTT Anti-FXa activity
LMWH	Dalteparin (Fragmin): 200 U/kg SQ QD Enoxaparin (Lovenox): 1 mg/kg SQ QD ³	Predominantly renal	3–5 hours	None required*
Fondaparinux (Arixtra)	5.0 mg SQ (<50 kg) 7.5 mg SQ (50–100 kg) 10 mg SQ (>100 kg)	Renal	17–21 hours	None required*
Warfarin (VKA) (Coumadin)	Initially 5 mg po QD, broad range (2.5–10 mg)	Extensive hepatic metabolism, Renal excretion for metabolites	Pharmacokinetics: 20–60 hrs, variable †Pharmacodynamics: 42–72 hours	PT/INR (2.0–3.0)

TABLE 4 Drugs for the Treatment of VTE—cont'd

DRUG	DOSING	ELIMINATION	HALF-LIFE	MONITORING
Dabigatran (Pradaxa)	Parenteral anticoagulant × 5-10 days, then dabigatran 150 mg po BID	>80% renal, 20% biliary Pro-drug	12–17 hours 14–17 hours (elderly)	None required
Rivaroxaban (Xarelto)	15 mg po BID × 21 days; then 20 mg po QD	66% renal, 33% biliary CYP450 substrate	5–9 hours 9–12 hours (elderly)	None required
Apixaban (Eliquis)	10 mg po BID × 7days, then 5 mg po BID	25% renal, 75% biliary CYP450 substrate	8–15 hours	None required
Edoxaban (Savaysa)	Parenteral anticoagulant × 5–10 days, then edoxaban 60 mg po QD (30 mg < 60 kg)	35% renal, 60% biliary	10–14 hours	None required
Betrixaban (Bevyxxa) [‡]	160 mg first dose, then 80 mg po QD for 35–42 days [‡]	11% renal, 85% biliary	19–27 hours	None required

UFH, Unfractionated heparin; LMWH, low-molecular-weight heparin.

*Anti-FXa activity can be used in selected circumstances such as pregnancy and extremes of body weight (BW) (BW <45 kg or >100 kg).

[†]Pharmacodynamics of coagulation protein recovery most relevant to in vivo effect of VKA.

[§]Exceeds dosage recommended by the manufacturer.

options. UFH may still be appropriate for patients experiencing inpatient VTE events, especially if a need for invasive procedures is anticipated (half-life, 1–2 hours). The therapeutic target range for UFH is a 1.5- to 2.5-fold increase over the baseline aPTT or 0.3–0.7 U/mL anti-factor Xa activity. In contrast, LMWH is administered subcutaneously and primarily cleared by the kidneys, resulting in predictable pharmacokinetics. Subcutaneous administration facilitates outpatient treatment and predictable pharmacokinetics allow weight-based dosing without laboratory monitoring. Fondaparinux (synthetic pentasaccharide) is exclusively cleared by the kidneys with a long half-life (17–21 hours) that allows for once-daily, weight-adjusted subcutaneous dosing. Fondaparinux similarly does not require routine laboratory monitoring, but caution is warranted in patients with mild renal insufficiency where drug accumulation may increase bleeding risk. Heparin therapy (UFH, LMWH, or fondaparinux) for VTE is administered for a *minimum* of 5 days followed by transition to longer-term oral anticoagulation with an oral vitamin K antagonist (VKA) or a direct oral anticoagulant (DOAC). Alternatively, rivaroxaban or apixaban can be initiated immediately after VTE diagnosis and bypass the need for heparin therapy (see below).

Historically, vitamin K antagonists (VKA) are the primary oral anticoagulants for the long-term treatment of VTE. Warfarin (Coumadin) is the VKA used almost exclusively in the United States. Warfarin and other VKA inhibit vitamin K-dependent γ -carboxylation of the coagulation zymogens (proenzymes). This post-translational modification is required for both efficient protein secretion and function (membrane binding) of coagulation factors VII, IX, X, and II. Vitamin K is oxidized during γ -carboxylation of these coagulation factors, and warfarin inhibits enzymatic regeneration of the reduced form of vitamin K, creating a functional deficiency. This mechanism of action is the basis for (1) the reversibility of the warfarin by administration of the reduced form of vitamin K, (2) the reduction in warfarin effect by dietary vitamin K, and (3) the enhancement of the warfarin effect by many antibiotics, as bacterial flora are a major source of vitamin K. Warfarin also undergoes extensive metabolism by the liver, which provides multiple opportunities for drug interactions. Thus genetic variation in liver metabolism, variable dietary vitamin K intake, and numerous potential drug interactions generate substantial individual variation in warfarin dose requirements.

Warfarin (2.5- to 10-mg initial dose) is usually started the same day as heparin, overlapped with parenteral heparin therapy for a *minimum* of 5 days and discontinued once a therapeutic warfarin level is obtained on two consecutive days. The warfarin effect is monitored by the international normalized ratio (INR), which

represents a prothrombin time (PT) that has been corrected for specific reagent sensitivity. The target INR for VTE treatment is 2.0 to 3.0. The pharmacodynamic effects of warfarin on the INR are primarily determined by the in vivo half-lives of the relevant coagulation factors. Thus the full effect of a warfarin dose change on the INR is usually not seen for 48 to 72 hours, correlating with the half-life of factors IX, X, and prothrombin (factor II). This delayed effect necessitates overlap with heparin therapy for at least 5 days, or longer if further warfarin dose titration is required to reach a therapeutic INR. Initial warfarin dosing should be conservative (2.5 mg daily) if enhanced sensitivity is expected, including patients that are elderly (>65 years old), low body weight (<45 kg), hypoalbuminemic (<2 g/dL), on antibiotic therapy or have poor oral intake.

The traditional heparin-warfarin regimen has been increasingly supplanted by the use of direct oral anticoagulants (DOAC). DOACs are orally available, low-molecular-weight compounds that directly inhibit the active site of either factor Xa (rivaroxaban [Xarelto], apixaban [Eliquis], edoxaban [Savaysa]), or thrombin (dabigatran [Pradaxa]). In general, these drugs possess predictable pharmacokinetics and relatively short half-lives, allowing fixed once- or twice-daily oral dosing without routine monitoring. Both rivaroxaban and apixaban are approved for initial use after the VTE diagnosis with a more intensive dose regimen that tapers to the standard maintenance dose after 21 days for rivaroxaban or 7 days for apixaban (Table 4). Edoxaban and dabigatran are approved for continued treatment of VTE at their standard maintenance dose after 5 to 10 days of a parenteral anticoagulant (usually LMWH). Differences in clearance mechanisms have implications for clinical usage. For instance, dabigatran is heavily dependent on renal clearance and can accumulate with increased bleeding risk in patients with significant renal insufficiency (CrCl <30 mL/min). In contrast, apixaban dosing is less affected by renal insufficiency but should not be used in patients with significant liver dysfunction or biliary stasis.

Comparison of Warfarin Versus DOACs

DOACs demonstrate equivalent efficacy to the traditional combination of LMWH and warfarin in the treatment of VTE. Advantages of the DOACs include rapid onset of action, predictable dose response, no monitoring requirement, elimination of parenteral therapy (rivaroxaban and apixaban), no significant diet interactions, limited drug interactions, and an overall safety signal equivalent to or better than warfarin. Meta-analysis of DOAC trials demonstrate that fatal bleeding, intracranial hemorrhage (ICH), and clinically relevant, non-major bleeding are reduced with

TABLE 5 Reversal Agents

DRUG	REVERSAL AGENT	DOSING	COMMENTS
Heparin	Protamine*	1–1.5 mg/100 U UFH IV	Hypersensitivity reactions, less effective vs. LMWH
Warfarin	4 factor PCC (Kcentra) FFP Vitamin K	25–50 U/kg IV 2–4 liters 1–10 mg oral or IV	Dose depends on INR, PCC favored over FFP Volume overload, Transf rxn Reversal takes 6–24 hours
Dabigatran	Idarucizumab (Praxbind)	2.5 g IV for 2 doses (within 15 min)	Drug specific monoclonal Fab fragment
Rivaroxaban Apixaban Edoxaban Betrixaban	Andexanet alfa 4 factor PCC†	800 mg IV bolus @ 30 mg/min, then 960 mg infusion @ 8 mg/min 50 U/kg IV	Reverses factor Xa active site inhibitors Andexanet alfa unavailable

*FDA approved for treatment of heparin overdose. Off-label uses: heparin neutralization (adults); intracranial hemorrhage associated with heparin or LMWH; LMWH overdose (adults).

†Evidence for reversal of factor Xa inhibitors by PCC is low quality.

DOACs compared to warfarin. The rate of GI bleeding was similar. Given the potentially life-changing nature of ICH, the lower rate with DOACs is particularly significant. Disadvantages of DOACs include cost, inability to monitor compliance with routine coagulation testing, the impact of renal function on drug clearance, and lack of widely available reversal agents. The relatively short half-lives of DOACs and recent development of reversal agents (Table 5) partially overcomes the reversibility advantage for warfarin. Largely based on safety profile and ease of use, recent guidelines provide a weak recommendation for DOACs over warfarin in patients without cancer.³

Cancer-Associated Thrombosis

VTE associated with cancer accounts for ~20% of all cases and clearly is a heterogeneous patient population. Treatment of cancer-associated thrombosis is problematic in that patients are at increased risk for both VTE recurrence and bleeding complications. In addition to the multiple drug interactions that complicate VKA use in cancer patients, LMWH demonstrates significantly lower rates of recurrent VTE relative to VKA therapy. Thus LMWH for the first 6 months after the event has been the standard recommendation. The role of DOACs in cancer-associated thrombosis continues to evolve. Meta-analysis of subgroups from the large DOAC VTE trials demonstrates no difference in VTE recurrence or major bleeding compared with LMWH for primarily low-risk cancer patients. Subsequent comparison of edoxaban with dalteparin (Fragmin) in a broader population of active cancer patients demonstrated a lower rate of VTE recurrence and higher rate of major bleeding. Ongoing studies will further address the role of DOACs in this setting. Duration of therapy is generally at least 6 months, but may be modified based on disease response, bleeding risk, and prognosis.

Special Considerations in the Acute Management of Venous Thromboembolism (VTE)

Although the vast majority of patients diagnosed with venous thromboembolism (VTE) should be promptly initiated on therapeutic anticoagulation, a limited number of acute presentations

may require a modified approach. These presentations include the following:

Massive Pulmonary Embolism (PE) With Hemodynamic Instability

Patients presenting with hemodynamically unstable PE (SBP < 90 mmHg for 15 minutes, requiring vasopressors or overt shock) are at high risk for right heart failure and death. The focus for these patients should be resuscitation (IV fluids, pressors, oxygenation, and airway control) and rapid confirmation of diagnosis (perfusion scan or CT pulmonary angiography). If highly unstable, then bedside ECHO may be used for a presumptive diagnosis based on right ventricular findings. Prompt thrombolytic therapy (tPA [Activase] 100 mg IV) or consideration of emergency endovascular therapy should be pursued, with the former being more readily available.

Patients who present with worsening right heart failure, pre-resuscitation cardiopulmonary arrest, free-floating thrombus, or high thrombus burden in the absence of systemic hypotension may also be considered for thrombolytic therapy. Many institutions have a pulmonary embolism response team (PERT) to facilitate decision making and institution of therapy. However, for the majority of patients presenting with evidence of right ventricular dysfunction (by ECHO or CT) without systemic hypotension (i.e., “sub-massive” or intermediate risk PE), the use of thrombolytic therapy remains controversial. This controversy stems from both heterogeneity in patient selection for these trials and the inability to demonstrate long-term benefits over anticoagulation alone.

Broader use of thrombolytic therapy is primarily limited by the increased risk of major bleeding (9.2%) versus anticoagulation (3.4%), which includes a 1.5% incidence of intracranial bleeding. Contraindications include previous intracranial hemorrhage, known intracranial vascular lesion or malignancy, ischemic stroke within 3 months, suspected aortic dissection, active bleeding or bleeding diathesis, and closed head/facial trauma within 3 months. Relative contraindications include poorly controlled hypertension, recent surgery (14 days), and pregnancy. The use of combined modalities (catheter-based fibrinolysis, pharmaco-mechanical clot dissolution) and lower doses of tissue plasminogen activator (tPA 50 mg IV) may modulate the bleeding risk, but currently broader application of thrombolytic therapy remain controversial.

Extensive Proximal Vein Lower Extremity Thrombosis

Proximal iliac vein thrombosis is often highly symptomatic and may result in severe postthrombotic syndrome (PTS). Rarely, compromise of the arterial supply may occur, as described for phlegmasia alba dolens (“milk leg”) and phlegmasia cerulea dolens. The former describes a swollen, white extremity with early compromise of arterial flow secondary to extensive DVT. The latter is an advanced stage characterized by severe swelling, cyanosis, and blue discoloration of the extremity—a precursor of venous gangrene. These entities are emergencies that require prompt anticoagulation, elevation, and consideration of endovascular intervention. The presence of bilateral proximal iliac vein thrombosis should prompt evaluation for IVC thrombus or agenesis, particularly in younger patients. Catheter-directed thrombolysis and endovascular approaches have been pursued in proximal iliofemoral venous thrombosis in an attempt to reduce the risk of severe PTS. Recent studies have been unable to demonstrate that the desired benefit in PTS reduction outweighs the increased risk of bleeding. Thus the routine use of thrombolytic therapy for proximal iliofemoral venous thrombosis cannot be recommended, and patient selection for this approach remains controversial.

Spontaneous Proximal Upper Extremity Thrombosis

The majority of upper extremity DVT is related to intravenous catheters, malignancy, or thrombophilia. Spontaneous upper extremity DVT in the absence of provocation is rare. This entity (Paget-Schroetter syndrome) tends to occur in a younger, often adolescent population with a recent history of exercise or strenuous

activity usually involving the dominant upper extremity. This presentation in the absence of usual VTE risk factors should prompt an evaluation for venous thoracic outlet syndrome (TOS). Because of the younger age of these patients and significant disability associated with PTS in the upper extremity (particularly the dominant hand), the initial approach has included thrombolysis (within 14 days), anticoagulation, and evaluation for venous TOS. However, no rigorous comparison of these approaches or combinations of approaches has been undertaken. If evidence for venous TOS is demonstrated, first rib resection on the affected side is often recommended. In the absence of a predisposing anatomical abnormality, an underlying thrombophilic state or occult malignancy should be considered.

VTE Presenting With Paradoxical Embolism

The occurrence of arterial embolism, most commonly cryptogenic stroke, in the presence of DVT and a right-to-left shunt (i.e., patent foramen ovale or PFO) suggests the diagnosis of paradoxical embolus. Standard anticoagulation for VTE is recommended, followed by PFO closure when complete. If indefinite anticoagulation is planned, the additional benefit of PFO closure is unclear.

Acute Venous Thromboembolism With Contraindication to Anticoagulation

Occasional patients diagnosed with acute VTE will have an absolute contraindication to anticoagulation. Placement of a temporary IVC filter may be considered in these patients to provide short-term protection from PE. However, the vast majority of contraindications to anticoagulation are temporary and definitive anticoagulation therapy should be instituted as soon as feasible. IVC filter use is associated with increased risk of lower extremity DVT. Evaluation for IVC filter removal should be planned within 3 to 6 months, depending on the clinical scenario.

Isolated Subsegmental Pulmonary Embolism and Incidental VTE

The enhanced sensitivity of current CT scanners and extensive use of CT angiography has led to an increased diagnosis of isolated subsegmental PE. Treatment of isolated subsegmental PE (where proximal DVT has been excluded) is controversial as the natural history and benefit of anticoagulation is unclear. If an isolated subsegmental defect occurs in a clinical context that is high risk for recurrent VTE (e.g., malignancy), therapeutic anticoagulation is preferred. Alternatively, for an isolated subsegmental PE occurring in a patient that is otherwise low risk for VTE recurrence, clinical surveillance is preferred. Based on the frequency of diagnostic and staging CT scans in cancer patients, an incidental diagnosis of VTE is not an uncommon finding. Although outcome data are limited in this setting, incidental VTE appears to have similar effects on mortality and risk of VTE recurrence. Because the outcomes for incidental and symptomatic VTE in cancer patients appear similar, most cases of incidental VTE should be treated similar to symptomatic VTE.

Special Circumstances for Anticoagulant Monitoring

The predictable dose responses for LMWH, fondaparinux and the DOACs allow use without monitoring. However, select circumstances exist where monitoring may be desirable. LMWH is the preferred anticoagulant in pregnancy, but weight-based dosing may not be as accurate during pregnancy. Periodic confirmation of therapeutic target levels (0.5–1.2 U/mL anti-factor Xa activity) 4 hours after subcutaneous injection is often recommended. Likewise, the accuracy of weight-based LMWH dosing with a body weight <45 kg or >100 kg is not extensively validated. Confirmation of therapeutic peak levels in these individuals is recommended. Similarly, a need for DOAC drug levels may arise when assessing compliance, bleeding with potential drug overdose, or for an emergent procedure. DOACs directed against factor Xa (rivaroxaban, apixaban, and edoxaban) are monitored with an anti-factor Xa activity assay using a drug-specific standard curve. Significant dabigatran drug effect is excluded with a normal thrombin time.

Alternatively, dabigatran drug effect can be detected by prolongation of the APTT or more specialized coagulation tests. The INR is not sensitive to dabigatran.

Reversal Agents

Acute reversal of anticoagulation may be required for drug overdose with clinically significant bleeding or emergent procedures. If the situation is non-emergent, holding warfarin (4–5 days depending on INR) or DOACs (2–3 days depending on renal function) is preferable. If urgent reversal is required, specific agents exist for UFH, warfarin, and, more recently, DOACs (Table 5). Although UFH overdose may be reversed with dose-adjusted protamine, the short half-life of UFH and potential toxicity of protamine often mitigate against use. Protamine is most commonly used to reverse high-dose UFH after cardiopulmonary bypass. LMWH overdose may also be treated with protamine, but significantly less effectively. Warfarin is fully reversed by administration of 4 factor prothrombin complex concentrate (PCC) or fresh frozen plasma (FFP). The 4-factor PCC dose is modified based on the INR and favored over FFP, which may be complicated by volume overload and transfusion reactions. Immediate reversal with PCC or FFP should be followed with 5 to 10 vitamin K by the oral or IV route. Vitamin K takes 6 to 24 hours to act but is critical to maintaining anticoagulant reversal because the PCC or FFP effect will wane based on plasma half-life of the coagulation factors. Notably, high doses of vitamin K can result in relative warfarin resistance for the ensuing 1 to 2 weeks. Lower doses of vitamin K (1–2 mg) may be appropriate for less serious bleeding where early reinitiation of warfarin is anticipated. Highly specific agents for the reversal of DOACs are now available. Dabigatran is rapidly reversed by administration of idarucizumab (Praxbind), a humanized monoclonal Fab fragment that neutralizes the parent drug and major metabolites. DOACs targeting factor Xa (rivaroxaban, apixaban, edoxaban, betrixaban [Bevyxxa]) may be rapidly reversed with Andexanet alfa (Andexxa), a truncated, inactive form of recombinant factor Xa that acts as a decoy for small molecules targeting the factor Xa active site. Andexanet alfa is approved only for patients treated with rivaroxaban and apixaban. Given the relatively short half-lives of the DOACs and high costs of pharmacologic reversal, these agents should be reserved for truly emergent procedures or clinically significant anticoagulant-related bleeding.

Duration of Anticoagulation

Standard treatment for a new episode of DVT or PE has traditionally been 3 to 6 months of therapeutic anticoagulation. The recommended duration of anticoagulation for VTE requires individualized analysis of the clinical presentation and patient specific factors that weigh both recurrence and bleeding risk (Figure 3).

Clinical Presentation

Recurrence risk varies widely based on clinical presentation (see Natural History). The key distinction is between events that occur in the absence (unprovoked) versus the presence (provoked) of established VTE risk factors (Table 1). The majority of cases with clinical risk factors present may be categorized as transient/reversible (e.g., surgery, estrogen) or permanent/non-reversible (e.g., dense hemiplegia secondary to stroke). Surgery is a major transient risk factor for VTE with a low recurrence risk (3% at 5 years). Three months of anticoagulation is sufficient for this population, while shorter durations are associated with increased risk of recurrence. Estrogen-related events have a similarly low risk of recurrence if re-exposure is avoided. A second category of VTE events occurs in association with a nonsurgical transient risk factor (leg injury, significant medical illness, travel-associated) and demonstrates an intermediate recurrence risk (15% at 5 years). This subgroup is substantially more heterogeneous than the surgical group, with a variety of triggering factors and broader recurrence risk estimates. VTE events associated with nonreversible clinical risk factors may require extended anticoagulation with periodic reassessment of risks and benefits. Unprovoked VTE demonstrates a high risk of recurrence (30% at 5 years) and, in many respects,

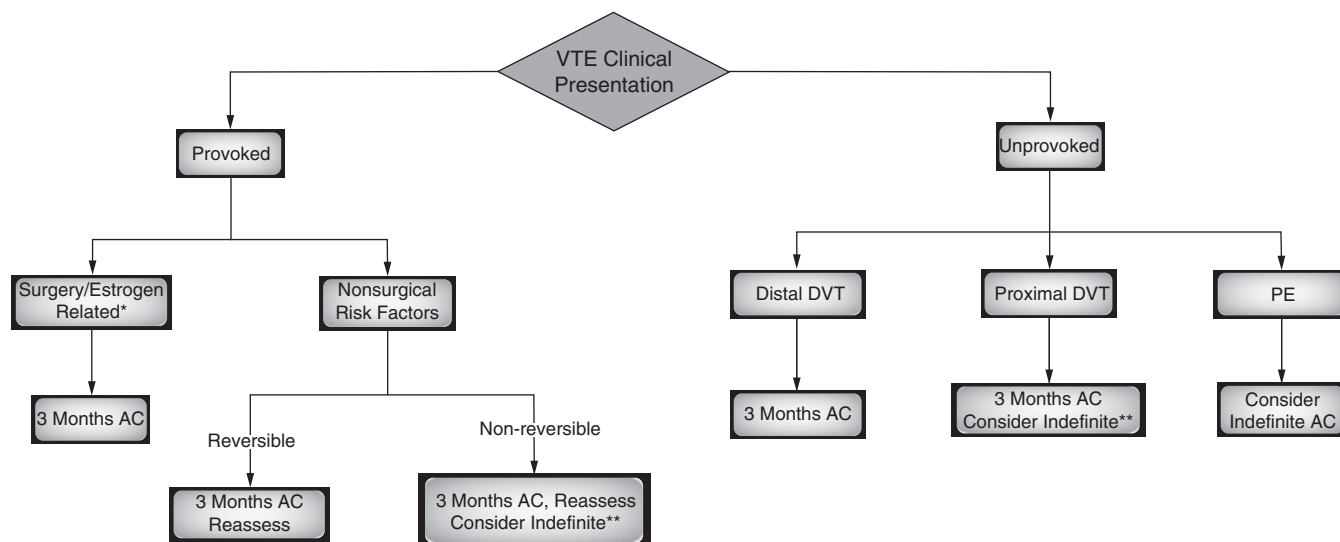

Figure 3 Suggested algorithm for treatment of VTE. AC = anticoagulation. *Estrogen-related includes oral contraceptives, hormone replacement therapy, pregnancy and puerperium. **Indefinite anticoagulation includes reduced dose DOAC options after initial 3 months therapeutic AC.

behaves as a chronic disease. Finally, patients with an underlying malignancy represent ~20% of VTE cases but are usually excluded from natural history studies. Cancer-associated thrombosis demonstrates a 15% annualized recurrence risk with longer-term risk more difficult to estimate based on competing mortality from the underlying cancer. These patients have concomitant increased bleeding risk, complicating the risk-benefit analysis for anticoagulation.

Thrombus Site

Thrombus location significantly influences recurrence risk, with more proximal events demonstrating higher rates of recurrence. Patients with isolated distal or calf vein DVT are half as likely to have recurrent events compared to proximal DVT or PE. Patients presenting with proximal DVT have similar recurrence risk to patients with PE. However, patients initially presenting with PE are substantially more likely to have a PE recurrence relative to patients presenting with DVT only. This finding takes on particular importance when one considers the cause specific mortality rate associated with PE is greater than 10%. Thus patients presenting with unprovoked PE deserve particular attention with regard to consideration of indefinite anticoagulation.

Standard Versus Indefinite Anticoagulation

Clinical presentation categorizes patients with regard to recurrence risk, which is critical to the decision between standard (3 months) and indefinite anticoagulation (Figure 3). This decision is also influenced by bleeding risk and requires clinical judgment. As above, VTE associated with surgical or estrogen-related provoking factors and distal DVT (provoked or unprovoked) should be treated with therapeutic anticoagulation for 3 months. Conversely, most patients with unprovoked proximal DVT or PE should be considered for indefinite therapy based on their substantial recurrence risk, unless they also have high bleeding risk. There is little rationale for arbitrary extended periods of anticoagulation beyond the standard 3 to 6 months, unless awaiting resolution of a risk factor (e.g., extended immobilization). Prolongation of anticoagulation beyond 6 months in patients with unprovoked VTE delays but clearly does not prevent recurrence. A number of strategies, including postanticoagulation D-dimer testing (3–5 weeks) and risk stratification models, have attempted to identify patients with unprovoked VTE for which anticoagulation may be safely stopped. Post-anticoagulation D-dimer testing is the most established strategy, further stratifying these patients into high (8.8%) and low (3.0%) first-year recurrence rates. Conversely, the presence of persistent or multiple antiphospholipid antibodies increases

recurrence risk (1.8- to 4.5-fold) for patients presenting with unprovoked VTE. Alternative approaches to risk reduction in unprovoked VTE include indefinite anticoagulation with reduced intensity DOACs or daily ASA. ASA reduces recurrence risk by ~1/3 in unprovoked VTE but is inferior to reduced dose rivaroxaban and apixaban.

VTE associated with nonsurgical risk factors is more problematic with regard to definitive assessment of recurrence risk. Patients who suffer VTE with minor provocations may have a recurrence rate that approaches unprovoked VTE. These patients should be treated for at least 3 months and reassessed. Clinical factors that may impact a decision for indefinite anticoagulation include underlying cardiopulmonary disease (decreased ability to tolerate recurrence), ongoing inflammation (inflammatory bowel disease, autoimmune disease, chronic infections), prolonged immobilization (stroke), and male sex. For patients with a prolonged but ultimately reversible risk factor (i.e., stroke immobility improving with physical therapy), prolongation of anticoagulation until resolution of the underlying risk factor is reasonable. Similarly, travel-associated thrombosis may be a recurring risk that requires an intermittent prophylaxis plan. Bleeding risk assessment is important to decisions regarding recommended duration of therapy. Major risk factors for bleeding on anticoagulation include: advanced age, previous bleeding history, cancer, renal or liver failure, previous stroke, diabetes mellitus, nonsteroidal inflammatory drugs or antiplatelet therapy, comorbidity and reduced functional capacity, recent surgery, frequent falls, and alcohol (Table 6). Additional risk assessment tools (e.g., HAS-BLED score) exist, primarily validated for warfarin therapy.

Clinical Decision Making

Particularly for clinical situations with modest evidence, shared decision making between physician and patient is desirable in determining the duration of anticoagulant therapy. Medical comorbidities affecting bleeding or fall risk in the elderly, patient anxiety about recurrent VTE events, and occupational/lifestyle risks for trauma may substantially impact anticoagulation decisions. Family history should be obtained with particular attention to first-degree relatives affected by VTE, including unprovoked events and age of presentation. Questions regarding the underlying cause for a VTE event often drive requests for thrombophilia evaluations. These requests generally fail to acknowledge the complex, multigenic basis for VTE and rarely contribute to clinical decision making (see “Genetics of Venous Thromboembolism”). The clinical presentation and family history are substantially more useful than identification of minor

TABLE 6 Risk Factors for Bleeding With Anticoagulant Therapy and Estimated Risk of Major Bleeding in Low-, Moderate-, and High-Risk Categories

Risk Factors

Age >65 y
 Age >75 y
 Previous bleeding
 Cancer
 Metastatic cancer
 Renal failure
 Liver failure
 Thrombocytopenia
 Previous stroke
 Diabetes
 Anaemia
 Antiplatelet therapy
 Poor anticoagulant control
 Comorbidity and reduced functional capacity
 Recent surgery
 Frequent falls
 Alcohol abuse
 Nonsteroidal antiinflammatory drug

Categorization of Risk of Bleeding

	ESTIMATED ABSOLUTE RISK OF MAJOR BLEEDING		
	LOW RISK (0 RISK FACTORS)	MODERATE RISK (1 RISK FACTOR)	HIGH RISK (≥2 RISK FACTORS)
Anticoagulation 0–3 mo			
Baseline risk (%)	0.6	1.2	4.8
Increased risk (%)	1.0	2.0	8.0
Total risk (%)	1.6	3.2	12.8
Anticoagulation after first 3 mo			
Baseline risk (%/y)	0.3	0.6	≥2.5
Increased risk (%/y)	0.5	1.0	≥4.0
Total risk (%/y)	0.8	1.6	≥6.5

Data from the 9th Edition of the Antithrombotic Guideline (AT9).

thrombophilia traits, which are poor predictors of VTE recurrence. Finally, when a decision is made to pursue indefinite anticoagulation, periodic reassessment of this decision is important. The risk-to-benefit ratio of anticoagulation may change as the patient's medical history evolves. The hematology consultant serves an important role in facilitating difficult anticoagulation decisions.

Prevention of Venous Thromboembolism

About 60% of VTE events are associated with recent hospitalization or surgery, and up to 70% of these cases are preventable. However, less than half of hospitalized patients receive appropriate prophylactic measures. Given the significant morbidity and mortality associated with VTE, primary prophylaxis strategies in

high-risk situations are of great medical importance and may provide a cost savings. Risk stratification of patients based on surgery or medical illness, patient characteristics (previous VTE, active cancer, duration of immobility, etc.), and bleeding risk impact recommendations for pharmacologic and mechanical prophylaxis. Pharmacologic agents include LMWH, fondaparinux, low-dose UFH, VKA, and DOACs. The focus in this section is primarily on heparin and DOACs given the available evidence. Mechanical prophylaxis includes graduated compression stockings (GCS) that are >15 mm Hg at the ankle or intermittent pneumatic compression devices (IPCs). IPCs enhance lower extremity deep vein blood flow and may increase fibrinolytic activity. These modalities can be used alone or in combination for patients with high bleeding risk who cannot use pharmacologic prophylaxis. IPCs are considered more effective than GCS alone, particularly after orthopedic surgery.

General Surgery

For general surgery patients, well-established risk assessment tools such as the Caprini or Rogers scores stratify patients by VTE risk to identify those who would benefit from pharmacologic prophylaxis. In general, if the risk of VTE is moderate to high and bleeding risk is low, pharmacologic prophylaxis with LMWH or low-dose UFH should be given. If the bleeding risk is high, intermittent pneumatic compression with or without GCS should be used. Ideally, the minimal duration of prophylaxis is 5 to 10 days but varies widely based on duration of bed rest, inpatient stay, and comorbid conditions. In patients with active cancer undergoing abdominopelvic surgery, prophylaxis should be extended to 4 weeks after surgery.

Orthopedic Surgery

Orthopedic procedures are associated with high risk of VTE, especially those involving the lower extremities and pelvic region. For patients undergoing total hip or total knee arthroplasty, pharmacologic prophylaxis using LMWH, UFH, DOACs, or adjusted-dose warfarin should be used if no contraindication exists. LMWH is quite effective and safe with the benefit of long-term experience with these agents. Low-dose DOACs have shown comparable efficacy to enoxaparin in this population with a similar low absolute risk of bleeding. Low-dose apixaban (2.5 mg twice daily), rivaroxaban (10 mg daily), and dabigatran (150 mg daily) appear safer than higher doses. Prophylaxis should continue at least 10 to 14 days, and prolongation up to a month should be considered for major orthopedic surgery. Low-dose aspirin has been shown to be effective for extended prophylaxis after initial acute phase of therapy (~5 days) with standard anticoagulant in patients undergoing total hip or knee arthroplasty; however, anticoagulants are generally favored for high-risk patients. IPCs should be used during the inpatient stay in addition to pharmacologic prophylaxis. If bleeding risk is high, IPCs should be used until pharmacologic agents can be safely administered. For arthroscopic procedures of the knee and other low-risk procedures, prophylaxis is generally not indicated unless other risk factors exist. A summary of available agents and recommendations for prophylaxis is provided (Table 7).

Acute Medical Illness

For hospitalized patients with medical illnesses, the risk of VTE is ~8 fold higher than the general population. Patients expected to be hospitalized with reduced mobility >3 days, a previous history of VTE, active infection or malignancy, recent surgery or trauma, heart failure or respiratory failure should be considered for prophylaxis. The Padua score is a prospectively validated risk assessment model that stratifies patients into groups with high (~11%) or low (0.3%) incidence of VTE. Current prophylaxis options for medical patients include LMWH, low-dose UFH, and fondaparinux. When bleeding risk is considered moderate to high, mechanical prophylaxis using IPCs or GCS should be used until it is safe to add anticoagulants. For low-risk patients admitted for short duration or remaining ambulatory, withholding prophylaxis may be appropriate. Clinical context and bleeding risk assessment should also impact these decisions.

TABLE 7 Risk Factor Stratification and Prophylaxis Options

RISK STRATIFICATION	RECOMMENDED PROPHYLAXIS	DURATION
Low Risk		
Same-day surgery Medical illness in a fully mobile patient	Early mobilization	-
Moderate Risk		
Most general surgery procedures	LMWH UFH IPC/GCS with or without pharmacologic prophylaxis as appropriate	5–14 days
Most acute medical illnesses	LMWH UFH Betrixaban [†]	Duration of inpatient stay Extended duration beyond hospitalization may be appropriate for very-high-risk patients in whom bleeding risk is low
High Risk		
Hip or knee replacement surgery	LMWH UFH Fondaparinux Rivaroxaban Apixaban Dabigatran* Adjusted dose Warfarin	At least 10–14 days Extended duration up to 4 weeks preferred ASA may be used subsequently for extended duration of therapy
General surgery with active cancer, previous VTE	LMWH** UFH Adjusted dose Warfarin	Extended duration (4 weeks) for abdominopelvic surgeries in cancer patients
Major Trauma, Spinal cord injury	IPC with or without GCS, use pharmacologic prophylaxis when appropriate	

Abbreviations: DVT: deep venous thrombosis; GC: graduated compression; IPC: intermittent pneumatic compression; LMWH: low-molecular-weight heparin; UFH: unfractionated heparin; VTE: venous thromboembolism.

[†]FDA approved for patients hospitalized for acute medical illness at high risk of VTE

*FDA approved for VTE prevention after hip replacement surgery

**Off-label use in cancer patients

^{††}Usually started postoperatively and adjusted to achieve an international normalized ratio of 2.0–3.0

Although pharmacologic prophylaxis is typically limited to the acute illness during the inpatient stay, analysis of population-based data suggests that ~75% of VTE events occur well after discharge, at a median of almost 3 weeks. Furthermore, increased compliance with inpatient prophylaxis over time has not resulted in the expected decrease in the rate of VTE. The effect of extended DOAC prophylaxis (35–42 days) has been examined in medical patients for apixaban, rivaroxaban, and betrixaban. Reduced-dose apixaban and rivaroxaban demonstrated similar VTE prevention to standard enoxaparin prophylaxis but increased bleeding events. Evaluation of betrixaban in a select patient group (elevated D-dimer and elderly) demonstrated modestly better VTE prevention relative to enoxaparin, with an increase in nonmajor but not major bleeding. Extended prophylaxis is an area of ongoing investigation with

unresolved issues that include appropriate patient selection and discerning the impact of specific anticoagulants versus prophylaxis duration on outcomes.

VIRAL AND MYCOPLASMAL PNEUMONIAS

Method of

Burke A. Cunha, MD; and Cheston B. Cunha, MD

CURRENT DIAGNOSIS

Influenza (human, avian, swine)

- Mild influenza A or B presents acutely with headache, fever, sore throat, plus/minus rhinorrhea.
- Severe influenza A presents with an acute onset (patients often able to name the hour the influenza began) and rapidly become bed bound.
- Headache, myalgias, and prostration may be severe.
- With swine influenza, gastrointestinal symptoms (e.g., nausea/vomiting or diarrhea) may be prominent.
- Auscultation of the lungs is quiet, disproportionate to the degree of respiratory distress. Influenza is an interstitial process and not alveolar, which explains the absence of rales.
- With severe influenza, patients rapidly become hypoxemic. Hypoxemia is accompanied by an A-a gradient >35, which indicates a interstitial oxygen diffusing defect.
- Severe tracheobronchitis is common and manifested by hemoptysis.
- Relative lymphopenia with monocytosis occurs early followed by thrombocytopenia and later leukopenia. Low titer elevations of cold agglutinins are not infrequent ($\geq 1:18$).
- Patients may have chest pain exacerbated by breathing mimicking pleuritic chest pain. This is the result of direct intracostal muscle involvement with the influenza virus, which results in myositis and pain on inspiration.
- The chest radiograph in early influenza, in mild to moderate cases, is normal or near normal, with minimal, if any, increase in interstitial markings. The chest radiograph in fulminant cases shows symmetrical bilateral patchy infiltrates without pleural effusion in 48 hours.

TABLE 7 Risk Factor Stratification and Prophylaxis Options

RISK STRATIFICATION	RECOMMENDED PROPHYLAXIS	DURATION
Low Risk		
Same-day surgery Medical illness in a fully mobile patient	Early mobilization	-
Moderate Risk

VIRAL AND MYCOPLASMAL PNEUMONIAS

Method of

Burke A. Cunha, MD; and Cheston B. Cunha, MD

CURRENT DIAGNOSIS

Influenza (human, avian, swine)

- Mild influenza A or B presents acutely with headache, fever, sore throat, plus/minus rhinorrhea.
- Severe influenza A presents with an acute onset (patients often able to name the hour the influenza began) and rapidly become bed bound.
- Headache, myalgias, and prostration may be severe.
- With swine influenza, gastrointestinal symptoms (e.g., nausea/vomiting or diarrhea) may be prominent.
- Auscultation of the lungs is quiet, disproportionate to the degree of respiratory distress. Influenza is an interstitial process and not alveolar, which explains the absence of rales.
- With severe influenza, patients rapidly become hypoxemic. Hypoxemia is accompanied by an A-a gradient >35, which indicates a interstitial oxygen diffusing defect.
- Severe tracheobronchitis is common and manifested by hemoptysis.
- Relative lymphopenia with monocytosis occurs early followed by thrombocytopenia and later leukopenia. Low titer elevations of cold agglutinins are not infrequent ($\geq 1:18$).
- Patients may have chest pain exacerbated by breathing mimicking pleuritic chest pain. This is the result of direct intracostal muscle involvement with the influenza virus, which results in myositis and pain on inspiration.
- The chest radiograph in early influenza, in mild to moderate cases, is normal or near normal, with minimal, if any, increase in interstitial markings. The chest radiograph in fulminant cases shows symmetrical bilateral patchy infiltrates without pleural effusion in 48 hours.

- Severe influenza A is accompanied by severe hypoxemia cyanosis, and may be followed by an early fatal outcome.
- Influenza pneumonia most often presents alone without bacterial superinfection, but bacterial infection may accompany (MSSA/CA-MRSA) or follow influenza (*S. pneumoniae* or *H. influenzae*).
- Purulent sputum with influenza indicates concurrent bacterial pneumonia usually caused by *S. aureus* (MSSA/MRSA). Bacterial pneumonia following influenza (after 1–2 weeks), is suggested by leukocytosis, focal or segmental pulmonary infiltrates, and purulent sputum; the pathogens are not *S. aureus*, but most commonly are *S. pneumoniae* or *H. influenzae*.
- A laboratory diagnosis may be made by multiplex PCR of respiratory secretions.

Mycoplasma pneumoniae

- In a patient with CAP and a dry nonproductive cough, without severe headache or myalgias, the most likely diagnosis is *M. pneumoniae*. *M. pneumoniae* CAP is commonly accompanied by nonexudative pharyngitis and/or loose stools or watery diarrhea.
- The temperature is usually less than 102°F (38.9°C) and is not accompanied by frank rigors or pleuritic chest pain.
- Relative bradycardia and elevations in the serum transaminases are not features of *M. pneumoniae* CAP.
- Respiratory viruses are often associated with mild elevations of cold agglutinins ($\leq 1:16$) but *M. pneumoniae* is the only pathogen causing CAP associated with highly elevated cold agglutinin titers ($\geq 1:64$). Elevated cold agglutinin titers occur in up to 75% of patients with *M. pneumoniae*, and occur early and transiently.
- In a patient with CAP, elevated cold agglutinin titers ($>1:8$) effectively rule out the typical pathogens, as well as *Legionella* species and *C. pneumoniae*.
- Elevated *M. pneumoniae* ELISA IgG titers indicate past exposure/infection and not current infection or co-infection with another pathogen.
- In the absence of an antecedent respiratory tract infection (e.g., nonexudative pharyngitis, otitis, etc., in the preceding 3 months), the presence of an increased *M. pneumoniae* ELISA IgM titer is diagnostic of acute infection.

- Therapy is equally efficacious with macrolides, doxycycline (Vibramycin), or a respiratory quinolone intravenously, orally, or in combination for 1 to 2 weeks.
- The mode of administration is determined by the severity of the CAP and the setting. Outpatients are usually treated orally. Patients hospitalized with severe CAP are initially treated intravenously and then changed to an oral agent.
- Macrolide resistance to *M. pneumoniae* has been described in children and reported in adults.

Influenza pneumonia is the most important cause of viral pneumonia in adults. Influenza A is the predominant type of influenza found in adults, and influenza B is more common in children. Influenza A has the potential for severe disease, occurs seasonally, and is the predominant type involved in influenza pandemics. *Mycoplasma pneumoniae* community-acquired pneumonia (CAP) was first recognized decades ago as distinctive from bacterial and viral pneumonias. It was originally described by Eaton as “Eaton agent” pneumonia caused by a pleuropneumonia-like organism (PPLO), later shown to be caused by *M. pneumoniae*. *M. pneumoniae* is a common cause of pneumonia in all age groups, but the peak incidence of *M. pneumoniae* CAP is in young adults. *M. pneumoniae* CAP is a common cause of ambulatory CAP.

The term *atypical pneumonia* was first applied to viral pneumonias because the clinical laboratory and radiologic findings were different from those caused by typical bacterial pulmonary pathogens. In influenza pneumonia, the clinical findings are confined to the trachea, bronchi, lung parenchyma, and central nervous system. *M. pneumoniae* CAP is a systemic infection with a pulmonary component. Over the years, atypical pneumonia has come to refer to pneumonia caused by systemic nonviral/nonbacterial pathogen agents that have a pulmonary component. Viral pneumonias are no longer considered atypical pneumonias. Atypical pneumonias may be divided into nonzoonotic and zoonotic atypical CAPs. Nonzoonotic CAPs are most commonly caused by *M. pneumoniae*, *Chlamydia pneumoniae*, or *Legionella* species, whereas the three most common zoonotic atypical pneumonias are caused by *Chlamydia psittaci* (psittacosis), *Francisella tularensis* (tularemia), or *Coxiella burnetii* (Q fever). All of the atypical pneumonias are distinct clinical entities that may be differentiated on the basis of their characteristic pattern of extrapulmonary organ involvement. Although some viruses may occasionally have extrapulmonary manifestations (i.e., influenza, adenovirus with viral pneumonias), the primary clinical features are confined to the lungs. *M. pneumoniae* is a critical cause of nonzoonotic atypical CAP, particularly in the ambulatory setting. *M. pneumoniae* CAP may be severe in patients with impaired host defenses or those with severe, preexisting cardiopulmonary disease.

Influenza (Human, Avian, and Swine)

Viral influenza pneumonia affects children and adults. Influenza B is the primary type causing mild influenza in children and adults. Influenza A is primarily an infection of adults that may be mild to severe. Influenza A has the potential for pandemic spread (e.g., swine influenza [H₁N₁]).

Influenza occurs during the winter months, usually peaking in February. Influenza is spread by aerosolized droplet infection from person to person and via fomites. Influenza A is classified into subtypes based on hemagglutinin (H) and neuramidase (N) surface proteins. An important characteristic of influenza A virus is antigenic drift, which refers to minor changes in surface protein shift in the neuramidase or hemagglutinin receptors. With influenza A, these surface receptor proteins are important in cellular adherence of the influenza virus and spread of influenza from respiratory epithelial cells. The vaccine for the flu season most often includes the influenza hemagglutinin and neuramidase types seen at the end of the preceding year's season. Prevention of attachment and spread of the virus is helpful to controlling the spread of influenza;

CURRENT THERAPY

Viral Influenza

- The aim of therapy is to inhibit the influenza virus and prevent its attachment/spread to uninfected respiratory epithelial cells.
- The neuramidase inhibitors shorten the course of influenza by 1 to 2 days and have antiviral activity. These agents are active against both influenza A and B.
- Most strains of human and avian, but not swine flu strains, are resistant to amantadine (Symmetrel) or rimantadine (Flumadine).
- Amantadine and rimantadine may have an important therapeutic effect in severe influenza A by increasing distal airway dilation and increasing oxygen action.
- Peramivir (Rapivab) may be useful in those unable to take oral neuraminase inhibitors.

Mycoplasma pneumoniae

- The agents active against *M. pneumoniae* are macrolides, tetracyclines, quinolones, and ketolides. β -Lactam antibiotics are not active against *M. pneumoniae* because the organisms do not contain a bacterial cell wall.
- Goals of therapy of *M. pneumoniae* CAP are to eradicate the infection, decrease the shedding of *Mycoplasma* in respiratory secretions posttherapy, and to prevent post-treatment asthma.

vaccine protection conferred by specific antibody response to influenza A is highly protective (approximately 80% in noncompromised hosts).

During the years when influenza B has been prevalent, vaccines for the subsequent year contain an influenza B component.

Clinical manifestations of influenza A in adults varies considerably from mild to fatal infection. Mild infection is usually manifested as an acute febrile illness characterized by headache and myalgias with dry unproductive cough and rhinorrhea. Mild influenza may be due to influenza A or B and usually resolves in a few days without complications in normal hosts who have good cardiopulmonary function.

Severe influenza A (human, avian, swine) occurs in normal healthy adults and may be fatal. The onset of severe influenza A (human, avian, swine) is sudden, and the patient often recalls the exact hour of onset. The patient is febrile with early/extreme prostration rendering the patient bedridden. Fever rapidly rises and may be accompanied by chills. Neck soreness, severe headache, and myalgias are typical. Sore throat, eye pain, conjunctival injection, and hemoptysis are frequently present. Chest pain worsened by deep inspiration is not truly pleuritic but rather reflects influenza A myositis of the intracostal muscles. Shortness of breath is related to the degree of hypoxemia. Severe influenza A causes an oxygen diffusion defect as manifested by an increased A-a gradient (>35). Profound hypoxemia may be accompanied by cyanosis. Hypotension caused by hypoxemia and vascular collapse may follow. The course of fulminant viral influenza A is of short duration.

Physical findings are few in viral influenza (i.e., conjunctival suffusion). Auscultation reveals absolutely quiet lungs because the infectious process is interstitial and not alveolar. Routine blood tests are usually unremarkable except for leukopenia, relative lymphopenia, and thrombocytopenia. Atypical lymphocytes are not present, but low titers of cold agglutinins may be present. Cold agglutinins (if present) have low titers less than or equal to 1:18. In fatal cases, a pale bluelike hue of the skin may be noted, and there may be bleeding from multiple orifices preterminally. The chest radiograph in uncomplicated influenza A is unremarkable or may have minimal perihilar bilateral increased prominence of interstitial markings. In severe influenza A pneumonia, the chest

radiograph shows bilateral symmetrical perihilar infiltrates without pleural effusions in <48 hours.

Patients may die from severe influenza A without superimposed bacterial pneumonia. Most deaths during the 1918–1919 pandemic were young military recruits who died early of influenza A pneumonia without bacterial pneumonia. Influenza may be complicated by bacterial pneumonia. Bacterial pneumonias complicating influenza may occur concurrently at presentation or may occur 1 to 2 weeks after an interval of improvement after the presentation of influenza. Influenza A presenting concurrently with bacterial pneumonia is caused by *Staphylococcus aureus*. In contrast to influenza alone, MSSA/CA-MRSA is manifested by an increase in fever, shaking chills, leukocytosis, purulent sputum, localized rales on auscultation, bacteremia, and focal/segmental infiltrates on chest radiograph that rapidly cavitate in less than 72 hours. Alternately, patients with influenza A may develop a secondary bacterial infection 1 to 2 weeks later. Secondary bacterial pneumonia is less severe and is usually caused by *Streptococcus pneumoniae* or *Haemophilus influenzae*.

Viral influenza-like illnesses (ILIs) most often present during the winter months or influenza season. For clinical and therapeutic purposes, it is important to differentiate influenza A from viral ILIs in hospitalized adults. Some clinical features may point to a specific ILI viral etiology, but a specific viral diagnosis can be made by viral respiratory PCR of nasopharyngeal swab specimens. The only viral ILI likely to mimic influenza A presenting with a fulminant severe viral CAP is MERS-CoA. The mimics of ILIs are presented (Table 1). The main non-viral mimic of influenza A in hospitalized adults is Legionnaire's disease (LD). LD may be different from influenza A and other viral ILIs by CXR findings and characteristic non-specific laboratory tests. With LD CAP, the CXR shows one or more non-focal infiltrates. Fever, usually $>102^{\circ}\text{F}$, is accompanied by relative bradycardia. With LD, the ESR is highly elevated $>90\text{ mm/h}$, the ferritin is highly elevated $>2\text{ xn}$, and the serum phosphorus is decreased early as is serum sodium. Although an elevated CPK and mild transaminitis often accompany LD, these findings are not uncommon in influenza A and some viral ILIs. There are few infections that may mimic the dry, productive cough of *Mycoplasma pneumoniae* CAP. Pertussis is most likely to mimic

TABLE 2 Mimics of *Mycoplasma pneumoniae* in Community Acquired Pneumonia (CAP) Hospitalized Adults

MYCOPLASMA CAP MIMICS	CHEST FILM FEATURES	CLINICAL CLUES
<i>C. pneumoniae</i>	<ul style="list-style-type: none"> • Ill defined lower lobe infiltrates (often ovoid) • No consolidation, cavitation or effusion 	<ul style="list-style-type: none"> • No seasonal predisposition • Hoarseness • Protracted dry cough • Mycoplasma-like illness that doesn't respond to erythromycin • Wheezing (in some) • No diarrhea • No cold agglutinins • Rhinorrhea proceeds dry cough (1–2 weeks)
Pertussis	<ul style="list-style-type: none"> • Perihilar ill defined infiltrates (“shaggy heart” sign) • No consolidation, cavitation or effusions 	<ul style="list-style-type: none"> • Protracted dry cough • Persistent cough (without typical “whoop” of children) • Afebrile or minimal fevers • Marked lymphocytes (>60%) • No cold agglutinins

mycoplasma. Pertussis, unlike mycoplasma, is not accompanied by watery diarrhea. The distinguishing laboratory feature of mycoplasma CAP is elevated cold agglutinins not found with pertussis. The key non-specific laboratory finding in pertussis is marked lymphocytosis (Table 2).

Anti-Influenza Therapy

Therapy of viral influenza is directed at inhibiting viral replication and preventing further infection of respiratory epithelial cells. The neuramidase inhibitors zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir (Rapivab) have anti-influenza A and B activity. Neuramidase inhibitors decrease the severity and duration of influenza symptoms by 1 to 2 days. Current flu strains are resistant to amantadine and rimantadine, but these drugs may still be useful to increase peripheral airway dilatation and oxygenation, which may be of critical importance in severe influenza A with severe hypoxemia. Mild influenza A/B may be treated with neuramidase inhibitors. Mild cases of influenza A should be treated at the onset of the illness. For severe influenza A, neuramidase inhibitors provide optimal anti-influenza therapy (Table 3). For human and avian influenza (H₅N₁), these antiviral drugs may be ineffective, but are effective against swine influenza.

TABLE 3 Adult Anti-Influenza Antivirals

ANTIVIRAL	TREATMENT DOSE	PROPHYLACTIC DOSE
Mild Influenza A/B		
Zanamivir (Relenza) [†]	2 inhalations (5 mg per inhalation) q12h × 5 d	2 inhalations (5 mg per inhalation) q24h × 5 d
Influenza A		
Oseltamivir (Tamiflu) [†]	75 mg (PO) q12h × 5 d*	75 mg (PO) q24h × 7 d
Peramivir (Rapivab)	600 mg (IV) over 30 min × 1 d	None

*For avian (H5N1) influenza, 150 mg (PO) q12h may be effective.

[†]Currently most human and avian influenza strains are resistant.

Mycoplasma pneumoniae

M. pneumoniae is a common cause of ambulatory CAP. It affects all age groups, and in normal hosts with intact cardiopulmonary function, *Mycoplasma* CAP is usually a mild, self-limiting infection. However, *M. pneumoniae* derives its importance from difficulty in diagnosis, the necessity for non-β-lactam therapy, and because of its effect on peripheral airways.

Mycoplasma CAP is one of the nonzoonotic causes of CAP (the others being *Legionella* and *Chlamydia pneumoniae*). *M. pneumoniae* is an atypical pneumonia that is a systemic infectious disease with a pulmonary component. It may be distinguished from other atypical pneumonias by its characteristic pattern of extrapulmonary organ involvement. *M. pneumoniae* CAP most closely resembles *C. pneumoniae* CAP clinically, but is very different from Legionnaires' disease in terms of its epidemiology, age distribution, pattern of extrapulmonary organ involvement, and severity.

Clinically, *M. pneumoniae* presents as a subacute febrile illness. Temperatures rarely exceed 102°F (38.9°C). Rigors are not a feature of *M. pneumoniae* CAP, but patients may complain of chilly sensations. Mild headache and/or myalgias are not uncommon. The most common presenting symptom in *Mycoplasma* CAP is the prolonged, nonproductive dry cough. Patients with *Mycoplasma* CAP often complain of or have mild nonexudative pharyngitis. Rhinorrhea and conjunctivitis are not features of *M. pneumoniae* CAP. Watery diarrhea is commonly present in *Mycoplasma* CAP, but abdominal pain is not a clinical finding. Other extrapulmonary manifestations are uncommon or rare (e.g., meningoenzephalitis, pericarditis, hemolytic anemia, glomerular nephritis, Guillain-Barré syndrome, erythema multiforme). *M. pneumoniae* has a distinctive pattern of extrapulmonary organ involvement that does not include cardiac involvement (relative bradycardia) or hepatic involvement, including normal serum glutamate-oxaloacetate transaminase (SGOT) or serum glutamate-pyruvate transaminase (SGPT). The distinguishing laboratory feature of *M. pneumoniae* CAP is elevated cold agglutinin titers. Although a variety of infectious and noninfectious diseases are associated with cold agglutinin elevations, they are usually of low titer (i.e., <1:16). There are no pulmonary infections presenting as CAP that are associated with high elevations of cold agglutinin titers (i.e., ≥1:64). Although elevated cold agglutinins occur early in up to 75% of patients with *M. pneumoniae* CAP, they are still diagnostically important when present. In a patient with CAP and a cold agglutinin titer greater than or equal to 1:64, the diagnosis of *M. pneumoniae* CAP is very likely.

M. pneumoniae may be differentiated from the typical bacterial pneumonias because of the presence of extrapulmonary findings, including nonexudative pharyngitis, loose stools or watery diarrhea, erythema multiforme, and high cold agglutinin. Patients with typical bacterial CAP usually have a more acute onset of presentation, a productive cough, and temperatures that may exceed 102°F (38.9°C), often accompanied by chills. Patients with typical pneumonia often have pleuritic chest pain, which is not a feature of *M. pneumoniae* CAP. Among the atypical pneumonias, the zoonotic pneumonias (i.e., tularemia, psittacosis, Q fever) may be eliminated from consideration if there is a recent zoonotic contact history with the appropriate vector.

C. pneumoniae resembles closely *M. pneumoniae* CAP. *C. pneumoniae* may be distinguished by the absence of cold agglutinins and the presence of hoarseness, which is a feature of *C. pneumoniae* but not *M. pneumoniae* CAP. Loose stools or watery diarrhea are not usual features of *C. pneumoniae* CAP. The most common clinical problem is differentiating *Legionella* from *Mycoplasma* CAP; this may be done by appreciating the differences in the pattern of extrapulmonary organ involvement with each of these pathogens. *Legionella* may be clinically differentiated from *Mycoplasma* by acuteness of onset or severity, the presence of relative bradycardia, temperatures greater than 102°F (38.9°C), and the presence of abdominal pain. From a laboratory standpoint, highly elevated cold agglutinin titers argue strongly against the diagnosis of *Legionella* and point to *M. pneumoniae*. Nonspecific laboratory tests in a patient with CAP that suggest *Legionella* and argue against *M.*

pneumoniae include otherwise unexplained hypophosphatemia, hyponatremia, microscopic hematuria, and increased creatinine. *Legionella* does not affect the upper respiratory tract as does *Mycoplasma* (e.g., nonexudative pharyngitis). Ear findings are not a feature of Legionnaires' disease but are common in *M. pneumoniae* CAP. The finding most likely to cause confusion between *M. pneumoniae* and *Legionella pneumophila* is the presence of loose stools or watery diarrhea, which is found in both.

M. pneumoniae may be cultured from the throat in viral culture media, but the diagnosis is usually made serologically. An elevated enzyme-linked immunosorbent assay (ELISA) or enzyme immuno-assay (EIA) IgM titer suggests acute or recent infection, but an elevated IgG titer indicates past exposure but not acute infection. Elevated IgG titers regardless of degree of elevation are not diagnostic of current infection with *M. pneumoniae* and only indicate previous antigenic exposure. *M. pneumoniae* ELISA IgM levels may take up to 3 months to decrease. Therefore, clinicians should take into account recent antecedent respiratory illness in order to properly interpret elevated IgM titers, including patients with nonexudative pharyngitis within 3 months prior to the presentation of CAP. The combination of an increased *M. pneumoniae* IgM titer and highly elevated cold agglutinin titers is virtually diagnostic of acute infection. Cold agglutinin titers are elevated transiently early and rapidly fall; the simultaneously elevated cold agglutinins and IgM titers of *M. pneumoniae* indicate active or current infection. In patients with CAP caused by another organism (e.g., *S. pneumoniae*), the presence of elevated *Mycoplasma* IgG titers does not indicate co-infection but only preexisting serologic exposure to *M. pneumoniae*.

Therapy

M. pneumoniae has a predilection for the respiratory epithelial cells and resides literally on their surface. Mycoplasmas have no definite cell wall like the typical pathogens causing CAP. Their position on the surface of the respiratory epithelium and their absence of a cell wall necessitates the therapeutic approach, which includes non- β -lactam antibiotics with the capacity to penetrate into the *Mycoplasma* organisms. Traditionally, macrolides and tetracyclines have been used successfully to treat *M. pneumoniae*. Both CAP tetracyclines and macrolides are effective against *Mycoplasma* because they interfere with intracellular protein synthesis at the ribosomal level. Tetracyclines penetrate intracellularly better than macrolides, with the exception of penetration into the alveolar macrophage, which is relevant in *Legionella*, but not *M. pneumoniae*, infections. Macrolides and tetracyclines are both active against *Mycoplasma*. Patients treated with macrolides or tetracyclines defervesce rapidly over 24 to 48 hours. Clinical defervescence manifests by an increased feeling of well-being and a decrease in fever. The dry cough persists during and after therapy regardless of the anti-*Mycoplasma* antimicrobial used.

There are important differences in the shedding rates of *Mycoplasma* from respiratory epithelial cells posttherapy when using tetracyclines instead of macrolides. Tetracycline therapy is associated with a more rapid decrease in shedding. Tetracyclines with better ability to penetrate intracellularly, such as doxycycline (Vibramycin), are the most rapid at decreasing *Mycoplasma* shedding, which is an important public health consideration. Mycoplasmas are transmitted by aerosolized droplet infection. Because patients with *Mycoplasma* have a prolonged cough, organisms not eliminated from respiratory epithelial cells may be aerosolized during coughing for weeks following the acute infection, spreading the infection to susceptible individuals via aerosolized droplets. The aim of therapy is to rapidly treat the patient's pneumonia and extrapulmonary sites of involvement. The secondary goal is to rapidly decrease shedding and aerosolization to prevent the spread of *Mycoplasma* to other individuals. An additional therapeutic goal is to decrease the incidence of post-*Mycoplasma* asthma seen in some patients. *M. pneumoniae* CAP may exacerbate preexisting asthma, but may also cause permanent post-CAP asthma in some individuals.

Until recently, doxycycline was the most active antimicrobial to use against *M. pneumoniae*. Currently, the "respiratory

TABLE 4 Antibiotics Effective Against *M. pneumoniae*

ANTIBIOTIC	DOSE (ADULT)
Mild/Moderate CAP	
Doxycycline	100 mg (IV/PO) q12h
Erythromycin	500 mg (base, estolate, stearate) (PO) q6h
Erythromycin lactobionate	1 g (IV) q6h
Clarithromycin (Biaxin)	500 mg (PO) q12h
Azithromycin (Zithromax)	500 mg (IV) q24h \times 2 doses, followed by 500 mg (PO) q24h
Severe CAP	
Levofloxacin (Levaquin)	500 mg (IV/PO) q24h, or 750 mg IV/PO q24h (may allow for shorter duration of therapy)
Moxifloxacin (Avelox)	400 mg (IV/PO) q24h

quinolones," levofloxacin (Levaquin) and moxifloxacin (Avelox), are highly active anti-*M. pneumoniae* antimicrobials. The respiratory quinolones and doxycycline penetrate cells efficiently and interfere with intracellular enzymes or protein synthesis of intracellular organisms. Respiratory quinolones and doxycycline are highly effective anti-*Mycoplasma* agents and rapidly decrease shedding of *M. pneumoniae* in respiratory secretions.

Therapy for *M. pneumoniae* is ordinarily 1 to 2 weeks. Patients who have impaired cardiopulmonary disease or compromised host may require 2 full weeks of therapy. In patients with borderline cardiopulmonary function, *M. pneumoniae* as with other relatively low virulence pathogens may present as severe CAP. Antimicrobial therapy for typical or atypical CAP should be directed against the presumed pathogen and not based on co-morbidities. Normal healthy hosts are treated with the same antimicrobial as patients hospitalized with severe CAP. Patients hospitalized with compromised cardiopulmonary function severe *Mycoplasma* CAP are most often initially treated intravenously with doxycycline (Vibramycin), a macrolide, or a respiratory quinolone. Most patients with *M. pneumoniae* CAP present in the ambulatory setting, which permits therapy with oral doxycycline, macrolide, or a respiratory quinolone (Table 4).

VIRAL RESPIRATORY INFECTIONS

Method of

Robert C. Welliver, Sr., MD

CURRENT DIAGNOSIS

- Rapid diagnostic kits are available for many common respiratory viruses. These tests are used increasingly to establish that antibiotic therapy is not necessary in many patients with febrile respiratory illnesses or with lower respiratory tract infections.
- The presence of wheezing on physical examination virtually excludes bacterial infection from consideration in subjects with lower respiratory disease.

CURRENT THERAPY

- The management of most viral respiratory infections consists of rest, adequate caloric and fluid intake, and management of fever and malaise.
- Corticosteroids are essential in the management of croup.
- Specific antiviral therapy is available only for influenza virus infection, and beneficial effects have been more readily achieved in prevention rather than treatment.

Viral infections of the respiratory tract are among the most common infections in humans, and they account for significant morbidity at all ages. Infants and young children can sustain six to eight such infections annually, and adults have an average of nearly two such infections per year.

Rhinoviruses are the most commonly identified etiologic agents and cause illness year-round. Other common causative agents during winter months include influenza viruses and respiratory syncytial virus, and enteroviruses predominate in summer months. The parainfluenza viruses also commonly cause respiratory infection, particularly in autumn (type 1) and late spring or summer (type 3). Coronaviruses, metapneumoviruses, adenoviruses, and other agents are identified less often.

Although each of these agents can cause a common cold, some viral infections are associated with characteristic patterns of respiratory disease. Most of these viruses can also exacerbate asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD).

Common Colds

Colds are the most common of the viral respiratory illnesses. Pharyngitis is usually the earliest sign of a cold, beginning a few days

after infection has taken place. Nasal congestion and clear or slightly cloudy rhinorrhea usually follow within 24 to 48 hours. Cough occurs in approximately 30% to 40% of those infected, and fluid can accumulate in middle ear or sinus cavities that have become blocked as a result of mucosal swelling. Ear and sinus cavity infections occur when this fluid is trapped for a week or more. Treatment with antibiotics is ineffective before this time, and they are ineffective especially in the absence of other clinical signs of ear and sinus infections.

Colds are a frequent cause of missed school and work, and even of mild morbidity, but they are rarely serious in otherwise healthy persons. The most appropriate approach to treatment therefore entails rest, with adequate nutrition and hydration. Agents that inhibit the activity of cyclooxygenase probably represent the most effective form of pharmacologic intervention. These compounds include acetaminophen (Tylenol) and the nonsteroidal anti-inflammatory agents (NSAIDs) such as ibuprofen (Motrin). They are effective in reducing fever and, perhaps more importantly in most colds, reducing malaise, headache, and pharyngitis.

Nasal congestion and some rhinorrhea during colds are related to dilation of blood vessels in the nose and sinuses. Vasoconstrictors have therefore been used extensively to attempt to reverse these symptoms. Oral decongestants such as pseudoephedrine (Sudafed) have minimal effect on nasal congestion, and can result in systemic hypertension, anxiety, and difficulty sleeping. The propensity for these compounds to cause cardiac arrhythmias in the very young child has led to recommendations against their use in the first year or two of life. Nasal sprays containing vasoconstricting agents such as oxymetazoline (Afrin) can result in mild temporary relief of nasal obstruction. However, the use of these compounds for more than 3 or 4 days can result in rebound vasodilation and paradoxically increased rhinorrhea.

Numerous investigations have evaluated the role of antihistamines in colds. The release of histamine itself is not associated with fever, cough, or malaise, so effects on these symptoms would not be expected. Furthermore, nasal congestion and discharge may be more related to the release of kinins, and not histamine. Indeed, the administration of antihistamines in adults and, particularly, in children has not demonstrated strikingly positive results. As many as 40% of subjects treated with placebo report beneficial effects. Side effects of histamine use, primarily sedation and dry mouth, are commonly encountered.

Cough can be one of the most irritating symptoms during colds. Cough during colds is principally caused by secretions entering the airway (postnasal drip) and not by inflammation of the airway itself. Therefore, it is not surprising that cough suppressants, especially codeine, have little effect on cough induced by colds. Antihistamines have also been found to be ineffective in relief of cough during colds.

Influenza-Like Illness

The influenza syndrome is defined as the abrupt onset of fever, headache, and striking degrees of malaise and prostration, often with intense myalgia. Respiratory symptoms can occur concurrently, but they might not be prominent features. The principal cause is, of course, influenza virus, although infection with many other viruses can cause similar (although not as intense) symptoms. The illness is generally self-limited, and most symptoms resolve over 4 or 5 days. Lassitude can persist for up to 2 weeks.

Influenza virus infection and influenza-like illness are best treated symptomatically, relying on rest, adequate intake of fluids and calories, and appropriate analgesic therapy. Compounds referred to as *M2 inhibitors* such as amantadine (Symmetrel) and rimantadine (Flumadine) have been approved for therapy. Positive outcomes from therapy with these agents are observed only when therapy is instituted within 48 hours after the onset of symptoms, and benefits are not striking. In recent years, resistance to *M2 inhibitors* has been commonly observed among circulating epidemic strains of influenza virus.

More recently, inhibitors of the activity of influenza viral neuraminidase have been used in treatment and prevention of influenza

VIRAL RESPIRATORY INFECTIONS

Method of

Robert C. Welliver, Sr., MD

CURRENT DIAGNOSIS

- Rapid diagnostic kits are available for many common respiratory viruses. These tests are used increasingly to establish that antibiotic therapy is not necessary in many patients with febrile respiratory illnesses or with lower respiratory tract infections.
- The presence of wheezing on physical examination virtually excludes bacterial infection from consideration in subjects with lower respiratory disease.

CURRENT THERAPY

- The management of most viral respiratory infections consists of rest, adequate caloric and fluid intake, and management of fever and malaise.
- Corticosteroids are essential in the management of croup.
- Specific antiviral therapy is available only for influenza virus infection, and beneficial effects have been more readily achieved in prevention rather than treatment.

Viral infections of the respiratory tract are among the most common infections in humans, and they account for significant morbidity at all ages. Infants and young children can sustain six to eight such infections annually, and adults have an average of nearly two such infections per year.

Rhinoviruses are the most commonly identified etiologic agents and cause illness year-round. Other common causative agents during winter months include influenza viruses and respiratory syncytial virus, and enteroviruses predominate in summer months. The parainfluenza viruses also commonly cause respiratory infection, particularly in autumn (type 1) and late spring or summer (type 3). Coronaviruses, metapneumoviruses, adenoviruses, and other agents are identified less often.

Although each of these agents can cause a common cold, some viral infections are associated with characteristic patterns of respiratory disease. Most of these viruses can also exacerbate asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD).

Common Colds

Colds are the most common of the viral respiratory illnesses. Pharyngitis is usually the earliest sign of a cold, beginning a few days

after infection has taken place. Nasal congestion and clear or slightly cloudy rhinorrhea usually follow within 24 to 48 hours. Cough occurs in approximately 30% to 40% of those infected, and fluid can accumulate in middle ear or sinus cavities that have become blocked as a result of mucosal swelling. Ear and sinus cavity infections occur when this fluid is trapped for a week or more. Treatment with antibiotics is ineffective before this time, and they are ineffective especially in the absence of other clinical signs of ear and sinus infections.

Colds are a frequent cause of missed school and work, and even of mild morbidity, but they are rarely serious in otherwise healthy persons. The most appropriate approach to treatment therefore entails rest, with adequate nutrition and hydration. Agents that inhibit the activity of cyclooxygenase probably represent the most effective form of pharmacologic intervention. These compounds include acetaminophen (Tylenol) and the nonsteroidal anti-inflammatory agents (NSAIDs) such as ibuprofen (Motrin). They are effective in reducing fever and, perhaps more importantly in most colds, reducing malaise, headache, and pharyngitis.

Nasal congestion and some rhinorrhea during colds are related to dilation of blood vessels in the nose and sinuses. Vasoconstrictors have therefore been used extensively to attempt to reverse these symptoms. Oral decongestants such as pseudoephedrine (Sudafed) have minimal effect on nasal congestion, and can result in systemic hypertension, anxiety, and difficulty sleeping. The propensity for these compounds to cause cardiac arrhythmias in the very young child has led to recommendations against their use in the first year or two of life. Nasal sprays containing vasoconstricting agents such as oxymetazoline (Afrin) can result in mild temporary relief of nasal obstruction. However, the use of these compounds for more than 3 or 4 days can result in rebound vasodilation and paradoxically increased rhinorrhea.

Numerous investigations have evaluated the role of antihistamines in colds. The release of histamine itself is not associated with fever, cough, or malaise, so effects on these symptoms would not be expected. Furthermore, nasal congestion and discharge may be more related to the release of kinins, and not histamine. Indeed, the administration of antihistamines in adults and, particularly, in children has not demonstrated strikingly positive results. As many as 40% of subjects treated with placebo report beneficial effects. Side effects of histamine use, primarily sedation and dry mouth, are commonly encountered.

Cough can be one of the most irritating symptoms during colds. Cough during colds is principally caused by secretions entering the airway (postnasal drip) and not by inflammation of the airway itself. Therefore, it is not surprising that cough suppressants, especially codeine, have little effect on cough induced by colds. Antihistamines have also been found to be ineffective in relief of cough during colds.

Influenza-Like Illness

The influenza syndrome is defined as the abrupt onset of fever, headache, and striking degrees of malaise and prostration, often with intense myalgia. Respiratory symptoms can occur concurrently, but they might not be prominent features. The principal cause is, of course, influenza virus, although infection with many other viruses can cause similar (although not as intense) symptoms. The illness is generally self-limited, and most symptoms resolve over 4 or 5 days. Lethargy can persist for up to 2 weeks.

Influenza virus infection and influenza-like illness are best treated symptomatically, relying on rest, adequate intake of fluids and calories, and appropriate analgesic therapy. Compounds referred to as *M2 inhibitors* such as amantadine (Symmetrel) and rimantadine (Flumadine) have been approved for therapy. Positive outcomes from therapy with these agents are observed only when therapy is instituted within 48 hours after the onset of symptoms, and benefits are not striking. In recent years, resistance to *M2 inhibitors* has been commonly observed among circulating epidemic strains of influenza virus.

More recently, inhibitors of the activity of influenza viral neuraminidase have been used in treatment and prevention of influenza

virus infection in adults and children. The first such compound released, zanamivir (Relenza), was administered by inhalation but was unpopular because of its irritating effects on the airway. An oral compound, oseltamivir (TamiFlu), has been used to prevent and to treat influenza virus infection. As with M2 inhibitors, it is believed that treatment should be started within the first 48 hours of symptoms and that prophylaxis should be instituted within 48 hours of exposure. Treatment with oseltamivir shortens the duration of subsequent illness by only about 24 hours. Treatment can prevent some of the complications of influenza infection, including pneumonia. The drug may be more effective as a therapeutic agent, because it may be up to 90% effective in preventing culture-positive symptomatic influenza illness. The recommended dose for adults is 75 mg orally every 12 hours for 5 days. In children, the appropriate dose based on body weight is 30 mg twice daily for children weighing less than 15 kg, 45 mg twice daily for children weighing 15 to 23 kg, 60 mg twice daily for children weighing 23 to 40 kg, and 75 mg twice daily for children weighing more than 40 kg. The principal side effect is nausea, which can be reduced by taking the drug with food.

In 2009, a novel H1N1 strain of influenza caused a worldwide pandemic. At the time of this writing, both this epidemic H1N1 strain as well as the seasonal influenza A/H3N2 and type B strains continue to circulate in the world. The considerable majority of these epidemic and seasonal strains continue to show sensitivity to oseltamivir, while most are resistant to M2 inhibitors. All strains continue to show sensitivity to zanamivir.

Croup

Croup is defined by the occurrence of hoarseness or laryngitis, a deep, brassy or barking cough, and inspiratory stridor. Airway obstruction in croup is caused by constriction in the subglottic area, often noted on radiographs by a steeple-shaped narrowing of the air column in this region. Affected children are usually afebrile and nontoxic in appearance.

Parainfluenza virus type 1 is the primary cause of croup, although infection with many different viruses can produce this illness, and influenza virus can cause a particularly severe form of croup. Bacterial secondary infection occurs uncommonly, but it can result in fever and severe obstruction of the airway. Administration of dexamethasone (Decadron)¹ at 0.6 mg/kg either orally or intramuscularly markedly reduces the rate of hospitalization, admission to the intensive care unit, and intubation for croup.

Bronchiolitis

Bronchiolitis represents the most common cause for hospitalization of infants in developed countries. Infants present with a history of several days of upper respiratory symptoms, followed by the rapid onset of wheezing and labored breathing. Respiratory syncytial

virus (RSV) is the most common cause and is the agent found in the most severe cases that result in respiratory failure. Contrasting with asthma, obstruction of the airway in bronchiolitis is a result of plugging of bronchioles with detached epithelium and inflammatory cells. Mucus plugging and constriction of smooth muscle are not prominent. Also in contrast with asthma is the absence of a sustained response to bronchodilators and corticosteroids among infants with bronchiolitis.

Therapy of bronchiolitis primarily consists of administration of supplemental oxygen and replacement of fluid deficits as needed. Ribavirin (Virazole)¹ is a compound with antiviral activity against RSV, but controlled studies have not demonstrated meaningful differences in outcomes between treated and untreated subjects. The compound is quite expensive and must be delivered via a special aerosol generator.

Palivizumab (Synagis), a preparation consisting of a monoclonal antibody against the fusion protein of RSV, has proved to be effective in reducing the rate of hospitalization for RSV infection by approximately 50% when given to high-risk infants. Infants who may be considered candidates for therapy include those with chronic lung disease, those born prematurely, and those with hemodynamically significant congenital heart disease. Doses of palivizumab (15 mg/kg) are given on a monthly basis throughout the local RSV season, usually November through March.

¹Not FDA approved for this indication.

ANKYLOSING SPONDYLITIS

Method of

John D. Reveille, MD

CURRENT DIAGNOSIS

- The diagnosis of ankylosing spondylitis rests on the presence of inflammatory back pain or restriction of spinal mobility in the presence of radiographic sacroiliitis.
- Generally, sacroiliitis as determined by standard radiographs does not appear until after 7 to 10 years of inflammatory back pain.
- When inflammatory back pain is present with other stigmata of spondyloarthritis (e.g., uveitis, enthesitis, inflammatory bowel disease) and standard radiographs are normal, MRI scanning of the sacroiliac joints or HLA-B27 testing, or both, can provide important diagnostic information.

CURRENT THERAPY

- Nearly half of patients with ankylosing spondylitis respond to high doses of nonsteroidal antiinflammatory drugs (NSAIDs) alone.
- Disease-modifying anti-rheumatic drugs (DMARDs), such as sulfasalazine (Azulfidine),¹ methotrexate (Trexall),¹ or leflunomide (Arava)¹, are effective for peripheral arthritis but not for axial disease.
- Anti-tumor necrosis factor treatment is very effective in controlling inflammatory symptoms in patients who do not respond adequately to NSAIDs and DMARDs.

¹Not FDA approved for this indication.

The term *ankylosing spondylitis* (AS), part of the spectrum of disease known as axial spondyloarthritis, comprises a group of chronic inflammatory diseases characterized by spinal and peripheral joint oligoarthritis, inflammation of the attachments of ligaments and tendons to bones (enthesitis), and, at times ocular or cardiac manifestations.

Epidemiology

The prevalence of AS parallels the frequency of HLA-B27. AS occurs in approximately 0.5% of persons of European descent and eastern Asian descent, with B27 seen in 8% and 6%, respectively. Higher incidences of AS are reported in eastern Europe and Scandinavia, where HLA-B27 is more common, and in certain Native American groups. AS is rare in Africans and Japanese, where HLA-B27 is rare. Men are affected three times more commonly than women. Recent data from the National Health and Nutrition Examination Survey have estimated the prevalence of axial spondyloarthritis to occur in more than one percent of the U.S. population.

Pathophysiology

AS is caused primarily by genetic factors, with a sibling recurrence risk ratio as high as 82 and twin-based studies estimating disease heritability to exceed 90%. The major histocompatibility complex (MHC) gene HLA-B27 confers the greatest known risk for AS and is found in up to 90% of patients of European and East Asian ancestry (although AS patients from the Middle East and Africa have lower B27 frequencies).

How HLA-B27 contributes to the pathogenesis of AS is not known. One theory is the arthritogenic peptide hypothesis: that AS results from HLA-B27 binding a unique peptide or a set of antigenic peptides derived from either triggering microorganisms or from self proteins. To date, however, none have been identified. In fact, recent data have shown that another gene that has been associated with AS worldwide: endoplasmic reticulum aminopeptidase (ERAP1)-which is involved in trimming peptides to the optimal length for loading onto the peptide binding groove for MHC class I presentation interacts with HLA-B27, resulting in *aberrant peptide presentation*. Secondly, HLA-B27 heavy chains self-associate to form homodimers, which can misfold in the endoplasmic reticulum, resulting in a proinflammatory unfolded protein response and be recognized at the cell surface by natural killer cells. A third hypothesis is that AS results from inability to effectively combat certain infections, such as from gut infection (i.e., alterations in the gut microbiome). HLA-B27-positive persons are more efficient at dealing with certain infections (hepatitis C and HIV) and less efficient at dealing with others (*Salmonella*, *Shigella*, *Chlamydia* species, and others). Older studies have implicated *Klebsiella pneumoniae*, although recent data have not borne this out. How these factors initiate disease onset is not known.

Less than 5% of HLA-B27-positive people in the general population develop AS or other spondyloarthritis, as opposed to 20% of HLA-B27-positive relatives of AS patients. Data from family studies and genomewide association studies have shown that most of the overall genetic risk for AS comes from HLA-B27. Other MHC genes, such as HLA-B60 (B*40:01) and MICA all contribute to susceptibility.

Over 42 non-MHC genes have been implicated in AS susceptibility, including those involved in IL-17 mediated immunity (*IL23R*, *TYK2*, *IL6R*, *IL7R*?, *IL7*?, *IL1R2/IL1R1*, *IL12B*), CD8 T cell function (*RUNX3*, *EOMES*, *IL7R*), peptide presentation (*ERAP1*, *ERAP2*, *LNPEPP*, *NPEPPS*), microbial sensing (*CARD9*, *NOS2*) as well as a number of others relevant to immune function (*ZMIZ1*, *FCGR2A*, *KIF21B*, *SH2B3*, *TNFRSF1A*, *GPR65*, *SULT1A1*, *GPR35*, *BACH2*, *ICOSLG*, *NKX2-3*).

Clinical Manifestations

The hallmark of AS is inflammatory back pain. This pain is classically characterized as a dull pain in the low back or in the buttocks and hips that begins before the age of 40 years, has an insidious onset, and lasts longer than 3 months. Inflammatory back pain is associated with morning stiffness lasting 30 minutes or longer, which responds readily to nonsteroidal antiinflammatory drugs (NSAIDs), is relieved with activity and worsened with rest, and often awakens the patient during the second half of the night. As the disease progresses, patients can develop limitation of spinal mobility, loss of lumbar and cervical lordosis, and kyphotic

deformities of the spine. This limitation of motion is initially the result of axial inflammation and muscle spasm but is contributed to over time by ossification of the ligamentous structures and ultimately bony fusion of the sacroiliac joints, apophyseal joints, and the outer fibers of the annulus fibrosis of the intervertebral disks.

Arthritis of the hips occurs in approximately 50% of patients with AS. About 10% of AS patients have arthritis of the joints of the hands, feet, wrists, and ankles. Enthesitis, inflammation of tendinous or ligamentous insertions onto bone, is one of the most characteristic findings of the AS and other spondyloarthritides, especially in the Achilles tendon and the plantar fascial insertions, although involvement of the ligamentous and tendinous insertions onto the pelvic bones is also encountered. Dactylitis or sausage digits—fusiform swelling of the entire digit due to inflammation and swelling of the flexor tenosynovium—also occasionally occurs.

AS also affects the gastrointestinal tract and eyes. About 6% of AS patients have inflammatory bowel disease (Crohn's disease or ulcerative colitis), and asymptomatic bowel inflammation is seen on ileocolonoscopy in up to 50% of patients with AS. Anterior uveitis occurs in about 40% of AS patients. It is usually unilateral with sudden onset, manifesting as a painful red eye with photophobia and blurred vision. It can recur periodically, although is rarely associated with permanent loss of vision. Similarly, about 10% of AS patients have psoriasis.

Diagnosis

The diagnosis of AS rests on the presence of inflammatory spinal pain or restriction of spinal and chest wall motion occurring in the setting of radiographic sacroiliitis (sclerosis, erosion, and even ankylosis of the sacroiliac joints). Plain radiographs of the spine show Romanus lesions (shiny corners) and squaring of the vertebral body owing to erosions at the attachments of the spinal ligaments early in disease, followed by formation of syndesmophytes owing to ossification of the outer layer of the annulus fibrosis and eventual ankylosis of the spine, producing a bamboo spine appearance.

Abnormalities on standard radiographs typically are not seen until up to 8 to 11 years after disease onset, leading to a significant delay in diagnosis and initiation of therapy. Radiographic changes can be detected with magnetic resonance imaging (MRI) years before the appearance of radiographic disease, with bone marrow edema adjacent to the inflamed sacroiliac joint and spinal joints. This preradiographic disease has resulted in the concept of axial spondyloarthritis, for which new criteria have been developed based on the presence of inflammatory back pain accompanied by the presence of a positive MRI or HLA-B27 typing and other spondyloarthritis features (e.g., uveitis, enthesitis).

Differential Diagnosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a disease of older persons, predominantly men, characterized by low back pain and stiffness. Characteristic findings are flowing calcification and ossification along the anterolateral segment of at least four contiguous vertebral bodies with the relative preservation of intervertebral disk height and the absence of apophyseal joint ankylosis. The sacroiliac joints are characteristically spared or show degenerative changes but not erosion or fusion, and the back pain is usually mechanical in nature.

Osteitis condensans ilii is a condition primarily noted in young multiparous women. It consists of increased bone density generally confined to a triangular area along the inferior aspect of the ilium adjacent to the sacroiliac joint. It is usually asymptomatic, and erosions and intra-articular ankylosis are rare.

Ochronosis is a rare hereditary metabolic disease in which the enzyme homogentisic acid oxidase is absent. It is characterized by abnormal pigmentation of the sclerae and ears. Ochronotic arthropathy manifests in the fourth decade, especially in the hips, knees, and shoulders. Although the spine can appear fused as in AS, characteristic findings include loss of disk height and calcification of the disks, which are not seen in AS.

Treatment

A great deal of educational information is available for patients (www.spondylitis.org). Unsupervised recreational exercise improves pain and stiffness, and back exercise improves pain and function in patients with AS, but these effects differ with disease duration. Health status is improved when patients perform recreational exercise at least 30 minutes per day and back exercises at least 5 days per week.

NSAIDs, used in high (antiinflammatory) doses on a daily basis, remain the starting point of treatment of spondylitis, and up to half of AS patients attain satisfactory symptom control with these agents alone. There are no strong data to suggest the superiority of any specific NSAID in patients with AS.

Disease-modifying antiinflammatory drugs (DMARDs), especially sulfasalazine (Azulfidine)¹ in doses of 2 to 3 g/day, but also methotrexate (Trexall)¹ (up to 25 mg once a week) and leflunomide (Arava)¹ 20 mg per day are effective in the treatment of peripheral joint involvement in AS, although not in axial disease.

Glucocorticoids such as prednisone (5–15 mg/day) are occasionally used by clinicians to augment the effect of NSAIDs, although owing to unproven efficacy and side effects, including osteoporosis, they are not recommended unless other treatments are not available. Intraarticular and peritendinous injections of depot steroids can provide relief of local flare-ups, although injecting around the Achilles tendon is not recommended because of the risk of tendon rupture.

TNF- α blockers have become a mainstay in AS treatment for those not responding to NSAIDs and DMARDs. Currently five are approved by the FDA for use in AS. Four are injected subcutaneously, including the soluble TNF- α receptor etanercept (Enbrel), given at 50 mg weekly, and the TNF- α monoclonal antibodies adalimumab (Humira) 40 mg every 2 weeks and golimumab (Simponi) 50 mg once a month and certolizumab pegol, 200 mg twice a month or 400 mg once per month. In addition, the TNF- α monoclonal antibody infliximab (Remicade) is infused at 5 mg/kg every 6 to 8 weeks intravenously. These medications have been shown to be beneficial in both the axial and peripheral manifestations of AS. Onset of action is rapid, and improvement is seen not only clinically but also on MRI, with clearing of bone marrow edema. Anti-TNF treatment is expensive, and complications can include infusion or injection site reactions, infections (especially from *Mycobacterium tuberculosis*), lymphoma (though not other malignancies), and the development of antinuclear antibodies following anti-TNF treatment, although reports of patients developing systemic lupus erythematosus or other connective tissue disease are rare.

Patients with AS also require surgical treatment on occasion. Total hip arthroplasty is the most common surgical procedure in patients with AS, and heterotopic new bone formation can be a potential problem. Patients with AS are at increased risk for vertebral fracture, often resulting in neurologic compromise due to osteoporosis. In general, halo vest immobilization is recommended. Surgical intervention may be necessary when neurologic impairment is seen. Also, osteotomies (open, polysegmental, and closing wedge) are occasionally employed to correct the fixed kyphotic deformities seen in patients with advanced AS.

Monitoring

The most widely used clinical measure of disease activity is the Bath Ankylosing Spondylitis Disease Activity (BASDAI) measure, a self-reported questionnaire consisting of six 10-cm horizontal visual analogue scales. This has been replaced recently by the Ankylosing Spondylitis Disease Activity Score (ASDAS), which includes elements of the BASDAI, a patient global assessment of disease activity, and C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR) assessments. It measures severity of fatigue, spinal and peripheral joint pain, localized tenderness, and morning stiffness. Functional impairment is measured by the Bath Ankylosing

¹Not FDA approved for this indication.

Spondylitis Functional Index (BASFI), another self-reported questionnaire with ten 10-cm visual analogue scales, including eight AS-specific questions and two on coping and daily life. Spinal mobility can be assessed by specific physical examination maneuvers, such as the Schober test, which measures lumbar flexion; chest wall expansion, which assesses costovertebral joint involvement; the occiput-to-wall measurement, which assesses cervical extension; and the lateral bending maneuver.

Laboratory markers of disease include C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Radiographic severity is measured by the Modified Stoke Ankylosing Spondylitis Spinal Score (mSASSS), a detailed scoring system comparable to the modified Sharp Score in rheumatoid arthritis. However, standard radiographs are complicated by low sensitivity to change and are not useful in gauging disease activity. MRI scanning is more helpful, particularly in measuring early or “pre-radiographic” disease activity, and has its highest specificity in the sacroiliac joints.

Complications

Cardiac manifestations, including conduction abnormalities and aortic valvular insufficiency, occasionally are seen in AS patients. The spectrum of pulmonary involvement in AS ranges from restricted chest wall movement from costovertebral joint fusion to a rare upper lobe–predominant interstitial lung disease. Other complications of AS include osteoporosis; spinal fracture, often accompanied by neurologic compromise; atlantoaxial subluxation; cauda equina syndrome; secondary amyloidosis; sleep disturbance; and depression.

BURSITIS AND TENDINOPATHY

Method of
Kyle Goerl, MD

CURRENT DIAGNOSIS

Tendinopathy

- Tendinitis is an inflammatory condition only present within the first weeks of a tendon injury.
- Tendinosis is a degenerative condition usually developing weeks after the initial injury.
- The diagnosis is typically made clinically with a thorough history and physical examination.
- Most tendinopathies occur secondary to overuse, and can be acute, chronic, or recurrent.
- Tendinopathies are usually characterized by pain, possible swelling, and dysfunction of the affected tendon.
- If the diagnosis is in question, magnetic resonance imaging and ultrasound are helpful diagnostic aides.

Bursitis

- Bursitis is an inflammatory reaction of a bursa.
- Bursitis is typically the result of overuse or trauma, but systemic illnesses can also cause bursitis.
- The olecranon, prepatellar, and trochanteric bursa are particularly susceptible to traumatic bursitis because of their location immediately under the skin with minimal subcutaneous fat for protection.
- Bursitis rarely occurs alone, so a search should be conducted for an associated condition such as tendinopathy or a tendon tear.
- Imaging studies demonstrate that lateral hip pain is usually tendinopathy, not “trochanteric bursitis,” a term that should be reserved for image-proven bursitis.
- Septic bursitis usually only affects the olecranon and prepatellar bursa, and care must be taken to distinguish it from aseptic bursitis.
- Common pathogens in septic arthritis include *Staphylococcus aureus* and β -hemolytic *Streptococcus*.
- If the diagnosis of septic bursitis is in question, aspiration should be performed, and the aspirate sent for Gram stain, cell count and differential, culture and crystal analysis, and blood should be sent for culture, complete blood count, C-reactive protein, and erythrocyte sedimentation rate.

CURRENT THERAPY

Tendinopathy

- Given that tendonitis is an inflammatory condition, NSAIDs should be considered. Ice, activity modification, and rest are also effective.
- Tendinosis is not an inflammatory condition, so NSAIDs are not usually a part of the treatment regimen.
- Tendinosis responds well to physical therapy and, in particular, eccentric exercises. Deep tissue massage with tools is also an effective treatment modality.
- Steroid injections can be effective for short term pain relief, but not for long-term healing, and should not be a routine part of the treatment plan. Steroid injections can be considered if the patient is in too much pain to perform physical therapy.
- Injections of blood products such as whole blood and platelet-rich-plasma, prolotherapy and sclerotherapy have varying levels of evidence supporting their effectiveness, but are reasonable alternatives to surgery.
- When conservative measures fail, more invasive procedures such as tenotomy, tendon scraping, and open débridement should be considered, but are rarely needed.

Bursitis

- Early treatment should include NSAIDs, ice, activity modification, and rest.
- If an associated condition like tendinopathy is discovered, appropriate treatment should target that condition as well, and typically involves physical therapy.
- In the event of septic bursitis, antibiotic treatment should be initiated. Parenteral medication should be heavily considered, given the high failure rate of oral antibiotics.
- Surgery is rarely needed for bursitis.

Tendinopathy

Background

Tendon is a connective tissue used to attach muscle to bone. Normal tendon tissue is dense and has a highly regular and fibrillar pattern. Tendinopathy is the term used to describe a clinical syndrome typically resulting from overuse of a tendon. Traditionally the term tendonitis has been used to describe all tendon injuries, but the suffix “-itis” indicates the presence of inflammation, and inflammation is only present early on in the tendinopathy disease process.

Spondylitis Functional Index (BASFI), another self-reported questionnaire with ten 10-cm visual analogue scales, including eight AS-specific questions and two on coping and daily life. Spinal mobility can be assessed by specific physical examination maneuvers, such as the Schober test, which measures lumbar flexion; chest wall expansion, which assesses costovertebral joint involvement; the occiput-to-wall measurement, which assesses cervical extension; and the lateral bending maneuver.

Laboratory markers of disease include C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Radiographic severity is measured by the Modified Stoke Ankylosing Spondylitis Spinal Score (mSASSS), a detailed scoring system comparable to the modified Sharp Score in rheumatoid arthritis. However, standard radiographs are complicated by low sensitivity to change and are not useful in gauging disease activity. MRI scanning is more helpful, particularly in measuring early or “pre-radiographic” disease activity, and has its highest specificity in the sacroiliac joints.

Complications

Cardiac manifestations, including conduction abnormalities and aortic valvular insufficiency, occasionally are seen in AS patients. The spectrum of pulmonary involvement in AS ranges from restricted chest wall movement from costovertebral joint fusion to a rare upper lobe–predominant interstitial lung disease. Other complications of AS include osteoporosis; spinal fracture, often accompanied by neurologic compromise; atlantoaxial subluxation; cauda equina syndrome; secondary amyloidosis; sleep disturbance; and depression.

- Surgery is rarely needed for bursitis.

Tendinopathy

Background

Tendon is a connective tissue used to attach muscle to bone. Normal tendon tissue is dense and has a highly regular and fibrillar pattern. Tendinopathy is the term used to describe a clinical syndrome typically resulting from overuse of a tendon. Traditionally the term tendonitis has been used to describe all tendon injuries, but the suffix “-itis” indicates the presence of inflammation, and inflammation is only present early on in the tendinopathy disease process.

TABLE 1 Tendinopathy Progression

	TENDONITIS	TENDINOSIS
Pathology	Inflammatory	Degenerative
Timing	Days to weeks	Weeks to years
Imaging	Typically unnecessary	Radiographs initially Ultrasound or magnetic resonance imaging for persistent symptoms

Inflammation may have resolved and inflammatory cells may no longer be present, but the patient may still have pain. At that point the disease process has changed from one of inflammation to a degenerative problem more appropriately termed tendinosis (Table 1).

Tendinopathies are characterized by pain, swelling, and impairment of functional activities of the affected region. They can be acute, chronic, or recurrent. The diagnosis is usually clinical based on history and physical examination. Typically, there is a history of repetitive motion, which can be anything from painting a wall to playing a sport like tennis. If this historical information is lacking, then a systemic medical condition should be considered.

With repetitive activities and inadequate recovery time tenocytes will begin producing inflammatory substances, and the load-bearing matrix of the tendon will begin to breakdown and become fibrotic. The collagen matrix becomes disorganized with fibers separating and healing in an erratic, disorganized manner. There is an increase in mucoid ground substance, hypercellularity, and pathologic vessel and sensory afferent nerve formation. The abnormal nerve formation likely contributes to the sensation of pain. This histopathological degenerative process is more appropriately called tendinosis. The degenerative mechanism appears to be multifactorial, with contributions from:

1. Classic inflammatory mediators like interleukins, prostaglandins, and substance P.
2. Altered load bearing on a tendon as in shoulder impingement.
3. Systemic influences such as aging.

Tendinopathy is occurring at higher rates in the developed world secondary to an increase in recreational sport participation. Lower extremity tendons, like the Achilles and patellar tendons, bear a large amount of tensile force (Table 2). Thirty percent of runners will suffer Achilles tendinopathy in their lifetime, with an odds ratio of 31:2 when compared with age matched controls, and repetitive exposure is a risk factor. One in 3 patients with Achilles tendinopathy do not participate in sports. With respect to patellar tendinopathy, jumping sports like volleyball and basketball are risk factors. Historically, most lateral hip pain was labeled “trochanteric bursitis.” Research using imaging techniques, including magnetic resonance imaging (MRI) and ultrasound (), has concluded that lateral hip pain around the greater trochanter is more likely caused by tendon tears or tendinopathy of the gluteus medius and gluteus minimus muscle-tendon complex than inflammation of the trochanteric bursa. Rarely is there an actual bursitis present,

TABLE 2 Common Tendinopathy Sites**Upper Extremity**

- Rotator cuff (especially supraspinatus)
- Medial epicondyle
- Lateral epicondyle (especially extensor carpi radialis brevis)
- First dorsal compartment of the wrist (De Quervain)

Lower Extremity

- Gluteus medius and gluteus minimus
- Iliopsoas
- Patellar
- Achilles

so the diagnosis “trochanteric bursitis” should no longer be used regularly unless there is documented bursitis on an imaging study. This is important because the patient is more likely to benefit long-term from physical therapy (PT) as opposed to nonsteroidal anti-inflammatory drugs (NSAIDs), or steroid injections, attributable to the underlying pathology being more likely tendon related than bursa related. Without an imaging study, the better term for lateral hip pain at this time is greater trochanteric pain syndrome (GTPS).

Many upper extremity tendons, such as those of the wrist, are adapted to gliding through synovial sheaths. The most commonly affected tendons in the upper extremity are the rotator cuff, specifically the supraspinatus tendon, and the common extensor tendon (more precisely the extensor carpi radialis brevis) involved in lateral epicondylopathy, commonly known as *tennis elbow*. Despite names like tennis elbow and golfer’s elbow, upper extremity tendinopathies (see Table 2) are more likely the result of repetitive motion from work or hobby related activities. When sports are a cause of upper extremity tendinopathy, they are typically sports requiring overhead motion like baseball, volleyball, and tennis. Up to 35% to 50% of adult tennis players will develop an elbow tendinopathy during their lifetime. A common cause of tendinopathy in the wrist is De Quervain tenosynovitis. De Quervain tenosynovitis affects the first dorsal compartment of the wrist containing the abductor pollicis longus and extensor pollicis brevis tendons. As the term “tenosynovitis” suggests, this condition results in irritation and swelling of not only the tendons themselves, but also of the synovial sheath encapsulating those tendons.

Some patients will develop tendinopathies without repetitive activity. Diseases of glucose metabolism and atherosclerosis are associated with a higher incidence of tendinopathy. Some common medications are also associated with tendinopathy including statins, fluoroquinolone antibiotics, and steroids, especially when steroids are injected intratendinously, which should be avoided.

Evaluation

On physical examination the affected tendon will sometimes appear swollen, and it is typically tender to palpation. The affected tendon-muscle complex may exhibit restricted flexibility, and stretching it or activating it against resistance may reproduce the patient’s pain.

When the diagnosis of a tendinopathy is in question, imaging can be helpful. Radiographs of the affected area should be considered, to look for abnormalities such as large calcifications within tendons (Figure 1, A). When the diagnosis is in question or the patient has failed a course of physical therapy, advanced imaging should be considered. This is usually accomplished by either ultrasound or MRI. Ultrasound can reveal thickening or structural changes within the tendon consistent with degeneration and other abnormalities such as calcification. As tendinopathies are commonly associated with bursitis, bursal thickening consistent with bursitis may also be seen (Figures 1, B–C, 2, and 3). Similar findings may be demonstrated on MRI (Figure 4).

Determining which imaging modality to use can be challenging. MRI is considered the gold-standard for diagnosing tendinopathies and has the advantage of demonstrating an anatomic overview of the affected area, in addition to providing soft tissue contrast. However, in trained hands, the advantages of ultrasound include ease of use, point-of-care examination, dynamic evaluation of the tendon and muscles, better resolution than MRI, and guidance for injections and procedures.

Prevention

Prevention is always the best option. Tendons do not respond well to acute changes in routine or long periods of rest. This should be kept in mind by athletes during the off-season, someone taking on a new labor job on an assembly line, or a secretary with a new work space. These “potential patients” should be eased into their new routines, because all of these scenarios are classic setups for the development of a tendinopathy. Maintaining activity during the offseason and preparing one’s self for changes in the workplace will help to mitigate the risk of tendinopathy development.

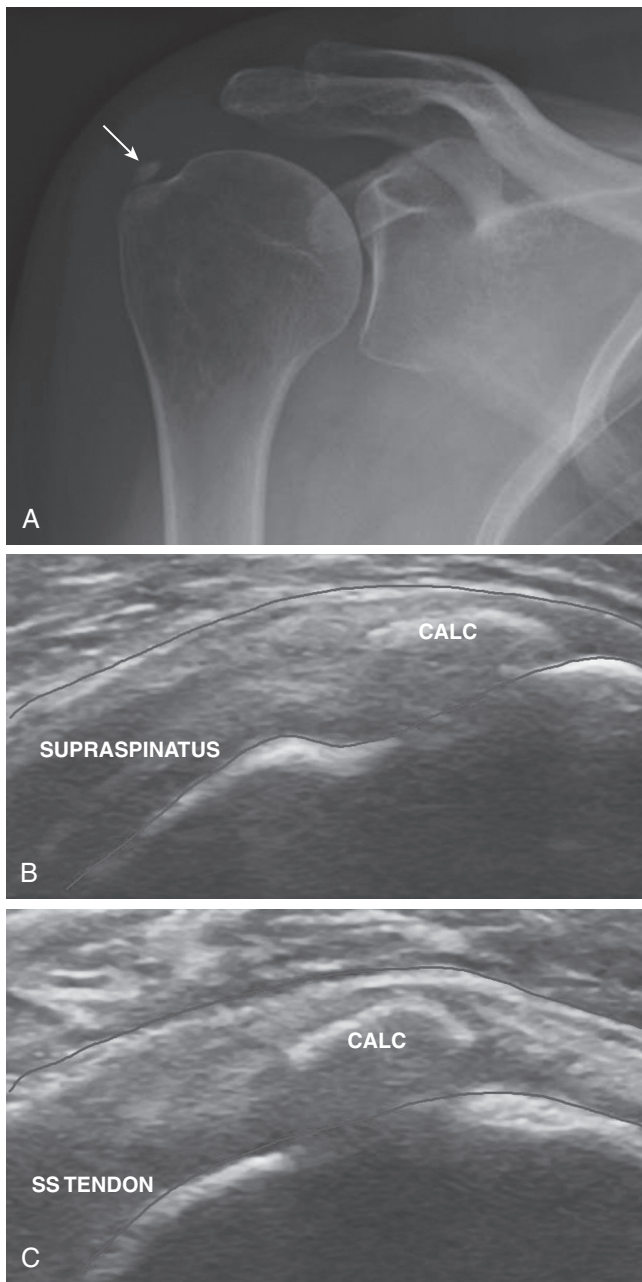

Figure 1 A, AP of the patient's shoulder demonstrating a calcific lesion near the humeral head. B, Long axis view; C, short axis view both by ultrasound of the same patient's supraspinatus tendon (*outline*) near its attachment at the humeral head. The humeral cortex shows as hyperechoic on the bottom of the tendon. The calcification is noted to be within the tendon near the attachment. Acoustic shadowing is noted underneath the calcification, which prevents viewing the entire calcific structure and the underlying humeral cortex. *Abbreviations:* CALC=calcification, SS=supraspinatus.

Treatment

Medications are rarely employed in the treatment of tendinosis because the patient usually does not present to the clinician's office until long after the disease process has begun. If the patient is caught early enough, for example within a week or two of the offending event (eg, lateral epicondylitis a week after painting a house), then the disease process is still likely an inflammatory one, and appropriately termed a tendonitis. In this case, NSAIDs are appropriate to try to stop the inflammatory process and ultimately try to prevent it from progressing to a degenerative process. Other effective treatments for tendonitis include activity modification, rest, and ice. However, if the patient has had pain for months,

Figure 2 A, Long axis view; B, short axis view both by ultrasound of a patellar tendon (*outline*) demonstrating tendinosis as evidence by the hypoechoic heterogeneous region outline, which represents the degeneration and irregularity of tendinosis. *Abbreviations:* DIST=distal, HFP=Hoffa's fat pad, MED=medial, LAT=lateral, LAX=long axis, P=patella, PROX=proximal, SAX=short axis.

Figure 3 A, long axis view; B, short axis view both by ultrasound of a supraspinatus tendon with a subacromial-subdeltoid bursitis. The tendon is hyperechoic and fibrillar, which is in contrast to the overlying hypoechoic bursa. *Abbreviations:* ANT=anterior, GT=greater tuberosity, HH=humeral head, LAX=long axis, POST=posterior, SAX=short axis, SUPRA T=supraspinatus tendon.

Figure 4 MRI appearance of tendinopathy. Sagittal T1-weighted image of the knee in a professional basketball player demonstrates abnormal signal and increased size in the patellar tendon, consistent with severe tendinopathy (*arrow*). The tendon is normally devoid of signal. (From Grainger RG, Allison DJ, Adam A, Dixon AK. Grainger and Allison's Diagnostic Radiology, 4th ed. Philadelphia: Churchill Livingstone; 2001.)

the process has likely progressed to tendinosis. The use of NSAIDs has been shown to negatively affect the repair mechanism involved in tendinosis, thus they should be used cautiously in this situation.

Expectations about healing tendinosis should be addressed early. To begin with, tendon healing takes significant time and effort on the part of the patient. Additionally, many of the treatment modalities used to heal tendons will produce a reasonable amount of pain in and of themselves. This is actually a good thing as it indicates the patient is working hard enough to heal and that the healing process is occurring. It is not uncommon to have minor setbacks during the rehabilitation process. There should be an overall trend from a state of disease to health, but the path to recovery is not typically linear. The initial management of tendinopathy should be rehabilitation through PT. The patient should be informed that the “work” of PT is not done at the therapist’s office, but it is done at home on their own. Failing to adhere to the treatment program will almost ensure a lack of recovery.

The exercises performed in PT aim to reorganize the degenerative matrix, reduce tenocyte activity, improve tendon compliance, and provide analgesia. Specifically, eccentric exercises have proven to be an effective treatment. An eccentric exercise is one that strengthens the muscle-tendon complex while lengthening the complex. For example, if a patient is being treated for lateral epicondylitis, the eccentric exercise would be to move the wrist from extension to flexion against resistance, lengthening the common extensor tendon. Strengthening exercises also work to hypertrophy the muscle, which is commonly atrophied after long periods of abnormal use from compensatory movement by the patient to try to reduce pain. The time needed for the exercises to work well is 3 months, which correlates with the time needed to form new fibroblasts, the presumed mechanism by which eccentric exercises work.

PT exercises should be done bilaterally as there is a proven cross-over effect for tendinopathies, whereby exercising the nonaffected

side actually improves the affected side. Adding static stretching to eccentric exercises has been shown to improve outcomes over eccentric exercises alone in patellar tendinopathy, and should be included in an effective rehabilitation program. Before releasing an athlete back to sports activity, the final components of an optimal rehabilitation program includes explosive concentric movements (e.g., weightlifting or box jumps), higher eccentric loading exercises (e.g., jumping from an elevated surface like a box and landing on the ground), and sports-specific movements like sprinting and cutting.

The other treatment modality commonly employed by a physical therapist in tendinosis is deep soft tissue massage with tools. These tools are used to scrape along the pathologic tendon, which promotes blood flow and inflammation leading to the breakdown of the degenerative tissue and ultimately healing of that tissue.

When these conservative measures fail, more aggressive treatment methods should be considered. It is important to point out that the following treatment options are supported by limited high quality evidence, but are nonetheless reasonable alternatives to a surgical procedure. Less invasive methods include extracorporeal shockwave therapy and low-intensity pulsed ultrasound. Glyceryl trinitrate patches are sometimes used to promote blood flow, and have been shown to provide some pain relief. Injections are common treatment modalities in tendinopathies. Steroid injections are commonly used, but usually provide short-term pain relief at best. There is evidence for long-term negative effects of steroids, so they should be used judiciously. A reasonable time to try a steroid injection is when the patient is experiencing so much pain that they are unable to perform therapy. Ultrasound guidance in the hands of a trained physician can help ensure that the injection is placed properly, and specifically not intratendinously. Other treatment options requiring a more trained physician, such as a sports medicine specialist, include prolotherapy, sclerotherapy, and biological blood product injections. Prolotherapy, the injection of hypertonic glucose, is thought to work by inducing a local inflammation-repair mechanism. In sclerotherapy, a sclerotic agent, typically polidocanol, is injected to degrade the tendinopathy pain generators, namely the abnormal vessels and sensory nerves within the tendinopathic tissue. Blood products, including whole blood and platelet-rich-plasma, are used with the intent to deliver a high concentration of growth factors to the tendinopathic tissue, where blood flow is typically low.

If the tendinopathy does not respond to these treatment options, then more invasive measures are typically considered. A tenotomy procedure uses a sharp object, typically a large bore needle, to repetitively fenestrate the degenerated portion of tendon tissue, as noted on ultrasound guidance, to cause bleeding, and stimulate tissue healing. There is a newer technique, whereby the outside of tendon is scraped with a needle or scalpel. The procedure is guided by increased color Doppler signal on ultrasound indicating high vascularity and presumed nerve formation. The recovery from these techniques is usually a minimum of 6 weeks, so they should be reserved for recalcitrant cases. Finally, an open procedure can be performed to remove macroscopically abnormal tissue through an incision in the tendon; unfortunately the recovery for this sort of a procedure is in the time frame of 4 to 12 months.

Bursitis

Background

Bursas are fluid filled sacs designed to reduce friction between various tissues including bones, skin, tendons, and muscles. Typically, there is little fluid within a bursa, but with irritation from overuse or trauma, the bursa may swell with fluid leading to pain and dysfunction. This is referred to as bursitis because of the inflammatory nature of the condition.

There are multiple locations in the body where bursitis more commonly occurs, including the shoulder, elbow, hip, and knee. Bursitis usually develops from either trauma or overuse, but systemic illnesses like rheumatoid arthritis, diabetes mellitus, gout or pseudogout, and immunosuppression may also lead to bursitis. Bursas that are more susceptible to traumatic bursitis include the

prepatellar, olecranon, and trochanteric bursas; they are closer to the skin and have little subcutaneous fat over them, thus they are more likely to sustain a direct impact. Both the olecranon and prepatellar bursa are also at risk for chronic irritation and trauma. Olecranon bursitis is seen in patients who frequently rest on their elbows, as in desk workers and truck drivers. Prepatellar bursitis is seen in patients who kneel for work like carpet layers and house cleaners.

Septic bursitis is rare, and it most commonly affects the olecranon and prepatellar bursa. This occurs via direct inoculation from the traumatic event. The most common organisms isolated are *Staphylococcus aureus* followed by β -hemolytic *Streptococcus*, with about 10% being polymicrobial infections.

The other bursas in the body are more susceptible to overuse injuries. The bursas around the shoulder most commonly affected include the subacromial-subdeltoid bursa, and the scapulothoracic bursa. Athletes who perform overhead movements in sports like baseball, softball, tennis, volleyball, and swimming are at greater risk for irritating these bursas. Of course, athletes are not the only people at risk for bursitis. Manual laborers working with their arms, especially when flexed or abducted regularly can also develop bursitis around the shoulder.

The hip and pelvis have multiple bursas, but the more commonly affected include the bursas around the greater trochanter and iliopsoas. As stated in the tendinopathy section, lateral hip pain is rarely caused by “trochanteric bursitis,” but there are bursas present under the gluteus maximus, gluteus medius, and gluteus minimus muscle-tendon complexes. Bursitis in this region is rarely found without an associated problem like gluteal tendinopathy, or iliotibial (IT) band syndrome. In fact, it is likely that one of these underlying problems led to the bursitis. There is also a bursa under the iliopsoas muscle as it crosses the iliopectineal eminence and anterior hip joint.

Rare causes of knee bursitis include irritation of the suprapatellar bursa, deep infrapatellar bursa, pes anserine bursa, semimembranosus bursa, and medial collateral ligament bursa (Voshell bursa). Bursitis at these locations is almost always from chronic overuse. In the ankle, the retrocalcaneal bursa may also be irritated from overuse.

Evaluation

Evaluation of a patient with suspected bursitis should always begin with a thorough history. Usually the clinician will discover a history of either trauma or overuse, but the patient should also be questioned about the presence of systemic illness. Physical exam of the affected region should include inspection for erythema and swelling. Warmth may be noted on palpation. Range of motion may be limited, but is not a consistent finding. Strength is rarely affected. The appearance of decreased strength may only reflect pain, not true weakness. True weakness would suggest an associated concern like tendinopathy or a tendon tear.

Patients with the presenting symptom of shoulder pain should be evaluated for rotator cuff tendinopathy and scapulothoracic dysfunction and winging, which predispose the athlete to impingement and bursitis. For patients complaining of hip pain, another symptom they may complain of is snapping. The patient should be questioned if the snap is reliably reproducible. If so, then have the patient demonstrate the snap. Snapping laterally is typically the gluteus maximus muscle or the iliotibial band snapping over the greater trochanter, and this is a risk factor for bursitis. If the snapping is anterior in the hip, it is likely the iliopsoas tendon snapping over the iliopectineal eminence or anterior femoral head, which can lead to iliopsoas bursitis.

For the olecranon and prepatellar bursas, special attention must be given to the fact that they are more likely to develop into a septic bursitis from a bacterial infection. If there is evidence of an abrasion in these particular areas, the physician needs to ensure there is not an associated infection. Erythema, progressive swelling, and painful range of motion may point towards the presence of an infection, but these symptoms are often present in aseptic bursitis as well, making the diagnosis difficult. Fever may be present,

but its absence does not rule out infection. If there is any concern for infection, the bursa needs to be aspirated and fluid sent for cell count and differential, crystal analysis, gram stain, and culture before starting antibiotics. Blood should also be sent for a complete blood count, C-reactive protein, erythrocyte sedimentation rate, and cultures.

Imaging is not always necessary to diagnose bursitis. Swelling and erythema over a known bursa may be enough to make a diagnosis, but if the diagnosis is in question, then imaging typically begins with radiographs. Radiographs can evaluate for bony abnormalities that may suggest an underlying reason for bursitis. For example, spurring on the undersurface of the acromion can be a risk factor for subacromial-subdeltoid bursitis. Radiographs can also be used to rule out fracture or to evaluate for a foreign body, especially in the setting of olecranon or prepatellar bursitis.

Further evaluation is typically done with either MRI or ultrasound. MRI offers the advantage of global assessment of the affected region, in addition to allowing enhancement of soft tissues. In skilled hands, ultrasound is an effective tool to demonstrate bursitis throughout the body (see Figure 3). Ultrasound also has the distinct advantage of real-time imaging during a dynamic examination of the affected tissue. If aspiration or injection is needed, ultrasound can help guide the procedure. Both MRI and ultrasound modalities are useful in assessing for associated diagnoses like tendinopathy.

Treatment

Bursitis treatment usually begins with conservative measures like rest or activity modification, NSAIDs, compression, padded splinting, and ice. If the bursitis is acute, it is typically responsive to these basic treatments. As stated previously in this chapter, it is common to find associated problems with the bursitis. These include rotator cuff tendinopathy, gluteal tendinopathy, and iliotibial band syndrome. It is imperative that these issues be treated as well or the bursitis will likely reoccur. This typically requires a home exercise plan usually best directed by a physical therapist.

If these problems fail to respond to this conservative approach, including rehabilitation, then a steroid injection can be considered. There is reasonable evidence that doing the injection under ultrasound guidance will lead to better outcomes, especially for the subacromial-subdeltoid bursa, but blind injections are certainly reasonable if ultrasound is not available. Research reveals that steroid injections for greater trochanteric pain syndrome demonstrate clinically relevant relief at 3 months postinjection when compared with usual care, but that difference disappears by 12 months. This is a common finding with steroid injections. Thus, it is reasonable to consider a steroid injection for pain relief, especially if the patient is unable to participate in PT, but it is unlikely to “fix” the patient’s problem long-term.

For olecranon and prepatellar bursitis, the clinician must first differentiate between septic and aseptic bursitis. If the bursa is infected, following aspiration and lab collection, antibiotics must be initiated. The decision about whether to use oral versus parenteral antibiotics and whether admission is warranted depends upon the severity of the infection and the reliability of the patient. Oral therapy should be used cautiously, as treatment failure has been seen in up to 39% to 50% of patients. The duration of antibiotic treatment is usually 10 to 14 days. Surgical intervention is rarely necessary, but should be considered in patients who fail to respond to incision and drainage and appropriate antibiotics, if there is suspicion of a foreign body, or there is an inability to adequately drain the bursa.

With aseptic bursitis of the prepatellar and olecranon bursas, the clinician should resist the urge to aspirate and inject with steroids. Aspiration and injection is a possible treatment option, but should only follow a failed conservative approach. The reason for this is that once drained, the bursa is likely to fill with fluid again quickly, and there is a risk for an iatrogenic infection. Steroids are also known to cause skin atrophy. A 6- to 8-week trial of the conservative approach is reasonable.

COMMON SPORTS INJURIES

Method of

Andrew S. T. Porter, DO

CURRENT DIAGNOSIS

- **Lateral Ankle Sprain**—Pain over lateral ankle ligament(s) with localized swelling. Often associated with laxity and pain with anterior drawer and/or talar tilt test. Obtain x-rays based on the Ottawa ankle and foot rules.
- **Medial Ankle Sprain**—Less common than lateral ankle sprain. Pain in the deltoid ligament with localized swelling. Obtain x-rays based on Ottawa ankle and foot rules.
- **High Ankle Sprain**—Syndesmotic injury. Pain with squeeze test and/or dorsiflexion with external rotation.
- **Osteochondral Ankle Injuries**—Most commonly seen in the talar dome. Associated with an ankle inversion injury and ankle pain. Often have a joint effusion and soft tissue swelling and can have mechanical symptoms (catching, locking, crepitus, and a feeling of giving way). Obtain x-rays initially and then magnetic resonance imaging (MRI) to grade degree of injury.
- **Anterior Cruciate Ligament (ACL) Injuries**—Most common after noncontact injuries. Physical examination reveals a diffuse knee effusion, positive Lachman, and/or anterior drawer test. Obtain x-rays then MRI for further evaluation.
- **Posterior Cruciate Ligament (PCL) Injuries**—Occur with varus/valgus stress with the knee in full extension. Physical examination reveals a positive posterior drawer and sag sign. Obtain x-rays then MRI for further evaluation.
- **Medial Collateral Ligament (MCL) Injuries**—Occur with valgus stress or twisting with or without contact. Physical examination reveals localized effusion and a positive valgus stress testing and tenderness to palpation along the MCL. Graded 1 to 3.
- **Osteochondral Knee Injuries**—Most commonly seen in the femoral condyle. Associated with a knee injury. Knee pain and, often, mechanical symptoms of the knee. Palpation of the femoral condyles with the knee in flexion reproduces pain. Obtain x-rays initially and then MRI to grade degree of injury.
- **Mallet Finger**—Disruption of the extensor mechanism insertion into the distal phalanx.
- **Jersey Finger**—Occurs after avulsion of the flexor digitorum profundus tendon from its insertion on the distal phalanx.
- **Proximal Interphalangeal (PIP) Joint Dorsal Dislocation**—Injury to the volar plate with or without an avulsion fracture.
- **Scaphoid Fracture**—Pain over the scaphoid with or without a fall on an outstretched hand injury is a scaphoid fracture until proven otherwise. Obtain wrist x-rays with a scaphoid view.
- **Tendinosis**—Repetitive chronic tendon injuries result in scarring, disorganization of fibers, degeneration, and are without an inflammatory component.

CURRENT THERAPY

- **Stress Fractures**—Most often seen in active patients as a result of excessive stress on normal bone from overactivity or normal stress on a bone that is deficient (osteoporotic, poor nutrition, or in female athlete triad). History is positive for bone pain, and physical examination reveals tenderness to palpation in the affected bone and often a positive tuning fork test, hop test, and fulcrum test. Obtain x-rays first, then MRI or bone scan if needed.
- **Spondylolysis/Spondylolisthesis**—Most often seen in young athletes with insidious onset low back pain and history of repetitive extension. Positive stork test. X-rays initially, and if negative, may proceed with limited CT and SPECT scan or MRI.
- **Lateral Ankle Sprain**—Treat with RICE (rest, ice, compression, elevation) and early rehab. Return to play (RTP) is generally 1 to 4 weeks and is based on functional progression. RTP with ankle brace.
- **Medial Ankle Sprain**—Treat with RICE and early rehab. RTP with ankle brace.
- **High Ankle Sprain**—Treat with RICE and boot for 1 to 3 weeks and then rehab. RTP takes a longer time compared with lateral ankle sprain.
- **Osteochondral Ankle Injuries**—Degree of injury is graded via MRI, and this guides treatment and RTP.
- **ACL Injuries**—ACL tears often need reconstruction that is individualized in active patients who require knee stability.
- **PCL Injuries**—Isolated PCL injuries often heal conservatively with protected weight bearing in an extension brace and knee rehab.
- **MCL Injuries**—Often heal conservatively with bilateral hinged knee brace and knee rehab. Generally, RTP in 2 to 6 weeks.
- **Osteochondral Knee Injuries**—Degree of injury is graded via MRI, and this guides treatment and RTP.
- **Mallet Finger**—Treat with continuous full-extension stack splinting of the distal interphalangeal joint for 6 weeks and then nighttime splinting and activity splinting for 6 weeks.
- **Jersey Finger**—Treatment is referral to orthopedic surgeon for surgical intervention.
- **PIP joint dorsal dislocation**—Reduce dislocation and obtain x-rays. Treat with progressive extension blocking splint with 30° to 40° of flexion and decrease by 10° per week.
- **Scaphoid Fracture**—If x-rays with scaphoid view are negative, place in a short-arm thumb spica cast and follow up in 2 weeks. If x-rays remain negative but pain persists, obtain a CT or MRI. Treat nondisplaced scaphoid fractures with short-arm thumb spica cast: proximal-third fractures 12 to 20 weeks, middle-third fractures 10 to 12 weeks, and distal-third fractures 4 to 6 weeks.
- **Tendinosis**—Treat by creating inflammation to facilitate healing.
- **Stress Fractures**—Treat with general treatment for stress fractures plus specific treatment based on stress fracture site.
- **Spondylolysis/Spondylolisthesis**—Treat with extension blocking brace, rest, rehabilitation with core strengthening and lower extremity flexibility, and gradual RTP.

Ankle Injuries

The ankle is the most common joint injured in athletes. Ankle sprains are common, as they represent 25% of all sports-related injuries. The Ottawa ankle and foot rules help in the decision to obtain x-rays (Box 1). In general, treatment will consist of RICE (rest, ice, compression, elevation), early mobilization, and rehab. Prevention of ankle injuries is important and consists of ankle braces, ankle taping, neuromuscular training program, and regular sport-specific warm-up exercises.

- **Scaphoid Fracture**—If x-rays with scaphoid view are negative, place in a short-arm thumb spica cast and follow up in 2 weeks. If x-rays remain negative but pain persists, obtain a CT or MRI. Treat nondisplaced scaphoid fractures with short-arm thumb spica cast: proximal-third fractures 12 to 20 weeks, middle-third fractures 10 to 12 weeks, and distal-third fractures 4 to 6 weeks.
- **Tendinosis**—Treat by creating inflammation to facilitate healing.
- **Stress Fractures**—Treat with general treatment for stress fractures plus specific treatment based on stress fracture site.
- **Spondylolysis/Spondylolisthesis**—Treat with extension blocking brace, rest, rehabilitation with core strengthening and lower extremity flexibility, and gradual RTP.

Ankle Injuries

The ankle is the most common joint injured in athletes. Ankle sprains are common, as they represent 25% of all sports-related injuries. The Ottawa ankle and foot rules help in the decision to obtain x-rays (Box 1). In general, treatment will consist of RICE (rest, ice, compression, elevation), early mobilization, and rehab. Prevention of ankle injuries is important and consists of ankle braces, ankle taping, neuromuscular training program, and regular sport-specific warm-up exercises.

- An ankle x-ray series is indicated if there is pain in the malleolar zone and any of these findings are made:
 - Tenderness over the lateral malleolus
 - Tenderness over the medial malleolus
 - Inability to bear weight four steps immediately after the injury or in the emergency department or physician's office
- A foot x-ray series is indicated if there is pain in the midfoot zone and any of these findings are made:
 - Tenderness over the base of fifth metatarsal
 - Tenderness over the navicular bone
 - Inability to bear weight four steps immediately after the injury and in the emergency department or physician's office

*X-rays are indicated if any of these criteria are met.

Data from Bachmann and colleagues (2003) and Tiemstra (2012).

Lateral Ankle Sprain

The most common ankle sprain is a lateral inversion sprain that results from landing on an inverted foot with or without plantarflexion. The lateral ankle ligaments are the anterior talofibular ligament (ATFL), calcaneofibular ligament, and the posterior talofibular ligament. The ATFL is the most commonly sprained ligament. Lateral ankle sprains are most commonly treated with RICE initially, then early ambulation, range of motion, progression into strengthening, and then proprioception rehabilitation. Proprioception rehabilitation includes balancing on one leg and performing balancing exercises on a wobble board. For example, patients can balance on one leg when brushing their teeth. Athletes should return to play (RTP) with a lace-up/velcro ankle brace after injury with or without taping. This added stability will help prevent future ankle injuries and also decrease the severity of ankle injuries. Most athletes will RTP in a few days to 4 weeks; this return is based on pain, obtaining full active range of motion and full strength, and functional stability.

Medial Ankle Sprain

Medial ankle ligament sprains are rare, account for < 10% of ankle injuries, and are often accompanied with a lateral malleolar fracture or syndesmotic injury. The medial ankle ligament is the deltoid ligament and is injured via external rotation or eversion. These ankle sprains are treated similarly to lateral ankle sprains.

High Ankle Sprain

High ankle sprains, also known as syndesmotic ankle sprains, occur through forced external rotation of a dorsiflexed foot most commonly but also occur by forced internal rotation of a fixed plantar flexed foot. The syndesmotic ligaments connect and stabilize the distal tibia to the distal fibula. The syndesmotic ligaments are the anterior tibiofibular ligament, posterior tibiofibular ligament, transverse tibiofibular ligament, interosseous ligament, and the interosseous membrane. Palpate the fibular head for pain. Pain on palpation of the fibular head might indicate a Maisonneuve fracture, a fracture of the proximal third of the fibula associated with syndesmotic disruption. A high ankle sprain has a longer healing time compared to a lateral ankle sprain. Often these need immobilization with a boot or cast for 1 to 4 weeks to help with healing before beginning rehab. RTP after a high ankle sprain depends on pain, achieving a full active range of motion, full strength, and functional stability. Incomplete healing of a high ankle sprain can result in distal tibia and fibula instability.

Osteochondral Ankle Injuries

Osteochondral injuries are injuries to the articular surface of a joint. These injuries range from small undisplaced depressions and cracks in the osteochondral surface to small pieces of articular cartilage and bone that break off of the articular surface and float within the joint. Osteochondral injuries occur most commonly on weight-bearing articular surfaces. In osteochondral injuries, osteonecrosis of subchondral bone occurs, resulting in separation of cartilage and subchondral bone from underlying, well-vascularized bone. The term *osteochondral lesion* (OCL) is favored over the previously used term *osteochondritis dessicans* because there might not be an inflammatory component of the injury. OCLs are often associated with repeated trauma or overuse in athletes. OCLs typically present with pain in the affected joint and can develop with a specific injury or over several months in highly active athletes. OCLs are more common in younger patients with open physes (growth plates) and are referred to as juvenile OCLs. Adult OCLs describe this condition in skeletally mature patients.

Osteochondral injuries are a cause for pain in up to 25% of ankle injuries and need to be considered when a patient presents with ankle pain. Acute osteochondral injuries in the ankle most commonly affect the talar dome (Figures 1–3) but can also be found in the distal tibia (Figure 4). OCLs are first evaluated by x-rays (see Figures 1 and 2) and then graded by magnetic resonance imaging (MRI) (Table 1). CT scan (see Figure 3) is sometimes utilized as

Figure 1 X-rays of the left ankle, AP and mortise views, which demonstrate a grade 2 osteochondral lesion (OCL) along the medial talar dome.

Figure 2 X-ray of the left ankle, mortise view, which demonstrates a grade 4 OCL along the lateral talar dome.

Figure 3 CT scan without contrast. Sagittal image of ankle, which demonstrates a grade 4 OCL of the talar dome.

well. Grade 1 to 3 juvenile OCLs and grade 1 to 2 adult OCLs are treated conservatively. Conservative treatment consists of no weight bearing (NWB) in a cast or boot for 6 to 10 weeks followed by partial weight bearing (PWB) to full weight bearing (FWB) over 2 to 6 weeks, followed with an ankle brace for 3 months, and ensuring adequate calcium and vitamin D intake to facilitate healing. Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided because they can slow bone healing, and OCLs are probably not an inflammatory process. For grade 4 juvenile OCLs, grade 3 and 4 adult OCLs, and those that have not clinically healed with conservative care operative treatment is required. Operative treatment options depend on OCL size and type and include removal of the OCL followed by transchondral drilling and

Figure 4 CT scan without contrast. Coronal image of ankle, which demonstrates a grade 1 OCL of the distal lateral tibia.

TABLE 1 Classification of Osteochondral Lesions

STAGE	PLAIN X-RAY FINDINGS	MRI FINDINGS
1	Depressed osteochondral fragment	Articular cartilage thickening and low signal changes in subchondral bone
2	Osteochondral fragment attached by bone	Articular cartilage breached, no synovial fluid around fragment
3	Detached nondisplaced fragment	Articular cartilage breached, synovial fluid around fragment
4	Displaced fragment	Loose foreign body

microfracture to stimulate fibrocartilage formation, fixation of the OCL with an osteochondral allograft, osteochondral autograft transfer, and autologous chondrocyte implantation.

Knee injuries—The knee joint lacks intrinsic bone stability, so most stability is from the major knee ligaments.

Anterior Cruciate Ligament Injuries

The anterior cruciate ligament (ACL) is the key stabilizer of the knee and is one of two major intraarticular knee ligaments, the other being the posterior cruciate ligament (PCL). Most ACL tears occur from noncontact injuries. Women experience ACL tears up to nine times more often than men do. The main function of the ACL is to prevent excessive anterior tibial translation relative to the femur. Patients who sustain an injury to their ACL often describe hearing a pop, feeling instability in their knee, experiencing pain immediately after the injury, and develop an associated knee effusion. On-the-field evaluation is ideal in an ACL injury, as the hamstrings will often start to tighten up shortly after the injury, preventing anterior tibial translation. This will prevent an isolated test of the ACL and give the false impression that an ACL endpoint is present when in fact the ACL is completely torn. The anterior drawer ([Figure 5](#)) and Lachman test ([Figure 6](#)) are the main physical examination tests to evaluate the ACL. Obtain x-rays and then MRI if an ACL tear is suspected. The blood supply to the ACL is poor and is provided by the middle geniculate artery

Figure 5 Anterior drawer test for ACL laxity. Patient's knee is flexed 90°. Examiner applies anterior force to the tibia in relation to the patient's femur to evaluate for laxity.

Figure 6 Lachman test for ACL laxity. Patient's knee is flexed 20°–30°. Examiner grasps the distal femur and proximal tibia and applies anterior force to the tibia and posterior force to the femur to evaluate for ACL laxity.

off of the popliteal artery. Because of the poor blood supply, ACL tears often need reconstruction if athletes want to return to a high level of activity and knee stability is needed. ACL reconstruction timing is important and often will occur 3 to 4 weeks after injury to allow for swelling to decrease, ROM and strength to improve, and inflammation to decrease. Also during this presurgical time, it is important to have patients perform pre-hab (presurgical rehabilitation), focusing on AROM and knee strengthening. A knee effusion will cause the quadriceps muscles to weaken and atrophy. Hamstring tendon autograft, patella tendon autograft, quadriceps tendon autograft, and allograft are all used for ACL reconstruction. Each graft has advantages and disadvantages and should be discussed with the orthopaedic surgeon before reconstruction and individualized for each patient. Continuing to participate in high-level activity after an ACL tear if undiagnosed can lead to a knee dislocation and further intraarticular knee injury.

PCL Injuries

The PCL is the other major intraarticular knee ligament. Isolated PCL injuries are much less common than ACL injuries and make up only 3.5% of ligamentous knee injuries in sports, with the remaining 96.5% of PCL injuries associated with multiligamentous knee injuries. PCL injuries, unlike ACL injuries, are the result of external forces (e.g., a soccer player sliding into the goal post and tearing his or her PCL). The main function of the PCL is to resist posterior tibial translation. Posterior drawer testing (Figure 7) and a sag sign test (Figure 8) are the physical examination tests used to evaluate the PCL. Obtain x-rays then MRI if a PCL tear is suspected. The blood supply to the PCL is better than the blood supply to the ACL. Isolated PCL injuries (grades 1 and 2) are treated conservatively because surgical reconstruction has not been shown to be helpful. Conservative treatment consists of protected weight bearing in an extension brace followed by quadriceps rehabilitation and ROM exercises. RTP is generally 4 to 6 weeks after a

Figure 7 Posterior drawer test for PCL laxity. Patient's knee is flexed 90°. Examiner applies posterior force to the tibia in relation to the patient's femur to evaluate for laxity.

Figure 8 Sag sign test for PCL laxity. Examiner views the tibia condyles from the lateral side to evaluate for a posterior sag (displacement) in the appearance that would indicate a PCL injury.

PCL injury. Surgical intervention is recommended for associated injuries to the ACL, medial collateral ligament (MCL), and posterior lateral corner (grade 3 PCL injury).

MCL Injuries

The MCL is an extraarticular ligament that resists knee valgus forces. An MCL sprain results from a valgus stress to a partially flexed knee. Athletes will present with localized pain and swelling along the medial aspect of the knee. Most MCL injuries are isolated ligament injuries, but more severe MCL injuries can involve tears of the medial meniscus and ACL, commonly referred to as the “terrible triad.” The MCL is examined by palpation and valgus stress testing at 0° and 30° of knee flexion. MCL injuries are graded 1, 2, or 3 depending on severity of injury. A patient with a grade 1 MCL sprain has pain in the MCL but no valgus stress testing laxity. A grade 2 MCL sprain has valgus stress testing laxity but a solid endpoint. A grade 3 MCL sprain has no endpoint with valgus stress

testing. Thankfully, the MCL has a rich vascular supply and can often heal conservatively. Treatment consists of RICE for the first 1 to 2 weeks and a bilateral hinged knee brace to facilitate healing. Weight bearing and ROM and strengthening exercises are started when they are tolerable. RTP after an MCL injury depends on the grade and generally takes 2 to 6 weeks.

Osteochondral Knee Injuries

Osteochondral injuries occur in the knee as well as in the ankle. Osteochondral injuries of the knee most commonly affect the lateral aspect of the medial femoral condyle but can be found anywhere along the medial or lateral femoral condyle, patella, or trochlea. History is significant for knee pain, with or without swelling and mechanical symptoms (catching, locking, crepitus, and feeling of giving way). On palpation, patients can have pain in the affected area with knee flexion with or without crepitus. Obtain x-rays initially (Figure 9) and then grade the OCL severity by MRI (Figure 10). CT scans are also utilized sometimes. Grade 1 to 3

Figure 9 X-ray of the bilateral knees, AP view, which demonstrates a grade 1 OCL along the right knee medial femoral condyle.

Figure 10 Magnetic resonance imaging (MRI) of the right knee, without contrast. Coronal T2 fat saturation image, which demonstrates a grade 4 OCL of the medial femoral condyle.

juvenile knee OCLs and grade 1 to 2 adult knee OCLs are treated conservatively. Grade 4 juvenile OCLs, grade 3 to 4 adult OCLs and all OCLs that have failed conservative care are treated operatively.

Hand Injuries

Mallet Finger

A mallet finger occurs after forced flexion of an actively extended distal interphalangeal (DIP) joint, resulting in disruption of the extensor mechanism insertion into the distal phalanx. Patients with a mallet finger are unable to actively extend the DIP joint. This injury can be associated with an avulsion fracture (Figure 11). For acute injuries, general treatment consists of continuous extension splinting of the DIP joint (0° to 10° of hyperextension) for at least 6 weeks. The 6-week clock starts over if the DIP joint is allowed to flex at all during the initial 6 weeks of treatment or if, at the end of the 6 weeks, the mallet finger is not completely healed. After the initial 6 weeks, it is recommended to continue with nighttime splinting and activity splinting for another 6 weeks to ensure adequate healing and avoidance of surgery. To perform this splinting, a stack splint is well tolerated and is protective (Figure 12). Orthopaedic referral is indicated if the patient is unable to obtain full passive extension of the DIP joint or if the avulsion fracture involves over 30% of the joint space.

Jersey Finger

A jersey finger results from the avulsion of the flexor digitorum profundus tendon from its insertion on the distal phalanx. This commonly occurs in football and rugby players when the tip of their flexed finger is caught in a jersey and the DIP joint of the finger is then forcefully extended. After this injury occurs, the patient is unable to actively flex the DIP joint. Treatment is urgent referral to an orthopaedic surgeon for surgical intervention.

Figure 11 X-ray of the left hand, lateral view, which demonstrates a mallet finger of the fifth finger. Note the flexion of the DIP joint and avulsion fracture of the distal phalanx that involves about 30% of the joint space.

Figure 12 Stack splint with Coban wrap added for stability that immobilizes the DIP joint at neutral to 5° of hyperextension.

Proximal Interphalangeal Joint Dorsal Dislocation

Proximal interphalangeal (PIP) joint injuries are the most common joint injuries in sports. Most PIP dislocations are dorsal and result from hyperextension with an axial load. Dislocations are described by the position of the distal fragment in relation to the proximal fragment. PIP dorsal dislocations cause injury to the volar plate with or without avulsion fracture. Pre-reduction x-rays are preferred if they can be obtained promptly (Figure 13). X-rays of the finger with at least one view being a true lateral view should be obtained to rule out fracture. However, many PIP dorsal dislocations occur on the playing field and it is reasonable to reduce these dislocations, buddy tape the affected finger, and allow the patient to RTP with x-rays obtained after the athletic competition. Reduction is usually uncomplicated and is performed urgently via hyperextending the joint, applying traction in plane with the finger, then flexing the joint. Post reduction films are a necessity (Figure 14). Stability testing of the collateral ligaments should be performed after the reduction. Full flexion and extension of the PIP joint will be possible if the joint is stable. A stable joint without a large avulsion fragment should be treated with a progressive extension blocking splint (Figures 15 and 16). Start with 30° to 40° of flexion and decrease by 10° per week over 3 to 4 weeks, then buddy tape the injured finger with activity PRN (8). Some PIP dorsal dislocations have a lateral component to them and these are treated similar to pure dorsal dislocations (see Figure 13). Orthopaedic surgeon referral is indicated if there is a large avulsion fracture or the joint is unstable.

Scaphoid Fracture

The scaphoid bone is the most common carpal bone that is fractured and is a common injury that is encountered in primary care. Interestingly, scaphoid fractures occur most commonly in young men. Scaphoid fractures occur less commonly in young children and the elderly because of the relative weakness of the distal radius compared with the scaphoid in these age groups. Often a scaphoid fracture is caused by a FOOSH (fall on an outstretched hand) injury. On physical examination, if the patient has pain over the

Figure 13 X-ray of the left hand, oblique view, which demonstrates a proximal interphalangeal (PIP) joint dorsal and lateral dislocation.

Figure 14 X-ray of the left hand, lateral status postreduction view, which demonstrates a relocated proximal interphalangeal (PIP) joint. Note the avulsion fracture of the middle phalanx.

Figure 15 Dorsal extension blocking splint at 30°–40° of flexion at the PIP joint. Note that there is no pressure over the PIP joint volar plate and that flexion and extension at the DIP joint is possible.

scaphoid tubercle or in the anatomical snuffbox with or without a history of a FOOSH injury, the clinician needs to have a high index of suspicion for a scaphoid fracture when evaluating the wrist x-rays. Obtain the standard wrist x-rays (AP, lateral, and oblique views) plus a dedicated scaphoid view (AP with ulnar deviation) and be aware that early imaging with x-rays is often unrevealing for a scaphoid fracture (Figure 17). If a fracture is not seen on x-rays, the clinician needs to have a high index of suspicion for a scaphoid fracture, place the patient in a short-arm thumb spica cast, and have the patient follow up in 2 weeks. If repeat x-rays remain negative and the patient continues to have scaphoid

Figure 16 Dorsal extension blocking splint at 30°–40° of flexion at the PIP joint. This figure illustrates the freedom of motion that is possible at the PIP joint (full flexion and limited extension) and the DIP joint (full flexion and extension).

Figure 17 Scaphoid view x-ray (AP view with ulnar deviation) is important to obtain in addition to your standard wrist views (AP, lateral, and oblique) when scaphoid fracture is suspected. This scaphoid fracture was not seen on the x-rays on the day of the injury. Patient continued to have wrist pain and then presented 10 weeks later, and x-rays were obtained demonstrating the scaphoid fracture.

pain, proceed with an MRI of the wrist with T2 fat saturation views or a CT scan. If a scaphoid fracture is noted on imaging, the location of the scaphoid fracture will guide treatment. Because the blood supply to the scaphoid is distal to proximal, scaphoid fractures are harder to heal than other carpal fractures. Nondisplaced middle-third or proximal-third scaphoid fractures are treated with a long- or short-arm thumb spica cast with the wrist at 20° to 30° of extension and the thumb in slight extension and abduction for 10 to 20 weeks. Middle-third fractures should be immobilized for 10 to 12 weeks. Proximal-third fractures should be immobilized from 12 to 20 weeks. It is much easier to regain flexion in the wrist after casting than it is to regain extension. If the elbow is incorporated in

the cast, it should be casted at 90° of flexion. A long-arm cast may decrease healing time, but it does not improve nonunion rates. A nondisplaced distal-third fracture should be treated in a short-arm thumb spica cast for 4 to 6 weeks. For displaced fractures or non-healing fractures, a referral to an orthopedic surgeon is recommended. Use acetaminophen for pain control and avoid non-steroidal antiinflammatory drugs (NSAIDs) because NSAIDs can impair bone healing. Ensure adequate energy availability via diet and adequate calcium and vitamin D intake (7), and avoid tobacco exposure to help heal the fracture. Bone health and bone nutrition are a part of the big picture in fracture healing.

Overuse Injuries

Tendinosis

The paradigm and management of tendon overuse injuries is changing. The term *tendinitis* is generally used to refer to painful overuse tendon conditions and implies that inflammation is present. However, the most common pathology in chronic painful tendons is tendinosis. Tendinosis occurs after repetitive injuries to a tendon results in intertendinous scarring, disorganization of tendon fibers, and degeneration. Tendinosis does not have an inflammatory component. Early on in a tendon injury, there is inflammation resulting in tendinitis, but after about 6 weeks this generally evolves into tendinosis. Early activity modification and treatment of tendinitis with NSAIDs and rehabilitation may prevent the development of tendinosis. Tendinosis is a problematic condition that affects many active people, young and old. To address these more chronic tendon injuries, healing is facilitated by creating an inflammatory response. To create inflammation, treatments such as eccentric strengthening (Figure 18), deep soft tissue massage with tools (e.g., gua sha or Graston, or ASTYM) (Figure 19), nitroglycerin patches (Nitro-Dur),¹ and musculoskeletal ultrasound-guided percutaneous needle tenotomy (with or without injection of autologous blood, prolotherapy, or platelet-rich plasma) have all been utilized and have been shown to be effective (Table 2). It is important to avoid NSAIDs when trying to create inflammation because NSAIDs will prevent the inflammatory response. This concept of tendinosis diagnosis and treatment can be utilized for tendons throughout the body and is most commonly applied to the Achilles tendon, patella tendon, iliotibial (IT) band, piriformis, gluteus medius, hamstrings, biceps, common elbow flexor tendon, and common elbow extensor tendon.

Stress Fractures

Stress fractures occur when osteoclastic activity overwhelms osteoblastic activity. Bone injury unfolds over a continuum of time, starting with normal bone that progresses to stress reaction, then stress fracture, and finally fracture if the bone continues to be injured. This can occur as a result of excessive stress on normal bone from overactivity or normal stress on a bone that is deficient (osteoporotic, poor nutrition, or in female athlete triad). Stress fractures are common injuries in athletes and occur most often in the lower extremities. Running sports account for 69% of stress fractures. Stress fractures should be considered in someone who is active, presents with bone pain, and who performs repetitive activities with limited rest or with a recent increase in activity. Physical examination tests to perform in the area of interest are palpation, the tuning fork test, the fulcrum test, and the hop test (Table 3). If a stress fracture is suspected, x-rays should be obtained, keeping in mind that it takes 2 to 3 weeks for signs of stress fracture (i.e., periosteal reaction, callus formation, fracture line) to show up on an x-ray, and often stress fractures do not show up on x-rays. If x-rays are negative and a diagnosis is needed to help guide care and RTP, a bone scan or MRI with T2 fat saturation views (Figures 20 and 21) should be obtained. The bone scan and MRI are equally sensitive, but an MRI is more specific and avoids patient radiation exposure. An MRI is more expensive. Because a bone scan can stay positive

¹Not FDA approved for this indication.

Figure 18 Eccentric exercises for Achilles tendinosis. (A) Patient begins with the injured leg straight and the ankle in flexion. The assistance of the uninjured leg was utilized to get in this starting position. (B) The ankle of the injured leg (right leg, in this case) is slowly lowered in a controlled fashion to full dorsiflexion to eccentrically strengthen (while lengthening the calf muscles) the right Achilles tendon. The left leg is then brought back down, and full plantarflexion in both ankles is performed, recruiting the uninjured leg to assist with getting back to position (A). (C) The eccentric exercise from (B) is repeated with the knee bent at 45°.

Figure 19 ASTYM® tools.

TABLE 2 Treatment of Tendinosis

TREATMENT MODALITY	DESCRIPTION
Deep soft tissue massage with tools (gua sha, Graston, ASTYM) (Figure 19)	One to three times per week for 4–6 wk; most common with athletic trainer certified or physical therapist
Nitroglycerin patches (Nitro-Dur) ¹	0.2 mg/h patch, cut in half and apply Q24 h to a different location on tendon for at least 6 wk
Eccentric strengthening (Figure 18)	3 sets of 15 exercises, twice daily, for 12 wk
Musculoskeletal ultrasound-guided percutaneous needle tenotomy with or without autologous blood injection, prolotherapy, or platelet-rich plasma	Referral to primary care sports medicine physician

¹Not FDA approved for this indication.

TABLE 3 Stress Fracture Physical Exam Tests

PHYSICAL EXAM TEST	POSITIVE TEST
Palpation	Pain over affected bone with palpation
Stork test (Figure 22)	Back extension with rotation while standing on one leg increases pain in the pars interarticularis region
Fulcrum test	Pain in fracture site while applying a bending force (e.g., over the exam table) to distal extremity while proximal extremity is kept relatively immobilized
Hop test	Hopping 10 times on affected leg reproduces pain at fracture site
Tuning fork test	Vibrating tuning fork over fracture site results in pain at site

for up to 18 months, clinical progress should not be monitored with a bone scan.

To prevent stress fractures, athletes should distribute loading forces on the bone with cross training and biomechanical adjustments (i.e., orthotics, proper shoes, stretches, strengthening, running mechanics), consume sufficient calories to maintain adequate energy availability, and ensure appropriate intake of calcium and vitamin D. A study by Lappe of female Navy recruits showed reductions in stress fractures in those consuming 2000 mg of calcium¹ and 800 IU vitamin D¹ daily, either as a supplement or through consumption of dairy products. Tobacco should be avoided. Additionally, women of child bearing age should try to maintain regular menses by consuming adequate calories and avoiding a negative energy balance.

General treatment for stress fractures can be grouped into nutrition, medication, and biomechanical recommendations. Nutrition recommendations include optimizing energy availability in the diet, ensuring adequate calcium and vitamin D intake, and avoidance of tobacco exposure. Medication recommendations include using acetaminophen as needed for pain control and avoidance of NSAIDs. Biomechanical recommendations are to offload the affected bone and reduce activity to pain-free functioning and pain-free cross-training. Crutches may be needed to offload the

Figure 20 MRI of the right hip without contrast. Coronal T2 fat saturation image demonstrates a compression-sided femoral neck stress fracture (note surrounding bone edema in white).

Figure 21 MRI of the right hip without contrast. Axial T2 fat saturation image that demonstrates a compression-sided femoral neck stress fracture (note fracture line in black and surrounding bone edema in white) that measures up to 11 mm.

injured area even more than a walking boot/cast or steal shank. The patient may require complete non-weight bearing (NWB) with the overall goal being to obtain pain-free ambulation during the initial treatment. [Tables 4 and 5](#) outline recommended guidelines for

TABLE 4 High-Risk Stress Fracture Initial Treatment

HIGH-RISK STRESS FRACTURE	INITIAL TREATMENT (IF STABLE AND NONDISPLACED)
Femoral neck (compression side) (Figures 20 and 21)	NWB for 6–8 wk then PWB to FWB over next 6–8 wk
Anterior tibia (tension side)	NWB for 6–8 wk then PWB to FWB over next 6–12 wk
Medial malleolus	Pneumatic lower leg boot for 6–8 wk
Navicular	NWB cast/boot for 6 wk then 6-wk RTP progression
Base of fifth metatarsal (Jones)	NWB cast/boot 6–8 wk
May consider surgery for quicker RTP	
Sesamoids	NWB cast/boot 6 wk

Abbreviations: NWB = non-weight bearing; PWB = partial weight bearing; FWB = full weight bearing.

TABLE 5 Low-Risk Stress Fracture Initial Treatment

LOW-RISK STRESS FRACTURE	INITIAL TREATMENT
Sacrum/pelvis	WBAT 7–12 wk
Femoral shaft	WBAT 6–8 wk
Posterior medial tibia (compression side)	WBAT boot 2–12 wk (longer time with cortical break) then transition to pneumatic tibial brace
Fibula	WBAT 1–4 wk
Metatarsal (2nd–5th)	Steel shank/walking boot 3–6 wk

Abbreviations: WBAT = weight bearing as tolerated.

protected weight bearing for specific stress fracture sites. Additional recommendations are to begin a rehabilitation program when tolerated and to stretch and strengthen supporting structures. Start a gradual increase in activity when the patient is pain-free.

Because of their propensity for delayed healing and nonunion, certain stress fractures are considered high risk, necessitate prompt treatment, and may ultimately require surgical fixation. Low-risk stress fractures have a lower incidence of delayed healing and nonunion. High-risk stress fractures that appear stable and nondisplaced can be treated nonoperatively with close follow-up. Consider referral to an orthopaedic surgeon for failed conservative treatment. Biomechanical forces along the bone with activity are used to classify tibia and femur stress fractures. For example, during running, the tibia and femur have different forces exerted on different parts of the bone. The tibia compresses posteriorly, so there is more compression along the posterior tibia and more tension along the anterior aspect of the tibia. The femoral neck compresses inferiorly and medially with running, so there is more compression along the inferior medial aspect of the femoral neck and more tension along the superior lateral aspect of the femoral neck. These variable forces on different parts of the bone affect the potential for delayed healing and nonunion.

Spondylolysis and Spondylolisthesis

Spondylolysis is a nondisplaced stress fracture of the pars interarticularis. Spondylolisthesis occurs when there is bilateral spondylolysis with listhesis (slippage) of the vertebral body. Spondylolisthesis is graded 1 to 4 depending on how much slippage is present with each grade, accounting for 25% (i.e., grade 1 = 0–25%).

Figure 22 Stork test: To assess localized spondylolysis pain, a single leg hyperextension rotation test (stork test) is performed. The patient stands on one leg and hyperextends and rotates the spine. Reproduction of the patient's pain is suggestive of a spondylolysis.

When a young athlete presents with low back pain, spondylolysis needs to be considered: this can be the cause of their pain up to 47% of the time. Spondylolysis is an overuse injury caused by repetitive hyperextension and/or rotation and has increased

Figure 23 Oblique view x-ray of the lumbar spine, which demonstrates a L3 and L4 spondylolysis.

Figure 24 SPECT scan lumbar spine, PA view, which demonstrates an acute bilateral L3 and L4 spondylolysis.

Figure 25 CT scan without contrast. Axial image at L3 shows bilateral pars interarticularis fractures that appear acute with jagged and nonsclerotic fracture edges.

incidence in ballet dancers, gymnasts, divers, soccer players, and football linemen. L5 is the most common level for a spondylolysis. The history is significant for insidious onset of deep pain in the low back exacerbated by extension. Physical examination shows a positive Stork test (see Table 3), often with reproduction of pain on the side of weight bearing (Figure 22). If history and physical exam are suggestive of a pars interarticularis injury, x-rays of the lumbar spine, including oblique views, should be obtained. Oblique view x-rays provide the best view to identify a spondylolysis even though they only demonstrate spondylolysis about 30% of the time when it is present (Figure 23). If x-rays are negative, proceed with MRI or with SPECT scan. If the SPECT scan is positive (Figure 24), then proceed with limited CT scan (Figures 25 and 26). If radiation exposure is a concern, or if high-definition MRI is readily accessible, thinly sliced stacked axial cuts with T2 fat saturation views in all planes using a high-definition MRI is the test of choice (Figure 27). A spectrum of recommended treatments and

Figure 26 CT scan without contrast. Axial image at L4 shows bilateral pars interarticularis fractures. Right L4 pars fracture appears more chronic in appearance, with sclerotic fracture edges on the lateral aspect. Left L4 pars fracture appears more acute, with more jagged-appearing edges.

Figure 27 MRI lumbar spine without contrast. Axial T2 fat saturation image at L5 that demonstrates a right L5 spondylolysis signified by right pars interarticularis bone edema in white at L5.

conservative approaches that allow for a prompt and safe RTP are reasonable. For acute spondylolysis, the recommended treatment consists of a warm and form-extension-blocking back brace worn all day except for showering and bathing (23–24 hours per day) for the first month of treatment in conjunction with rest from activity. During the second month, use of the brace during the day with rehabilitation is suggested. Rehabilitation consists of core strengthening and lower extremity flexibility. The third month consists of a gradual return to activity, continuing core strengthening and

Figure 28 Lateral view x-ray of the lumbar spine, which demonstrates a grade 1 L5 spondylolisthesis.

flexibility, and wearing the brace with activity. When treating spondylolysis, a healed pars interarticularis injury is defined as pain-free activity that may include bony union of the pars interarticularis stress fracture or fibrous nonbony union. Generally, the patient should wear the brace for at least 1 year with activity and sometimes longer depending on the severity of injury. Utilize acetaminophen for pain, avoid NSAIDs, ensure adequate energy availability, maximize calcium and vitamin D intake, and avoid tobacco exposure to facilitate bone healing.

The general goal for spondylolisthesis treatment is to prevent further slippage; treatment is similar to that for spondylolysis. Surgical referral is indicated for grade 2, 3, or 4 spondylolisthesis (Figure 28).

Method of

Molly Hinshaw, MD; and Susan Lawrence-Hylland, MD

CURRENT DIAGNOSIS

Lupus Erythematosus

- The erythematous-violaceous and variably pruritic, tender, or scaly eruption is photosensitive.
- Mild to moderate systemic involvement may include arthritis and pleurisy.
- Severe systemic involvement may include nephritis, cerebritis, vasculitis, and severe cytopenias.
- Associated findings include antiphospholipid antibodies associated with thromboembolism or stroke, Raynaud's phenomenon, and sicca symptoms.

Dermatomyositis and Polymyositis

- Photosensitive, violaceous-erythematous, poikilodermatous, and variably scaly patches occur around eyes, on extensor extremities (especially over joints), upper back, scalp, and dystrophic nail folds with prominent telangiectasias.
- Patients may have or develop myositis or pulmonary involvement.
- Age-appropriate cancer screening is required for adults.

Scleroderma

- Patients have firm, variably pruritic, and indurated plaques.
- Localized scleroderma (i.e., morphea or asymmetric sclerotic plaques) may be seen.
- Limited systemic sclerosis is characterized by symmetric sclerosis of distal extremities, and patients may have systemic disease.
- Diffuse systemic sclerosis is characterized by symmetric sclerosis of the trunk and proximal extremities, and patients may have systemic disease.
- Sclerodactyly (i.e., thickening of skin of digits) may occur in patients with systemic sclerosis.
- Pulmonary, cardiac, and gastrointestinal screening should be done for patients with systemic sclerosis.
- Patients with systemic sclerosis should be evaluated and monitored for renal crisis.
- Raynaud's phenomenon may develop in patients with systemic sclerosis.

CURRENT THERAPY

Lupus Erythematosus

- Patients should be counseled on photoprotection measures.
- Localized cutaneous disease is treated with medium- to high-potency topical corticosteroids, and intralesional triamcinolone acetonide 10 mg/mL (Kenalog-10) is added if needed.
- Mild to moderate systemic involvement is treated with low- to medium-potency prednisone 5 to 20 mg/day and with antimalarials.
- Severe disease is treated with prednisone 1 mg/kg/day with a taper based on clinical response. Steroid-sparing agents include azathioprine (Imuran),¹ mycophenolate mofetil (CellCept),¹ methotrexate (Rheumatrex),¹ and cyclophosphamide (Cytoxan).¹
- Thromboembolism or stroke is treated by anticoagulation with warfarin (Coumadin), aspirin, or heparin.
- Sicca syndrome is treated with frequent water intake, saliva replacement, artificial tears, routine dental care, and pilocarpine (Salagen).

Dermatomyositis and Polymyositis

- Patients should be counseled on photoprotection measures.
- Medium-potency topical corticosteroids and calcineurin inhibitors are used for cutaneous disease.
- Prednisone 1 mg/kg/day is first-line therapy for muscle or pulmonary disease.
- Methotrexate¹ 10 to 25 mg/week is a steroid-sparing agent used for muscle involvement.
- Hydroxychloroquine (Plaquenil)¹ 200 mg/day is used for persistent skin involvement.

Scleroderma

- For localized scleroderma, UVA¹ 20 to 60 J/cm² or psoralen plus UVA (PUVA) is used to resolve established lesions; high-potency corticosteroids and calcipotriene (Dovonex)¹ may help to reduce pruritus and inflammation in new lesions; and systemic prednisone¹ or methotrexate¹ may be used for rapidly progressive new lesions.
- Treatment of systemic sclerosis is primarily aimed at limiting complications.
- Physical therapy is used for contractures.
- Systemic sclerosis is treated with cyclophosphamide (Cytoxan),¹ mycophenolate mofetil (CellCept),¹ methotrexate¹ 10 to 25 mg/week, and photopheresis.
- Renal crisis is treated with captopril (Capoten)¹ 6.25 mg three to six times/day and titrated to effect.
- Raynaud's is treated with warming techniques, calcium channel blockers, antiadrenergic agents, antiplatelet drugs, and topical vasodilators.

¹Not FDA approved for this indication.

Lupus Erythematosus

Lupus erythematosus is an autoimmune connective tissue disease that may localize to the skin or involve several organ systems. A complete review of systems with evaluation of positive findings is necessary to thoroughly assess patients for signs of systemic lupus as defined by the American Rheumatism Association. Cutaneous lupus erythematosus manifests in chronic, subacute, and acute forms. A punch biopsy from within an erythematous lupus lesion is useful for confirming the diagnosis.

Clinical Features

Discoid lupus and tumid lupus are the two forms of chronic cutaneous lupus erythematosus. Discoid lupus lesions are tender or pruritic, erythematous to violaceous, scaly plaques that typically occur on sun-exposed skin. The lesions resolve with scarring, and when the lesions affect the scalp, they cause scarring alopecia. Tumid lupus manifests as pruritic, erythematous to violaceous, nonscaly plaques that typically preferentially affect the face and trunk.

The lesions of subacute cutaneous lupus erythematosus occur as erythematous to violaceous, scaly macules and as annular or polycyclic patches. These lesions are commonly located on sun-exposed skin and heal without scarring.

Acute cutaneous lupus erythematosus is exemplified by malar erythema (i.e., butterfly rash) and by poikiloderma (i.e., hyperpigmentation, telangiectasias, and epidermal atrophy). It is a manifestation of systemic lupus erythematosus (SLE). Cutaneous lesions may be widespread. In addition to the American Rheumatism Association criteria, patients with SLE may also develop Raynaud's phenomenon, hypercoagulability, and overlap syndromes with Sjögren's disease, dermatomyositis, and other conditions.

Hydrochlorothiazide (HydroDIURIL), terbinafine (Lamisil), minocycline (Minocin), procainamide (Pronestyl), hydralazine (Apresoline), and isoniazid (Nydrazid) are a few of the pharmaceutical agents that cause drug-induced lupus. This disease manifests with synovitis, photosensitivity, and positive serology results, and it may have cutaneous lesions that do not necessarily abate with cessation of the medication.

Management

Prevention

All patients with lupus erythematosus should be counseled on photoprotection, including protecting skin from sunlight and avoiding sun exposure during peak hours (i.e., between 10 AM and 2 PM). Ultraviolet A and B wavelengths may cause lupus to flare. Broad-spectrum sunscreen with an SPF of 30 or higher and that contains titanium, zinc, Mexoryl (L'Oreal), or Helioplex (Neutrogena) should be used whenever patients are outdoors. Photoprotective clothing, available from multiple vendors, is useful for limiting sun exposure.

Patients with lupus are relatively immunosuppressed by their disease. Vaccinations should be kept up to date, although there is a debate about the necessity and safety of vaccination against meningococcal disease (*Neisseria meningitidis*) (Menactra, Menomune), varicella-zoster virus (Zostavax), and *Streptococcus* (Pneumovax).

Treatment of Cutaneous Lupus Erythematosus

Medium-potency topical corticosteroids should be used for lupus localized to the skin, and they are used as adjunct treatment for patients with systemic lupus. Use of triamcinolone 0.1% cream (Flutex) for lesions on the head and neck until symptoms subside or up to 2 weeks continuously is an appropriate starting strength. Ointment-based vehicles are useful for lesions on the trunk and extremities. They are also the vehicles of choice on the scalp of patients of African American descent. Foam or liquid- or lotion-based corticosteroids work well in the scalp of other ethnic groups and can be used on the trunk and extremities. If lesions persist, the corticosteroid can be occluded, or intralesional injections with triamcinolone can be repeated monthly as needed. Intralesional triamcinolone acetonide at concentrations of 5 mg/mL (Kenalog) can be injected into lesions on the face or neck and doses of 10 to 20 mg/mL (Kenalog-10, Kenalog) into lesions on the trunk or extremities. Intralesional corticosteroids may cause mild discomfort, atrophy of the skin or subcutis, or stretch marks. Topical calcineurin inhibitors such as pimecrolimus (Elidel)¹ or tacrolimus (Protopic)¹ may be used for maintenance treatment but are not recommended for new or active lesions because they do not work quickly. Recurrent or refractory cutaneous lesions require systemic treatment.

Treatment of Systemic Lupus Erythematosus

Antimalarials, including hydroxychloroquine (Plaquenil),¹ are disease-modifying agents that limit the progression of lupus. Hydroxychloroquine, chloroquine (Aralen),¹ and quinacrine² (at compounding pharmacies) raise the pH of inflammatory cells, inhibiting inflammatory pathways that cause end-organ damage in patients with SLE.

Hydroxychloroquine is typically used first at 200 mg daily for 2 weeks and then increased to 400 mg daily. Patients need laboratory monitoring and a baseline and then yearly eye examination because the medication may be deposited in the retina over time. Hydroxychloroquine exerts its effects within 2 to 3 months of beginning treatment. Its effects are diminished in smokers.

Depending on end-organ involvement in SLE, immunosuppression with systemic corticosteroids such as prednisone at doses of 1 mg/kg/day is appropriate. Steroid-sparing drugs such as methotrexate (Rheumatrex),¹ acitretin (Soriatane),¹ or mycophenolate mofetil (CellCept)¹ are added. After signs of inflammation subside, prednisone is tapered.

Treatment of Musculoskeletal Manifestations

Arthralgia is a common complaint that can usually be managed with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs). For true arthritis unresponsive to the previously described measures, hydroxychloroquine¹ 200 mg twice daily can be added. After that, treatments similar to those used for

rheumatoid arthritis can be added, although the antitumor necrosis factor agents usually are avoided in lupus. Methotrexate¹ 7.5 to 25 mg PO once weekly may be used along with folic acid¹ 1 mg daily to help limit side effects. Routine toxicity monitoring includes frequent complete blood cell counts and liver tests. Azathioprine (Imuran)¹ 0.5 to 2 mg/kg can be used with frequent monitoring of complete blood cell counts and liver tests. A sample for testing the thiopurine methyltransferase activity level should be drawn before initiating therapy because a genetic deficiency can lead to severe pancytopenia. Leflunomide (Arava)¹ 10 to 20 mg PO once daily can be used with frequent blood cell counts and liver tests. Low-dose glucocorticoids (prednisone 5–10 mg/day) may be used as a bridge to steroid-sparing therapy and to treat intermittent flares.

Treatment of Hematologic Manifestations

Autoimmune cytopenias are common and are often a defining feature of SLE. Lymphopenia (absolute lymphocyte count <1500 cells/microliter) does not require therapy. Hemolytic anemia in SLE is the result of antierythrocyte antibodies that activate complement, and it is treated with prednisone at a dose based on clinical severity. Typically, 1 mg/kg/day, or approximately 60 mg, is used for 4 to 6 weeks, with gradual tapering as long as the response is maintained. For severe hemolytic anemia, pulse methylprednisolone (Solu-Medrol) 1 g IV for 3 consecutive days can be tried, followed by the previously described standard dosing. For patients who do not respond to glucocorticoids or are unable to taper prednisone to low doses, other treatments can be used. They may include azathioprine¹ 1.5 to 2.5 mg/kg/day, mycophenolate mofetil¹ 1000 to 2000 mg/day in divided doses, danazol (Danocrine)¹ 300 to 600 mg/day in divided doses, intravenous immunoglobulin,¹ or rituximab (Rituxan)¹ 375 mg/m² weekly for four doses.

Immune thrombocytopenia results from antiplatelet antibodies that identify platelets for early destruction. Treatment is indicated when patients have signs or symptoms of spontaneous bleeding or when the platelet count drops below 50,000/mL. The initial treatment approach with glucocorticoids is similar to that used for hemolytic anemia. For patients with chronic thrombocytopenia or for those who cannot achieve an acceptable long-term dose of prednisone, steroid-sparing agents, including azathioprine,¹ mycophenolate mofetil,¹ danazol,¹ rituximab,¹ and intravenous immunoglobulin¹ can be used in doses similar to those used for hemolytic anemia. Dapsone,¹ cyclosporine (Sandimmune, Neoral),¹ and cyclophosphamide (Cytoxan)¹ have also been used.

Thrombotic thrombocytopenia purpura may occur in SLE, and it must be differentiated from immune thrombocytopenia because treatment requires emergent plasmapheresis. Manifestations of thrombotic thrombocytopenia purpura include fever, microangiopathic hemolysis, and central nervous system and renal abnormalities.

Antiphospholipid antibodies include the lupus anticoagulant, anticardiolipin antibodies, and β_2 -glycoprotein. They are associated with coagulopathy, thrombocytopenia, late-trimester miscarriage, and heart valve abnormalities. Antiphospholipid antibodies that can be determined with blood testing but are not associated with thromboembolism do not require treatment. Low-dose aspirin¹ may be considered but has not been shown to prevent future thrombosis. Hydroxychloroquine¹ 200 mg twice daily has been shown to reduce the risk. Patients with antiphospholipid antibodies who develop thromboembolism need lifelong treatment with warfarin (Coumadin). A goal international normalized ratio (INR) remains controversial because different studies advocate for high-intensity warfarin (INR >3) or low-intensity therapy (INR >2). For women who have suffered a miscarriage determined to be related to antiphospholipid antibodies, low-dose aspirin and heparin 5000 units SQ twice daily may increase the likelihood of a successful pregnancy.

¹Not FDA approved for this indication.

²Not available in the United States.

¹Not FDA approved for this indication.

Treatment of Renal Manifestations

Many patients with SLE have mild to severe renal involvement. Diagnosis by renal biopsy is important to establish the type of kidney involvement. Lupus nephritis is considered one of the more severe manifestations of the disease, and treatment is aimed at preventing renal failure. Treatment should be coordinated with a rheumatologist or nephrologist.

Class I disease requires no specific therapy. The class IIb pattern with more than 1 g of proteinuria can be treated with moderate-dose prednisone (20 mg/day for 6 weeks to 3 months), followed by tapering. Class III and IV patterns of disease have the same prognosis and are treated similarly with high-dose prednisone (1 mg/kg/day) for at least 6 weeks before tapering, based on clinical response, by 10 mg a week to a maintenance of 10 to 15 mg/day. In addition to prednisone, cytotoxic therapy is initiated with cyclophosphamide¹ 0.5 to 1 g/m² of body surface area monthly for 6 months and tapered to every 3 months, based on clinical response, for a total of 2 to 3 years. Cyclophosphamide has serious toxicities, including hemorrhagic cystitis, bone marrow suppression, infertility, teratogenicity, and increased risk of malignancy. 2-Mercaptoethane sulfonate sodium (Mesna)¹ can be given with each infusion to minimize bladder toxicity. Class V disease can be treated with prednisone alone, similar to class IIb disease, unless there are coexisting features of class III or IV disease, for which treatments outlined previously should be implemented.

An acceptable alternative to cyclophosphamide for class III and IV disease is mycophenolate mofetil¹ 2 to 3 g/day in divided doses combined with corticosteroids (dosing outlined earlier). This appears to be an effective therapy with fewer side effects than traditional therapy.

Treatment of Nervous System Manifestations

Neuropsychiatric involvement is common in patients with lupus. Symptoms can range from mild to severe and include headache, aseptic meningitis, neuropathy, myelopathy, cognitive dysfunction, seizures, cerebritis, and stroke. A thorough evaluation is necessary to define the cause of nervous system dysfunction and differentiate it from a medication side effect. For seizures, antiepileptic therapy is used, preferably in coordination with a neurologist. Lupus cerebritis and transverse myelitis are two of the more serious manifestations that need to be treated emergently with aggressive immunosuppression in coordination with a rheumatologist or neurologist. Treatment includes high-dose corticosteroids and cyclophosphamide,¹ similar to treatment for lupus nephritis.

Dermatomyositis and Polymyositis

Clinical Features

Dermatomyositis may affect skin and muscle. Cutaneous dermatomyositis manifests with violaceous erythema of characteristic areas, including the periorbital skin (i.e., heliotrope rash), upper back (i.e., shawl sign), dorsal hands (i.e., Gottron's papules), scalp, lateral thighs (i.e., Holster sign), and periungual skin, where dilated capillary loops and erythema are observed. Patients may report muscle weakness. As in lupus, a punch biopsy of an actively inflamed cutaneous lesion shows characteristic features.

Evaluation of patients with cutaneous dermatomyositis is not complete without assessment for systemic involvement. Serum aldolase is the most specific marker for myositis, and it can be used as a measure of response to treatment. Creatinine kinase and alanine aminotransferase levels may be elevated but are not specific indicators. An electromyogram shows dampening of signals, and a muscle biopsy shows a characteristic pattern of myositis. Inflammatory lung disease, diagnosed by the characteristic pattern on chest computed tomography, bronchoalveolar lavage, or biopsy, may be life limiting and therefore should be treated aggressively, similar to lung disease in scleroderma. Adult patients should have age-appropriate cancer screening because dermatomyositis is a paraneoplastic phenomenon in 10% to 50% of patients.

Some patients present with characteristic cutaneous dermatomyositis but no systemic involvement (i.e., dermatomyositis sine myositis). The risk of concurrent or subsequent cancer development is thought to be increased. These patients require monitoring for systemic involvement that may develop over time.

Treatment

Patients with dermatomyositis need photoprotection similar to patients with lupus. Periodic evaluation by clinical examination and review of systems allows for early intervention for developing visceral or muscle involvement.

Cutaneous dermatomyositis is treated the same as lupus (see earlier). Dermatomyositis with systemic involvement is initially treated with immunosuppression using prednisone at doses of 1 mg/kg/day. Steroid-sparing agents are incorporated early in the disease and include antimalarials (methotrexate,¹ azathioprine,¹ and mycophenolate mofetil¹) at doses that are used in treating lupus.

Scleroderma

Clinical Features

Scleroderma is a sclerosing condition of skin or viscera, or both. The cause is unknown, but transforming growth factor- β plays a role. Type I and III collagens are excessively produced, as are other substances, including glycosaminoglycans, tenascin, and fibronectin.

Cutaneous scleroderma without Raynaud's phenomenon or clinically relevant systemic involvement is also known as *morphea*. Morphea has different distribution patterns, including guttate, linear, segmental, or diffuse distribution, but it is always characterized by indurated plaques that are inflammatory initially, have an advancing inflammatory ("lilac") border as they progress, and then become hyperpigmented. The cutaneous lesions may restrict movement of joints and can cause restricted growth of underlying structures, particularly when they develop in childhood.

Systemic sclerosis may affect the respiratory, renal, cardiovascular, genitourinary, and gastrointestinal systems and vascular structures. Raynaud's phenomenon may be the first presenting symptom of systemic sclerosis, and it can be severe, leading to digital ulcerations and autoamputation. The American College of Rheumatology has defined criteria for the diagnosis.

Tests for antinuclear antibodies are positive in approximately 95% of patients, who typically present with a homogeneous or speckled pattern. A nucleolar pattern is more specific for systemic sclerosis. Anticentromere antibodies are present in 60% to 90% of patients with limited disease but are rare in diffuse disease. Topoisomerase I (Scl-70) antibodies are positive in 30% of patients with diffuse disease and are associated with pulmonary fibrosis. Anti-PM-Scl antibodies are present in overlap syndromes and are associated with myositis and renal involvement.

Treatment

Treatment of Limited Scleroderma

For limited scleroderma, treatment with topical medium-potency corticosteroids such as triamcinolone 0.1% ointment (Kenalog) plus calcipotriene (Dovonex)¹ 0.005% cream or intralesional triamcinolone¹ 20 mg/mL may slow progression of active lesions or improve the pruritus and cutaneous stiffness that typify cutaneous scleroderma. For rapidly evolving disease, prednisone¹ 1 mg/kg/day and methotrexate¹ 15 to 20 mg/week may help slow progression of disease. UVA¹ given over 36 treatments at doses of 30 to 60 mJ/cm² or PUVA (oral methoxsalen [8-MOP] 10 mg taken 2 hours before treatment with UVA light) can soften the existing plaques of morphea.

Treatment of Systemic Sclerosis: Raynaud's Phenomenon

First-line treatment for Raynaud's phenomenon is preventive, with cold avoidance and the use of warming techniques. If pharmacotherapy is required, extended-release calcium channel blockers

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

such as nifedipine (Procardia XL)¹ starting at 30 mg/day or amlodipine (Norvasc)¹ starting at 5 mg/day may be useful. If this is not helpful, the α -blocker prazosin (Minipress)¹ 1 mg three times daily or the angiotensin receptor blocker losartan (Cozaar)¹ 50 mg daily may be helpful. Antiplatelet therapy with low-dose aspirin¹ (81 mg/day) or dipyridamole (Persantine)¹ 50 to 100 mg three or four times daily may be useful. Topical vasodilators such as nitroglycerin ointment (Nitro-Bid)¹ applied to the base of the affected finger three times daily can be helpful in refractory disease. Digit-threatening ischemia may be treated with an intravenous prostaglandin such as alprostadil (Prostin VR)¹ or iloprost (Ilomedine),⁵ which require peripheral or central access. Patients with severe recurrent digital ischemia may ultimately benefit from surgical sympathectomy.

Treatment of Gastrointestinal Manifestations

The most common gastrointestinal manifestation is esophageal reflux caused by esophageal dysmotility. Proton pump inhibitors such as omeprazole (Prilosec)¹ 20 mg twice daily should be used and may prevent the development of esophageal strictures. Prokinetic drugs such as metoclopramide (Reglan)¹ 10 mg four times daily can be helpful. Erythromycin¹ 500 mg three or four times daily can help esophageal and gastric hypomotility. Small bowel hypomotility can lead to bacterial overgrowth, resulting in malabsorption and diarrhea. Rotating antibiotics that include metronidazole (Flagyl),¹ ciprofloxacin (Cipro),¹ and amoxicillin/clavulanate (Augmentin)¹ can be used.

Treatment of Pulmonary Manifestations

Inflammatory lung disease occurs commonly in patients with scleroderma and can be life limiting. Cyclophosphamide¹ at doses of up to 2 mg/kg/day for up to 2 years may slow progression of pulmonary disease. Pulmonary hypertension occurs more commonly in limited systemic sclerosis than in diffuse disease. Symptomatic patients may receive treatment with prostacyclin analogues, which require continuous infusions. The endothelin receptor antagonist bosentan (Tracleer)¹ can be given orally starting at 62.5 mg twice daily. Liver tests should be monitored frequently. At this point, care is typically coordinated with a cardiologist to monitor disease progression and treatment response. Anticoagulation for pulmonary hypertension may improve survival because of the frequent occurrence of pulmonary arterial thrombosis.

Treatment of Renal Manifestations

Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril [Capoten]¹) beginning at 6.25 mg three to six times daily and titrated for blood pressure control) have dramatically reduced the incidence of renal failure and death due to renal crisis. Avoidance of prednisone at doses greater than 15 mg/day is also important in reducing the risk of renal crisis.

¹Not FDA approved for this indication.

FIBROMYALGIA

Method of

Charles Kodner, MD

CURRENT DIAGNOSIS

- The diagnosis of fibromyalgia can be made based on symptom scores or physician global impression; there is no gold standard, and diagnosis no longer depends on trigger point examination.
- Lab and imaging studies should be ordered to rule out competing diagnoses that seem likely based on patient presentation; fibromyalgia should not be considered a "diagnosis of exclusion."
- It is not necessary to obtain rheumatologic tests if conditions such as systemic lupus are clinically unlikely.

CURRENT THERAPY

- Structured exercise and antidepressants, particularly serotonin-norepinephrine reuptake inhibitors (SNRIs), form the mainstay of treatment for fibromyalgia.
- Other antidepressants and muscle relaxants can provide symptom relief as well.

Epidemiology

Owing to lack of a diagnostic gold standard, estimates of the prevalence of fibromyalgia in the population are difficult to determine. Approximately 5% of the overall US population meet clinical criteria for fibromyalgia; this increases to approximately 10% to 15% among primary care patients. This translates to roughly 5 million to 10 million individuals in the United States with fibromyalgia. Fibromyalgia is typically diagnosed in patients aged 30 to 60, but adolescents or younger children may meet diagnostic criteria, and symptoms may persist or be diagnosed in older adulthood. While previously felt to have a roughly 10:1 female-to-male distribution, fibromyalgia is increasingly recognized in men and the gender distribution is thought to be closer to 3:1 female to male.

Pathophysiology

The pathophysiology of fibromyalgia is far better understood now than it was a decade ago. Though many patients likely have elements of both fibromyalgia and somatization, fibromyalgia should no longer be considered primarily a somatizing process. Likewise, though anxiety and depression often coexist with fibromyalgia, the widespread pain in fibromyalgia is clearly not fully explained by psychological factors. There is strong evidence from imaging studies and other investigations that fibromyalgia is due to multiple neurologic mechanisms related to abnormal processing of painful stimuli in the central nervous system. Key aspects of this include central amplification of nonpainful peripheral sensations (allodynia), aberrant activation of the pain system with an increased response to painful stimuli (hyperalgesia), and an impaired central nociceptive system or descending inhibition of pain perceptions. Fibromyalgia is primarily a global problem in pain and sensory processing with impaired central mediation of pain sensations.

This understanding of the underlying physiologic processes in fibromyalgia has immediate application in patient education, management, and assessment of comorbid symptoms.

Antiplatelet therapy with low-dose aspirin¹ (81 mg/day) or dipyridamole (Persantine)¹ 50 to 100 mg three or four times daily may be useful. Topical vasodilators such as nitroglycerin ointment (Nitro-Bid)¹ applied to the base of the affected finger three times daily can be helpful in refractory disease. Digit-threatening ischemia may be treated with an intravenous prostaglandin such as alprostadil (Prostin VR)¹ or iloprost (Ilomedine),⁵ which require peripheral or central access. Patients with severe recurrent digital ischemia may ultimately benefit from surgical sympathectomy.

Treatment of Gastrointestinal Manifestations

The most common gastrointestinal manifestation is esophageal reflux caused by esophageal dysmotility. Proton pump inhibitors such as omeprazole (Prilosec)¹ 20 mg twice daily should be used and may prevent the development of esophageal strictures. Prokinetic drugs such as metoclopramide (Reglan)¹ 10 mg four times daily can be helpful. Erythromycin¹ 500 mg three or four times daily can help esophageal and gastric hypomotility. Small bowel hypomotility can lead to bacterial overgrowth, resulting in malabsorption and diarrhea. Rotating antibiotics that include metronidazole (Flagyl),¹ ciprofloxacin (Cipro),¹ and amoxicillin/clavulanate (Augmentin)¹ can be used.

Treatment of Pulmonary Manifestations

Inflammatory lung disease occurs commonly in patients with scleroderma and can be life limiting. Cyclophosphamide¹ at doses of up to 2 mg/kg/day for up to 2 years may slow progression of pulmonary disease. Pulmonary hypertension occurs more commonly in limited systemic sclerosis than in diffuse disease. Symptomatic patients may receive treatment with prostacyclin analogues, which require continuous infusions. The endothelin receptor antagonist bosentan (Tracleer)¹ can be given orally starting at 62.5 mg twice daily. Liver tests should be monitored frequently. At this point, care is typically coordinated with a cardiologist to monitor disease progression and treatment response. Anticoagulation for pulmonary hypertension may improve survival because of the frequent occurrence of pulmonary arterial thrombosis.

Treatment of Renal Manifestations

Angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril [Capoten]¹) beginning at 6.25 mg three to six times daily and titrated for blood pressure control) have dramatically reduced the incidence of renal failure and death due to renal crisis. Avoidance of prednisone at doses greater than 15 mg/day is also important in reducing the risk of renal crisis.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

FIBROMYALGIA

Method of

Charles Kodner, MD

CURRENT DIAGNOSIS

- The diagnosis of fibromyalgia can be made based on symptom scores or physician global impression; there is no gold standard, and diagnosis no longer depends on trigger point examination.
- Lab and imaging studies should be ordered to rule out competing diagnoses that seem likely based on patient presentation; fibromyalgia should not be considered a "diagnosis of exclusion."
- It is not necessary to obtain rheumatologic tests if conditions such as systemic lupus are clinically unlikely.

CURRENT THERAPY

- Structured exercise and antidepressants, particularly serotonin-norepinephrine reuptake inhibitors (SNRIs), form the mainstay of treatment for fibromyalgia.
- Other antidepressants and muscle relaxants can provide symptom relief as well.

Epidemiology

Owing to lack of a diagnostic gold standard, estimates of the prevalence of fibromyalgia in the population are difficult to determine. Approximately 5% of the overall US population meet clinical criteria for fibromyalgia; this increases to approximately 10% to 15% among primary care patients. This translates to roughly 5 million to 10 million individuals in the United States with fibromyalgia. Fibromyalgia is typically diagnosed in patients aged 30 to 60, but adolescents or younger children may meet diagnostic criteria, and symptoms may persist or be diagnosed in older adulthood. While previously felt to have a roughly 10:1 female-to-male distribution, fibromyalgia is increasingly recognized in men and the gender distribution is thought to be closer to 3:1 female to male.

Pathophysiology

The pathophysiology of fibromyalgia is far better understood now than it was a decade ago. Though many patients likely have elements of both fibromyalgia and somatization, fibromyalgia should no longer be considered primarily a somatizing process. Likewise, though anxiety and depression often coexist with fibromyalgia, the widespread pain in fibromyalgia is clearly not fully explained by psychological factors. There is strong evidence from imaging studies and other investigations that fibromyalgia is due to multiple neurologic mechanisms related to abnormal processing of painful stimuli in the central nervous system. Key aspects of this include central amplification of nonpainful peripheral sensations (allodynia), aberrant activation of the pain system with an increased response to painful stimuli (hyperalgesia), and an impaired central nociceptive system or descending inhibition of pain perceptions. Fibromyalgia is primarily a global problem in pain and sensory processing with impaired central mediation of pain sensations.

This understanding of the underlying physiologic processes in fibromyalgia has immediate application in patient education, management, and assessment of comorbid symptoms.

Familial predisposition and poorly understood genetic factors account for a portion of patients with fibromyalgia. Low levels or low activity of neurotransmitters involved in pain processing is also likely involved. Functional and anatomic neuromuscular abnormalities have not been consistently found in fibromyalgia. The role of inflammation in this condition (formerly known as “fibrositis” but renamed “fibromyalgia” to emphasize pain without inflammation) remains unclear.

Risk Factors

While biologic and genetic susceptibility undoubtedly plays a role in the development of fibromyalgia, a number of life events or mental health conditions may “trigger” the disease into activity in previously pain-free and high-functioning individuals. A great deal of attention in the evolving understanding of fibromyalgia focuses on resiliency and coping ability; individuals in whom these cognitive skills are impaired are more likely to develop fibromyalgia.

The relationship between fibromyalgia and posttraumatic stress disorder (PTSD) is complex, and roughly half of patients with fibromyalgia also meet the criteria for PTSD. While PTSD is considered a risk factor for fibromyalgia, a patient’s traumatic experience may either precede or follow the development of the chronic pain and symptoms of fibromyalgia, and statistically fibromyalgia is also likely a risk factor for PTSD, probably via the mechanism of reduced resiliency. In practice it is common to identify a history of traumatic events in patients with fibromyalgia, and patients with chronic pain and mood symptoms should be sensitively interviewed about a history of childhood abuse, domestic violence, sexual assault, or other traumatic life events. Other stressors such as major illness or surgery may also function as triggers to initiate fibromyalgia symptoms in individuals predisposed to have this condition.

Clinical Manifestations

The core symptoms of fibromyalgia include chronic widespread pain, fatigue, and sleep disturbance. Mood symptoms such as anxiety or depressed mood are very common symptoms as well. Disease criteria define chronic pain in this context as greater than 3 months, and widespread as pain in the right and left sides of the body, above and below the waist, and in the axial skeleton. Patients often have tenderness at muscles and tendon insertion sites, a finding that was emphasized in earlier diagnostic criteria but is now felt to be nonsensitive as a diagnostic criterion. Joint stiffness, lack of energy, and cognitive symptoms such as forgetfulness or problems concentrating are typical symptoms of fibromyalgia. Fibromyalgia patients often report limitations in physical functioning and often present to medical attention because their pain and fatigue have reached the point of interfering with normal daily activities.

Patients who exhibit the underlying pathophysiology of fibromyalgia, including altered central processing of pain signals as noted earlier, commonly experience similar chronic functional pain syndromes. When evaluating patients with presumed fibromyalgia, physicians should inquire about irritable bowel syndrome (IBS) (which has a very strong overlap with fibromyalgia: approximately half of patients with fibromyalgia have IBS), vulvodynia, interstitial cystitis (IC), temporomandibular joint (TMJ) pain, chronic back pain, endometriosis and chronic pelvic pain (including chronic nonbacterial prostatitis in men), and noncardiac chest pain. Identification of such associated syndromes, with an explanation of their shared physiologic basis, can often provide significant reassurance to patients who are troubled by multiple chronic pain problems with repeatedly normal diagnostic tests.

Diagnosis

At the present time, there is no gold standard for the diagnosis of fibromyalgia, since a specific physiologic or anatomic defect cannot be identified on routinely available diagnostic studies; hence the diagnosis is always presumptive, though patients with appropriate findings on history and physical examination can be diagnosed with fibromyalgia to a degree of certainty that is sufficient to begin treatment.

Traditionally, the diagnosis of fibromyalgia relied on finding tenderness on digital palpation of 11 out of 18 designated tender-point sites; this approach is based on the 1990 American College of Rheumatology (ACR) diagnostic criteria for fibromyalgia. However, growing recognition of limitations to the older ACR criteria led to a new set of diagnostic criteria published in 2010. These limitations are primarily that they will leave a significant subpopulation of patients with fibromyalgia undiagnosed; that the tender-points examination is not consistently positive across patients or in a given patient over time; that many physicians simply weren’t using them; and that the physical and cognitive symptoms of fibromyalgia are more common, more important to patients, and more diagnostically relevant than are the physical examination findings.

The updated ACR criteria (Table 1) focus on symptoms rather than tender points and represent the most current diagnostic

TABLE 1 2010 American College of Rheumatology Criteria for Diagnosing Fibromyalgia

A patient satisfies diagnostic criteria for fibromyalgia if the following three conditions are met:

- Widespread Pain Index (WPI) is ≥ 7 and Symptom Severity (SS) scale score is ≥ 5 , OR WPI is between 3 and 6 and SS scale score is ≥ 9 .
- Symptoms have been present at a similar level for at least 3 months.
- The patient does not have another disorder that would otherwise explain the pain.

Widespread Pain Index

Over the past 7 days, indicate the areas where you have had pain or tenderness (score 0–19):

neck
upper back
chest or breast
abdomen
lower back
left jaw
left shoulder
left upper arm
left lower arm
left hip
left upper leg
left lower leg
right jaw
right shoulder
right upper arm
right lower arm
right hip
right upper leg
right lower leg

Symptom Severity Scale Score

Part A. For the each of the 3 symptoms below, indicate the level of severity over the past week using the following scale: 0 = no problem; 1 = slight or mild problems, generally mild; 2 = moderate, considerable problems, often present; 3 = severe problems: pervasive, continuous, and/or life disturbing. Add up the total score.

- ___ Fatigue
- ___ Waking unrefreshed
- ___ Cognitive symptoms

Part B. Considering somatic symptoms in general,* indicate whether the patient has: 0 = no symptoms; 1 = 1 to 10 symptoms; 2 = 11 to 24 symptoms; or 3 = 25 or more symptoms.

Add the scores for Parts A and B; this is the SS score, which can range from 0 to 12.

*Somatic symptoms that might be considered include muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problems, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

From Wolfe F. The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. *Arthritis Care Res* 62 [5]:600–610, 2010.

standard for fibromyalgia. Fibromyalgia should not be considered a “diagnosis of exclusion” since it can be actively diagnosed on clinical grounds using the ACR criteria or other means as discussed later.

There is no laboratory test or imaging study that can confirm a diagnosis of fibromyalgia, and in general laboratory testing is not necessary when the diagnosis seems evident. However, testing patients with chronic fatigue for anemia, electrolyte disturbances, and thyroid disease is appropriate. Unless there are suggestive findings such as joint inflammation, rash, anemia, or renal insufficiency, diagnoses such as systemic lupus, rheumatoid arthritis, or other connective tissue disorders are unlikely. A “rheumatology panel” of lab tests such as erythrocyte sedimentation rate, antinuclear antibodies, C-reactive protein, and rheumatoid factor tests have poor diagnostic value and should only be ordered if connective tissue disorders are clinically suspected. It is not necessary to “rule out” these conditions before making a presumptive diagnosis of fibromyalgia.

While the formal symptom surveys (see Table 1) and/or tender-point examination can be used to support the diagnosis, it is also reasonable to establish a working diagnosis of fibromyalgia purely on a combination of widespread pain, fatigue, and sleep disturbance, if there is no evidence of another specific diagnosis. This is enough to begin empiric treatment for presumptive fibromyalgia, while any other diagnostic assessment proceeds concurrently. These three diagnostic approaches—tender points, symptom survey, and global impression of the patient—all have equal validity but will identify slightly different subsets of patients who are likely to have fibromyalgia.

Differential Diagnosis

Inflammatory arthropathies (rheumatoid arthritis, systemic lupus, psoriatic arthritis) should be considered in patients with poly- or pauciarticular joint pain; these conditions are characterized by joint inflammation with swelling, warmth, and/or erythema, whereas fibromyalgia lacks evidence of joint inflammation.

Myopathies such as statin-induced muscle spasm, polymyositis, or polymyalgia rheumatica can be identified via a history of causative medications, pain and tenderness in large muscle groups, or focal tenderness in muscles rather than in tendon insertion points as with fibromyalgia.

For patients presenting with diffuse joint pain, osteoarthritis remains the most common diagnosis. Osteoarthritis generally affects a typical distribution of joints (knees, hips, ankles, interphalangeal joints, spine) and is aching rather than cramping; osteoarthritis also generally lacks the predominant symptoms of fatigue and mood changes that typify fibromyalgia.

Many patients with primary mood disorders can present with chronic pain symptoms, including somatization symptoms or worsening of chronic physical symptoms. There is considerable overlap among patients with mood disorders who have pain and patients with fibromyalgia who have more predominant mood symptoms; distinguishing these as separate disorders is probably unnecessary since the diagnoses can coexist and management is essentially the same. Pain and mood symptoms are inseparable in fibromyalgia as with some other rheumatologic conditions. Patients with fibromyalgia should be evaluated and treated for mood disorders and sleep disturbance as part of their overall management.

Myofascial pain syndrome (MPS) deserves special consideration in the differential diagnosis for fibromyalgia, given significant symptom overlap in these very different conditions. MPS generally causes chronic pain in multiple myofascial “knots” or trigger points and can occur in any part of the body. The deep, aching muscle pain of MPS may have a wide range of severity but is somewhat different in character and distribution from the widespread and variable pain of fibromyalgia. Though there is clearly overlap in presenting symptoms, MPS is characterized by a stronger component of focal trigger-point tenderness, which is reproducible on trigger-point palpation. These trigger points also need not be in the typical distribution of tender points classically described in fibromyalgia.

Patient Education and Counseling

Patients with fibromyalgia have often had disabling pain and fatigue for months or years, seen many physicians, had multiple normal diagnostic tests or ineffective treatments, and been told that “there is nothing wrong with them.” In addition to recommending medications and activities to reduce symptoms and improve functionality, a vital aspect of managing fibromyalgia is effective patient education and counseling. The time spent on educating patients about their illness can independently improve fibromyalgia symptoms and patient well-being and should be included as part of an active fibromyalgia management approach. Patient education, empiric treatment for fibromyalgia, and potential testing for other conditions can proceed concurrently.

Establishing the specific diagnosis of fibromyalgia, giving patients a recognized diagnostic label for often-confusing symptoms, and affirming or validating the reality of patients’ symptoms are critically important. Despite an absence of objective findings on physical examination or diagnostic testing, patients’ pain and fatigue are very real and often disabling, and the therapeutic value of empathy and affirmation cannot be overstated.

While simply having a diagnosis is often helpful for patients, educating them (at an appropriate level of sophistication) about the pathophysiology and symptoms of fibromyalgia can improve their understanding of, and potentially their adherence to, recommended treatment. Describing fibromyalgia as “a disorder of the pain signaling system in the body” may be helpful for some patients, while others may benefit from handouts, recommended websites or online support groups, or even review articles from the medical literature. Once diagnosed, patients often report improved satisfaction with their health, fewer long-term symptoms, and reduced health care utilization and costs.

Our knowledge of the long-term prognosis for fibromyalgia is limited, and it is difficult to give patients a clear picture of how their illness will evolve. Many patients “learn to live with” their symptoms, and the severity of symptoms often diminishes over time; some patients seem to find their fibromyalgia symptoms less troubling as they grow older and develop other medical problems, while some develop stronger resiliency or coping mechanisms over time. Describing these possible outcomes, while emphasizing the lack of physiologic or bodily harm with fibromyalgia, is at present the best we can offer when discussing disease prognosis.

Describing the range of conditions comorbid with fibromyalgia can be important for patients who experience seemingly unconnected symptoms that they have not previously recognized as having a common underlying cause.

As with other chronic illnesses, patient self-monitoring can be helpful to involve patients in their own care and treatment decisions. A number of smartphone apps exist to help patients track their symptoms, participate in support communities, and learn about their illness, and appropriate patients may be directed to consider these resources. CatchMyPain (<https://www.catchmypain.com/>) and FibroMapp (<http://fibromapp.com/>) are only two of many such resources.

One important aspect of managing fibromyalgia is assessing new or worsening symptoms as they emerge. Patients with fibromyalgia often present to their primary care physician with new or worsening pain or other physical complaints; these should be evaluated and diagnosed as for any other patient visit. While symptoms should not automatically be dismissed or attributed to fibromyalgia, a “fibro flare” should be strongly considered in the differential diagnosis.

Nonpharmacologic Treatment

Nondrug treatment plays a very important role in the overall management of fibromyalgia. Chief among these is the role of regular, structured exercise to improve patients’ activity tolerance and pain symptoms, possibly via referral for formal physical therapy. Patients should be specifically educated about the benefits of exercise and should be given instructions or a prescription for the quantity and type of exercise recommended. Aerobic exercise is best for improving functionality and symptoms, but the decision should be

based on the type of physical activity that patients will find most acceptable. Stretching exercises, yoga, tai chi, and other types of physical activity are all reasonable to recommend to patients based on their interest. Some patients have very poor exercise tolerance and should be given specific instructions to engage in simple walking, without doing other chores or duties, as structured exercise, even if it is for just 5 to 10 minutes per day. It is often important to engage family members in the need to promote regular exercise and not to contribute to the patient adopting the “sick role” for secondary gain.

Many patients with fibromyalgia turn to complementary and alternative medicine (CAM) therapies for symptom relief, and some physicians prefer to recommend them in addition to, or in lieu of, prescription medications. While individual patients often find benefit from various CAM therapies, none of them have any strong evidence for efficacy in a general fibromyalgia population. A great many CAM therapies have been studied in patients with fibromyalgia, including massage, hydrotherapy, acupuncture, homeopathic remedies (vitamins, plant-based products, etc.), anthocyanidins,⁷ capsaicin,¹ and S-adenosylmethionine.⁷ Still other CAM therapies used in fibromyalgia include nutritional, herbal, and hormonal supplements; Ayurvedic medicine; and hypnosis. All of these may have benefit in individual patients, but none have strong aggregate evidence for effectiveness such that one should be more strongly recommended than another. Physicians should ask patients about their use of CAM therapies, or their interest in them, and should educate patients about uncertain risks and benefits. If patients are interested in trying otherwise safe CAM therapies for fibromyalgia, physicians should support that interest and work with patients to identify some form of objective symptom score to see if the CAM therapy (or any other treatment) provides measurable relief of symptoms. Using such a measure will help avoid unnecessary drug–herbal interactions, side effects, or costs to the patient.

Pharmacologic Treatment

Owing to the significant variation in patient symptoms and severity, as well as study design limitations in studies of drug treatment for fibromyalgia, it is difficult to make conclusive statements about the “best” drug for fibromyalgia. Physicians should develop an individualized treatment plan that incorporates medications tailored to a specific patient’s symptom complex and tolerance for medications. Most patients with fibromyalgia will require a combination of two or more medications to control their unique complex of symptoms.

Duloxetine (Cymbalta), milnacipran (Savella), and pregabalin (Lyrica) are US Food and Drug Administration (FDA)–approved medications for treating fibromyalgia, and are effective for treating multiple symptoms. However, multiple different medication classes are used to treat fibromyalgia; Table 2 briefly summarizes the evidence-based efficacy for different drug classes.

Selective serotonin reuptake inhibitors (SSRIs) have slight benefit for reducing pain, and serotonin–norepinephrine reuptake inhibitors (SNRIs) can help with most symptoms of fibromyalgia including pain, sleep disturbances, and depressed mood. SNRIs including milnacipran, duloxetine, and venlafaxine (Effexor)¹ are currently considered first-line treatment for fibromyalgia; they may be most effective in patients in whom fatigue and concentration symptoms are particularly troubling. If SSRIs are used for fibromyalgia patients, in general the older, less selective SSRIs may have better efficacy for improving pain, particularly at higher doses than are usually used for depression; the newer SSRIs (citalopram [Celexa],¹ escitalopram [Lexapro],¹ and desvenlafaxine [Pristiq]¹) are in general less effective in relieving symptoms of fibromyalgia.

Tricyclic antidepressants (TCADs) reduce pain, fatigue, and sleep disturbances. On average the expected magnitude of benefit

TABLE 2 Evidence for Efficacy of Drug Classes Used to Treat Fibromyalgia

DRUG CLASS	EVIDENCE FOR EFFICACY*
SNRIs (duloxetine [Cymbalta], milnacipran [Savella])	+++
TCADs and cyclobenzaprine (Flexeril) [†]	+++
α_2 - δ ligands (gabapentin [Neurontin], [†] pregabalin [Lyrica])	++
NSAIDs and simple analgesics	+
SSRIs	+

Abbreviations: NSAIDs=nonsteroidal antiinflammatory drugs; SNRIs=serotonin–norepinephrine reuptake inhibitors; SSRIs=selective serotonin reuptake inhibitors; TCADs=tricyclic antidepressants.

*Using the following scale: –=limited or no evidence for efficacy; +=slight evidence for efficacy; ++=moderate evidence for efficacy; +++=strong evidence for efficacy.

[†]Not FDA approved for this indication.

from TCADs for symptom relief is less than that for SNRIs, though a greater number of patients may experience slight benefit, often owing to increased sleep via the sedating side effects of TCADs. When effective, TCADs can improve multiple fibromyalgia symptoms, though side effects often limit patients’ ability to tolerate these medications.

Cyclobenzaprine (Flexeril)¹ (which is structurally similar to TCADs), and potentially other muscle relaxants, are almost as effective as SNRIs in improving pain symptoms, sleep, and quality of life. Muscle relaxants are often used in conjunction with antidepressants in treating fibromyalgia.

Antiepileptics (pregabalin [Lyrica] and gabapentin [Neurontin]¹) may also be useful adjunct treatments to reduce pain in some fibromyalgia patients, but the average magnitude of benefit is small. Cognitive and other side effects often lead to drug discontinuation.

Nonsteroidal antiinflammatory drugs (NSAIDs) are ubiquitously used to treat musculoskeletal pain and often used to treat fibromyalgia. However, given the debatable role of inflammation in this illness, it is not surprising that patients may try multiple different NSAIDs without relief. In light of the many possible complications of long-term NSAID use, these drugs should only be used in treating fibromyalgia when they clearly have strong benefits in a particular patient and should not be continued if they are unhelpful.

Opioid use in fibromyalgia remains challenging and controversial. Opioids seem less likely to be effective based on their mechanism of action, since there is no peripheral tissue damage in fibromyalgia. Concerns about cognitive and other side effects; the possibility of opioid-induced allodynia or hyperalgesia; and the risk of opioid addiction, misuse, or diversion all appropriately limit the use of this class of drugs for fibromyalgia. However, opioids are still used safely and effectively in some patients with fibromyalgia, with symptom or functionality benefits and without medication misuse. In highly selected patients at low risk for medication misuse, and in whom multiple other adequate treatment trials have failed, opioids may be considered as part of the overall management of this disorder.

A number of other drug classes have been explored in treating fibromyalgia but currently have limited if any consistent evidence for efficacy; these include atypical antipsychotics (olanzapine [Zyprexa]¹), dopamine receptor antagonists (pramipexole [Mirapex]¹), cannabinoids, low-dose naltrexone,¹ and others.

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

¹Not FDA approved for this indication.

Monitoring

There are no laboratory, imaging, or physiologic tests used to monitor fibromyalgia. Symptom scoring measures exist, but they do not have the same evidence for improved outcomes with regular monitoring or a “treat to target” approach, as do measures such as the Patient Health Questionnaire-9 (PHQ-9) used for depression. At the present time, close follow-up with patients at a frequency suitable for the severity of their symptoms or functional limitations represents the best form of disease monitoring. Patients may also choose to track their own symptoms and physical activity quantitatively using apps or other methods as mentioned earlier.

Complications

There are no complications from fibromyalgia in the sense of physiologic morbidity or mortality. However, the persistence of untreated symptoms can have severe consequences for quality of life, work and social functioning, health care utilization, and mental health or emotional distress. While the medications used to treat fibromyalgia have potentially severe risks such as QT prolongation with TCADs, in general they do not have serious complications when used appropriately.

- The hallmark for making the diagnosis of JIA is the presence of warm, thickened synovial membranes that can be palpated around the joints of affected children. The presence of hypertrophic synovial tissue around the joint(s) of a child with a typical history and clinical setting is virtually diagnostic of JIA.

CURRENT THERAPY

- Nonsteroidal antiinflammatory drugs
- Systemic glucocorticoids in select instances
- Oral or subcutaneous methotrexate (particularly for polyarticular disease)
- Anti-TNF (tumor necrosis factor) therapies, particularly for polyarticular disease
- Anti-IL-1 (interleukin-1) therapies, particularly in systemic disease

The term *juvenile idiopathic arthritis* (JIA) is now the internationally accepted term to describe a family of illness characterized by chronic inflammation of synovial membranes. It replaces, but does not completely overlap, the diagnostic classification system that used the term *juvenile rheumatoid arthritis*. Three major phenotypes of JIA are recognized: oligoarticular, polyarticular, and systemic. In addition, the accepted international classification scheme recognizes other subtypes (e.g., enthesitis-associated arthritis, which overlaps the family of conditions previously designated *spondyloarthropathies*) that have distinct clinical phenotypes and that the clinician must recognize against the general background of children presenting with musculoskeletal complaints. Because each of these subtypes represents a distinct phenotype based on presentation, age of onset, differential diagnosis, and therapy, each of these illnesses is described as a distinct entity.

Oligoarticular Juvenile Idiopathic (Pauciarticular) Arthritis (Pauciarticular Juvenile Rheumatoid Arthritis)

Epidemiology

Oligoarticular JIA (*pauciarticular JRA* under the old American College of Rheumatology criteria) is typically a disease of preschoolers of European descent. This subtype of JIA is quite rare in African American children, children from the Indian subcontinent, and Native American children.

Risk Factors

Specific human leukocyte antigen (HLA) alleles, particularly in the class II locus, are known to confer risk for this JIA subtype. However, different alleles are seen in different ethnic subgroups, even in European populations. Thus, the presence of specific HLA alleles is not clinically useful for the diagnosis of most forms of monoarticular JIA. Older boys presenting with monoarthritis might, in fact, have what is now termed enthesitis-associated arthritis (EAA), for which the presence of class I HLA allele B27 can often be a diagnostic clue, because this allele is a major risk factor for developing EAA.

Young age (onset before the age of 3 years) and the presence of antinuclear antibodies (ANA) are specific risk factors for the development of uveitis in children with established disease. Slit-lamp examinations (see “[Complications](#)”) are recommended every 4 months for children in this high-risk group.

Pathophysiology

The pathophysiology of this form of JIA is not well understood. Once generally accepted as an autoimmune disease, the high percentage of autoantibodies (especially ANA) in perfectly healthy children makes it more difficult to assess their pathologic significance in children with arthritis. Under any circumstances, what is generally accepted is that leukocyte invasion of the synovium transforms it into a growing, locally invasive tissue that secretes

JUVENILE IDIOPATHIC ARTHRITIS

Method of

James N. Jarvis, MD

CURRENT DIAGNOSIS

- Isolated musculoskeletal pain is almost never the presenting complaint of children with chronic forms of arthritis. Relatively *painless* joint swelling, often associated with gait disturbance, is more common.
- The laboratory has very limited use in making the diagnosis of juvenile idiopathic arthritis (JIA). Anti-nuclear antibody (ANA) tests have limited utility because they are so commonly positive in perfectly healthy children (as many as 30%), and the titers that healthy children have directly overlap those seen in children with JIA. Thus, the test cannot discriminate a healthy child from one with JIA and should not be used for that purpose. Rheumatoid factor (RF) tests have the opposite problem: They are seldom positive in children with JIA, and only the minority of children with positive RF tests have JIA or any other rheumatic disease. The low positive and negative predictive values of the test make it virtually useless for diagnostic purposes. This test should never be ordered as a means of evaluating musculoskeletal pain in children.

Monitoring

There are no laboratory, imaging, or physiologic tests used to monitor fibromyalgia. Symptom scoring measures exist, but they do not have the same evidence for improved outcomes with regular monitoring or a “treat to target” approach, as do measures such as the Patient Health Questionnaire-9 (PHQ-9) used for depression. At the present time, close follow-up with patients at a frequency suitable for the severity of their symptoms or functional limitations represents the best form of disease monitoring. Patients may also choose to track their own symptoms and physical activity quantitatively using apps or other methods as mentioned earlier.

Complications

There are no complications from fibromyalgia in the sense of physiologic morbidity or mortality. However, the persistence of untreated symptoms can have severe consequences for quality of life, work and social functioning, health care utilization, and mental health or emotional distress. While the medications used to treat fibromyalgia have potentially severe risks such as QT prolongation with TCADs, in general they do not have serious complications when used appropriately.

- The hallmark for making the diagnosis of JIA is the presence of warm, thickened synovial membranes that can be palpated around the joints of affected children. The presence of hypertrophic synovial tissue around the joint(s) of a child with a typical history and clinical setting is virtually diagnostic of JIA.

CURRENT THERAPY

- Nonsteroidal antiinflammatory drugs
- Systemic glucocorticoids in select instances
- Oral or subcutaneous methotrexate (particularly for polyarticular disease)
- Anti-TNF (tumor necrosis factor) therapies, particularly for polyarticular disease
- Anti-IL-1 (interleukin-1) therapies, particularly in systemic disease

The term *juvenile idiopathic arthritis* (JIA) is now the internationally accepted term to describe a family of illness characterized by chronic inflammation of synovial membranes. It replaces, but does not completely overlap, the diagnostic classification system that used the term *juvenile rheumatoid arthritis*. Three major phenotypes of JIA are recognized: oligoarticular, polyarticular, and systemic. In addition, the accepted international classification scheme recognizes other subtypes (e.g., enthesitis-associated arthritis, which overlaps the family of conditions previously designated *spondyloarthropathies*) that have distinct clinical phenotypes and that the clinician must recognize against the general background of children presenting with musculoskeletal complaints. Because each of these subtypes represents a distinct phenotype based on presentation, age of onset, differential diagnosis, and therapy, each of these illnesses is described as a distinct entity.

Oligoarticular Juvenile Idiopathic (Pauciarticular) Arthritis (Pauciarticular Juvenile Rheumatoid Arthritis)

Epidemiology

Oligoarticular JIA (*pauciarticular JRA* under the old American College of Rheumatology criteria) is typically a disease of preschoolers of European descent. This subtype of JIA is quite rare in African American children, children from the Indian subcontinent, and Native American children.

Risk Factors

Specific human leukocyte antigen (HLA) alleles, particularly in the class II locus, are known to confer risk for this JIA subtype. However, different alleles are seen in different ethnic subgroups, even in European populations. Thus, the presence of specific HLA alleles is not clinically useful for the diagnosis of most forms of monoarticular JIA. Older boys presenting with monoarthritis might, in fact, have what is now termed enthesitis-associated arthritis (EAA), for which the presence of class I HLA allele B27 can often be a diagnostic clue, because this allele is a major risk factor for developing EAA.

Young age (onset before the age of 3 years) and the presence of antinuclear antibodies (ANA) are specific risk factors for the development of uveitis in children with established disease. Slit-lamp examinations (see “[Complications](#)”) are recommended every 4 months for children in this high-risk group.

Pathophysiology

The pathophysiology of this form of JIA is not well understood. Once generally accepted as an autoimmune disease, the high percentage of autoantibodies (especially ANA) in perfectly healthy children makes it more difficult to assess their pathologic significance in children with arthritis. Under any circumstances, what is generally accepted is that leukocyte invasion of the synovium transforms it into a growing, locally invasive tissue that secretes

JUVENILE IDIOPATHIC ARTHRITIS

Method of

James N. Jarvis, MD

CURRENT DIAGNOSIS

- Isolated musculoskeletal pain is almost never the presenting complaint of children with chronic forms of arthritis. Relatively *painless* joint swelling, often associated with gait disturbance, is more common.
- The laboratory has very limited use in making the diagnosis of juvenile idiopathic arthritis (JIA). Anti-nuclear antibody (ANA) tests have limited utility because they are so commonly positive in perfectly healthy children (as many as 30%), and the titers that healthy children have directly overlap those seen in children with JIA. Thus, the test cannot discriminate a healthy child from one with JIA and should not be used for that purpose. Rheumatoid factor (RF) tests have the opposite problem: They are seldom positive in children with JIA, and only the minority of children with positive RF tests have JIA or any other rheumatic disease. The low positive and negative predictive values of the test make it virtually useless for diagnostic purposes. This test should never be ordered as a means of evaluating musculoskeletal pain in children.

cytokines (thus sustaining the inflammatory process) and proteolytic enzymes that can injure surrounding joint structures.

Prevention

This illness is not known to be preventable.

Clinical Manifestations

Children with pauciarticular JIA typically present with a combination of relatively painless joint swelling, often in combination with gait disturbance. The gait disturbance, when present, is typically more prominent after periods of inactivity (e.g., first thing in the morning or after a nap). Verbalized musculoskeletal pain is almost never a prominent presenting complaint. Although children seldom verbalize pain, they might express some distress when the affected joint is moved.

Diagnosis

This illness typically occurs in preschool children, with a female-to-male ratio of about 3:1. In older children and teenagers with monoarticular disease, diagnoses other than JIA should be considered. Children typically present with relatively painless swelling of a lower extremity joint.

Gait disturbance, most prominent after periods of inactivity (e.g., first thing in the morning or after an afternoon nap), is often a prominent symptom. Careful palpation of lower extremity joints typically reveals warm, thickened synovial tissue. An effusion might or might not be present if the affected joint is a knee. Laboratory tests are not particularly helpful, except in excluding other diagnoses (e.g., Lyme disease, leukemia).

The diagnosis is typically established on the basis of the history and physical examination. Laboratory studies may be necessary to exclude other causes of monoarticular or oligoarticular joint swelling, particularly in children not in the typical demographic (e.g., older children or children of non-European ancestry). No single laboratory test or set of laboratory tests establishes the diagnosis. ANA and rheumatoid factor (RF) tests are particularly unhelpful, because of the low positive predictive value of the former and the low positive and negative predictive values of the latter.

Differential Diagnosis

In a typical clinical setting, the diagnosis is usually straightforward. In areas of North America and Europe where Lyme disease is endemic, Lyme disease is a more common cause of monoarticular joint swelling than oligoarticular JIA. Lyme arthritis can usually be established or excluded on the basis of a screening enzyme-linked immunosorbent assay (ELISA) and Western blot analysis. In preschoolers presenting with severe musculoskeletal pain in a lower extremity joint, acute lymphocytic leukemia should be considered and investigated with one or more complete blood counts (CBC, performed serially), a serum lactate dehydrogenase (LDH), and possibly plain films to examine for periosteal elevation around the affected joint. In children from ethnic groups not typically within the oligoarticular JIA risk group (e.g., Native American children), a more determined search for nonrheumatic causes of monoarticular arthritis (e.g., tuberculosis) may be advisable.

Treatment

The goals of treatment are to rapidly re-establish normal function, prevent further intrusiveness of the disease process into normal activities, and prevent damage to the affected joint(s) and atrophy of the surrounding muscles. Rapid restoration of normal function is increasingly being addressed by the use of intraarticular steroid injections. Daily administration of nonsteroidal antiinflammatory drugs (NSAIDs; e.g., naproxen [Naprosyn], 10–20³ mg/kg/day) can often accomplish this same aim but take considerably longer to demonstrate efficacy. In a few cases, synovitis is intractable even with the combination of NSAIDs and joint injection, and in these cases, methotrexate, given either orally or subcutaneously at 10 to

20 mg/m²/week, typically provides good disease control. Treatment of uveitis is discussed later.

Monitoring

The disease process itself is monitored by interim histories and physical examinations. Slit-lamp examinations are a critical component of the monitoring of all children with JIA, because uveitis is typically indolent and asymptomatic. Children on daily NSAIDs should have a CBC (to monitor for occult blood loss) as well as comprehensive metabolic panel and urinalysis (to monitor for renal toxicity) at least twice a year. The same laboratory studies should be performed in children on methotrexate, although pediatric rheumatologists typically monitor more frequently (every 3–4 months) in children on that drug.

Complications

Before effective therapies were available, muscle atrophy and joint contracture were common complications of this form of JIA. Such sequelae are rare with current approaches to treatment. Uveitis remains the single most common and serious complication of this form of JIA and, even with new and more aggressive therapies, uveitis often results in loss of some visual acuity in the affected eye(s). Diagnosis of this complication can only be made under slit-lamp examination, because signs and symptoms develop only later, when visual acuity is already severely compromised. Children in the highest risk group should have slit-lamp examinations at least three times per year. The high-risk group includes children with a new diagnosis, who are 3 years of age or younger, and who are ANA positive; note that the ANA in this setting is used for prognostic, not diagnostic, purposes. The risk of uveitis is lifelong, and slit-lamp examinations should continue on a yearly basis throughout adulthood.

First-line therapy for uveitis typically includes topical corticosteroids. However, methotrexate and anti-tumor necrosis factor (TNF) monoclonal antibodies (infliximab [Remicade],¹ adalimumab [Humira]) have been shown to be effective in children with disease that is refractory, persistent, or recurrent.

Oligoarticular (pauciarticular) juvenile idiopathic arthritis

Epidemiology

Polyarticular JIA occurs in all age groups (although cases diagnosed in children younger than 1 year of age are rare) and in all ethnic groups. Polyarticular disease is further subcategorized based on the presence or absence of immunoglobulin M (IgM) RFs detected by standard laboratory tests. RF-positive children tend to be older (school-aged children and adolescents) and have severe synovitis, morning stiffness, and other constitutional symptoms. This subtype is more strongly represented among African American and Native American patients, where it represents as many as 50% of all cases of polyarticular JIA. It is rare in European and European-descended children, representing only 10% of all cases of JIA in that population.

RF-negative JIA occurs at all ages in European and European-descended children, from preschool ages to adolescence. African American and Native American children tend to be school-aged or adolescents.

Risk Factors

Specific HLA class II alleles are known to confer risk for RF-negative polyarticular JIA, but, as with pauciarticular disease, these associations vary among different ethnic groups and are not sufficiently strong to be useful diagnostically. Alleles subsumed under the HLA-DR4 group are associated with RF-positive disease, particularly in Native Americans.

Pathophysiology

The pathophysiology of polyarticular JIA is poorly understood. It was once thought to be a typical autoimmune disease in which

³Exceeds dosage recommended by the manufacturer.

¹Not FDA approved for this indication.

autoreactive T cells initiate an immune reaction against (unknown) joint or synovial antigens, but that concept has come under challenge. Disease biomarker studies have suggested an important role for innate immunity in this JIA subtype, particularly monocytes and neutrophils. Under any circumstances, leukocyte infiltration of the synovium transforms it into a proliferating, invasive, and immunologically active tissue. Secretion of both cytokines and proteolytic enzymes plays an important role in causing local tissue damage. Gene expression profiling studies of peripheral blood suggest important roles for interferon (IFN)- γ and TNF- α in either initiating or sustaining the chronic inflammatory response.

Prevention

This illness is not known to be preventable. Given the strong association between tobacco smoking and HLA-DR4-positive RA in adults, it is possible that measures used to prevent tobacco abuse could reduce the incidence of disease in high-risk populations, such as members of specific Native American tribes.

Clinical Manifestations

Because of the wide age range affected, clinical manifestations vary significantly for this JIA subtype. Preschoolers typically present with joint swelling and gait disturbance. Failure to gain or loss of major motor milestones is a fairly rare but well-described presentation in this age group. Joint swelling is the most common presenting complaint in older children and adolescents. Less than 20% of children with JIA verbalize pain at all on initial presentation. Morning stiffness lasting for an hour or more is typically seen in all age groups. Older children with wrist or finger involvement (or both) commonly complain of difficulty with fine motor tasks, such as playing a musical instrument.

Diagnosis

As with oligoarticular JIA, musculoskeletal pain is not a common complaint at presentation in children with polyarticular JIA. Joint swelling, gait disturbance, or, in younger children, loss of (or failure to achieve) major motor milestones are more common presentations.

As with oligoarticular JIA, the laboratory is of limited utility. The diagnosis is made on the basis of the history and physical examination. The critical physical finding in polyarticular JIA is the presence of warm, thickened synovial membranes, typically including both large (knees, ankles) and small (fingers, toes) joints.

The diagnosis is established on the basis of a typical history (swelling in multiple joints, morning stiffness) and a physical examination demonstrating warm, thickened synovial membranes around multiple joints. Involvement of at least one wrist and small joints of the hands is typical. As with all other forms of childhood-onset arthritis, the laboratory is only of marginal use in making the diagnosis and is more useful in excluding other diagnoses. RF tests are singularly unhelpful and should not be ordered for diagnostic purposes. ANA tests are helpful only in excluding the diagnosis of systemic lupus erythematosus (SLE; see later under “[Differential Diagnosis](#)”). Thrombocytosis and mild anemia may be seen in severely affected children, but in such cases the history and physical examination have usually established the diagnosis without need of the laboratory.

Differential Diagnosis

Acute postinfectious arthritis can mimic polyarticular JIA. A distinguishing feature of postinfectious arthritis is the prominence of joint pain as a presenting complaint. Acute RF occasionally mimics polyarticular JIA, but the joint swelling of acute RF is typically exceptionally painfully and migratory (i.e., swelling moves from joint to joint and seldom lasts more than 24 hours in any given joint).

Acute leukemia occasionally manifests with painful swelling in multiple joints and should be considered in a child with swelling and severe musculoskeletal pain.

SLE is another entity that can present with swelling in multiple joints and constitutional symptoms. ANA tests may be helpful in

establishing this diagnosis if the titer is 1:1080 or more. Titers between 1:320 and 1:640 are ambiguous, because these results can be seen in healthy children and in children with JIA. Serum C3 and C4 levels and a urinalysis should always be drawn when an ANA test is being requested for diagnostic purposes, because most children with SLE have low serum complement levels and an abnormal urinalysis. Thus, abnormal results from these tests can often clarify the ambiguity that emerges with ANA titers between 1:320 and 1:640.

Treatment

The goals of therapy for polyarticular JIA are identical to those for pauciarticular JIA: to rapidly reestablish normal function, prevent further intrusion of the disease process into normal activities, and prevent damage to the affected joint(s) and atrophy of the surrounding muscles. Very few children with polyarticular JIA have adequate clinical responses on NSAIDs alone, although these drugs (most commonly naproxen, 10–20³ mg/kg/day in two divided doses) are often used.

More aggressive treatment approaches are now typical in pediatric rheumatology, supported by recently published data that demonstrate that only 5% of children with this disease achieve remission within 5 years. Combinations of methotrexate (10–20 mg/m² given orally or subcutaneously), NSAIDs, and oral steroids are often used in children as first-line treatment. Joint injections with triamcinolone (Aristopan) are used to quickly restore function when activities of daily living or comfort are compromised by synovitis in one or a few joints. TNF inhibitors (etanercept [Enbrel], infliximab,¹ adalimumab) have all shown efficacy in children who have failed methotrexate, and there is a growing trend to use these drugs earlier in the disease course or even at presentation in severely affected children.

There is limited experience in pediatric rheumatology with the IL-1 inhibitor anakinra (Kineret),¹ particularly in JIA, and many children find the required daily injections burdensome. Inhibitors of T cell costimulation signals (e.g., abatacept [Orencia]) have shown some efficacy in children but are generally reserved for children who have failed other therapies. Autologous stem cell transplantation has been shown to be efficacious in children who have failed multiple therapies and have a poor quality of life because of severe, persistent synovitis.

Monitoring

Monitoring for NSAIDs and methotrexate is described under the section on oligoarticular arthritis. Potential hepatic, renal, and bone marrow toxicities of TNF inhibitors are monitored exactly as is done for methotrexate. Because the TNF inhibitors can unmask latent tuberculosis, a PPD is required before starting anti-TNF therapy. All children with polyarticular JIA should be monitored for uveitis through routine slit-lamp examinations (see below).

Children on methotrexate and etanercept (with or without concomitant corticosteroid therapy) should be considered immunosuppressed. Thus, fever, unexplained pulmonary infiltrates, or other signs of infection might need to be investigated more vigorously than in an otherwise healthy child. Fever is almost never a sign of the underlying arthritis.

Complications

Uveitis is a complication of all forms of JIA, including polyarticular JIA. As with oligoarticular JIA, younger children who are ANA positive are at highest risk for this complication, and routine slit-lamp examinations are recommended. Treatment of uveitis is described in the section on oligoarticular arthritis. Anemia of chronic inflammation is often seen in children with severe polyarticular JIA. The most efficient way of treating this complication is

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

to resolve the inflammatory process as rapidly as possible, and providing oral iron can attenuate or resolve this problem.

A severe, albeit rare, complication of polyarticular JIA is an entity called *macrophage activation syndrome*. This severe, sometimes fatal, complication is described in detail in the section on systemic disease.

Severe joint destruction is becoming rare in children with polyarticular JIA, but it still occurs, particularly in children who are RF positive. Joint replacement surgery has sometimes been useful in this setting.

Systemic-Onset Juvenile Idiopathic Arthritis

Epidemiology

All age groups are affected by systemic-onset JIA. This is one of the few forms of JIA that affects boys and girls equally. After RF-positive polyarticular JIA, this is the rarest form of JIA. However, this form of JIA may be proportionally more common in some Asian countries, including Japan.

Risk Factors

There are no known risk factors for this illness. Unlike other types of JIA, there are no convincing HLA associations with this subtype.

Pathophysiology

As with all the other forms of JIA, the pathophysiology of this illness is poorly understood. Mouse models that overexpress human IL-6 mimic many of the features of the human illness, including growth failure. The importance of IL-6 has been corroborated in gene-expression studies from Japan. Gene-expression profiling in affected children also demonstrates a prominent role for IL-1 and IL-1-regulated genes. These findings together suggest an important role for innate immunity in disease pathogenesis. How these findings fit together, or how they explain the chronic synovitis that eventually evolves during or after the febrile phase of the disease, remains to be elucidated.

Prevention

There are no known preventive measures for systemic-onset JIA.

Clinical Manifestations

Children typically present with fever and rash. The fever commonly occurs at regular intervals once, twice, or three times a day. When the fever is present, the child can appear to be quite ill. In contrast, between febrile episodes, the child can appear active, playful, and near normal. The patterned occurrence of the fever and the child's often-robust appearance between febrile episodes are important clues to the diagnosis. Once the febrile episodes begin, they invariably occur daily. Other diagnoses should be pursued in a child with intermittent fever who goes entire days without a febrile episode. The characteristic salmon-colored rash may be present all the time or appear only with the fever. In cases where the rash is continuously present, it can become more prominent during febrile periods. The rash is macular, often confluent in areas, and present on the trunk and extremities but not usually the palms and soles.

The synovitis might appear at the time of the fever and rash or only appear days, weeks, or months later. The presence of joint pain is not diagnostically useful, because many febrile children have this complaint. The presence of morning stiffness or gait disturbance should prompt a very careful examination of the lower extremities for proliferative synovium around the knees, ankles, or small joints of the feet.

An acute phase response is quite typical, and its absence should lead to the pursuit of other diagnoses. White blood cell counts of more than 20,000/mm³ are common, and counts below 15,000/mm³ are relatively uncommon. Platelet counts are typically greater than 500,000/mm³, and it is not unusual to see erythrocyte sedimentation rates of more than 80 mm/hour.

Diagnosis

Fever and rash are the typical presenting complaints in children with systemic-onset JIA. The fever typically occurs daily, not

intermittently. Other diagnostic entities (e.g., Epstein-Barr virus [EBV] infection) should be considered in children with intermittent fever. The fever typically occurs regularly, in a once, twice, or (more rarely), thrice daily pattern. When the fever is present, the child usually appears quite ill; affected children appear surprisingly well in periods between febrile episodes. Querying parents and caretakers for this very typical feature of the disease can be useful diagnostically. The rash, when present, typically intensifies when the fever is present. A brisk acute phase response is typically seen. White blood cell counts of more than 20,000/mm³ and platelet counts of more than 500,000/mm³ are common.

The diagnosis is made based on the history and physical examination and the exclusion of other explanations for fever. The diagnosis can be challenging to make in children who have not yet developed synovitis. This is one form of JIA where the laboratory can be somewhat helpful, because the absence of leukocytosis and thrombocytosis makes systemic onset JIA less likely. Determined efforts to exclude infection, malignancy, and other inflammatory disorders (e.g., Kawasaki's disease) are often required before the diagnosis of systemic-onset JIA can be established.

Differential Diagnosis

The differential diagnosis for systemic JIA is broad and includes infectious (e.g., EBV and cytomegalovirus [CMV] infection), malignant (e.g., lymphoma, neuroblastoma, and leukemia), and other inflammatory (e.g., Kawasaki's disease) etiologies. The latter can be difficult to exclude in a toddler and, thus, the importance of the details of the history and physical; for example, toddlers with Kawasaki's disease are typically irritable even when they are afebrile, but children with systemic-onset JIA often appear quite comfortable between febrile episodes. Younger children (younger than 10 years) might not make the heterophile antibody that is detected in the monospot test for EBV, and antibody titers to specific EBV antigens (usually available in standard EBV antibody panels) should be requested to exclude this diagnosis. Bone marrow examination may be required to exclude malignancy, especially if corticosteroid therapy is anticipated.

Treatment

Corticosteroids, given either as daily oral prednisone (1–2 mg/kg/day) or as methylpredisone (Medrol) pulses (500 mg/m²/dose) are usually effective in controlling the systemic symptoms. In Japan, where systemic disease is quite common, anti-IL-6 monoclonal antibody therapy with tocilizumab (Actemra)¹ has been shown to be effective in controlling both systemic and articular disease. Clinical trials of tocilizumab are underway in North America. Recent work has also shown promising results for the IL-1 receptor antagonist anakinra,¹ based on measured clinical efficacy and responses measured by gene expression profiling. The longer acting agent, canakinumab, has shown efficacy in children with systemic JIA and is approved for that use. Canakinumab may be better tolerated by children because of its monthly dosing schedule. Methotrexate (10–20 mg/m²/week) remains a standard treatment for persistent articular disease, which is typically treated using approaches much like those used for polyarticular disease. Cyclosporine (Neoral)¹ has demonstrated some efficacy for both systemic and articular disease in children who have failed other agents.

Monitoring

Monitoring is the same as for polyarticular JIA. Uveitis is not as common in systemic-onset JIA as in other forms of JIA.

Complications

The hematologic and articular complications of systemic-onset JIA are essentially the same as those seen in polyarticular disease. A serious, sometimes lethal, complication of systemic JIA is macrophage activation syndrome. Macrophage activation syndrome

¹Not FDA approved for this indication.

comprises endothelial cell activation and hepatic and cerebral dysfunction typically heralded by otherwise unexplained decreases in serum hemoglobin, white blood cell, and platelet counts. Elevations in serum ASL/ALT and serum ferritin are other diagnostic clues. Bone marrow aspiration might reveal erythrophagocytic macrophages; their presence is diagnostic, but their absence does not exclude macrophage activation syndrome and should not delay therapy. The development of macrophage activation syndrome should be considered a medical emergency, and affected children should be referred immediately to facilities with experience in caring for this complication.

Enthesitis-Associated Arthritis

Epidemiology

Enthesitis-associated arthritis describes a group of arthritides characterized by male predilection, involvement of the axial skeleton (e.g., hips, sacroiliac joints, cervical spine), extraarticular inflammation (bursae, tendon insertions or entheses, plantar fascia), and acute uveitis. This is the most common form of childhood-onset arthritis on the Indian subcontinent and in some Native American tribes. It might also be more common among children from Mexico and Central America than it is among European and European-descended children.

Risk Factors

HLA-B27 represents an important risk factor in all populations. Between 80% and 90% of European Americans with enthesitis-associated arthritis are HLA-B27 positive. African American patients are less commonly HLA-B27 positive (60%–70%), so the absence of HLA-B27 should not exclude the diagnosis in this population.

Pathophysiology

Current evidence suggests a causative role for HLA-B27. Rats expressing the human HLA-B27 gene develop a clinical picture nearly identical to the human disease. HLA-B27 transgenic rats raised in germ-free environments do not develop the disease, suggesting that normal commensural flora, particularly intestinal flora, play an important role. The connection between gastrointestinal flora and human disease is corroborated by the development of postinfectious arthritic syndromes (e.g., Reiter's syndrome) in HLA-B27-positive adolescents and adults after salmonella, shigella, or chlamydia infection. Finally, the high prevalence of arthritis strongly resembling enthesitis-associated arthritis in patients with inflammatory bowel disease suggests a link between the arthritis and loss of integrity of the gastrointestinal mucosal barrier. Recent research interest has therefore focused on antigen processing by gut-associated lymphoid tissue, although no single pathogenic model has emerged.

Prevention

There are no known preventive measures.

Clinical Manifestations

Enthesitis-associated arthritis demonstrates a wide variety of clinical presentations. The practitioner may be confronted with a pre-school or school-aged boy with monoarticular joint swelling virtually indistinguishable from oligoarticular JIA (male sex and the older age of the child may be important diagnostic clues). School-aged and adolescent patients often present with unilateral or bilateral hip pain. The pain is characteristically worse in the morning and better with activity, which helps distinguish it from other causes of hip pain in teens (e.g., slipped capital femoral epiphysis), which typically cause pain that is worse with activity and better with rest. Finally, some patients present with an acute polyarthritis very similar to polyarticular JIA. Selective involvement of the distal interphalangeal joints of the fingers with sparing of the proximal interphalangeal joints is a typical pattern. Low back pain is very seldom a presenting complaint, unlike in adults with HLA-B27-mediated forms of arthritis.

Diagnosis

The disease typically occurs as a monoarthritis, often involving the hip. This is the only form of JIA where pain is typically a prominent presenting complaint. Hip pain, made worse with rest and better with activity, is a common presenting complaint. Unlike in adults, back pain is only an infrequent presenting complaint in children. The diagnosis is supported (but not established) by the presence of HLA-B27 on peripheral blood leukocytes.

As with all the other forms of JIA, the diagnosis is established on the basis of the history and physical examination. Hip disease typically is associated with pain on internal and external rotation of the affected hip(s), with some loss of range of motion. The presence of extraarticular inflammation (e.g., pain or swelling around the Achilles tendons, plantar fasciitis, bursitis of the hips or shoulders) can be helpful diagnostic clues. Nail pitting, sometimes with frank onycholysis, is sometimes seen. Diffuse swelling of a single toe (saw-sage toe) is a characteristic finding, as is painful arthritis of the first metatarsophalangeal joint.

The laboratory can be helpful in making the diagnosis. HLA-B27 is present in 80% to 90% of patients of European descent. Elevations in erythrocyte sedimentation rate or anemia associated with chronic inflammation are sometimes seen. Imaging studies of the hips can show cartilage loss with or without periarticular demineralization. Changes in the sacroiliac joints are seldom seen at presentation but they can evolve over the course of the disease; their appearance strongly supports the diagnosis.

Differential Diagnosis

Because of the broad spectrum of clinical presentations, the differential diagnosis is likewise broad. Transient synovitis of the hip must be considered in younger children complaining of hip pain. In older children, this same complaint can raise the possibility of Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, idiopathic avascular necrosis, or axial skeletal tumors (e.g., Ewing's sarcoma). Hip pain in children is almost always an indication for obtaining plain films.

Oligoarticular JIA and polyarticular JIA are almost always considered in patients presenting with peripheral arthritis. Acute, self-limited, postinfectious arthritis is sometimes in the differential diagnosis.

Treatment

Therapeutic goals and approaches are virtually identical to those for polyarticular JIA.

Monitoring

See the section on polyarticular JIA.

Complications

Acute, painful uveitis is a common complication of this form of arthritis and can even be the presenting complaint. Pain; red, inflamed sclerae; and photophobia almost invariably lead patients to seek medical attention quickly. Most patients with acute uveitis respond well to topical corticosteroids. Inflammation of the genital tract (sterile urethritis, balanitis) are less common complications.

Progressive joint destruction, particularly in affected hips, can occur even with aggressive management. Sacroiliitis can be seen in older patients or patients with long-standing disease. Frank ankylosis of the spine is rare before adulthood.

OSTEOARTHRITIS

Method of

David H. Neustadt, MD

CURRENT DIAGNOSIS

- Improved understanding and knowledge of the pathogenesis of osteoarthritis have led to increasing optimism for the 20 to 30 million osteoarthritis sufferers in the United States.
- Osteoarthritis is now known to involve inflammatory mechanisms, not mechanical wear and tear, as believed in the past.

CURRENT THERAPY

- Although there is no cure for osteoarthritis, coping strategies including simple measures such as weight reduction and modification of activities to reduce stress and load on the joints should be emphasized.
- Pharmacotherapy includes acetaminophen (Tylenol), other simple analgesics, and judicious use of nonsteroidal antiinflammatory drugs. Opioids should be avoided, except during the first few days of post-operative surgery when joint replacement procedures have been carried out.
- When usual medical measures fail to control the pain of osteoarthritis, intraarticular injections of a corticosteroid is the next step.
- A painful effusion is the major indication for arthrocentesis, aspiration, and if fluid is not infectious, instillation of a corticosteroid preparation.
- After a corticosteroid injection for knee osteoarthritis, increased therapeutic response results if a postinjection rest regimen is imposed. The patient remains in bed or at rest for 3 days and then uses walking devices (cane or crutches) for 2 to 3 weeks.
- The main factors that influence the therapeutic response from a series of hyaluronan injections are the extent of loss of cartilage and severity of the osteoarthritis disease in the affected knee.
- Total knee and hip replacement procedures are considered when nonoperative management fails to adequately control symptoms and pain.

Osteoarthritis (OA) (degenerative joint disease) is the most commonly encountered rheumatic disorder and the major cause of disability and reduced activity after 50 years of age. Radiographic evidence of OA is found in up to 85% of people older than 65 years. Autopsies indicate evidence of OA in weight-bearing joints of almost all persons by the age of 45 years.

In spite of the evidence of pathologic changes of OA found in Java and Neanderthal human skeletons and dinosaur skeletons, OA was confused with rheumatoid arthritis (RA) until the turn of the 20th century. It is characterized pathologically by involvement of cartilage, varying from fissures and microfibrillations in

early disease to erosive destruction in advanced disease. Weight-bearing or shearing forces are transmitted to the subchondral bone, leading to sclerosis, cyst formation, and bone remodeling. Osteophytes (spurs) develop at the margins of joints, and new cartilage proliferates over these bony spurs.

An inflammatory component is present in most patients with symptomatic OA. The traditional belief that OA is simply a wear-and-tear condition associated with the stress of advancing years is not tenable. This mistaken belief is considered the major reason for the relatively slow progress of cartilage and bone research and investigation into the etiology and pathogenesis of OA. During the past decade, much new knowledge on cartilage, including metabolic changes, genetic mutations, metalloproteinases, and possible diagnostic biomarkers and inflammatory mediators, has fostered considerable excitement and interest in new approaches for the prevention, monitoring, and treatment of OA.

Although the cause of OA is unknown, contributing factors include genetic history, trauma, overweight, overuse of joints, and aging. An additional risk factor recognized more recently is leg length disparity (inequality), which seems to be associated with greater hip or knee joint pain. OA may be classified into primary (idiopathic) and secondary forms. Secondary OA results from trauma or repetitive overuse of a specific joint; an inflammatory form of arthritis such as RA, repeated attacks of gout, or septic arthritis; developmental problems such as congenital dysplasia of a hip or slipped capital femoral epiphysis; or metabolic and miscellaneous causes including hemophilic arthropathy, ochronosis (alkaptonuria), and osteonecrosis. Thus, OA may be considered a (final) common pathway resulting from a host of many different problems.

Joints commonly affected in OA include the large, weight-bearing, and frequently used joints, such as the hips and knees, spine, distal interphalangeal (DIP) joints (Heberden's nodes), and trapeziometacarpal (carpometacarpal thumb base) and first metatarsophalangeal joint (bunion). Joints often spared in OA include the metacarpals, the wrists, the shoulders, and the ankles (except in ballet dancers).

Clinical Features

The onset of OA is insidious, and the course is slowly progressive. Clinical features include variable pain and mild stiffness, with associated limited motion; bony enlargement with or without tenderness; synovitis of the knees; and functional impairment with malalignment (varus or valgus deformities) when advanced involvement of the knees or hips develops. There are no specific laboratory abnormalities or specific (disease) markers of the disease, except in ochronosis.

Radiographs and other imaging procedures demonstrate evidence of OA, manifested chiefly by a narrowed joint space (loss of cartilage), osteophyte formation, and secondary subchondral sclerosis. There may be a poor correlation between symptoms and underlying abnormal structural findings on x-ray images. Special subsets of OA and significant associated conditions include inflammatory (cystic erosive) OA, calcium pyrophosphate dihydrate disease (chondrocalcinosis), and diffuse idiopathic skeletal hyperostosis (DISH).

Treatment

The optimal management program for OA should be individualized to the specific problems and clinical syndromes presented by each patient (Box 1).

General Considerations

Realistic reassurance that the patient does not have a serious, potentially crippling disease such as RA and adequate understanding of what to expect are of paramount importance for successful management. Education of the patient is the basic foundation of the treatment program. The updated OA booklet provided by the National Arthritis Foundation is a useful supplement to education. Involving spouses and other family members in coping skills training may be helpful. Understanding the patient's problem

Osteoarthritis (OA) (degenerative joint disease) is the most commonly encountered rheumatic disorder and the major cause of disability and reduced activity after 50 years of age. Radiographic evidence of OA is found in up to 85% of people older than 65 years. Autopsies indicate evidence of OA in weight-bearing joints of almost all persons by the age of 45 years.

In spite of the evidence of pathologic changes of OA found in Java and Neanderthal human skeletons and dinosaur skeletons, OA was confused with rheumatoid arthritis (RA) until the turn of the 20th century. It is characterized pathologically by involvement of cartilage, varying from fissures and microfibrillations in

early disease to erosive destruction in advanced disease. Weight-bearing or shearing forces are transmitted to the subchondral bone, leading to sclerosis, cyst formation, and bone remodeling. Osteophytes (spurs) develop at the margins of joints, and new cartilage proliferates over these bony spurs.

An inflammatory component is present in most patients with symptomatic OA. The traditional belief that OA is simply a wear-and-tear condition associated with the stress of advancing years is not tenable. This mistaken belief is considered the major reason for the relatively slow progress of cartilage and bone research and investigation into the etiology and pathogenesis of OA. During the past decade, much new knowledge on cartilage, including metabolic changes, genetic mutations, metalloproteinases, and possible diagnostic biomarkers and inflammatory mediators, has fostered considerable excitement and interest in new approaches for the prevention, monitoring, and treatment of OA.

Although the cause of OA is unknown, contributing factors include genetic history, trauma, overweight, overuse of joints, and aging. An additional risk factor recognized more recently is leg length disparity (inequality), which seems to be associated with greater hip or knee joint pain. OA may be classified into primary (idiopathic) and secondary forms. Secondary OA results from trauma or repetitive overuse of a specific joint; an inflammatory form of arthritis such as RA, repeated attacks of gout, or septic arthritis; developmental problems such as congenital dysplasia of a hip or slipped capital femoral epiphysis; or metabolic and miscellaneous causes including hemophilic arthropathy, ochronosis (alkaptonuria), and osteonecrosis. Thus, OA may be considered a (final) common pathway resulting from a host of many different problems.

Joints commonly affected in OA include the large, weight-bearing, and frequently used joints, such as the hips and knees, spine, distal interphalangeal (DIP) joints (Heberden's nodes), and trapeziometacarpal (carpometacarpal thumb base) and first metatarsophalangeal joint (bunion). Joints often spared in OA include the metacarpals, the wrists, the shoulders, and the ankles (except in ballet dancers).

Clinical Features

The onset of OA is insidious, and the course is slowly progressive. Clinical features include variable pain and mild stiffness, with associated limited motion; bony enlargement with or without tenderness; synovitis of the knees; and functional impairment with malalignment (varus or valgus deformities) when advanced involvement of the knees or hips develops. There are no specific laboratory abnormalities or specific (disease) markers of the disease, except in ochronosis.

Radiographs and other imaging procedures demonstrate evidence of OA, manifested chiefly by a narrowed joint space (loss of cartilage), osteophyte formation, and secondary subchondral sclerosis. There may be a poor correlation between symptoms and underlying abnormal structural findings on x-ray images. Special subsets of OA and significant associated conditions include inflammatory (cystic erosive) OA, calcium pyrophosphate dihydrate disease (chondrocalcinosis), and diffuse idiopathic skeletal hyperostosis (DISH).

Treatment

The optimal management program for OA should be individualized to the specific problems and clinical syndromes presented by each patient (Box 1).

General Considerations

Realistic reassurance that the patient does not have a serious, potentially crippling disease such as RA and adequate understanding of what to expect are of paramount importance for successful management. Education of the patient is the basic foundation of the treatment program. The updated OA booklet provided by the National Arthritis Foundation is a useful supplement to education. Involving spouses and other family members in coping skills training may be helpful. Understanding the patient's problem

BOX 1**Comprehensive Management Program for Osteoarthritis**

Education of the patient and family
 Coping measures: Rest and modification of activities of daily living
 Measures to reduce joint loading
 Physical therapy, occupational therapy, assistive devices
 Pharmacotherapy
 Intraarticular therapy (corticosteroid suspensions and hyaluronan)
 Total joint replacement procedure

permits reasonable delegation of responsibilities for chores and engaging in activities. Patients and spouses who are better informed about the disease and its outlook are generally better able to cope with the condition. Cognitive behavior techniques can help patients confront the variability of symptoms, the effects of rest and exercise, and emotional aspects.

Prophylactic Measures

Reducing the impact of the load and shearing force on an osteoarthritis joint not only can diminish symptoms but also can retard progression of the disease. Explaining the biomechanical factors enables the patient to understand the need for rest and protection of the affected joints. Weight reduction by dietetic means is strongly encouraged for the obese patient. Protective and preventive measures for the knee include avoiding weight-bearing knee bending, stair climbing, jogging, and prolonged walking. Knee loading during weight bearing can be avoided by using a high chair or stool, elevated toilet seat, knee supports or braces, and walking devices (Box 2).

Nonpharmacologic Therapy

The most important aspect is specific instructions for balanced rest and exercise (preferably at home). Exercises should be mainly isometric (nonmovement), such as quadriceps muscle strengthening, stretching, and range-of-motion exercises.

Instructions should be given for joint protection with measures to conserve energy and on the use of any needed assistive aids, such as canes, crutches, walkers, splints, back supports and braces, cervical supporting collars, and proper shoes with any needed modifications and orthotics.

Heat modalities should be prescribed in the form of hot showers or tub soaks, hot packs such as a Bed Buddy (microwavable cervical collar or back wrap), and a warm pool for water aerobic exercises. These measures ameliorate discomfort and facilitate the exercise program. Diathermy, short wave, and ultrasound methods are relatively expensive and of questionable benefit. The use of a hot tub or whirlpool bath, especially after exercise or work, may be of palliative benefit.

Job and recreational activities must be assessed and modified if necessary to avoid overuse of affected joints. Sexual counseling may be needed, especially in some patients with severe knee, hip, or back involvement.

Pharmacotherapy

The basic program of education and reassurance of the patient, joint rest and protection, and physical measures can control

symptoms in some patients with early mild OA. Many patients, however, require drug therapy. Although no available drugs predictably reverse or halt the inexorable progression of the disease, the drugs do reduce pain and inflammation, enhancing the patient's quality of life.

Analgesics

Some patients with OA have minimal inflammation and can be managed with analgesics alone. Analgesic agents (non-narcotic) currently available include acetaminophen (Tylenol) and tramadol (Ultram). Effective dosages of acetaminophen are 1.0 to 1.3 g administered every 8 hours or three or four times daily (do not exceed 4 g/day). Adverse effects are rare, but caution must be exercised in patients who have preexisting renal or liver conditions. Tramadol can be given in 50-, 100-, 200-, or 300-mg tablets up to two to three times daily for pain relief (do not exceed 400 mg of immediate-release tablets per day or 300 mg of extended-release tablets per day). These drugs are generally well tolerated, and nausea, vomiting, and dizziness are the most common adverse effects. A combination preparation, Ultram 37.5 plus acetaminophen (Ultracet), is available. Propoxyphene (Darvon and Darvon products), longstanding, useful, and safe analgesics, unfortunately have been removed from the approval list by the Food and Drug Administration (FDA). Duloxetine (Cymbalta) 60 mg daily was introduced as a compound for pain caused by fibromyalgia syndrome. Recently, the drug received approval by the FDA for mild to moderate pain resulting from OA. Duloxetine has minor adverse effects, the most common of which is nausea that usually subsides when the medication is continued for a period of approximately 6 to 10 days. In large, controlled clinical trials, nausea occurred in up to 24% of patients taking duloxetine versus 8% of the placebo group. The drug has been reported as occasionally causing mild renal lab alterations. Discontinuing the drug brings about clearing of the renal dysfunction within 1 to 2 weeks. Duloxetine is considered relatively safe when the patient is seen for a checkup every 2 to 3 months and has laboratory tests to include routine urinalysis, serum creatinine, and BUN. Patients who have a history of elevated blood pressure should be cautioned to have their blood pressure checked every 2 to 3 months. Duloxetine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs). Rare interactions can cause a serious reaction. The drug is known to cause mydriasis occasionally. In view of this problem it should not be used in patients who have uncontrolled narrow-angle glaucoma. Duloxetine may increase the risk of bleeding; therefore patients should be cautioned about taking the medication with aspirin or other possible anticoagulants. In a double-blind, randomized, placebo-controlled study of patients with chronic pain due to OA of the knees, there was significant improvement with duloxetine versus the placebo. I advise avoiding regular use of opioids. Opioids may be needed occasionally for intense pain, but the benefits are limited owing to the common gastrointestinal adverse events and the potential for addiction.

Antiinflammatory Agents

A much-discussed report compared acetaminophen 4 g/day with ibuprofen (Advil, Motrin) 1200 to 2400 mg/day in OA of the knee. The clinical results demonstrated no significant difference in efficacy among the three treatment groups. Critical analysis of this comparative study, however, discloses a short duration of the treatment trial (4 weeks) and a relatively low antiinflammatory dosage (up to 2400 mg) of ibuprofen. In my experience and that of many others, pain in OA patients is often not adequately controlled with pure analgesics, whereas nonsteroidal antiinflammatory drugs (NSAIDs) in adequate dosage can provide significant clinical improvement.

Nonacetylated salicylates are widely used in OA. Compounds currently available include salsalate, choline magnesium trisalicylate, and magnesium salicylate. These agents are weak prostaglandin (cyclooxygenase) inhibitors, thus avoiding the ant clotting effect and potential adverse effect on the gastrointestinal tract and kidneys. Side effects are relatively uncommon and minor with

BOX 2**Measures to Protect Knees**

Avoid knee bending during weight bearing
 Avoid steps when possible
 Use high chair or high stool
 Use elevated toilet seat
 Use cane, crutches, or walker for prolonged walking
 Do isometric quadriceps muscle-strengthening exercises

nonacetylated salicylates when administered in a dosage of 1 to 1.5 g twice daily. Gastrointestinal and cardiovascular problems have not been reported. Salicylism with ototoxicity is a rare side effect.

If simple analgesics and salsalate fail to provide adequate relief, one of the many currently available NSAIDs may be selected for a therapeutic trial. Clinical trials with naproxen, diclofenac, and sulindac showed significantly greater improvement of the NSAID when compared with high-dose acetaminophen. The chief limiting factor in the use of NSAIDs is the possible induced gastric pathologic changes, disturbed renal function, and potential increased cardiac events.

Cost and compliance also must be given consideration. Many of the NSAIDs are now available in dosage forms that can be given once or twice daily, which helps overcome the compliance problem.

Currently available NSAIDs are all similar in their proposed mechanism of action but vary considerably in their pharmacokinetics, dosage, clinical response, and side effects. The variability of the effects of different NSAIDs in patients is significant and unpredictable. All NSAIDs are metabolized in the liver, except two available compounds, sulindac (Clinoril) and nabumetone (Relafen), which are called prodrugs; they are not converted to active drugs until after absorption and hepatic biotransformation. The prodrug effect might partially spare the gastrointestinal tract and also produces less suppression of renal prostaglandins. Etodolac (Lodine) reportedly has fewer gastric complications, and endoscopy does not demonstrate the typical gastric erosions found in the gastric mucosa of the majority of patients taking older NSAIDs.

Concomitant prophylactic use of misoprostol (Cytotec) has been recommended to protect gastric mucosa in patients with a previous history of peptic ulcer or gastrointestinal bleeding. Unfortunately, misoprostol causes cramps and diarrhea in a relatively high percentage of patients. A gastroprotective agent, such as a proton pump inhibitor, will reduce the risk of gastrointestinal adverse effects.

The question of potential deleterious effect on cartilage versus chondroprotective properties by various NSAIDs remains controversial.

Cyclooxygenase 2 Inhibitors

Prostaglandin synthesis in humans is catalyzed by two enzyme forms of cyclooxygenase: cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2).

COX-1 is constitutively expressed and is considered responsible for suppression of physiologic functions including gastric mucosal protection. In contrast, COX-2 is induced by inflammatory mediators and is responsible for inflammation without any significant effect on the gastric mucosa. The development of agents that selectively inhibit the COX-2 pathway without significant gastrointestinal adverse effects was considered an extremely important advance.

Currently only one COX-2-specific inhibiting NSAID is FDA approved and available. Celecoxib (Celebrex) is equivalent to the older nonselective NSAIDs with regard to therapeutic effectiveness, but the risk of gastrointestinal toxicity and adverse effects on platelet aggregation is lessened. The risk of renal side effects is probably comparable with that of the conventional NSAIDs. A trial assessing the effect of celecoxib on cardiovascular events found a slightly higher risk of cardiovascular events but chiefly only at higher doses (400 mg/day or greater). Celecoxib can be used with low-dose aspirin (81 mg) daily and anticoagulants including warfarin (Coumadin).

Intraarticular Injections

Corticosteroids

After many years of controversy concerning intraarticular corticosteroid therapy in OA, there is now consensus that this form of therapy is of considerable value when it is indicated and skillfully administered. Although early on it is still preferable to attempt to control symptoms by simple measures with oral therapy, rather than by local injection, when faced with relatively acute painful

conditions such as synovitis of the knee or inflamed Heberden's nodes, quick and sometimes lasting relief can be obtained with intrasynovial steroid injection. This form of treatment is considered an adjunct to a conventional management program.

A painful knee effusion is the most common indication for arthrocentesis followed by a local corticosteroid injection. The remote potential deleterious effect of instability developing in the knee can be avoided by giving injections at infrequent intervals and prescribing a strict postinjection rest regimen. Specific instructions are given to the patient to refrain from weight-bearing activity for 3 days, except getting up for meals and going to the bathroom. The patient is advised to reduce loading of the injected knee by using a cane or crutches with a three-point gait during weight bearing for 2 to 3 weeks after the procedure. This rest regimen delays escape of the steroid suspension from the joint cavity and promotes a longer duration of response to the injection. I have observed numerous patients with OA of the knee associated with large recurrent synovitis who had been given three to five or more local injections with only transient benefit. When a strict postinjection rest program was imposed, these patients obtained substantial improvement in the duration of the effect, and some achieved indefinite "cures." The remote risk of introducing infection from the procedure is minimized by adhering to a meticulous aseptic technique.

Another important indication for arthrocentesis and intraarticular steroid therapy is OA associated with crystal synovitis due to calcium pyrophosphate dihydrate disease (CPPD) pseudo-gout or pseudogout. Diagnosis is confirmed by radiographic findings of chondrocalcinosis and polarized microscopic identification of the specific crystals in the fluid. Treatment, including aspiration and administration of intraarticular steroids, is usually successful in controlling the acute synovitis.

Hyaluronans (Hyaluronic Acid, Hyaluronate)

Intraarticular hyaluronan, approved by the FDA in 1997 as a new procedure for clinical use in OA of the knee, represents a valuable addition to the therapeutic armamentarium for the treatment of OA. The clinical use of intraarticular hyaluronan in painful OA of the knee was introduced in Europe in the 1990s. The mechanism of action of hyaluronate is termed *viscosupplementation*, an effort to restore normal viscoelastic properties to the pathologically altered synovial fluid. Other possible beneficial effects include protection of the chondrocytes, antiinflammatory effects, and improvement of the mechanics of joint motion.

Numerous preparations of FDA approved hyaluronan preparations are in wide use in the United States. Initially, all hyaluronans were extracted from rooster combs. Table 1 lists the more common hyaluronans that are available for injecting knee osteoarthritis. The hyaluronan products are injected in a series of three, four, or five at weekly intervals in accordance with the patient's response. All the hyaluronans are highly purified natural preparations except Hylan G-F20, which is cross-linked with added formaldehyde and vinyl

TABLE 1 Some Common FDA-Approved Hyaluronans and Their Molecular Weights

PRODUCT	MW (kDa)	DOSE (WEEKLY)
Hylan G-F20 (Synvisc)*	5000–6000	3 × 16 mg
High-molecular-weight hyaluronan (Orthovisc)	1000–2900	3–4 × 30 mg
Sodium hyaluronate (Hyalgan)	500–720	3–5 × 20 mg
Sodium hyaluronate (Supartz)	620–1200	5 × 25 mg
1% Sodium hyaluronate (Euflexxa)†	2400–3600	3 × 20 mg

*Not pure; contains formaldehyde and vinyl sulfones. Human synovial fluid MW is 350–500 kDa.

†Derived from biologic fermentations.

sulfone in an effort to increase retention in the joint cavity. Effectiveness and duration of improvement are similar with all the products. Undesirable complications and adverse effects are limited to rare local mild pain, with the exception of the cross-linked Hylan G-F20, which can cause a severe acute inflammatory reaction (SAIR, or pseudoseptic reaction) in approximately 2% to 8% of patients injected with the product.

Newer hyaluronan products are non-animal-derived preparations that are developed from biological fermentation of streptococcal origin. Until recently, these hyaluronans have been available only in Europe. One of these products (Euflexxa) has been approved by the FDA for use in the United States. This preparation would be especially useful in the rare patient who is allergic to avian products. Hyaluronan therapy has been studied in other specific joints including the hip, shoulder, ankle, and first carpometacarpal joints. Approval from the FDA is expected. Drawbacks of intraarticular hyaluronan include difficulty injecting and limited response in patients with extreme obesity and severe advanced osteoarthritis of the knee (grade 4 Kellgren classification). Retreatment with intraarticular hyaluronic acid 1 year after the first series is safe and effective in patients whose initial course of therapy was successful. A new hyaluronan preparation (Monovisc) has been developed, containing 4 or 5 times the amount of hyaluronan used in the usual knee injection, which is given in a series of 3 or 4 weekly injections. Monovisc is a cross-linked sodium hyaluronate. It is designed to treat the symptoms of osteoarthritis with only one injection. The response and results have not been compared directly in a clinical trial to date. The approach, if effective, would simplify the procedure, especially for "needle shy" patients.

Joint Lavage and Arthroscopy

Lavage of the arthritic knee may be performed with arthroscopic visualization. The authors of a recent double-blind, sham-controlled evaluation concluded that "most, if not all" of the effects of tidal irrigation seem to be attributable to a placebo effect. Arthroscopy permits inspection of the joint cavity. Associated abnormalities such as ligamentous and meniscal tears can be observed in conjunction with osteoarthritis. Calcified loose bodies can be removed, and débridement can be carried out.

Treatment of Cystic Erosive (Inflammatory) Osteoarthritis

Cystic erosive OA is the genetically determined clinical syndrome manifested by lumpy-bumpy fingers with involvement of the DIP joints (Heberden's nodes) and proximal interphalangeal joints (Bouchard's nodules). It rarely causes significant pain except during the early developing stage. It is important to strongly reassure the patient that this is not a serious crippling disease, emphasizing the distinction of the knobby nodes from the swelling of the synovitis of RA. However, if the thumb base joint (trapeziometacarpal, first carpometacarpal) is involved, abduction splinting or local injection may be necessary for relief of pain.

Occasionally, when OA of the fingers is symptomatic, warm soaks; application of an analgesic balm, such as triethanolamine, after the warm soaks; and the wearing of spandex gloves during sleep at night are useful. When a digital node is inflamed, local instillation of a few drops of a corticosteroid suspension often provides prompt relief.

If symptoms persist, a cautious trial with one of the topical analgesic pepper plant creams (capsaicin) such as Zostrix may be worthwhile. Capsaicin is an inhibitor of substance P, the neuropeptide pain mediator. The topical cream is safe, and a local burning or transient stinging sensation during application is the only troublesome adverse effect. The stinging diminishes with use after a few days.

New Approaches

Disease-Modifying Drugs

The purpose of the investigational disease-modifying drugs is to play a role in either enhancing the biosynthesis of cartilage matrix or preventing enzymatic degradation and inhibiting catabolic

cytokine activity in an attempt to induce cartilage repair and restore joint homeostasis.

Tetracycline (Sumycin)¹ and its congeners [doxycycline (Vibramycin),¹ minocycline (Dynacin)¹] have shown evidence of inhibiting enzymatic degradation of cartilage, including that by stromelysin, collagenase, and gelatinase, in dog, guinea pig, and rabbit models of OA. A proposed long-term clinical trial in human subjects is in progress.

Hydroxychloroquine (Plaquenil)¹ and chloroquine (Aralen)¹ have been administered successfully for many years in RA and systemic lupus erythematosus. Recently, anecdotal and retrospective uncontrolled studies have reported the efficacy of hydroxychloroquine in retarding the progression of inflammatory (cystic) erosive OA. It has been suggested that the beneficial action of hydroxychloroquine is due to its inhibitory effects on lysosomal enzymes and the secretion of interleukin-1. Experience thus far suggests that this agent may be promising in inflammatory OA.

Other novel therapeutic approaches that are under study but lack conclusive significant data at this time include insulin-like growth factors, transforming growth factor- β , and glucosamine, a proteoglycan component and a growth factor for cartilage. In ongoing studies, an antinerve growth factor antibody, fully humanized, effectively reduces pain and improves function in subjects with knee osteoarthritis. Undesirable effects so far are minor, including a rare, transient, mild peripheral neuritis.

Chondrocyte Transplantation

Chondrocyte transplantation was initially developed and carried out in Sweden for localized cartilage damage resulting from trauma in young subjects. A subsequent report described relatively successful treatment of 23 patients who had chondral defects of the knee and were given autologous chondrocyte transplantation combined with periosteal grafting. The expectation that the procedure will "cure" OA lesions remains an unmet possibility for the future. Regeneration of articular cartilage is a complex process and will require long-term evaluation of the function of the new cartilage and prospective controlled clinical studies to confirm the value of the procedure.

Gene Therapy

Gene therapy is an exciting new technology that holds promise for the future but requires considerable further investigation and refinement. Techniques to introduce gene transfer in conjunction with autologous cultured chondrocytes are being explored.

Glucosamine and Chondroitin Sulfate

Glucosamine⁷ and chondroitin⁷ sulfate are over-the-counter nutraceuticals (dietary supplements) that have considerable anecdotal data touting their symptom-modifying effects. Some reports have suggested that glucosamine can retard or modify structural changes of OA, but convincing evidence for this effect is lacking. The drugs are well tolerated and have no significant adverse effects. Recently published studies have no evidence or significant data demonstrating that either of these preparations used alone or in combination prevents or reduces pain in osteoarthritis of the knee. These so-called nutraceuticals cause no serious adverse effects, but any true clinical value remains to be shown.

Surgery

When appropriate medical (nonoperative) management fails to adequately control pain, and functional disability significantly interferes with lifestyle, surgical options should be considered.

Available procedures include osteotomy for joint malalignment (varus knee deformities); arthroscopy, especially for specific lesions such as calcified loose bodies or meniscal tears; and arthrodesis (fusion) for unstable joints, when joint replacement is not indicated

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

or declined. Arthrodesis may be the optimal procedure in young, overweight, active patients with severe OA involving a single knee.

Partial or total arthroplasty, especially total knee and hip replacement, may be carried out in patients in whom medical management fails to adequately control symptoms. An estimated 125,000 total hip replacements, most of which are for OA, are performed each year in the United States. Total knee replacement (total knee arthroplasty) is an increasingly gratifying operation for advanced knee OA. Innovative approaches and new techniques, including the development of minimally invasive procedures (MIS), bodes well for the future.

OSTEOPOROSIS

Method of

Alexei DeCastro, MD; Scott Bragg, PharmD; and
Peter J. Carek, MD, MS

CURRENT DIAGNOSIS

- Evaluation of risk factors for osteoporosis and related fractures is always recommended.
- Screening for osteoporosis with bone mineral density testing in women age 65 years and older is recommended.
- In women younger than 65 years old and equal or increased risk of osteoporosis compared with 65-year-old women, bone mineral density testing is recommended.
- Determination of bone mineral density is indicated for those with osteoporotic fractures to determine the severity of the disorder.
- Clinical and laboratory evidence of secondary causes of osteoporosis should be pursued in all patients with osteoporosis.
- Vertebral fracture assessment and trabecular bone scores could be considered in addition to bone mineral density testing to augment fracture risk assessment.
- Current evidence is insufficient to recommend screening for osteoporosis in men.

CURRENT THERAPY

- A comprehensive nutritional orientation targeting normal body weight is recommended. Additionally, healthy bone orientation requires adequate ingestion of calcium and vitamin D.

- New evidence does not show major benefit in taking calcium and vitamin D for primary prevention. For secondary prevention, calcium intake should be at least 1200 mg/day, including supplements, when necessary. Vitamin D consumption should at least be 800 to 1000 IU daily to prevent insufficiency.
- Weight-bearing and muscle-strengthening exercises are important tools to reduce the risk of falls and fracture.
- Antiresorptive therapy is indicated for postmenopausal women and men age 50 years and older with hip or vertebral fractures without major trauma.
- Antiresorptive therapy is indicated for postmenopausal women and men age 50 years and older with bone mineral density T-scores ≤ -2.5 at the lumbar spine, femoral neck, or total hip, after proper evaluation.
- Antiresorptive therapy is indicated for postmenopausal women and men age 50 years and older with low bone mass and high 10-year fracture risk. The 10-year fracture risk is considered high if the 10-year hip fracture probability is 3% or more or if the 10-year probability of a major osteoporosis-related fracture is 20% or more based on the fracture risk assessment tool (FRAX) from the US-adapted algorithm from the World Health Organization.
- Treatment of premenopausal women and men less than 50 years old with antiresorptive therapy is controversial. Z-scores of ≤ -2.0 indicate osteoporosis. However, antiresorptive treatment is often reserved for glucocorticoid-induced osteoporosis in patients with moderate to high fracture risk or patients with multiple fragility fractures.
- The drugs currently approved by the Food and Drug Administration (FDA) for preventing or treating osteoporosis include bisphosphonates (alendronate [Fosamax], ibandronate [Boniva], risedronate [Actonel], and zoledronic acid [Reclast]), calcitonin (Miacalcin), estrogen-only or estrogen/progesterone hormone therapy, raloxifene (Evista), denosumab (Prolia), and parathyroid hormones (teriparatide [Forteo] and abaloparatide [Tymlos]).
- The assessment of therapeutic response can be monitored by bone mineral density. Normally, bone mineral density testing is repeated every 2 years after initiation of pharmacotherapy. However, in some conditions (eg, glucocorticoid therapy) 1-year intervals may be warranted.

Osteoporosis is a skeletal disease characterized by low bone mass and structural deterioration of bone tissue that is associated with decreased bone strength and increased susceptibility to fractures. Its clinical relevance is increasing due to the associated morbidity and mortality associated with the disease. The signs and symptoms of osteoporosis, such as back pain, height loss, and thoracic kyphosis, not only are usually late manifestations of previously unrecognized vertebral fractures but can also be important risk indicators for future fractures. A challenge to primary care clinicians is to find the best screening method(s) to identify patients at highest risk for fracture who would benefit from a preventive or therapeutic intervention.

The World Health Organization (WHO) has defined osteoporosis as a condition in which bone mineral density (BMD) assessed by dual-energy x-ray absorptiometry (DEXA) at the lumbar spine or hip is decreased compared with a young-adult reference population. Osteoporosis is seen in postmenopausal women or men over age 50 with a bone mineral density 2.5 standard deviations (SDs) below normal (T-score ≤ -2.5). Osteopenia, a milder degree of bone loss, is seen in the same populations with less BMD decline (T-score of -1.0 to -2.4). Although the risk of fracture increases significantly with decreasing BMD, large observational studies have demonstrated that osteoporotic fractures can occur across a wide spectrum of BMDs. These events may be related not only to bone quantity but also to bone quality, a component not measured by DEXA scans. Qualitative determinants of bone strength include trabecular bone scores, microcracks, mineralization defects, bone geometry, cell death, changes in bone size, and

or declined. Arthrodesis may be the optimal procedure in young, overweight, active patients with severe OA involving a single knee.

Partial or total arthroplasty, especially total knee and hip replacement, may be carried out in patients in whom medical management fails to adequately control symptoms. An estimated 125,000 total hip replacements, most of which are for OA, are performed each year in the United States. Total knee replacement (total knee arthroplasty) is an increasingly gratifying operation for advanced knee OA. Innovative approaches and new techniques, including the development of minimally invasive procedures (MIS), bodes well for the future.

Osteoporosis is a skeletal disease characterized by low bone mass and structural deterioration of bone tissue that is associated with decreased bone strength and increased susceptibility to fractures. Its clinical relevance is increasing due to the associated morbidity and mortality associated with the disease. The signs and symptoms of osteoporosis, such as back pain, height loss, and thoracic kyphosis, not only are usually late manifestations of previously unrecognized vertebral fractures but can also be important risk indicators for future fractures. A challenge to primary care clinicians is to find the best screening method(s) to identify patients at highest risk for fracture who would benefit from a preventive or therapeutic intervention.

The World Health Organization (WHO) has defined osteoporosis as a condition in which bone mineral density (BMD) assessed by dual-energy x-ray absorptiometry (DEXA) at the lumbar spine or hip is decreased compared with a young-adult reference population. Osteoporosis is seen in postmenopausal women or men over age 50 with a bone mineral density 2.5 standard deviations (SDs) below normal (T-score ≤ -2.5). Osteopenia, a milder degree of bone loss, is seen in the same populations with less BMD decline (T-score of -1.0 to -2.4). Although the risk of fracture increases significantly with decreasing BMD, large observational studies have demonstrated that osteoporotic fractures can occur across a wide spectrum of BMDs. These events may be related not only to bone quantity but also to bone quality, a component not measured by DEXA scans. Qualitative determinants of bone strength include trabecular bone scores, microcracks, mineralization defects, bone geometry, cell death, changes in bone size, and

changes in bone turnover. Even though a low BMD defines osteoporosis, a fragility fracture (ie, low-trauma fracture) can also be used to clinically diagnose osteoporosis.

Although there is no universally accepted screening tool for patients at risk for osteoporotic fracture, the WHO and U.S. Preventive Services Task Force (USPSTF) recommend screening in women > 65 years old and in women younger than 65 who are at equal or increased risk of osteoporosis compared with 65-year-old women (Level B). To identify patients at increased risk, they use a decision support tool to calculate the 10-year risk of a hip fracture and a major osteoporotic fracture. The fracture risk assessment tool (FRAX) considers several major independent risk factors, including BMD of the femoral neck, previous fracture history, family history of fracture, age, sex, ethnicity, glucocorticoid use, alcohol abuse, current smoking status, and possible secondary osteoporosis causes. Nevertheless, many women with osteoporosis go unrecognized and untreated. In one study, it was reported that only 49% of women were evaluated and treated despite these screening guidelines. Another study showed overscreening of patients at low risk (46% for women 50–59 and 59% for women 60–64 without risk factors) and underscreening of patients at high risk (58% for women 65–74 and 43% for women ≥ 75).

Epidemiology

Osteoporosis is the most common metabolic disorder of the skeleton. The estimated prevalence of osteoporosis is highest in Mexican Americans, followed by non-Hispanic whites, and lowest in non-Hispanic blacks. Worldwide, 200 million women suffer from osteoporosis, and those women have an estimated 65% lifetime risk of a fragility fracture. In men with osteoporosis, the lifetime risk of osteoporotic fracture is estimated at 42%. Both of these numbers may rise with increases in life expectancy. In the United States, approximately 8 million women and 2 million men have osteoporosis, and 34 million men and women have osteopenia. After the fourth decade of life, fracture rates in women are twice those in men. In addition, hip fracture has a seasonal influence, with an increase during winter months in temperate countries. Hip fractures are reported to cause a mortality rate of 10% to 20% at 12 months, but they cause a higher rate of deaths in men than women. Up to 25% of those with hip fractures require long-term nursing home care.

Screening

Risk factors for osteoporosis should be considered at well visits or during all visits in high-risk individuals. Nonmodifiable risk factors are genetic background, advancing age, female sex, low socioeconomic status, Mexican Americans or non-Hispanic whites, personal history of fracture, family history of fracture in a first-degree relative, and rheumatoid arthritis. Modifiable risk factors consist of low body weight, hormonal deficiencies, smoking, alcohol abuse, an inactive lifestyle, and a diet low in calcium and vitamin D. In addition, certain medications that affect skeletal homeostasis, such as glucocorticoids, immunosuppressive medications, anticonvulsants, loop diuretics, levothyroxine, and proton pump inhibitors, are also possible modifiable risk factors that need to be assessed. Because patients with chronic kidney disease may have hormonal interactions between PTH, calcium, and phosphate, their risk for osteoporosis should be considered and assessed. However, routine BMD measurement is not recommended for all patients with chronic kidney disease.

Several decision support tools are available to help identify patients who are at high risk for osteoporosis and fracture. The most common risk scores include the fracture risk assessment tool (FRAX), the simple calculated osteoporosis risk estimation, the osteoporosis self-assessment tool, and the osteoporosis risk assessment instrument. However, the USPSTF guideline recommends using FRAX because it incorporates the most risk factors and provides a 10-year absolute fracture risk. FRAX uses history such as age, body mass index, parental fracture history, and tobacco and alcohol use. The FRAX tool incorporates DEXA results but does not require this information to estimate fracture risk, so it can be

used to identify women who may benefit from DEXA screening. The USPSTF recommends screening with a DEXA in postmenopausal women <65 years old if their 10-year fracture risk with FRAX is 9.3% or higher, although there is evidence that other decision support tools have comparable sensitivity and negative predictive values and rely on fewer factors.

The National Osteoporosis Foundation (NOF) and the International Society for Clinical Densitometry recommend screening all men 70 years and older and men 50 to 69 years of age based on risk factors. However, the USPSTF guidelines state that insufficient evidence is available to support screening for osteoporosis in men. Other screening risk assessments such as vertebral imaging and trabecular bone scores may be considered in addition to DEXA scans to help identify asymptomatic vertebral fractures or quantify bone microarchitecture. These techniques may help better characterize 10-year fracture risk or guide treatment decisions with antiresorptive therapy, although both screening tests are not discussed in the USPSTF guidelines because of limited data with these screening modalities.

Pathophysiology

Although osteoporosis is often thought of as synonymous with decreased BMD, this association is not always present. Several factors can lead to decreased bone strength, including small bone size, increased length of the femoral neck, cortical porosity, decreased viability of osteocytes, and others.

Peak bone mass is the maximum bone mass achieved in life and typically occurs in the patient's third decade of life. Differences in the peak bone mass may be secondary to genetic, hormonal, and environmental variables. The contribution of genetic variants is unclear with no studies that associate genetic variants with fracture risk or decreasing BMD. Mexican Americans and Asian Americans have lower BMDs than whites. However, lower hip fracture rates are reported in Mexican Americans and Asian Americans than in whites. Increases in body size and skeletal load also play a role in peak bone mass. Physical activity during childhood also enhances bone mass, whereas chronic diseases during childhood may decrease BMD.

Age-related bone loss is a significant factor in the development of osteoporosis. Bone resorption begins to overtake bone formation with advancing age. Men, however, are less likely to develop bone loss because of greater bone gain during puberty and no sudden loss of estrogen. Hormonal deficiency causes bone loss by unbalancing the homeostasis normally present and the bone remodeling rate (i.e., osteoclast-induced bone resorption vs osteoblast-supported bone formation). Estrogen loss initially affects trabecular bone after menopause. After a few years, bone loss continues to occur more slowly and primarily affects cortical sites. This slower phase is associated with a decreased number of osteoblasts and a slower bone formation rate. It is also theorized that androgen loss has detrimental effects on BMD, but it is uncertain how much. Still, both sex hormone deficiencies play a role in bone loss in both men and women. Also, there is evidence that aging itself seems to be an independent risk factor for bone loss. Another contributing factor to osteoporosis development and fractures is loss of muscle strength, which may increase the risk for falls and the severity of falls.

Clinical Manifestations

There are typically no clinical manifestations of osteoporosis until a patient actually has a fracture. The signs and symptoms associated with osteoporosis correspond to direct or indirect manifestations of these fractures. For example, vertebral fractures may be asymptomatic and can be clinically inconspicuous. Patients may have height loss, back pain, and thoracic kyphosis, which can cause dyspnea due to pulmonary restrictive lung disease and constipation. A fracture may be the first sign of a systemic disease associated with osteoporosis, as well as a complication from glucocorticoid therapy or solid organ transplantations. Many factors may contribute to the osteoporosis after organ transplantation, such as immunosuppressive medications or derangements of the parathyroid-calcium-vitamin D and the pituitary-gonadal axes.

Diagnosis

Osteoporosis is diagnosed either clinically or radiographically. It can be established after the occurrence of a fragility fracture, such as a low-trauma fracture of appendicular or axial bones, excluding the skull. The initial evaluation includes a history to assess for clinical risk factors for fracture, evaluation for secondary conditions that contribute to bone loss, a physical examination, basic laboratory tests, and assessment of medications that increase fracture risk. Most cases of osteoporosis are diagnosed by DEXA scan of the total hip, femoral neck, or lumbar spine, with a T-score of -2.5 or below. Bone mass measurements by DEXA must be interpreted in relation to the patient's age, ethnicity, fracture history, family background, previous medications, timing of menopause, and other concomitant disorders.

Other techniques for measuring bone mass besides DEXA scans exist. These include ultrasound of the calcaneus, wrist, and finger and computed tomography of the spine and peripheral quantitative computed tomography of the wrist and tibia. However, these modalities may be limited by factors such as radiation exposure and cost. DEXA scans give an accurate and precise estimate of BMD and has been a proven, cost-effective tool.

DEXA results are expressed as a T-score and a Z-score. The T-score was established by the WHO and is the number of SD difference between the patient's BMD and a sex- and ethnicity-matched young-adult reference population. The T-score should be used in the evaluation of men age 50 and older and postmenopausal women. The T-score provides an indication of the risk for developing fractures because of the association of fractures with decreasing T-scores. A T-score that is -2.5 SD or more is diagnostic of osteoporosis; a T-score that is between -1.0 and -2.4 SD below the mean is defined as low bone mass, also known as *osteopenia*. A T-score of -2.5 SD or below plus a fragility fracture is termed *severe osteoporosis*. BMD measurements may be different across various bone sites in the same patient. These discrepancies may likely be related to differences in skeletal compartments (trabecular vs. cortical) at distinct sites. The lowest T-score of the lumbar spine, femoral neck, and total hip should be used to classify the degree of osteoporosis.

The Z-score is the number of SDs the patient's BMD differs from a reference population matched for age, sex, and ethnicity. A low Z-score of -2.0 SD or below may help identify patients who need further evaluation for secondary causes of osteoporosis, such as long-term corticosteroid steroid use or the adolescent female athlete triad. Z-scores should be used in the evaluation of adult men younger than age 50, premenopausal women, and children. Less evidence exists for characterizing the severity of disease or need for antiresorptive treatment in these populations, and making comparisons can be difficult. For example, there is no great way to compare the BMD of a child to an adult who has achieved peak bone mass.

Biochemical markers reflect the activity of the bone-remodeling unit. These markers, such as urinary pyridinoline and deoxypyridinoline, are called *bone turnover markers*. Their roles in the management of osteoporosis have not been well established. Future use of these biochemical markers may be helpful in determining risk and for monitoring patients treated with antiresorptive therapy.

Differential Diagnosis

Because osteoporosis is radiographically or clinically identified from a history, the differential focuses on a comprehensive workup of potential secondary causes of osteoporosis. If evaluation does not support a clear secondary cause, there is currently little evidence for additional testing in postmenopausal women. However, in premenopausal and perimenopausal women, additional testing could be considered if there is no clear cause found by history and physical examination. More than 50% of men with vertebral collapse fractures are reported to have secondary causes of osteoporosis. Common causes of osteoporosis in men are long-term use of glucocorticoids, hypogonadism, alcohol abuse, myeloma, and gastrointestinal, thyroid, and parathyroid disorders. It is important

to note most recommendations for screening and diagnosis are based on expert opinion.

Prevention

Prevention of osteoporosis is important because bone loss with aging is difficult to correct. Treatment stabilizes the disease by increasing BMD, reducing fracture risk, and, in the case of parathyroid hormone, restoring bone strength. Lower peak bone mass established in early adulthood may determine bone strength and fracture risk decades later. Therefore prevention starts with good nutrition, physical activity, and exercise that optimize bone mass during bone-forming years. Other lifestyle factors that can be modified are discouraging cigarette smoking and excessive alcohol intake. Medications that may be harmful to bone health, such as glucocorticoids and anticonvulsants, should be closely monitored and used for the minimum duration.

Calcium and vitamin D are both physiologically vital in bone formation. However, studies are conflicting on the benefits of primary prevention using calcium and vitamin D. Some studies have shown increases in BMD and reduction of fracture risk in at risk patients given both calcium and vitamin D. The NOF recommends 1200 mg of elemental calcium and 800 to 1000 IU of vitamin D daily for postmenopausal women. New evidence, however, does not support dietary or supplemental calcium or vitamin D to reduce the risk of fractures in adults in primary prevention of high-risk individuals.

Treatment

Nonpharmacologic Therapy

Nondrug therapy includes addressing risk of falls, diet, exercise, and smoking. Vision deficits, gait abnormalities, cognitive impairment, dizziness, and balance problems need to be addressed to prevent falls. Performing a formal home safety evaluation and modifying the patient's living environment by improving lighting and removing loose rugs can enhance safety. Physical therapy evaluation and treatment can address both balance and gait issues. Medications need to be reviewed that pose a risk of falls due to their side-effect profile.

Ensuring adequate nutrition is an initial approach in treating osteoporosis, especially calcium and vitamin D. Studies showing the efficacy of calcium on fracture primary prevention are mixed, with some meta-analyses showing benefit and others showing no effect. Although primary prevention benefit is unclear, adequate calcium and vitamin D consumption should be encouraged when used with antiresorptives to reduce the risk of hypocalcemia with bisphosphonates and ensure optimal efficacy of these agents. Because an optimal dosing is not standardized, a daily intake of at least 1200 mg of calcium and 800 to 1000 IU of vitamin D is recommended for all women with osteoporosis by the NOF. Calcium and vitamin D supplements are often used because of low dietary consumption of each and reduced sun exposure with aging. Both calcium carbonate and calcium citrate can be used, but caution should be used because of constipation and gastrointestinal upset. Concerns about renal adverse events, particularly nephrolithiasis, exist with excessive dietary and/or supplemental calcium.

The appropriate vitamin D level remains unclear, with mixed evidence and different experts advocating for different goal values. Some studies suggest that a serum 25-hydroxyvitamin D level of at least 30 ng/mL is needed to reduce falls and improve physical function in the elderly. However, some experts advocate for treating only severely low 25-hydroxyvitamin D values <20 ng/mL because of mixed evidence with slightly low vitamin D values. In patients with confirmed vitamin D insufficiency, administration of 50,000 IU of oral ergocalciferol (vitamin D₂ [Drisdol]) given once-weekly for 8 to 12 weeks is safe and effective. This regimen is followed by a repeat serum 25-hydroxyvitamin D value to determine the need for further treatment with more than 50,000 IU doses or whether maintenance vitamin D₃ can be started at 1000 IU daily. High-dose vitamin D may increase the risk of falls, so caution should be used.

TABLE 1 Efficacy of Approved Drugs for Osteoporosis Treatment on Fracture Risk

MEDICATION	ROUTE	DOSE	CLINICAL EVIDENCE OF EFFICACY		
			VERTEBRAL	HIP	NONVERTEBRAL
Alendronate (Fosamax)	Oral	Oral 10 mg daily or 70 mg weekly	+	+	+
Risedronate (Actonel)	Oral	5 mg daily or 35 mg weekly	+	+	+
Zoledronic acid (Reclast)	IV	5 mg yearly	+	+	+
Ibandronate (Boniva)	Oral	150 mg monthly	+	—	—
	IV	3 mg every 3 months	+	—	—
Denosumab (Prolia)	SubQ	60 mg every 6 months	+	+	+
Abaloparatide (Tymlos)	SubQ	80 mcg daily	+		+
Teriparatide (Forteo)	SubQ	20 mcg daily	+		+
Raloxifene (Evista)	Oral	60 mg daily	+	—	—
Bazedoxifene/ conjugated equine estrogen (Duavee) ¹	Oral	20/0.45 mg daily	+	—	—
Conjugated equine estrogen (Premarin) ¹	Oral	0.625 mg daily	+	+	+
Calcitonin (Miacalcin)	Nasal	200 IU daily	+	—	+
	IM or SubQ	100 IU	+	—	+

Abbreviations: IM = intramuscular; IU = international units; IV = intravenous; SubQ = subcutaneous.

¹Not FDA approved for this indication.

Regular physical activity and performing aerobic, weight-bearing, and resistance exercises are effective in increasing spine BMD. Patients should exercise at least 30 minutes three times per week. However, there is no evidence that high-intensity exercise provides greater benefit. Smoking cessation and moderate alcohol consumption should be stressed to reduce the risk for fracture as well.

Pharmacologic Treatment

All drugs approved by the FDA for osteoporosis reduce vertebral fracture risk. Many of the antifracture effects of these medications are not due to an increase in BMD but rather to an improvement in qualitative measures of bone strength. The drugs approved by the FDA to treat or prevent osteoporosis are noted in Table 1. The mechanisms of each class of osteoporosis agent is slightly different and primarily work through decreasing bone resorption by inhibiting osteoclasts or increasing bone formation by stimulating osteoblasts. The bisphosphonates (e.g., alendronate [Fosamax], risedronate [Actonel], ibandronate [Boniva], zoledronic acid [Reclast]) impair osteoclastic resorption through the inhibition of farnesyl diphosphate synthase, a key enzyme that supports osteoclast activity. Estrogen, raloxifene (Evista), a selective estrogen receptor modulator or SERM, and bazedoxifene² inhibit osteoclastogenesis through blocking the receptor activator of nuclear factor kappa B ligand/osteoprotegerin (OPG) system expressed on osteoblasts that signal the production of osteoclasts. Denosumab (Prolia), a monoclonal antibody, works similarly to estrogen by inhibiting the receptor activator of nuclear factor kappa B ligand system for osteoclast formation. Calcitonin (Miacalcin) works through a different mechanism by inhibiting osteoclast activity through the calcitonin receptor. Lastly, parathyroid hormone (i.e., teriparatide [Forteo], abaloparatide [Tymlos]) stimulates osteoblast bone formation, increasing calcium absorption in the gastrointestinal track, and promoting renal tubular calcium reabsorption.

There are different approved indications for bisphosphonates in patients with osteoporosis. Alendronate and risedronate are indicated for the prevention and treatment of postmenopausal osteoporosis, treatment of osteoporosis in men, and treatment of

glucocorticoid-induced osteoporosis. Ibandronate is approved only for prevention and treatment of postmenopausal osteoporosis. Daily and intermittent doses of ibandronate have demonstrated benefit on reducing vertebral fractures. Zoledronic acid 5 mg by intravenous (IV) administration is approved for once-yearly treatment of postmenopausal osteoporosis, and 5 mg IV administered once every other year is approved to prevent osteoporosis. Zoledronic acid is the only osteoporosis therapy proved to all cause reduce mortality and may be a preferred option in those who cannot tolerate or are nonadherent with oral therapy in addition to its potential mortality benefits. In patients with an osteoporotic hip fracture, it is essential that they receive treatment with a bisphosphonate after surgery to modify the subsequent risk of fracture at any site. There have been concerns that bisphosphonates started soon after surgery could disrupt bone remodeling and fracture healing, but current evidence shows that early administration of bisphosphonates does not delay fracture healing. Therefore they should be given immediately to reduce subsequent fractures.

Side effects of oral bisphosphonates include esophageal and gastric irritation and musculoskeletal pain. They must be taken with a full glass of water, and a 30- to 60-minute wait is required before reclining or any oral intake to lower the risk of upper gastrointestinal adverse effects. IV bisphosphonates are associated with hyperthermia, episcleritis, uveitis, and hypocalcemia. The proper duration of therapy for oral bisphosphonate therapy is unknown. Low-risk patients may consider discontinuing therapy after 3 to 5 years once the risks and benefits are weighed. There have been reports of subtrochanteric fractures with bisphosphonates, particularly alendronate when used longer than 5 years. Young women are particularly prone to these fractures, which often require surgical intervention. Prodromal symptoms that have been linked to this syndrome include proximal femur pain and evidence of previous stress fracture or cortical thickness on x-ray. Osteonecrosis of the jaw is another very rare but serious complication seen with long-term bisphosphonate use.

Estrogen is an effective therapy at reducing all types of fracture and is often reserved for women unable to use other options because of potential serious consequences. These complications include thromboembolism, stroke, myocardial infarction, and some types of cancer. Raloxifene, on the other hand, improves BMD and reduces the risk of vertebral fractures, but not nonvertebral or hip fractures. Unfortunately, it can exacerbate the

²Not available in the United States.

vasomotor symptoms of menopause and increases the risk of thromboembolic events. Raloxifene may be considered in postmenopausal women with osteoporosis who cannot tolerate bisphosphonates, have no vasomotor symptoms, have a low risk of venous thromboembolism, and have a high breast cancer risk. A new selective estrogen receptor modulator, bazedoxifene plus conjugated equine estrogens (Duavee), has been approved for prevention of postmenopausal osteoporosis and vasomotor symptoms with menopause. It might prove to be an alternative to raloxifene, but it's still associated with many of the serious precautions seen with estrogen therapy.

Denosumab (Prolia), 60 mg subcutaneously twice a year, is a human monoclonal antibody approved for treatment of men and postmenopausal women with osteoporosis who are at high risk for fracture. In a large trial involving more than 7000 postmenopausal women, denosumab was administered for 3 years and showed significant efficacy in reducing the risk of vertebral, non-vertebral, and hip fractures compared to placebo. The safety profile of denosumab has been demonstrated in long-term trials, although there was a reported modest increase in skin infections with continued use. Long-term risks of atypical fractures and osteonecrosis of the jaw have been reported with denosumab similar to bisphosphonates, so it is recommended to reevaluate the need for continued treatment after 3 to 5 years.

Parathyroid hormones (i.e., teriparatide, abaloparatide) have recognized antifracture effects on both vertebral and nonvertebral sites. Currently, therapy with either treatment should be limited to 2 years for postmenopausal women, men, or in patients with glucocorticoid-induced osteoporosis. The maximum 2-year duration is based on reports of increased risk of osteosarcoma, which has only been seen in laboratory animals exposed to high doses. Consequently, teriparatide is contraindicated in patients with risk of osteosarcoma, such as those with Paget disease of the bone, previous skeletal radiation, or unexplained elevations of alkaline phosphatase. Adverse effects may include orthostatic hypotension, hypercalcemia, nausea, arthralgia, risk of renal stones, and leg cramps. In addition to its approved indications, some experts recommend using one of the anabolic options in patients who experience an atypical fracture or patients who have not improved on bisphosphonates. No evidence exists for combining anticatabolic and anabolic classes of drugs for additive benefits. However, it is recommended that after a period of 2 years of use, sequential therapy with an antiresorptive should be started to avoid posttreatment bone loss.

New Agents

Romosozumab⁵ is a monoclonal antibody that works by bidding and inhibiting sclerostin, a bone protein, thereby increasing bone formation and decreasing resorption. There is robust evidence showing better effectiveness at reducing hip, vertebral, and nonvertebral fractures when compared head-to-head with alendronate over 24 months. It was rejected, however, by the FDA in 2017 because of a concern for an increase in cardiovascular events. It remains unclear if and when romosozumab will become FDA approved for osteoporosis as a result of this safety finding.

⁵Investigational drug in the United States.

PAGET'S DISEASE OF BONE

Method of

Ian R. Reid, MD

CURRENT DIAGNOSIS

- Suspect the presence of Paget's disease in those patients with bone pain, bone deformity, isolated elevation of alkaline phosphatase, or lytic/sclerotic lesions on radiographs.
- Paget's disease is diagnosed from plain radiographs.
- Bone scintigraphy identifies the affected bones and allows some assessment of disease activity.
- Biochemical markers of bone turnover allow more precise assessment of turnover and response to therapy.
- Serum total alkaline phosphatase activity is the most cost-effective marker, although bone-specific alkaline phosphatase and procollagen type I N-terminal propeptide (PINP) are marginally more sensitive.

CURRENT THERAPY

- Zoledronate (zoledronic acid, Reclast) 5 mg given as a single infusion over 15 minutes; retreatment is seldom required within 5 years.
- Alendronate (Fosamax) 40 mg/day for 6 months; retreatment may be required between 2 and 6 years.
- Risedronate (Actonel) 30 mg/day for 2 months; retreatment may be required between 1 and 5 years.

vasomotor symptoms of menopause and increases the risk of thromboembolic events. Raloxifene may be considered in postmenopausal women with osteoporosis who cannot tolerate bisphosphonates, have no vasomotor symptoms, have a low risk of venous thromboembolism, and have a high breast cancer risk. A new selective estrogen receptor modulator, bazedoxifene plus conjugated equine estrogens (Duavee), has been approved for prevention of postmenopausal osteoporosis and vasomotor symptoms with menopause. It might prove to be an alternative to raloxifene, but it's still associated with many of the serious precautions seen with estrogen therapy.

PAGET'S DISEASE OF BONE

Method of

Ian R. Reid, MD

CURRENT DIAGNOSIS

- Suspect the presence of Paget's disease in those patients with bone pain, bone deformity, isolated elevation of alkaline phosphatase, or lytic/sclerotic lesions on radiographs.
- Paget's disease is diagnosed from plain radiographs.
- Bone scintigraphy identifies the affected bones and allows some assessment of disease activity.
- Biochemical markers of bone turnover allow more precise assessment of turnover and response to therapy.
- Serum total alkaline phosphatase activity is the most cost-effective marker, although bone-specific alkaline phosphatase and procollagen type I N-terminal propeptide (PINP) are marginally more sensitive.

CURRENT THERAPY

- Zoledronate (zoledronic acid, Reclast) 5 mg given as a single infusion over 15 minutes; retreatment is seldom required within 5 years.
- Alendronate (Fosamax) 40 mg/day for 6 months; retreatment may be required between 2 and 6 years.
- Risedronate (Actonel) 30 mg/day for 2 months; retreatment may be required between 1 and 5 years.

Figure 1 A, Bone scintigram in a patient with Paget's disease, demonstrating the multifocal nature of the condition and the presence of normal bone at other sites. B, Tibia affected by Paget's disease. The upper tibia is of increased density and width as a result of osteoblast overactivity, whereas the lower part of the affected bone shows a lytic region (between arrows) resulting from osteoclastic bone resorption. Below this, the bone is normal. (Copyright I. R. Reid, used with permission.)

Paget's disease is a focal skeletal condition in which one or more bones has a clearly circumscribed area of increased turnover (Figure 1A). Either osteoblasts or osteoclasts may predominate at a given time, resulting in sclerosis or lysis, respectively. Areas that are initially lytic often become sclerotic later, and it is common to see both changes within the same bone (see Figure 1B). Unaffected areas of the skeleton are completely normal, in marked contrast to some rare congenital conditions which are sometimes (inappropriately) referred to as early-onset or juvenile Paget's disease. Such conditions (e.g., familial expansile osteolysis, idiopathic hyperphosphatasia) have different etiologies, clinical presentations, and responses to treatment when compared to Paget's disease.

Etiology

Within pagetic bone, there is a loss of the usual tight control of bone cell function, and the bone-resorbing cells (osteoclasts) and bone-forming cells (osteoblasts) both exhibit overactivity. In the case of osteoclasts, this leads to local areas of bone loss, which can result in deformity or fracture. Osteoblast overactivity leads to the random laying down of new bone, which is disorganized in its structure, mechanically inadequate, and prone to deformity. Osteoblast overactivity can also lead to bone expansion, resulting in bone pain, premature arthritis (if it affects articular surfaces), and nerve compression (e.g., in the spine or skull). Figure 1B shows the effects of osteoblast and osteoclast overactivity on the structure of an affected tibia. The disease progresses along a long bone at a rate of about 1 cm per year, so most patients have had active disease for 1 or more decades before presentation. Typically, the disease progresses until the entire bone is involved. However, Paget's disease does not spread from one bone to another, so the number of affected bones remains constant throughout the disease course.

Paget's disease sometimes runs in families, and about 10% of patients are reported to have an affected relative. This observation has led to much work seeking genetic associations of the condition.

It is now apparent that mutations of the gene for sequestosome 1 are associated with Paget's disease in some families. Other research has focused on possible environmental causes, and a slow viral infection has been suggested. Evidence that the prevalence of Paget's disease has decreased in recent decades would be consistent with altered exposure to an environmental agent. However, both the genetic and environmental hypotheses fail to account for the focal nature of the condition, which in some ways resembles a benign neoplasm.

Altered gene expression in osteoblasts and bone marrow stromal cells from pagetic bone has been demonstrated recently, including increased levels of dickkopf-1, interleukin-1, and interleukin-6. These changes are likely to result in stimulation of osteoclast proliferation and inhibition of osteoblast growth, leading to development of the characteristic lytic bone lesions. This work suggests that the key abnormality may reside in the osteoblast, rather than the osteoclast, as was assumed in the past. Uncertainties remain regarding the primary abnormality giving rise to this condition.

Epidemiology

Paget's disease is classically a condition of older adults, most patients being older than 60 years of age at diagnosis. There is a male preponderance in some studies. It is overwhelmingly a condition of individuals with European forebears, particularly from the United Kingdom and Western Europe (excluding Scandinavia), where about 6% to 7% of the older population is affected. Among older white Americans, the prevalence is about 2%. There is evidence that prevalence and disease severity are both declining, possibly reflecting change in an environmental etiologic factor. It is extremely uncommon in individuals with predominantly Asian or Polynesian ancestry, although it is observed in some black populations.

Clinical Presentation

The most common symptoms attributable to Paget's disease are bone and joint pain. The bone pain is typically worse at rest and may trouble patients particularly at night. With skull involvement, pounding headaches can result. If Paget's disease leads to deformity of joint surfaces, premature arthritis occurs. This is particularly common at the hips. Deformity in long bones can occur, and involvement of the radius or weight-bearing bones of the lower limb often manifests in this way. Microfractures, which can be very painful, sometimes occur over the convexity of a deformed, weight-bearing bone. These can progress to complete fractures. Fractures can also occur through an area of active lytic disease in a weight-bearing bone.

Deafness is a common manifestation of Paget's disease and is caused by involvement of the bones of the middle ear or compromise of the eighth cranial nerve. More rarely, other neurologic syndromes can arise from nerve entrapment, including paraplegia as a result of spinal cord involvement.

Some pagetic patients are asymptomatic and are diagnosed because of an incidental finding of elevated circulating levels of alkaline phosphatase. The diagnosis may also result from an incidental radiographic finding, such as in studies of the urinary tract. Commonly, only one or two bones are involved, although disease may be more widespread. The pelvis, vertebral bodies, long bones, and skull are the most common sites, but almost any bone can be involved.

Diagnosis

Serum alkaline phosphatase, the most widely available marker of osteoblast activity, is usually elevated; however, if only one bone is involved, this test can be normal. In any patient with an elevation of alkaline phosphatase, it is important to determine whether this is coming from liver or bone. This question is usually addressed by other liver function tests, although assays of bone-specific alkaline phosphatase and of other osteoblast-specific markers (e.g., procollagen type I N-terminal propeptide [PINP]) are available. If the elevation of alkaline phosphatase is bony in origin, it is important to rule out other bone conditions such as metastatic cancers (e.g.,

breast, prostate). This is usually done by identifying the sites of skeletal abnormality on a bone scintigram and then obtaining plain radiographs of the abnormal areas.

Paget's disease has a characteristic appearance on plain radiographs, showing either bony rarefaction or sclerosis (depending on whether the osteoclastic or osteoblastic phase is predominating), disorganization of trabecular architecture, and the other abnormalities already discussed (e.g., deformity). Bone biopsy is not usually necessary to confirm the diagnosis.

Other biochemical markers of osteoblast or osteoclast activity, such as breakdown products of bone collagen, have been used in Paget's disease. Total alkaline phosphatase, bone alkaline phosphatase, PINP or N-terminal telopeptide of type I collagen (NTX) identified more than 95% of pagetic subjects in one cohort of pagetic subjects, although the poorer precision of NTX reduced its utility in monitoring the effects of treatment. Osteocalcin, C-telopeptide of type I collagen, and urinary free deoxypyridinoline are less useful for assessment of baseline activity and monitoring response to therapy. Total alkaline phosphatase remains the most widely used test because of its low cost and wide availability.

Treatment

Treatment of Paget's disease almost always relies on the potent bisphosphonates. These compounds have a very high affinity for the bone surface, where they remain for years. They are ingested by osteoclasts when bone is resorbed and inhibit a key enzyme in the mevalonate pathway, farnesyl pyrophosphate synthase. This results in disruption of the osteoclast cytoskeleton and cell death. Bisphosphonates are preferentially taken up at sites of high bone turnover, which accounts for their utility as bone scintigraphy agents, and therefore target active pagetic bone.

The injectable bisphosphonate pamidronate (Aredia) has been used for many years in the treatment of Paget's disease. It is typically given as a series of infusions of 60 to 90 mg, each administered over a period of 1 to 2 hours. Pamidronate produces partial or complete remissions of disease activity that last for up to several years. The first administration of the drug may be accompanied by mild flu-like symptoms, which settle over 24 to 48 hours and usually do not recur. Their resolution can be hastened by the use of paracetamol (acetaminophen, Tylenol) or similar agents.

More recently, potent oral bisphosphonates such as alendronate (Fosamax) and risedronate (Actonel) have become widely used. These are administered daily over periods of 2 to 6 months and produce good disease control. The duration of treatment chosen in the pivotal clinical trials was arbitrary to some extent, and individual patients may require longer or shorter initial courses to achieve remission. Oral bisphosphonates have a very low bioavailability. Therefore, they must be taken in a fasting state, with a glass of water, and at least 30 minutes before consumption of food or other fluids. Positively charged ions (including calcium supplements, antacids, and mineral supplements) bind avidly to bisphosphonates and impair their absorption, so they must be taken at a different time of day. Potent bisphosphonates can cause irritation to the upper gastrointestinal tract and should not be prescribed to patients with inflammation or ulceration in that region. Patients should remain upright for 30 minutes after taking oral bisphosphonates to minimize the risk of reflux and associated esophagitis or ulceration.

The preferred treatment at present is the more potent intravenous bisphosphonate zoledronate (Reclast), which is administered in a single dose of 5 mg over 15 minutes. It has been compared with the standard 2-month course of risedronate in two randomized, controlled trials. At 6 months, 96% of patients receiving zoledronate had a therapeutic response, compared with 74% of those randomized to risedronate ($P < 0.001$). Alkaline phosphatase levels normalized in 89% of patients in the zoledronate group and in 58% of those in the risedronate group ($P < 0.001$). Zoledronate showed a more rapid onset of action and superior effects on quality-of-life measures. Perhaps the most impressive data with zoledronate have been those from the open follow-up of responders in these studies. Six years after drug administration, relapse had occurred in 0.7% of those receiving zoledronate but in 20% of risedronate-treated patients.

Therefore, zoledronate produces much more sustained responses to therapy than have hitherto been possible.

Potent bisphosphonates can cause mild hypocalcemia, which is usually asymptomatic and not a cause for concern. However, in patients with marked vitamin D deficiency, hypocalcemia can be more severe and sustained. Therefore, it is important to ensure that patients are vitamin D sufficient before receiving these drugs—a serum 25-hydroxyvitamin-D level greater than 40 nmol/L is more than adequate. Many physicians prescribe calcium to patients receiving bisphosphonate therapy (given in the evening if the oral bisphosphonate is given in the morning) as a further protection against hypocalcemia.

In the past, the weak bisphosphonate etidronate (Didronel) was used to treat Paget's disease. This is much less effective than the agents discussed previously. If used in high doses or for more than a few months, it carries the risk of producing osteomalacia, which can lead to bone pain and fractures. Therefore, it no longer has a place in the treatment of Paget's disease. Calcitonin (Miacalcin Injection) has also been relegated to an historical role only, because its efficacy is much less than that of the potent bisphosphonates and its effects are rapidly reversed after cessation of therapy. Denosumab (Prolia)¹ has some efficacy, but also appears to be inferior to zoledronate.

There are several philosophical approaches to Paget's disease management, none of which is strictly evidence based. There is general agreement that patients with symptoms attributable to Paget's disease should receive treatment. This is clear-cut in patients who have bone pain at the site of a pagetic lesion, but it is a common observation that antipagetic drugs can produce variable degrees of improvement in pain from joints adjacent to pagetic bone. Patients with neurologic complications from spinal cord or other nerve entrapments also improve with antipagetic therapy.

Treatment aimed at preventing complications of Paget's disease is variably endorsed, because there is no clinical trial evidence that treatment prevents the progression of deformity, the development of pagetic symptoms, or fracture. However, it is clear that treatment leads to a restoration of normal bone histology (Figure 2) and radiographic healing of lytic lesions and that, in the absence of such intervention, both bone lysis and deformity progress. It

¹Not FDA approved for this indication.

Figure 2 Section of a bone trabecula affected by Paget's disease, viewed under polarized light to show orientation of lamellae. In the center of the trabecula, the collagen fibers are chaotically laid down (woven bone), consistent with active Paget's disease. Over the outer surfaces, collagen is organized in parallel lamellae, indicating the restoration of normal bone microarchitecture after treatment with alendronate. (Reprinted with permission from: Reid IR, Nicholson GC, Weinstein RS, et al: Biochemical and radiologic improvement in Paget's disease of bone treated with alendronate: A randomized, placebo-controlled trial. *Am J Med* 1996;101:341-48.)

seems unreasonable to withhold safe therapies that are able to halt histologic and radiologic disease progression. Therefore, many experienced physicians endorse the provision of antipagetic therapy for individuals with lytic lesions in long bones; lesions at sites that are likely to lead to neurologic complications, arthritis, or deformity; or involvement of the skull that could compromise hearing. Expert opinion also supports the use of antipagetic therapy before elective surgery on pagetic bone, because this approach reduces the vascularity of pagetic bone and results in less perioperative blood loss. On the other hand, Paget's disease in asymptomatic patients whose future risk of complications is thought to be low (e.g., with involvement of the ilium) is commonly managed without specific pharmaceutical intervention, although the availability of a safe, single-dose treatment with zoledronate is increasing the inclination to treat.

When providing treatment targeted at these goals, it is important to consider how adequacy of therapy can be judged. In the case of patients with pain, maximal relief of pain is an important endpoint. Lytic lesions should be treated and monitored with sequential radiographs until healing is apparent. Activity at other sites can be assessed indirectly with biochemical markers of bone turnover, although these are much less sensitive in patients with monostotic disease. In this context, there can be considerable residual activity at a single affected site without the markers being abnormal. Bone scintigrams provide the most sensitive method of assessing local disease activity.

In the past, Paget's disease caused substantial morbidity in the elderly population. However, it is now possible to achieve adequate and sustained disease control with use of intravenous zoledronate. Prompt use of these agents, when indicated, can be expected to halt disease progression and to effectively prevent the development of significant complications from this condition.

POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

Method of

Mark A. Matza, MD, MBA; and John H. Stone, MD, MPH

CURRENT DIAGNOSIS

Polymyalgia Rheumatica

- Age is greater than 50 years.
- Symptoms include pain, aching, or stiffness in the bilateral shoulders, neck, hips, or thighs in the absence of weakness.
- Constitutional symptoms such as fever, fatigue, and weight loss can be present. Peripheral arthritis occasionally occurs.
- Giant cell arteritis (GCA) symptoms are present in approximately 20% of cases.
- Acute-phase reactants (erythrocyte sedimentation rate and C-reactive protein concentration) are typically elevated, but a

wide range of values is observed, from normal values to dramatic elevations.

- Ultrasound can be used to assess for synovitis, tenosynovitis, or bursitis in the shoulder girdle.

Giant Cell Arteritis

- Age is greater than 50 years.
- Acute-phase reactants (erythrocyte sedimentation rate and C-reactive protein concentration) are typically elevated, but a wide range of values is observed, from normal values to dramatic elevations.
- Symptoms include new-onset headaches (often temporal), scalp tenderness, jaw or tongue claudication, and vision changes such as diplopia, amaurosis fugax, or blindness.
- Constitutional symptoms such as fever, fatigue, and weight loss are often present.
- Approximately 50% of patients with GCA also have polymyalgia rheumatic either concurrently or before diagnosis.
- Temporal arteries may be bulging, irregular, or tender on examination, but they may also be normal. Bruits can often be auscultated in the presence of large-vessel disease.
- Imaging with computed tomography, magnetic resonance, or positron emission tomography–computed tomography angiography can be used to evaluate for aortic arch involvement.
- Ultrasound scanning of the temporal arteries can be used to assess for the characteristic “halo sign.”
- Temporal artery biopsy is the diagnostic test of choice for patients presenting with cranial symptoms, but false-negative results may occur.

CURRENT THERAPY

Polymyalgia Rheumatica

- Prednisone at a dose of 15 to 20 mg/day (or equivalent) is used initially, with tapering to begin after one month of treatment. The starting dose should be continued for 1 full month to suppress the disease effectively and then tapered to 10 mg by the end of month 2 of treatment. Prednisone can then be tapered off at the rate of 1 mg/month for a total prednisone duration of approximately 1 year.
- Should symptoms recur with tapering, the last effective dose of prednisone can be resumed.
- Tocilizumab (Actemra)¹ can be considered should symptoms be refractory to glucocorticoid taper.

Giant Cell Arteritis

- Treatment should not be delayed while awaiting temporal artery biopsy.
- Prednisone¹ at a dose of 1 mg/kg or approximately 60 mg (or equivalent) should be started if the diagnosis is suspected.
- Pulse dose methylprednisolone¹ (1 gm daily for 3 days) should be initiated if vision changes occur.
- Tocilizumab (Actemra) should be started as soon as possible in the absence of contraindications such as diverticulitis. Most patients with GCA should be treated with the combination of tocilizumab and prednisone from the start of therapy; that is, prednisone treatment should begin immediately, and tocilizumab treatment initiated as soon as approval is obtained.
- All patients with GCA should be treated with aspirin¹ (81 mg/day) in addition to tocilizumab and prednisone.
- Glucocorticoids can be tapered to discontinuation over a period of 4 to 6 months if tocilizumab is used concomitantly with prednisone. Patients treated with glucocorticoid monotherapy require longer prednisone treatment courses. Prophylaxis for glucocorticoid-induced osteoporosis with bisphosphonates, calcium, and vitamin D should be considered.

¹Not FDA approved for this indication.

seems unreasonable to withhold safe therapies that are able to halt histologic and radiologic disease progression. Therefore, many experienced physicians endorse the provision of antipagetic therapy for individuals with lytic lesions in long bones; lesions at sites that are likely to lead to neurologic complications, arthritis, or deformity; or involvement of the skull that could compromise hearing. Expert opinion also supports the use of antipagetic therapy before elective surgery on pagetic bone, because this approach reduces the vascularity of pagetic bone and results in less perioperative blood loss. On the other hand, Paget's disease in asymptomatic patients whose future risk of complications is thought to be low (e.g., with involvement of the ilium) is commonly managed without specific pharmaceutical intervention, although the availability of a safe, single-dose treatment with zoledronate is increasing the inclination to treat.

When providing treatment targeted at these goals, it is important to consider how adequacy of therapy can be judged. In the case of patients with pain, maximal relief of pain is an important endpoint. Lytic lesions should be treated and monitored with sequential radiographs until healing is apparent. Activity at other sites can be assessed indirectly with biochemical markers of bone turnover, although these are much less sensitive in patients with monostotic disease. In this context, there can be considerable residual activity at a single affected site without the markers being abnormal. Bone scintigrams provide the most sensitive method of assessing local disease activity.

In the past, Paget's disease caused substantial morbidity in the elderly population. However, it is now possible to achieve adequate and sustained disease control with use of intravenous zoledronate. Prompt use of these agents, when indicated, can be expected to halt disease progression and to effectively prevent the development of significant complications from this condition.

¹Not FDA approved for this indication.

Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are related and often overlapping systemic inflammatory disorders that typically affect patients older than 50 years of age. Women are more commonly affected than men, and whites more so than blacks and Hispanics. Both conditions are characterized by elevated acute phase reactants. Symptoms range from proximal muscle aching to blindness. Most patients respond swiftly to glucocorticoid treatment, but many patients fail to maintain disease control during or after prednisone tapers. Interleukin-6 receptor blockade with tocilizumab (Actemra) has been confirmed to be effective for the treatment of GCA in a randomized clinical trial and is approved by regulatory agencies all over the world. Tocilizumab should be used in combination with glucocorticoids in most patients with GCA and in patients with PMR who are unable to maintain steroid-induced remissions.

Polymyalgia Rheumatica

Clinical Presentation

PMR is characterized by symmetric proximal joint pain that typically occurs in the context of elevated inflammatory markers and nearly always targets patients older than 50 years of age. Symptom onset can be swift, but patients sometimes delay seeking medical attention for days to weeks. Morning stiffness is generally prolonged greater than 45 minutes. Patients have a negative rheumatoid factor and negative assays for anti-CCP antibodies. Other joints can be affected, manifesting as hand, wrist, or knee arthritis. Constitutional symptoms can be seen with weight loss, fatigue, and low-grade fever. The frequency of PMR increases with age and the disorder is encountered most often in whites. Physical examination demonstrates tenderness and limited active range of motion of the shoulder and hip girdle. Patients typically have substantially better range of motion with passive limb movements.

Diagnosis

Diagnosis is made on the basis of the clinical presentation and physical examination. The response to prednisone is also often a telling indication of PMR: most patients experience dramatic clinical improvements within 24 to 48 hours. Most patients have elevated acute phase reactants, but these markers are not dramatically increased in all patients and are normal in some. Ultrasound can be used to detect synovitis, tenosynovitis, or bursitis. GCA occurs in approximately 20% of patients with PMR. Therefore these patients should be queried closely to detect any symptoms that suggest GCA, namely headaches, scalp tenderness, jaw claudication, and visual disturbances.

A minority of patients with presentations of PMR eventually declare their true underlying inflammatory arthritis to be rheumatoid arthritis (RA). Such patients can convert from seronegative to seropositive (i.e., positive rheumatoid factor or anti-CCP antibodies) at some point in follow-up. The presence of distal joint symptoms might help predict the evolution to RA, but the development of RA cannot be predicted if seronegative at baseline.

Treatment

Patients with PMR are treated with antiinflammatory medications. Prednisone at a dose of 15 to 20 mg (or prednisone equivalent) is often used initially. Symptoms should dramatically improve within 1 to 2 days, but some patients require a few days longer to achieve clear responses. Although patients with PMR respond essentially universally to appropriate doses of glucocorticoids, treatment failures over the course of glucocorticoid tapers or after discontinuation are common. A dose of 10 mg should be achieved relatively quickly by 2 months unless refractory. After 10 mg, the prednisone taper should be slowed, and the dose decreased by approximately 1 mg per month based on symptoms and inflammatory markers. Should symptoms recur, prednisone can be increased to the last effective dose and the taper again slowed by approximately 1 mg every 2 months.

Most patients can taper off prednisone completely; however, in some a low dose of prednisone may be required to prevent the recurrence of symptoms. For patients with PMR who require

excessive prednisone to maintain disease control, interleukin-6 receptor blockade with tocilizumab¹ should be considered.

Giant Cell Arteritis

Clinical Presentation

GCA is a large vessel vasculitis with a predilection for the proximal aorta and its primary branches, particularly the vessels of the head and neck. Essentially every patient is older than 50 years of age at diagnosis, and the disease incidence increases with each decade. Symptoms, often referred to as “cranial symptoms” (to be distinguished from symptoms of large-vessel vasculitis), can include new-onset headaches, scalp tenderness, jaw or tongue claudication, diplopia, and vision changes.

Visual symptoms, the most worrisome effects of GCA because they may herald irreversible blindness in one or even both eyes, often consist of amaurosis fugax or the sudden onset of monocular blindness through the mechanism of anterior ischemic optic neuropathy or central retinal artery occlusion. Permanent vision loss occurs in at least one eye in approximately 15% of untreated patients. Unfortunately, vision loss frequently occurs as the symptom that finally brings the patient to medical attention, at a time when preventive treatment is too late.

Approximately 40% of patients with GCA also have PMR, characterized by pain and stiffness in the shoulder and hip girdles and occasionally by more distal joint involvement (e.g., the wrists). Conversely, 20% of those with PMR eventually develop GCA. Patients can have fevers and constitutional symptoms such as weight loss and fatigue. GCA is a common cause of fever of unknown origin in the elderly. Extracranial vasculitis can occur in the proximal aorta and its branches and can ultimately lead to aortic aneurysm formation. Among the primary branches of the aorta, the subclavian arteries are involved most commonly. Bruits auscultated above or below the clavicle are a key physical examination finding, as is a reduction in the upper extremity pulses. Intracranial vessels are seldom affected in GCA, but an important exception is occasional posterior vertebrobasilar circulation involvement, which can lead to strokes.

Diagnosis

GCA is diagnosed based on a combination of the clinical presentation, inflammatory markers (i.e., erythrocyte sedimentation rate [ESR] and CRP), imaging, and biopsy. The temporal arteries may be bulging, irregular, or tender on examination; however, they may also be normal on examination, even if temporal artery biopsy subsequently confirms the presence of GCA. Bruits can be auscultated should the proximal aorta be involved. The ESR is greater than 50 mm/hr in most cases, but population-based studies confirm that the ESR is <50 mm/hr in approximately 10% of patients. Aortic arch involvement can be detected with imaging modalities such as computed tomography, magnetic resonance, or positron emission tomography-computed tomography angiography. Imaging abnormalities on cross-sectional imaging typically include long segments of smooth arterial narrowing and concentric thickening of the arterial wall. Temporal artery duplex ultrasound scanning may reveal a characteristic “halo sign,” caused by edema within and around the blood vessel wall. Temporal artery biopsy is the test of choice for diagnosis; however, false-negative results can occur for a variety of reasons in GCA, including the fact that the arterial involvement is often segmental (i.e., characterized by “skip lesions”).

Treatment

Treatment with high-dose glucocorticoids should not be delayed to obtain a temporal artery biopsy. A dose of prednisone¹ 1 mg/kg or approximately 60 mg (or prednisone equivalent) should be initiated promptly when a diagnosis of GCA is considered. Lower doses (e.g., 40 mg/day) can be used for individuals who are frail and elderly. If visual involvement has occurred, pulse dose

¹Not FDA approved for this indication.

methylprednisolone¹ 1000 mg daily for 3 days can be initiated followed by high-dose oral glucocorticoids. The optimal duration of a prednisone taper in GCA is not certain. In one randomized clinical trial, the percentage of patients achieving sustained disease remission at 1 year was essentially the same regardless of whether patients received a 6-month or 12-month prednisone taper. Sustained remissions were achieved in only 14% and 18% of patients, respectively. Thus, although high-dose glucocorticoids are effective at controlling GCA and inducing remission in most patients, the great majority of patients experience disease flares whenever prednisone is tapered to a lower dose (e.g., less than 15 mg/day) or discontinued.

The interleukin-6 receptor blocker tocilizumab (Actemra) is now approved worldwide for the treatment of GCA in combination with glucocorticoids. The addition of tocilizumab leads to substantial improvement in the rate of glucocorticoid-free remissions at 1 year and a reduction in the cumulative prednisone dose by approximately 50%. Tocilizumab can be administered either intravenously (8 mg/kg each month) or subcutaneously (165 mg each week). The high rate of treatment failure with regimens involving prednisone alone suggests that all patients without contraindications to tocilizumab should be treated with the combination of tocilizumab and prednisone initially, followed by an aggressive prednisone taper designed to discontinue prednisone within 4 to 6 months. The optimal duration of tocilizumab therapy is not known at this time, but data from ongoing investigations will inform this question soon. Patients who are not able to discontinue prednisone entirely can usually be controlled well with the combination of tocilizumab and low-dose prednisone.

Aspirin¹ (81 mg/day), which has been shown in retrospective studies and a meta-analysis to reduce the incidence of vision loss, should be used in all patients without contraindications. Prophylaxis for glucocorticoid-induced osteoporosis with bisphosphonates, calcium, and vitamin D should be considered, particularly since GCA tends to afflict elderly individuals, many of whom have significant comorbidities at baseline, including osteoporosis. Prophylaxis for *Pneumocystis jiroveci* pneumonia may also be considered in appropriate clinical circumstances, particularly when prolonged or recurrent courses of high-dose glucocorticoids are required.

¹Not FDA approved for this indication.

RHEUMATOID ARTHRITIS

Method of

Arthur Kavanaugh, MD; and Sriharsha Cherukumilli Grevich, MD

CURRENT DIAGNOSIS

Criteria for classifying patients as having RA:

- Presence of clinical synovitis (swelling) in at least one joint not explained by another disease (e.g., psoriatic arthritis, systemic lupus erythematosus, or other rheumatic diseases manifest with inflammatory arthritis)

- Having a cumulative score of at least 6 out of 10 from the following four categories (using highest score from each category):

	POINTS
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	3
> 10 joints with inclusion of at least 1 small joint (may also include joints other than those listed above, except for the excluded joints)	5

- Joint involvement (includes tender or swollen joints indicative of active synovitis; large joints include shoulders, elbows, hips, knees, and ankles. Small joints include metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists. Distal interphalangeal joints, first carpometacarpal joints, and first metatarsophalangeal joints are excluded.)
- Serologic categories (RF = rheumatoid factor, ACPA = anticitrullinated protein antibody. Negative value is \leq ULN (upper limit of normal for respective lab test); low-positive is $>$ ULN but $\leq 3 \times$ ULN; high-positive is $> 3 \times$ ULN)

	POINTS
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3

III. Acute-phase response

	POINTS
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1

IV. Duration of symptoms (based on patient self-reported symptoms of synovitis)

	POINTS
< 6 weeks	0
≥ 6 weeks	1

Other patients classified as having RA:

- Patients with radiographic changes that are very characteristic of rheumatoid arthritis (e.g., periarticular bony erosions) who have fulfilled the above criteria in the past
- Patients with long-standing symptoms (either active or inactive and with or without treatment) who have fulfilled the above criteria in the past based on retrospective data

CURRENT THERAPY

Nonpharmacologic Treatment

- Patient and family education and longitudinal supportive care should be provided by physicians and their staff.
- Physical therapy and occupational therapy assists patients with compromised activities of daily living.
- Dynamic and aerobic conditioning exercises improve mobility, strength, and psychological well-being.

Pharmacologic Treatment

NSAIDs and Selective Cyclooxygenase 2 (COX-2)

Inhibitors

- Joint function is improved by reducing joint pain and swelling.

Glucocorticoids

- Glucocorticoids can relieve signs and symptoms of disease and may slow its progression.
- Low-dose glucocorticoids, such as < 10 mg of prednisone daily or the equivalent, should be administered.
- Local injections of depot formulations of corticosteroids are given.

methylprednisolone¹ 1000 mg daily for 3 days can be initiated followed by high-dose oral glucocorticoids. The optimal duration of a prednisone taper in GCA is not certain. In one randomized clinical trial, the percentage of patients achieving sustained disease remission at 1 year was essentially the same regardless of whether patients received a 6-month or 12-month prednisone taper. Sustained remissions were achieved in only 14% and 18% of patients, respectively. Thus, although high-dose glucocorticoids are effective at controlling GCA and inducing remission in most patients, the great majority of patients experience disease flares whenever prednisone is tapered to a lower dose (e.g., less than 15 mg/day) or discontinued.

The interleukin-6 receptor blocker tocilizumab (Actemra) is now approved worldwide for the treatment of GCA in combination with glucocorticoids. The addition of tocilizumab leads to substantial improvement in the rate of glucocorticoid-free remissions at 1 year and a reduction in the cumulative prednisone dose by approximately 50%. Tocilizumab can be administered either intravenously (8 mg/kg each month) or subcutaneously (165 mg each week). The high rate of treatment failure with regimens involving prednisone alone suggests that all patients without contraindications to tocilizumab should be treated with the combination of tocilizumab and prednisone initially, followed by an aggressive prednisone taper designed to discontinue prednisone within 4 to 6 months. The optimal duration of tocilizumab therapy is not known at this time, but data from ongoing investigations will inform this question soon. Patients who are not able to discontinue prednisone entirely can usually be controlled well with the combination of tocilizumab and low-dose prednisone.

Aspirin¹ (81 mg/day), which has been shown in retrospective studies and a meta-analysis to reduce the incidence of vision loss, should be used in all patients without contraindications. Prophylaxis for glucocorticoid-induced osteoporosis with bisphosphonates, calcium, and vitamin D should be considered, particularly since GCA tends to afflict elderly individuals, many of whom have significant comorbidities at baseline, including osteoporosis. Prophylaxis for *Pneumocystis jiroveci* pneumonia may also be considered in appropriate clinical circumstances, particularly when prolonged or recurrent courses of high-dose glucocorticoids are required.

¹Not FDA approved for this indication.

CURRENT THERAPY

Nonpharmacologic Treatment

- Patient and family education and longitudinal supportive care should be provided by physicians and their staff.
- Physical therapy and occupational therapy assists patients with compromised activities of daily living.
- Dynamic and aerobic conditioning exercises improve mobility, strength, and psychological well-being.

Pharmacologic Treatment

NSAIDs and Selective Cyclooxygenase 2 (COX-2)

Inhibitors

- Joint function is improved by reducing joint pain and swelling.

Glucocorticoids

- Glucocorticoids can relieve signs and symptoms of disease and may slow its progression.
- Low-dose glucocorticoids, such as < 10 mg of prednisone daily or the equivalent, should be administered.
- Local injections of depot formulations of corticosteroids are given.

- Bridge therapies should be given for flare-ups or when patients are starting treatment.

Disease-Modifying Antirheumatic Drugs (DMARDs)

- DMARDs can preserve joint integrity and function by reducing joint damage.
- Commonly used DMARDs:
 - Methotrexate (Rheumatrex) oral, 7.5–25 mg/week; SC injection (Otrexup) 7.5–25 mg/week
 - Hydroxychloroquine (Plaquenil) oral, 200 mg twice daily
 - Sulfasalazine (Azulfidine-EN Tabs) oral, 1000 mg twice or three times daily³
 - Leflunomide (Arava) oral, loading dose 100 mg/day for 3 days then 20 mg/day in a single dose, if tolerated; otherwise, 10 mg/day
 - Cyclosporine A (Neoral, Gengraf) oral, 2.5–4 mg/kg/day in divided doses (twice daily)
 - Combinations of DMARDs that have been effective in RA include methotrexate plus cyclosporine, methotrexate plus efllunomide, and methotrexate plus sulfasalazine plus hydroxychloroquine.
 - Tofacitinib (Xeljanz): Oral 5 mg twice daily (monotherapy or in combination with nonbiologic disease-modifying antirheumatic drugs).

Biologic Response Modifiers (Biologics)

- Biologics are commonly used in combination with methotrexate, or less commonly with other DMARDs.
- They slow or prevent disease progression (particularly TNF inhibitors) and can induce remission.
- TNF- α inhibitors include the following:
 - Infliximab (Remicade) IV infusion, doses between 3–10 mg/kg (mean dose, \approx 5 mg/kg) with additional similar doses at 2 and 6 weeks after the first infusion and then every 8 weeks thereafter
 - Etanercept (Enbrel) SC injection, 50 mg/week as a single dose or 25 mg biweekly³
 - Adalimumab (Humira) SC injection, 40 mg every other week (also approved for use weekly)
 - Certolizumab pegol (Cimzia) SC injection, 400 mg initial dose with additional similar doses at 2 and 4 weeks after initial dose and then every 4 weeks thereafter (or 200 mg every other week)
 - Golimumab (Simponi) SC injection 50 mg once a month. Also available as IV infusion (Simponi Aria), 2 mg/kg with additional similar doses at 4 weeks after the first infusion and then every 8 weeks thereafter.
 - Anti-CD20 antibody: Rituximab (Rituxan) IV infusion, two 1000-mg infusions separated by 2 weeks; further treatments are typically given after 6 months when disease activity recurs
 - CTLA-4-immunoglobulin: abatacept (Orencia) IV infusion, dosage between 500 and 1000 mg based on weight (dose approximates 10 mg/kg). Initial dose is followed by doses 2 and 4 weeks later, with further doses every 4 weeks thereafter. Also available SC injection 125 mg/week given within a day following a single IV loading dose.
 - Interleukin-1 receptor antagonist: anakinra (Kineret) SC injection 100 mg/day
 - Interleukin-6 receptor antibody: tocilizumab (Actemra) IV infusion, dosage between 4 and 8 mg/kg in adults (maximum dose 800 mg) every 4 weeks. Also available in SC injection: 162 mg every 2 weeks, with the option to move to weekly (patients \geq 100 kg can start at 162 mg weekly)

Surgical Treatment

- Surgery is used for patients with intolerable pain, loss of range of motion, or structural joint damage that leads to limitation of function.
- Procedures include joint fusion, synovectomy, total joint arthroplasty, and partial joint replacement or remodeling.

³Exceeds dosage recommended by the manufacturer.

Epidemiology

Rheumatoid arthritis (RA) is a progressive, systemic inflammatory disease that affects about 0.5% to 1% of the population worldwide. RA is associated with substantial morbidity and accelerated mortality and exerts a tremendous economic toll on affected patients, their families, and society. Women are three to four times more likely to be affected than men. The peak age of onset is between 40 and 60 years, but it is possible to get RA at any age. RA also affects the elderly and young children.

Pathophysiology

Even though there has been progress in deciphering the cellular and molecular mechanism of RA, the cause is still not fully defined. RA is characterized by synovial and vascular proliferation with the formation of pannus tissue, which results in damage to articular cartilage and adjacent subchondral bone. Activation of specific CD4⁺ T cells, potentially in response to unidentified antigens, in an immunogenetically susceptible individual is hypothesized to be an early event in this process. Activated T cells orchestrate a cell-mediated immune response, stimulating and interacting with monocytes or macrophages, synovial fibroblasts, osteoclasts, B cells, and many other cell types. The cascade of inflammatory mediators that is released contributes to the sustenance of the ongoing immune activation and directly causes signs, symptoms, and sequelae of the disease, such as destruction of joints. Joint destruction, which may be considered the sequela of untreated inflammation over time, correlates directly with functional disability. Impaired function correlates with many key outcomes, such as increased mortality and greater costs.

Diagnosis

RA diagnosis is mainly clinical based on physical findings, patient history and ongoing observation of symptoms, signs, and response to therapy. The 2010 American College of Rheumatology (ACR)/EULAR classification criteria for the diagnosis of RA is presented above in the current diagnosis section.

Treatment

The main goals of treatment for RA are to alleviate pain, prevent or limit joint damage, optimize quality of life, avoid complications of therapy, and improve or preserve function. Novel therapies with specific targets are being designed based on the improved understanding of the pathophysiology of RA. Adoption of an aggressive approach early in the course of the disease is thought to be the best way to prevent irreversible joint damage and to spare patients years of pain and discomfort. Remission, once a purely hypothetical consideration, is now considered to be an appropriate and attainable goal, largely because of the introduction of new therapies, particularly biologic agents, and new treatment paradigms, particularly the frequent assessment of disease activity with resultant changes in treatment to achieve low disease activity.

Treatment response in clinical trials is typically measured using the ACR criteria for measuring improvement of arthritis. The ACR20 refers to 20% improvement in tender and swollen joint counts and 20% improvement in three of the five additional measures: patient and physician global assessments of arthritis, pain, disability, and an acute-phase reactant, such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP). Variations that define higher levels of response—the ACR50 and ACR70, which require improvements in individual measures exceeding 50% and 70%, respectively—are more stringent outcomes. The Health Assessment Questionnaire (HAQ) and Short Form 36 (SF-36) are used to calculate functional disability and health-related quality of life, respectively. Joint damage in patients with RA is assessed by quantifying radiographic changes characteristic of RA, including joint space narrowing and periarticular bony erosions.

Treatment of RA begins after the diagnosis is established, baseline activity is assessed, and prognosis is estimated. Therapy is initiated with patient education about the disease and the treatments

available. Symptoms can be controlled to some extent with nonsteroidal antiinflammatory drugs (NSAIDs) and low-dose oral glucocorticoids or glucocorticoid joint injections. Ideally, disease-modifying antirheumatic drugs (DMARDs) should be started soon after diagnosis is established (e.g., within 3 months). Further care is determined by assessing disease activity and response to treatment. The Current Therapy box lists commonly used treatments for RA and includes trade names and usual maintenance doses for these drugs.

Analgesics and Nonsteroidal Antiinflammatory Drugs

Analgesics (e.g., acetaminophen, tramadol [Ultram], opioids) are used to relieve pain, but they do not reduce inflammation or prevent joint destruction. NSAIDs (e.g., aspirin, ibuprofen [Motrin], naproxen [Naprosyn], ketoprofen [Orudis], piroxicam [Feldene], diclofenac [Voltaren], celecoxib [Celebrex]) reduce pain and inflammation (at higher doses) but do not slow joint damage. These drugs are used as adjuncts but are not usually the sole treatment for RA because they do not prevent disease progression.

Although many over-the-counter analgesics and NSAIDs are available and are perceived by patients to be benign, they are not risk-free. Narcotic analgesics should be used with caution because of their potential for habituation and toxicity with chronic use. NSAIDs work by inhibiting cyclooxygenase enzyme isoforms COX-1 and COX-2. COX-1 is constitutively expressed by many cells, whereas COX-2 production is usually increased at sites of inflammation. Side effects with chronic use of NSAIDs include gastrointestinal irritation, rash, fluid retention, and the potential for renal toxicity. Acetaminophen (Tylenol), a non-NSAID COX inhibitor, does not cause gastrointestinal irritation, but it may cause severe hepatotoxicity, and it potentially interacts with warfarin (Coumadin). The frequency of NSAID-induced ulcers can be reduced with concomitant use of proton pump inhibitors or misoprostol (Cytotec). COX-2 inhibitors were developed because their more specific activity was expected to control signs and symptoms of arthritis with less risk of gastrointestinal complications. However, two of the three COX-2 inhibitors approved in the United States were withdrawn because of concerns about thrombotic and atherosclerotic toxicities. The remaining available COX-2 inhibitor, celecoxib, seems to have a safety profile comparable to other NSAIDs in that regard.

Glucocorticoids

Oral glucocorticoids at lower doses (e.g., < 10 mg prednisone equivalent per day) are often used to control pain, inflammation, and stiffness, and they can potentially slow the progression of joint damage. However, because of the possibility of significant side effects, especially with long-term use at a high dose, glucocorticoids are most commonly used for short-term treatment of very active or aggressive RA, usually in combination with NSAIDs and DMARDs. They are often tapered when the disease is under control.

Side effects of glucocorticoids include changes to appetite and weight, glucose intolerance or hyperglycemia, infection, osteoporosis, mood and sleep disturbances, hypertension, suppression of the hypothalamic-pituitary axis, and interference with wound healing, among others. Administering calcium and vitamin D supplementation, bisphosphonates, calcitonin (Miacalcin),¹ parathyroid hormone (teriparatide [Forteo]),² and estrogen² or testosterone² replacement can reduce the risk of bone loss in patients taking corticosteroids.

Intraarticular glucocorticoid injections can provide dramatic but usually temporary clinical improvement in patients who have a disease flare-up in a single or a few joints. Most clinicians think that no more than one injection in any 3-month period should be made in a given joint. The need for more repeated injections suggests that the overall treatment plan requires reevaluation.

Disease-Modifying Antirheumatic Drugs

DMARDs are the mainstay of treatment for RA because they can modify various aspects of the immune and inflammatory responses, potentially controlling signs and symptoms of disease and slowing its progression. Extensive clinical studies of DMARDs have demonstrated reductions in joint damage, preservation of joint function, and higher rates of productivity. DMARDs are considered first-line therapy for all patients with newly diagnosed RA. The standard of care is to initiate DMARD therapy early, such as within the first 3 months of the disease for patients with established RA who, despite adequate treatment with NSAIDs, have ongoing joint pain, significant morning stiffness or fatigue, active synovitis, evidence of active inflammation (e.g., persistent elevation of the ESR or CRP level, actively inflamed joints), or radiographic joint damage. Because DMARDs may take 2 to 6 months to reach full effect, NSAIDs and sometimes glucocorticoids can be used in the interim to reduce pain and swelling. The duration of DMARD use may be limited by loss of efficacy or development of toxicity.

Methotrexate (Rheumatrex) is the most commonly used DMARD because of its oral, once-weekly administration, well-defined safety profile, demonstrated efficacy, and low cost. Sulfasalazine (Azulfidine EN-tabs) or hydroxychloroquine (Plaquenil) tend to be used in persons whose disease is considered milder or more slowly progressive. They are also used in combination with methotrexate for aggressive disease. Leflunomide (Arava) was shown in several phase III trials to offer comparable efficacy to methotrexate and sulfasalazine against active RA. Older drugs in this class (e.g., parenteral or oral gold [gold sodium thiomalate² or auranofin], azathioprine [Imuran], D-penicillamine [Cuprimine]) were shown to be effective in older clinical trials, but they are much less commonly used now largely because of lower efficacy and poor tolerability.

In RA, methotrexate's mechanism of action may be related to its inhibition of inflammation, presumably by increasing the local release of adenosine. Clinical response may take 6 to 8 weeks to be seen. The mean dose used among RA patients worldwide is approximately 17.5 mg/week, although many clinicians initiate therapy at lower doses to help ensure tolerability. Most clinicians consider 25 mg/week to be a maximum dose. Higher doses are not clearly associated with better disease control but may be associated with more toxicity. Parenteral administration may be used at doses higher than 15 mg/week because of more predictable absorption. Many RA patients have taken methotrexate successfully for years, attesting to its efficacy and safety.

Leflunomide (Arava) is a prodrug that is actively metabolized after oral administration. This active metabolite inhibits dihydroorotate dehydrogenase, which interferes with pyrimidine synthesis and ultimately leads to inhibition of activated T cells and other cells. To minimize toxicity, the maintenance dose of 20 mg/day can be reduced to 10 mg/day.

Tofacitinib (Xeljanz) is an oral Janus kinase (JAK) inhibitor for treatment of moderate to severe RA. It can be used as a monotherapy or in combination with methotrexate or another nonbiologic DMARD. Tofacitinib has been shown to be a more effective monotherapy agent than methotrexate in reducing signs and symptoms of rheumatoid arthritis and the progression of structural joint damage. In patients with inadequate response to methotrexate or TNF inhibitor therapy, tofacitinib has been shown to be effective as a single agent or in combination with methotrexate.

Although DMARDs represent a major advance in the management of RA, they are not without risks or limitations. Methotrexate is associated with rare but serious side effects, including bone marrow suppression, hypersensitivity pneumonitis, and hepatotoxicity. It may also slightly increase the risk of infection. It must be used with caution in patients with preexisting liver disease, renal impairment, significant pulmonary disease, or alcohol abuse. Less serious but common side effects of methotrexate include stomatitis, gastrointestinal effects, headache, fatigue, and liver transaminase elevations. Folic acid supplementation can prevent many of the minor side effects. Leflunomide can lead to elevated liver enzyme levels, weight loss, hypertension, diarrhea, reversible alopecia,

¹Not FDA approved for this indication.

²Not available in the United States.

²Not available in the United States.

and myelosuppression. Leflunomide inhibits cytochrome P-450 (CYP) 2C9, so there is a theoretical potential for interactions with other drugs that are also CYP2C9 substrates. Methotrexate and leflunomide necessitate regular monitoring of liver enzymes and complete blood cell counts at regular intervals. Treatment should be stopped for any persistent or severe abnormalities. Common side effects of tofacitinib include a risk of infections, lymphopenia, neutropenia, hyperlipidemia, liver function test abnormalities, and increased serum creatinine levels. To prevent serious adverse effects, especially infections, tofacitinib should not be used in combination with a biologic agent or azathioprine or cyclosporine.

Other side effects seen with various DMARDs include gastrointestinal intolerance and rash. Although antimalarial drugs (e.g., hydroxychloroquine) have been reported to cause ocular toxicity, with current dosages and preparations, this reaction is rare. Sulfasalazine may cause cutaneous adverse events (e.g., urticaria, maculopapular rash, photosensitivity) and hematologic side effects. Cyclosporine's use has been limited by its toxicity; side effects include headache, tremors, hypertension, and renal insufficiency. Patients taking cyclosporine (Neoral) require regular monitoring of blood pressure and serum creatinine levels. Some DMARDs (e.g., cyclophosphamide [Cytoxan],¹ chlorambucil [Leukeran], azathioprine [Imuran]) may promote the development of secondary malignancies. Some DMARDs are teratogenic and abortifacient and therefore should not be used during pregnancy or breast-feeding and must be discontinued for an appropriate amount of time, typically 3 months or more, before any attempts to conceive.

Biologic Response Modifiers

The introduction of biologic agents was driven largely by three factors: recognition of the unmet clinical need for more effective treatments based on an appreciation of the significantly poor outcomes of uncontrolled RA; improved understanding of the immunopathogenesis of RA; and advances in biopharmaceutical science allowing the development of specific inhibitors of relevant targets within the dysregulated immune system.

Traditional therapies such as NSAIDs, corticosteroids, and DMARDs may help ameliorate the symptoms of RA, but they rarely induce sustained remission, and they can have toxicities that prevent their long-term use. Newer therapies, many of which are large protein molecules such as monoclonal antibodies or soluble receptor constructs, are referred to as biologic agents. Biologic agents, particularly inhibitors of tumor necrosis factor (TNF), have changed the treatment paradigm for RA. They can inhibit various components of the immune system and inflammatory response that are central to the pathogenesis of RA. The goal is to adopt an early, proactive approach to treatment to prevent the damage from chronic synovial inflammation. Studies have shown that biologic agents can slow disease progression, control signs and symptoms of disease, improve function, and improve quality of life. They are typically used in combination with DMARDs, most commonly methotrexate, to potentiate treatment responses. This newer class of antirheumatic drugs can be further subclassified according to their specific target or mechanism.

TNF- α Inhibitors

Use of TNF- α inhibitors in combination with methotrexate is considered by many to be the gold standard for treatment of RA. TNF- α is a soluble 17-kDa protein homotrimer that binds to two receptors: type 1 TNF receptor and type 2 TNF receptor. A versatile, multipotent cytokine, it induces production of other inflammatory cytokines such as interleukin-1 (IL-1), IL-6, and granulocyte-monocyte colony-stimulating factor (GM-CSF) and chemokines such as IL-8. TNF- α causes tissue destruction by promoting release of matrix metalloproteinases, upregulates cell trafficking through adhesion molecules and chemokines, increases the breakdown of

proteoglycans in the cartilage, and potentiates osteoclast differentiation and activation. There is abundant evidence that TNF inhibition dramatically improves patient outcomes for RA and other autoimmune systemic inflammatory conditions, including psoriasis, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease.

Most RA patients respond to TNF- α inhibitors with a reduction in signs and symptoms, improved quality of life, and preservation of functional status; some even achieve clinical remission of disease. Radiographic evidence shows that TNF- α inhibitors inhibit radiographic disease progression to an extent not seen with any previous agents. From an immunologic standpoint, TNF- α inhibitors do not represent a cure, and maintenance of clinical efficacy almost always requires continued therapy, certainly for patients with long-standing RA. Five of the available biologic agents are inhibitors of TNF- α : infliximab (Remicade), etanercept (Enbrel), adalimumab (Humira), golimumab (Simponi), and certolizumab pegol (Cimzia).

Infliximab, a chimeric human/mouse monoclonal anti-TNF- α monoclonal antibody, was shown to be effective initially in open trials, followed soon by double-blind, placebo-controlled, randomized clinical trials. Inhibition in the progression of joint damage and improvement in health-related quality of life and functional status were observed in patients treated with infliximab. It is used mostly in combination with methotrexate, which decreases immunogenicity and produces synergy in clinical outcomes.

Etanercept is a recombinant form of the human receptor that is fused to the Fc fragment of the human immunoglobulin G1. Clinical trials have shown etanercept to be effective in improving the signs and symptoms of RA when used as monotherapy and in combination with methotrexate; it also inhibits disease progression and optimizes functional status and quality of life.

Adalimumab is a human anti-TNF- α monoclonal antibody. The efficacy of adalimumab on the signs and symptoms of RA has been proved in various studies, and it has demonstrated benefit in terms of improving quality of life and functional status and in attenuating the progression of joint damage.

Certolizumab pegol is a PEGylated Fab' fragment of a humanized monoclonal anti-TNF antibody. Golimumab is a human anti-TNF- α monoclonal antibody. Both of these agents have been shown to improve signs and symptoms of disease and physical function and to prevent disease progression in patients with active RA.

TNF antagonists exhibit a rapid onset of action, provide significant clinical response, improve quality of life, and most importantly substantially inhibit radiographic progression of disease. Most patients on TNF antagonists are still treated with methotrexate because studies have shown that TNF antagonists work better in this combination. There are some safety concerns because reports of opportunistic infections, tuberculosis, lymphoma, administration reactions, immune or autoimmune responses, and demyelinating syndromes have emerged with TNF antagonist treatment. Some patients do fail to respond or eventually lose the ability to respond. Other biologic agents can be effective for patients who fail anti-TNF therapy.

B-Cell Directed Therapy

Mounting evidence suggests that B cells play an active role in RA. B cells can accumulate in the synovium, form aggregates, produce autoantibodies such as rheumatoid factor (RF), and function as antigen-presenting cells that aid in the activation of CD4⁺ T cells. These findings provide the rationale for targeting B cells in RA patients. Rituximab (Rituxan) is a monoclonal antibody directed against the CD20 antigen found on the surface of B cells. When bound to CD20, rituximab depletes B cells through various mechanisms, including complement-mediated lysis, antibody-dependent cytotoxicity, and apoptosis.

Rituximab treatment induced depletion of peripheral-blood B cells for 6 months or longer, but the levels of immunoglobulins in the serum (IgG, IgA, IgM) did not change substantially. RF levels decreased substantially. Despite the prolonged depletion of

¹Not FDA approved for this indication.

peripheral-blood B cells, the overall incidence of infection was similar in the control group and the rituximab groups. However, an increased rate of infusion-related reactions was identified for the rituximab group compared with the placebo group. In patients with active RA who failed one or more anti-TNF- α therapies, rituximab significantly reduced signs, symptoms, fatigue, and disability and improved health-related quality of life.

T-Cell Directed Therapy

T-cell activation plays a central role in the pathogenesis of RA. For example, the rheumatoid synovium contains a preponderance of CD4⁺ T cells. It is thought that these cells are stimulated by arthritogenic antigens to initiate synovial inflammation. Cytotoxic T lymphocyte-associated antigen 4 (CTLA4) is expressed on the surface of T cells within days after they have become activated. CTLA4 binds to and prevents CD80 and CD86 from binding to CD28, thereby effectively blocking the costimulatory signal required for activation of T cells. Blocking CD28 costimulation has been shown to induce T-cell anergy.

Abatacept (Orencia), an inhibitor of T-cell costimulation, is a fusion protein construct consisting of the extracellular component of CTLA4 fused to the Fc region of human IgG, which increases its half-life. The high affinity of CTLA4-Ig for CD28 prevents B7-mediated costimulation. Abatacept has improved signs and symptoms of disease, helped maintain physical function, and reduced progression of joint damage in patients with active disease despite concomitant methotrexate. Similarly, it improved signs and symptoms, physical function, and health-related quality of life in RA patients refractory to TNF- α inhibition.

Interleukin-1 Receptor Antagonist

Interleukin-1 (IL-1) appears to have a prominent role in synovial inflammation and displays many overlapping effects with TNF- α . RA patients have increased levels of IL-1 in the plasma and synovial fluid, and its concentration has been correlated with disease activity. Similar to TNF- α , IL-1 can activate a variety of inflammatory cells and mediators using some overlapping signal transduction pathways.

Anakinra (Kineret) is a subcutaneously administered IL-1 receptor antagonist. Anakinra has been shown in several studies to reduce the signs and symptoms of RA; however, the extent of improvement is less than that seen with TNF antagonists. Combination therapy with anti-IL-1 and anti-TNF is contraindicated because of an observed increase in the risk of adverse events in a study in which patients were treated with anakinra and etanercept. Anakinra usually is well tolerated, and the most common side effect is injection site reactions. The need for daily injectable administration and the modest efficacy compared with TNF inhibitors have limited the use of anakinra.

IL-6 Receptor Antibody

IL-6 is an inflammatory cytokine that may contribute to the immune-pathophysiology of several autoimmune systemic inflammatory disorders, including RA. To date, the greatest experience with IL-6 inhibition has been with tocilizumab (Actemra), a humanized monoclonal antibody with specificity toward the IL-6 receptor (IL-6R). Tocilizumab has been proven effective in various subsets of RA patients, including those previously exposed to TNF inhibitors, and it is approved in those countries worldwide for the treatment of RA. In addition, it has been approved for use in patients with systemic juvenile idiopathic arthritis (sJIA), a potentially devastating condition characterized by abundant systemic inflammation. It has been shown to reduce signs and symptoms and improve functional status and to inhibit radiographic

progression in patients with active RA. Potential adverse effects that may be associated with IL-6 inhibition include risk for infection, alteration in serum lipid profiles, decreased neutrophil counts, and elevated liver function tests.

Biologic agents have different mechanisms, methods of delivery, and side effects. A patient who does not respond to or cannot tolerate one may still have a good outcome with another. Although they are commonly used in combination with methotrexate, biologic agents usually are not given in combination with each other, because this approach may increase risk without much increase in benefit. Because biologic agents modulate part of the immune response, there is concern about potential side effects related to impaired immune function, such as increased risk of minor and serious infections and secondary malignancies.

Biologic agents require parenteral administration: subcutaneous injections (e.g., etanercept, adalimumab, anakinra, certolizumab, golimumab) or intravenous infusions (e.g., infliximab, abatacept, rituximab, tocilizumab). These routes are less convenient than orally administered drugs and can be associated with administration reactions, such as injection-site or infusion reactions. Biologic agents are also more expensive than traditional DMARDs, which has affected their use. However, the increased clinical benefit seen with these agents needs to be considered in any comprehensive cost-efficacy analysis.

Conclusions

RA is a prevalent disease and a leading cause of physical disability. There is no cure for RA. However, with available agents applied appropriately, clinical remission is the goal of therapy and is a realistic expectation for some patients. When remission is not achieved, the rheumatologist must look for the most effective combination of therapies to alleviate pain, maintain function, and maximize quality of life. Methotrexate is still the mainstay of long-term care, but newer biologic DMARDs provide additional benefits. The role of biologic agents is still evolving. Their use is often reserved for patients who fail to respond to methotrexate, but the trend is toward earlier use of these agents. NSAIDs and glucocorticoids are useful for bridge therapy in patients with acute symptoms, especially while waiting for DMARDs to reach their maximal effect. Patients should be evaluated periodically for evidence of disease activity and progression and for drug toxicity. The management strategy should be changed if there is progressive joint damage or evidence of ongoing activity after 3 months of maximal treatment, or if treatment is poorly tolerated.

CHLAMYDIA TRACHOMATIS

Method of

Tracy L. Williams, MD

**CURRENT DIAGNOSIS**

- Screen all sexually active woman 25 years of age or younger for *C. trachomatis* annually regardless of symptoms per the CDC recommendations.
- Symptomatic patients should be tested regardless of gender.
- Reinfection with *C. trachomatis* is common.
 - Retest all patients who have a history of *C. trachomatis* or *N. gonorrhea* at 3 to 6 months following treatment, regardless of whether their partner(s) were treated.
 - If the patient does not follow up at 3 to 6 months, then retest upon presentation for medical care within the first 12 months posttreatment.
- Patients who screen positive for *C. trachomatis* need to be screened for gonorrhea, syphilis, and HIV.
- Perform test of cure on pregnant patients at 3 to 4 weeks posttreatment and repeat in 3 to 6 months, preferably in the third trimester if the pregnant woman was diagnosed during the first trimester.
- Rescreen pregnant patients for other sexually transmitted infections (STIs) 3 months posttreatment including gonorrhea, syphilis, and HIV.

**CURRENT THERAPY**

- Azithromycin (Zithromycin) 1 g orally in a single dose or doxycycline (Vibramycin) 100 mg orally twice a day for 7 days are the recommended regimens for nonpregnant patients and for presumptive treatment for *C. trachomatis*.
- All of the patient's recent sexual partners need referral and treatment.
 - The patient's last sexual contact should be referred and treated if it has been more than 60 days since the patient had a sexual partner.
 - The partner needs to be treated for *C. trachomatis* even if his or her personal STI results are negative.
- Counsel patients and their partners to abstain from sexual contact until 7 days after one-dose therapy or after the final dose of the 7-day regimen.
- The CDC recommends that patients who test positive for gonorrhea should also receive presumptive treatment for *C. trachomatis* because coinfection is common.

Epidemiology

Chlamydia trachomatis is the most common notifiable sexually transmitted infection (STI) in the United States, with an incidence of over 1.5 million cases per year according to the Centers for

Disease Control and Prevention (CDC) in 2015. Women age 15 to 19 years are the most commonly affected, followed by women age 20 to 24. The incidence of *C. trachomatis* has steadily climbed yearly since it became a federally mandated notifiable disease; part of this is an artifact of improved screening practices that are discovering disease in asymptomatic patients.

C. trachomatis costs an estimated \$2.4 billion annually. Cost-benefit analyses have consistently shown prioritizing screening efforts in asymptomatic women to be cost-effective.

Risk Factors

The risk of contracting *C. trachomatis* increases with: multiple sexual partners; unprotected sex including vaginal, oral, and anal intercourse; anal-receptive intercourse; and men having sex with men. The risk increases in the presence of other coinfections including human immunodeficiency virus (HIV) or herpes simplex virus (HSV). African Americans have a fourfold higher incidence compared to their white counterparts (13% versus 2.4%, respectively).

Pathophysiology

Chlamydia trachomatis is an obligate intracellular parasite. It is found only in human cells, but can live on fomites for up to 30 hours. Previous infections do not yield protection against future infections with *C. trachomatis*. *C. trachomatis* does not infect the squamous epithelium of the vaginal vault, but can infect the urethra, the squamocolumnar junction of the cervix, the rectal mucosa, and the oropharynx.

Prevention

Prevention depends on screening of asymptomatic patients, who make up a large portion of the infected population. The CDC updated its recommendations for screening in 2010, with emphasis continuing to be on annual screening of all sexually active women age 25 years and younger. The United States Preventive Services Task Force (USPSTF) has similar recommendations but uses age 24 years and younger.

The CDC and the USPSTF found insufficient evidence to recommend routine screening of men based on cost-effectiveness, efficacy, and practicality, but screening of symptomatic men or men in areas with high prevalence of *Chlamydia*, including men having sex with men, men in correctional facilities, and men visiting STI clinics, is recommended. Overall, screening of men is recommended so long as it does not detract resources from the screening of women. Symptomatic patients should be tested regardless of gender.

Men who have sex with other men are at high risk for bacterial and viral STI. The CDC STI screening recommendation in this group is an annual test for urethral infection with *C. trachomatis* and *N. gonorrhea*. The preferred methodology is testing the urine using nucleic acid amplification technique (NAAT). Men who have receptive anal intercourse are recommended to have annual anal screening for both *C. trachomatis* and *N. gonorrhea*. Men who have oral receptive sex are also advised to have pharyngeal screening for *N. gonorrhea* but not *C. trachomatis*. The NAAT is only Food and Drug Administration (FDA)-approved on urine in the above scenarios but is used off-label in laboratories that have met all regulatory requirements.

Patients who screen positive for *Chlamydia* need to be screened for other STIs, including gonorrhea, syphilis, and HIV.

Abstinence and monogamous relationships are ideal to help prevent the transmission of *C. trachomatis*. Safer sex practices to limit the spread of *C. trachomatis* include the consistent use of condoms. Epidemiologic studies show that people often base their decision to use condoms on their perception of their partner's risk. Given the high prevalence of asymptomatic *C. trachomatis* infections in certain American populations, selective condom use is not an effective strategy.

Clinical Manifestations

Most infections are asymptomatic. However, some women will report vaginal discharge, postcoital or intermenstrual bleeding, or lower abdominal pain. Men are more commonly symptomatic than women and may report dysuria or urethral discharge.

Untreated *C. trachomatis* in women has significant health sequelae. Approximately 40% of women with untreated *Chlamydia* go on to develop pelvic inflammatory disease (PID). Women with PID may become infertile (20%), develop debilitating chronic pelvic pain (18%), or suffer ectopic pregnancy (9%).

Men do not tend to suffer as severe sequelae from *C. trachomatis*. The most common illness is urethritis, but men may also suffer epididymitis, proctitis, and conjunctivitis. Reactive arthritis is also more common in men.

Diagnosis

Tests used for detection of *C. trachomatis* can be divided into molecular (NAAT, DNA probing, and hybrid capture), antigen detection (direct immunofluorescence and enzyme immunoassay), and cell culture.

The most reliable method of testing for *C. trachomatis* is NAAT. It is FDA-approved for use on vaginal/endocervical secretions, male intraurethral swabs, and first-catch urine. It is not FDA-approved for rectal or oropharyngeal use but is used off label in laboratories as described above. The primary benefit of NAAT is the lack of a need for viable organisms to induce a positive test result; this increases its sensitivity to more than 95% because of the ability

to detect *C. trachomatis* even if only one copy of the targeted RNA or DNA is present. Its specificity is also desirable at 99%.

C. trachomatis cell culture is used as the reference standard for all testing but has many limitations, including expense, long turnaround time (72 hours), and transport and specimen storage requirements. Its sensitivity is 80% to 85%. It is not readily available.

Limiting barriers to screening is important. If testing in the clinic is difficult to arrange, self-collected vaginal swab specimens perform at least as well as other approved specimens using NAAT. First-catch urine NAAT testing is also more acceptable to many patients, particularly asymptomatic men and women who do not otherwise need a pelvic examination.

Differential Diagnosis

Infection with *Chlamydia* is often asymptomatic but is included in the differential diagnosis of various organ system complaints. It should be ruled out in any sexually active patient presenting with urethritis, mucopurulent cervicitis, epididymitis, and proctitis. There is significant overlap in the symptoms caused by *C. trachomatis* with *N. gonorrhea*, so testing for both bacteria with NAAT is preferred. Other agents that are included in the differential diagnosis after *C. trachomatis* and *N. gonorrhea* have been ruled out include: *Trichomonas vaginalis*, HSV, adenovirus, *Mycoplasma* species, and *Ureaplasma*. More specifically, persistent urethritis after treatment with doxycycline (Vibramycin) can be caused by infection with *T. vaginalis* or doxycycline-resistant *Urea urealyticum* or *Mycoplasma genitalium*.

C. trachomatis should be ruled out in newborn infants with conjunctivitis in the first 30 days of life or pneumonia at 1 to 3 months of life, especially if they were born to mothers with untreated chlamydial infections.

Treatment

Recommendations for treatment regimens are summarized in Box 1. The benefit of using single-dose azithromycin (Zithromycin) is the ability to directly observe the patient taking the therapy. The 7-day course of doxycycline (Vibramycin) has comparable cure rates to azithromycin, but decreased compliance.

BOX 1 *Chlamydia trachomatis*: Recommended Treatment Regimens by Clinical Syndrome

Cervicitis or urethritis or for presumptive treatment in nonpregnant patient*

- Azithromycin (Zithromycin) 1 g orally in a single dose
- or
- Doxycycline (Vibramycin) 100 mg orally twice a day for 7 days

Alternative regimens (one of the following)

- Erythromycin base (E-Mycin) 500 mg orally four times a day for 7 days
- or
- Erythromycin ethylsuccinate (EES) 800 mg orally four times a day for 7 days
- or
- Levofloxacin (Levaquin)¹ 500 mg orally once daily for 7 days
- or
- Ofloxacin (Floxin) 300 mg orally twice a day for 7 days

- Erythromycin ethylsuccinate (EES) 800 mg orally four times a day for 7 days
- or
- Levofloxacin (Levaquin)¹ 500 mg orally once daily for 7 days
- or
- Ofloxacin (Floxin) 300 mg orally twice a day for 7 days

Pregnant patient with cervicitis or urethritis*

- Azithromycin 1 g orally in a single dose
- or
- Amoxicillin 500 mg orally three times a day for 7 days

Alternative regimens

- Erythromycin base 500 mg orally four times a day for 7 days
- or
- Erythromycin base[†] 250 mg orally four times a day for 14 days
- or

- Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days
- or
- Erythromycin ethylsuccinate[‡] 400 mg orally four times a day for 14 days

Epididymitis

- Ceftriaxone (Rocephin) 250 mg IM in a single dose
- plus
- Doxycycline 100 mg orally twice a day for 10 days
- Ophthalmia neonatorum or *C. trachomatis* pneumonia**
- Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into 4 doses daily for 14 days[‡]

Recommended regimen for children who weigh 3C45 kg

- Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into 4 doses daily for 14 days

Recommended regimen for children who weigh 226545 kg but who are 3C8 years old

- Azithromycin 1 g orally in a single dose

Recommended regimens for children aged 22658 years

- Azithromycin 1 gram orally in a single dose
- or
- Doxycycline 100 mg orally twice a day for 7 days

Inpatient and outpatient PID

- Please refer to PID chapter for treatment regimens

Providers should consult the Centers for Disease Control and Prevention's website at <http://cdc.gov/std/treatment> for up-to-date treatment recommendations.

¹Not FDA approved for this indication.

[†]Consider concurrent treatment for gonococcal infection if prevalence of gonorrhea is high in the patient population under assessment.

[‡]The lower-dose and longer-treatment option with erythromycin can be considered if gastrointestinal tolerance is an issue.

[§]Infants <6 weeks of age who are treated with erythromycin should be followed for signs and symptoms of infantile hypertrophic pyloric stenosis.

Presumptive treatment for *C. trachomatis* should be considered for high-risk patients with cervicitis. High-risk patients include women up to 25 years old, those with new or multiple sexual partners, those who engage in unprotected sex, especially if follow-up cannot be ensured, and those for whom a relatively insensitive diagnostic test is used in place of NAAT.

The CDC also recommends presumptive treatment for patients being treated for *N. gonorrhea*. Coinfection is common, as illustrated in a study that found 20% of men with *N. gonorrhea* and 42% of women with *N. gonorrhea* were also infected with *C. trachomatis*. Cotreatment is also recommended in the hope that it will impede the development of antimicrobial-resistant *N. gonorrhea*.

Chlamydia trachomatis is a reportable infectious disease. The patient is instructed to refer all of his or her sexual partners for testing and treatment if they have had sexual contact during the previous 60 days. If the patient has not been sexually active for the last 60 days, then the patient is to refer his or her most recent sexual contact. The patient's recent sexual partners should be treated empirically even if their personal STI evaluation returns negative results. The patient and his or her sexual partners should be counseled to abstain from sexual activity for 7 days post treatment. Reinfection, rather than recurrence, is the more common etiology of repeat *C. trachomatis* infection.

Expedited partner therapy is an option in certain cases. This entails the patient delivering the antibiotic to his or her partner (s) without a physician first seeing the patient. Patients are to give their partners written materials on the importance of following up with a physician if any signs of complications occur (e.g., pelvic pain in women or testicular pain in men). It can be used effectively in certain situations but is not routinely recommended in men who have sex with men because of the high risk for coexisting infections, especially undiagnosed HIV infection, in their partners. Please refer to the CDC website (www.cdc.gov/std/ept) to check on legality in individual states. In general, utilizing the traditional patient-physician model is preferred.

Infants born to women with untreated *C. trachomatis* infection are at increased risk for vertical transmission. Prophylactic treatment with oral erythromycin (E-Mycin) for *C. trachomatis* is not recommended. The state-mandated standard erythromycin eye ointment (Ilotycin) that all newborns receive is still indicated. Overall, infants born to infected mothers need to be closely monitored for any signs and symptoms of infection and treated appropriately.

Intrauterine devices (IUDs) have regained popularity in the United States after they were implicated in causing PID in the 1970s. The IUD has evolved and now the risk of PID appears increased only in the first three weeks postinsertion. If *C. trachomatis* or PID is contracted with an IUD in place, practitioners must decide if the IUD should be removed. Research has found insufficient evidence to mandate removal, but close follow-up is mandatory.

Monitoring

Repeat testing is recommended for all patients treated for *C. trachomatis* at 3 to 6 months regardless of the treatment status of the patient's partner(s) because reinfection is so common. If the patient does not follow up at 3 to 6 months, he or she should be retested upon presentation for medical care within the first 12 months posttreatment.

Test of cure, which is testing at 3 to 4 weeks posttreatment, is recommended only for pregnant patients. Testing for cure earlier than 3 to 4 weeks increases the rate of false positive results. If the initial diagnosis was in the first trimester of pregnancy, testing should be repeated in 3 to 6 months, preferably in the third trimester. Rescreening for other STIs should be performed upon retesting for *Chlamydia*.

Complications

C. trachomatis is a major public health concern because it results in serious health complications and sequelae. In women it can cause PID, endometritis, ectopic pregnancy, infertility, salpingitis, and perihepatitis (Fitz-Hugh-Curtis syndrome). In men it is associated

with postgonococcal or nongonococcal urethritis and epididymitis. Reactive arthritis can occur in both men and women.

C. trachomatis is especially problematic in pregnancy because it is associated with an increased risk of preterm labor and preterm premature rupture of membranes. Infants born to women infected with *Chlamydia* risk suffering pneumonia and conjunctivitis.

C. trachomatis pneumonia can present as an afebrile pneumonia often with a staccato cough without wheezing between 1 and 3 months of life. *C. trachomatis* conjunctivitis, also known as ophthalmia neonatorum, is uncommon in the United States, but worldwide it is the number one cause of blindness. It usually presents within the 5th and 12th day of life but can present at up to 1 month of age. State-mandated prophylactic eye ointment given to babies at birth mainly helps prevent gonococcal ophthalmia; it does not prevent perinatal transmission of *Chlamydia* from mother to infant. Therefore the screening of pregnant women and ultimate treatment of their *Chlamydia* during pregnancy is the best method of preventing complications in newborn infants.

CONDYLOMATA ACUMINATA

Method of

M. Chantel Long, MD

CURRENT DIAGNOSIS

- Condylomata acuminata are usually flesh-colored, brown, or gray and can be flat, plaque-like, or exophytic papules, giving them the classic "cauliflower" appearance.
- The lesions may be single or multiple and can range in size from minute to several centimeters in diameter.
- When the appearance of the lesion is typical, confirmatory tests are usually unnecessary.
- Suspicious lesions or uncertain diagnoses warrant biopsy to rule out malignancy.

CURRENT THERAPY

- In the absence of dysplasia, treatment of subclinical human papilloma virus infection is not recommended.
- The goal of therapy is to eliminate symptoms, namely clinically apparent warts, rather than address the underlying HPV infection.
- Common treatment options include podofilox (Condylox), imiquimod (Aldara, Zyclara), sinecatechins (Veregen), podophyllin resin (Podocon-25), trichloroacetic acid (Tri-Chlor), cryotherapy, and surgery.

Presumptive treatment for *C. trachomatis* should be considered for high-risk patients with cervicitis. High-risk patients include women up to 25 years old, those with new or multiple sexual partners, those who engage in unprotected sex, especially if follow-up cannot be ensured, and those for whom a relatively insensitive diagnostic test is used in place of NAAT.

The CDC also recommends presumptive treatment for patients being treated for *N. gonorrhea*. Coinfection is common, as illustrated in a study that found 20% of men with *N. gonorrhea* and 42% of women with *N. gonorrhea* were also infected with *C. trachomatis*. Cotreatment is also recommended in the hope that it will impede the development of antimicrobial-resistant *N. gonorrhea*.

Chlamydia trachomatis is a reportable infectious disease. CONDYLOMATA ACUMINATA

Method of

M. Chantel Long, MD

CURRENT DIAGNOSIS

- Condylomata acuminata are usually flesh-colored, brown, or gray and can be flat, plaque-like, or exophytic papules, giving them the classic "cauliflower" appearance.
- The lesions may be single or multiple and can range in size from minute to several centimeters in diameter.
- When the appearance of the lesion is typical, confirmatory tests are usually unnecessary.
- Suspicious lesions or uncertain diagnoses warrant biopsy to rule out malignancy.

CURRENT THERAPY

- In the absence of dysplasia, treatment of subclinical human papilloma virus infection is not recommended.
- The goal of therapy is to eliminate symptoms, namely clinically apparent warts, rather than address the underlying HPV infection.
- Common treatment options include podofilox (Condylox), imiquimod (Aldara, Zyclara), sinecatechins (Veregen), podophyllin resin (Podocon-25), trichloroacetic acid (Tri-Chlor), cryotherapy, and surgery.

Epidemiology

Condylomata acuminata, commonly known as genital warts, is a sexually transmitted disease caused by the human papilloma virus (HPV). It is estimated that 20 million people are infected with HPV in the United States, with the highest prevalence in adolescents and young adults. Lifetime incidence of HPV infection is greater than 50% and appears to be increasing, making it the most common sexually transmitted disease.

Risk Factors

Risk factors associated with HPV infection include sex with an infected partner, early age at first sexual intercourse, multiple sexual partners, history of sexually transmitted infections, cigarette smoking, and lack of condom use. The majority of patients whose sexual partner has condyloma will themselves develop condyloma within 3 months. An even larger percentage of people are believed to develop subclinical infection.

Pathophysiology

About 90% of warts are caused by HPV types 6 and 11; condyloma can be coinfecting with types 16, 18, 31, 33, 35, and 45, which have oncogenic potential. Genital skin appears to be less susceptible to the oncogenic potential of HPV compared to the transformation zones of the cervix and anal canal.

The virus is easily transmitted via sexual contact. Vertical transmission and autoinoculation are possible. The average incubation period between infection and appearance of condyloma ranges from 3 months to several years. Condyloma can persist or recur after therapy, undergo malignant transformation, or spontaneously regress.

Prevention

Prevention options include HPV vaccination, abstinence, routine condom use, and limiting sexual partners. Once patients have condyloma, they should be encouraged to use condoms consistently. Educate patients that condoms can decrease transmission but might not completely prevent infection.

Two HPV vaccine series are currently available in the United States. Gardasil is a quadrivalent HPV vaccine indicated for male and female patients aged 9 to 25 years for prevention of cervical cancer and genital warts. Cervarix is the bivalent vaccine indicated for female patients aged 9 to 25 years for prevention of cervical cancer.

Clinical Manifestations

Most genital warts are asymptomatic on presentation, although patients can present with complaints of a "bump." Localized irritation, pruritus, pain, or bleeding can occur, and symptoms may vary based on the location and size of the lesions. Usually, the warts appear flesh-colored, brown, or gray and can be flat, plaque-like, or exophytic papules, giving them the classic "cauliflower" appearance. The lesions may be single or multiple and range in size from minute to several centimeters in diameter. Flat HPV lesions might not be grossly visible.

The majority of HPV infections are either subclinical or unrecognized. Clinically apparent disease might represent only a small portion of the actual infected area.

Diagnosis

When the clinical appearance of the lesion is typical, confirmatory tests are usually unnecessary. The entire anogenital tract should be examined because of the widespread nature of HPV. A magnifying glass and anoscopy may be helpful for thorough detection and examination. Application of dilute 3% to 5% acetic acid solution to the skin surface can help detect subtle HPV lesions by producing an acetowhitening of the condyloma; however, this is not a specific test and is not routinely recommended. Pap smears or tissue biopsy can provide histopathologic confirmation of the diagnosis. Biopsy is recommended to rule out malignancy in any suspicious lesions,

such as large or rapidly growing condyloma; pigmented, atypical, friable, bleeding, or ulcerated lesions; sites of previous treatment failure; areas of recurrence; acetowhite lesions; or lesions in immunocompromised patients. Although costly and not recommended, HPV identification via DNA testing can be performed.

Differential Diagnosis

Table 1 outlines the differential diagnosis for condylomata acuminata.

Treatment

In the absence of dysplasia, the Centers for Disease Control and Prevention recommends no treatment of subclinical HPV infection. The goal of treatment is to eliminate symptoms, namely clinically apparent warts, rather than address the underlying HPV infection. Current treatments do not eradicate the virus.

Ideally, treatment of condyloma should continue until all warts are gone. A repeated course of therapy is often required to achieve a wart-free state. Recurrence may be due to latent HPV in the surrounding normal tissue, HPV reinfection, or improper selection or use of a therapy modality. Nearly all treatment regimens have similar efficacy and rates of intolerance and toxicity. All are known to cause local pain and irritation. Any given treatment has a 40% to 80% rate of wart clearance and up to a 50% recurrence rate. It is unknown whether eliminating warts will decrease infectivity of current or future sexual partners.

The factors to consider when deciding on treatment include location and size of the warts, the patient's tolerance and preference, cost, convenience, and the clinician's preference. Patient-applied options allow the patient greater control; however, this requires good compliance, and the warts must be accessible by the patient or caregiver. Provider-applied treatments are good choices for large treatment areas. Data regarding the efficacy of using more than one modality at a time are lacking. It is common practice for health care providers to combine treatment modalities. Table 2 outlines current therapy regimens. Topical fluorouracil (Efudex)¹ is no longer recommended. Failure to respond after four treatments or failure to clear within 3 months warrants a change in therapy modality and possible reevaluation of the diagnosis.

Advise patients to abstain from sexual activity while undergoing treatment for genital warts.

Monitoring

Counseling of patients regarding prevention and recognition of condyloma as well as screening and treatment of sexual partners

¹Not FDA approved for this indication.

TABLE 1 Differential Diagnosis

LESION	APPEARANCE
Verruca vulgaris	Occurs anywhere Tends to be thicker, drier, and hyperkeratotic
Molluscum contagiosum	Occurs anywhere Smooth, round papules with central umbilication
Seborrheic keratoses	Occurs anywhere Multiple waxy, rough, hyperpigmented papules
Condyloma latum	Moist, rounded, white papules of syphilis
Pearly penile papules	Smooth, uniform, small, 1–2 mm at corona, benign
Vestibular papillae	Both sides of vulva, female equivalent of pearly penile papules
Lichen planus	Purplish, pruritic rash or flat-topped polygonal papules
Nonpigmented nevi	Occurs anywhere Flat or raised, reddish or flesh colored

TABLE 2 Treatment Regimens

DRUG	USE ON	ADVANTAGES	DISADVANTAGES	INSTRUCTIONS
Patient Applied				
Podofilox 0.5% gel or solution (Condylox)	Moist warts	Relatively inexpensive	Avoid in pregnancy Avoid on mucous membranes Do not exceed 10 cm ² area Do not exceed 0.5 mL daily; can have systemic side effects	Apply bid × 3 d, then 4 d off Repeat weekly May use for 4–6 cycles
Imiquimod 5% cream (Aldara)	Dry or moist warts		Avoid with large warts >10 cm ² Requires compliance Hypo- or hyperpigmentation of treated skin can occur	Apply nightly on dry warts Apply every other night on moist warts Use up to 16 wk Wash off after 6–10 h
Sinecatechins 15% ointment (Veregen)	Dry warts		Avoid in pregnancy Avoid in immunocompromised patients	Apply tid Use up to 16 wk Do not wash off
Provider Applied				
Podophyllin resin (Podocon-25, Podofilm)	Moist warts	Use on large warts May use on urethral meatus	Avoid in pregnancy Do not exceed 10 cm ² area Do not exceed 0.5 mL daily; can have systemic side effects	Apply thin layer with cotton tip Allow to air dry Repeat weekly Leave on for 4 h Do not cover May leave on overnight if tolerated
Trichloroacetic acid (TCA) (Tri-Chlor 80%)	Small, few Moist warts	May use on vagina, cervix May use on anal warts May use in pregnancy	Avoid with dry and large warts	Apply sparingly with cotton tip Air dry Repeat weekly to every other week Do not allow to “run” on normal skin Neutralize with soap or sodium bicarbonate
Cryotherapy	Small, few, flat Dry or moist	May use in pregnancy May use liquid nitrogen in vagina, meatus, anus	Avoid with large warts Avoid cryoprobe use in vagina or anus	Freeze q1–2wk Freeze 1–2 mm border May offer/need local anesthesia
Surgery	Small or large Dry or moist	May use on anal warts Use on large warts and large treatment areas	Avoid in patients with bleeding disorder	Scissors, shave biopsy, punch excision, curettage, cautery, laser
Interferon-α-2b injections (Intron A)	Refractory warts		Expensive Flulike side effects	Multiple intralesional injections Several times a week Often requires specialty referral
Laser vaporization	Refractory warts	May use on intraurethral and large warts as well as large treatment areas	Expensive	Requires specialty referral

should be part of the comprehensive management plan. One should consider testing for other sexually transmitted diseases because they often coexist with HPV. Encourage patients to discuss their HPV diagnosis with sexual partners. Asymptomatic partners likely harbor a subclinical infection, and examination for genital warts is appropriate if lesions are suspected. Discuss the need for smoking cessation and regular physician examinations, including Pap smears, as ways to prevent early HPV-related neoplasm.

Complications

Anogenital HPV infection with high-risk genotypes is associated with squamous cell carcinoma of the cervix, vagina, vulva, penis, and anus. Persistent HPV infection is the most important risk factor for development of cervical intraepithelial neoplasia and cancer.

GENITAL ULCER DISEASE: CHANCROID, GRANULOMA INGUINALE, AND LYMPHOGRANULOMA

Method of
Todd Stephens, MD

Chancroid, granuloma inguinale, and lymphogranuloma venereum (LGV) are important genital ulcer diseases that should be included in the differential diagnosis of patients presenting with anal or genital ulcers with or without inguinal adenopathy. Syphilis and herpes simplex virus testing should be considered on all such patients because of similarities in clinical presentation. Testing or treatment for other potential sexually transmitted infections (STIs), including HIV, should be considered given the high risk for concomitant infection.

Chancroid

History

Chancroid, also called soft sore, was first distinguished from the hard chancre of syphilis by Ricord in 1838. Ducrey, in Naples, demonstrated that inoculation of material from the chancroid ulcer into the skin of the forearm could reproduce the ulcer, and he went on to identify the causative organism, which bears his name.

Epidemiology

Chancroid is an important cause of genital ulceration in most countries of the developing world, accounting for about 10 million cases annually. Chancroid was diagnosed in 60% of patients who had genital ulcers and who presented to STI clinics in Africa before the HIV epidemic. Now, herpes simplex lesions represent a higher percentage. The prevalence of this disease is highest among commercial sex workers, and the presence of chancroid lesions significantly increases the risk of transmission of HIV. Although generally rare in industrialized countries, there have been several well-documented outbreaks in urban centers of North America, particularly among men who have sex with men.

Etiology

Chancroid is caused by *Haemophilus ducreyi*, a small anaerobic Gram-negative bacillus that forms streptobacillary chains on Gram stain and grows only on enriched media.

Clinical Features

After an incubation of 3 to 7 days, a papule appears that soon ulcerates, leaving a soft ulcer with an undermined edge and a purulent base. Vesicles are not seen. About half of patients develop unilateral inguinal adenopathy (Figure 1). Both the adenopathy and the lesions are very painful. Lesions can be single or multiple,

Figure 1 Chancroid. This photo shows an early chancroid ulcer on the penis along with accompanying regional inguinal adenopathy. (Courtesy of Dr. Pirozzi, Centers for Disease Control and Prevention.)

and atypical presentations occur. Kissing lesions often occur on adjacent cutaneous surfaces. Not infrequently, a giant ulcer develops with several smaller satellite ulcers around the periphery, which can mimic the ulcerative phase of herpes simplex. More than half of the lesions occur on the prepuce, particularly in uncircumcised men. In women, the majority of lesions are on the fourchette, labia, and perianal area. Adenopathy can progress to bubo formation with tender, overlying erythema. These buboes can rupture and produce inguinal abscesses.

Diagnosis

Gram stain of smears obtained from the ulcer base has been advocated in the past for diagnosis, but this lacks both sensitivity and specificity. The preferred diagnostic modality is swabs for culture from the ulcer base or undermined edge. These are plated directly on enriched media (GC agar and Mueller-Hinton agar base) and incubated for 72 hours in an atmosphere of 5% carbon dioxide at 33°C. Polymerase chain reaction (PCR) and immunochromatography tests are also available.

Treatment

The Centers for Disease Control and Prevention (CDC) recommend a syndromal management approach in which a positive diagnosis is suggested if the patient has one or more painful ulcers and no evidence of syphilis or herpes simplex virus. Ulcers with painful adenopathy are pathognomonic (Table 1 lists antimicrobial treatment). The safety and efficacy of azithromycin (Zithromax) for pregnant and lactating women have not been established. Ciprofloxacin (Cipro)¹ is contraindicated during pregnancy and lactation. No adverse effects of chancroid on pregnancy outcome have been reported. Serologic testing for syphilis, HIV, and other appropriate STIs should be performed. Chancroidal ulcers should be kept clean with regular washing in soapy water and kept dry. Fluctuant buboes might require incision and drainage, which is preferable over needle aspiration. Treatment of all sexual partners within 60 days should be pursued, and treatment is similar to that for the source patient. Patients should not engage in sexual activity until the ulcers are healed.

Granuloma Inguinale (Donovanosis)

History

Granuloma inguinale was first recognized in India, where Donovan observed, in an oral lesion of the disease, the bodies that bear his name. There is considerable confusion about terminology between this disease and LGV, because various similar synonyms have been used inconsistently. Adding to the confusion, Donovan's name is associated with two tropical diseases that he discovered: leishmaniasis, with the discovery of intracellular protozoan inclusions that bear his name (Leishman-Donovan bodies), and granuloma inguinale (whose intracellular inclusions were believed to be caused by protozoa but are now known to be caused by bacteria).

Epidemiology

Endemic areas are localized to a few specific areas of the tropics, particularly India, Papua New Guinea, Brazil, and the eastern part of South Africa, particularly Durban. Commercial sex workers and men are primarily involved.

Etiology

The disease is caused by an encapsulated Gram-negative coccobacillus *Klebsiella granulomatis* (previously known as *Calymmatobacterium* or *Donovania granulomatis*).

Clinical Features

A firm, painless papule or nodule is the presenting sign of granuloma inguinale. The incubation period is variable from 3 to 40 days from inoculation. This nodule quickly ulcerates, and the base is

TABLE 1 Clinical Features and Treatment Summary of Chancroid, Granuloma Inguinale, and Lymphogranuloma Venereum

FEATURES AND TREATMENT	CHANCROID	GRANULOMA INGUINALE	LYMPHOGRANULOMA VENEREUM
Clinical Features			
Incubation period	3–7 days	3–40 days	1–28 days
Primary lesion	Papule	Papule	Papule or vesicle
Ulcerative lesion painful	Yes	No	No
Lymphadenopathy	Yes (unilateral)	No	Yes (unilateral or bilateral)
Base	Purulent	Raised, easily bleeds	Nonvascular
Border	Round, raised, undermined edges	Irregular, expansion along skin folds	Irregular, ragged
Treatment			
Treatment of choice (any of the options listed)	Azithromycin (Zithromycin) 1 g Ciprofloxacin (Cipro) ¹ 500 mg bid × 3 d Ceftriaxone (Rocephin) ¹ 250 mg IM once	Azithromycin ¹ 1 g PO on day 1 followed by 500 mg PO daily for 3 weeks Doxycycline (Vibramycin) 100 mg bid × 3 wks	Azithromycin ¹ 1 g weekly × 3 wk Doxycycline 100 mg bid × 3 wk
Alternative treatment (any of the options listed)	Erythromycin (Ery-Tab) ¹ 500 mg qid × 7 d	Azithromycin ¹ 1 g PO qwk × 3 wk Erythromycin ¹ 500 mg qid × 3 wk Ciprofloxacin ¹ 750 mg bid × 3 wk Trimethoprim/Sulfamethoxazole ¹ : One double-strength (160 mg/800 mg) tablet PO bid × 3 wk	Erythromycin ¹ 500 mg qid × 3 wk

¹Not FDA approved for this indication.

highly vascular, is beefy red, and bleeds easily. Lymphadenopathy is not part of the clinical presentation of this disease, distinguishing granuloma inguinale from chancroid and LGV. However, the ulcer can be easily confused with chancroid, condyloma lata, ulcerated verrucous warts, and squamous carcinoma. Untreated, the ulcers slowly expand, particularly along skin folds toward the inguinal region or anus (Figure 2). The ulcers are flat and raised and have slightly hypertrophic margins, but the bases are typically free of pus and necrotic debris. Less-common presentations include extra-genital lesions involving the neck and mouth; cervical lesions that resemble carcinoma; and involvement of the uterus, tubes, and ovaries, producing hard masses, abscesses, or frozen pelvis.

Diagnosis

Diagnosis requires the demonstration of intracellular Donovan bodies from Giemsa or Wright staining of smears taken from a swab of the ulcer base or from biopsy material.

Figure 2 Granuloma inguinale. (Source: NEHC http://www.nhec.med.navy.mil/hp/sharp/std_pictures.htm)

Treatment

See Table 1 for antimicrobial treatment. Treatment should be continued until lesions are resolved and, if possible, a little longer to reduce the risk of relapse.

Lymphogranuloma Venereum

History

LGV was first differentiated from syphilis in 1906 by Wasserman, though the first full description of the disease was given by Durand, Nicolas, and Favre in 1913. In 1925, Frei developed an intradermal skin test that gave positive responses in most LGV patients. The term “tropical bubo” was associated with the disease later.

Epidemiology

LGV is largely confined to the tropics and is not a common STI. The global overall incidence is in a decline. It is seen more commonly in men, but since 2004, there has been a resurgence manifesting as proctitis in North America and Europe among HIV-positive men who have sex with men.

Etiology

LGV is a chlamydial infection caused by the invasive L1, L2, and L3 serovars of *Chlamydia trachomatis*, an intracellular gram-negative bacterium.

Clinical Features

LGV is essentially a systemic disease whose natural course is divided into three distinct phases. The initial phase of LGV is normally an inconspicuous genital lesion beginning as a typically small, painless papule or vesicle occurring 1 to 28 days after inoculation. This papule or vesicle quickly ulcerates and heals without a scar, and it often goes unrecognized by the patient (Figure 3). However, the second phase of LGV is the development of increasingly painful lymphadenopathy, often with fever and malaise. The lymphadenopathy progresses to bubo formation over 1 to 2 weeks. When a sexually active adult patient presents with an inguinal bubo not associated with genital ulcers, LGV is an important diagnosis to consider. The infected nodes are usually unilateral

Figure 3 Lymphogranuloma venereum. **A**, Small ulcerative lesion near corona of penis (arrow). **B**, Bilateral inguinal adenopathy, with developing groove sign as adenopathy expands above and below the inguinal ligament. (A courtesy Ronald Ballard, Reproduced with permission from *The Diagnosis and Management of Sexually Transmitted Infections in South Africa*, 3rd ed., Johannesburg, South African Institute for Medical Research, 2000. B courtesy Connexions (http://cnx.org/content/m14883/latest/Case_10-pres1-1.jpg).

(bilateral in a third of cases) and often coalesce into a matted mass that can project outwards above or below the inguinal ligament, producing the pathognomonic groove sign present in 20% of patients with LGV. The buboes are likely to rupture, forming multiple sinuses. Untreated, LGV can cause extensive lymphatic damage, resulting in elephantiasis of the genitalia. Anal involvement, likewise, can lead to perirectal abscesses, fistulas, and rectal strictures. These complications represent the late phase of LGV.

Diagnosis

The diagnosis of LGV can only be confirmed using PCR methods of smears, scrapings, or aspirated material. Alternatively, the ability to perform micro-immunofluorescence serology testing using a fluorescein-conjugated monoclonal antibody and viewing the slide with a fluorescence microscope can demonstrate the inclusion bodies within the cytoplasm of macrophages. Gram staining by itself lacks appropriate sensitivity or specificity. Additional laboratory findings include leukocytosis, elevated erythrocyte sedimentation rate, and increases in immunoglobulin G and cryoglobulins.

Treatment

Antimicrobial treatment is summarized in [Table 1](#). Needle aspiration or incision and drainage of fluctuant buboes may be required for symptomatic relief but are not routinely recommended for treatment because drainage can delay healing. Fistula openings should receive sterile dressings. One of the primary goals of treatment of LGV is to prevent long-term complications such as anogenital strictures or fistulas. Plastic surgical operations may be of benefit in cases with extensive rectal strictures or elephantiasis of the genitalia. However, these surgical interventions should only be performed after a prolonged course of antibiotics. Scars should be monitored to detect malignant change.

Management of Sex Partners

Any person having had sexual contact with a patient with LGV within 60 days before the onset of the patient's symptoms should

be examined and presumptively treated with azithromycin¹ 1 gram orally as a single dose or doxycycline 100 mg orally twice a day for seven days. Symptomatic patients should be treated with longer treatment regimens.

¹Not FDA approved for this indication.

GONORRHEA

Method of

John Brill, MD, MPH

CURRENT DIAGNOSIS

- Gonorrhea is caused by the gram-negative diplococcus *Neisseria gonorrhoeae*.
- Asymptomatic gonococcal infections are common in men and women, particularly in extragenital locations.
- Molecular tests are more sensitive than culture for diagnosis, particularly in extragenital locations.
- All patients diagnosed with gonorrhea should be tested for other sexually transmitted infections, including HIV.
- Annual screening for *N gonorrhoeae* infection is recommended for all sexually active women aged <25 years and for older women at increased risk for infection.

CURRENT THERAPY

- The combination of ceftriaxone (Rocephin) 250 mg intramuscularly and azithromycin (Zithromax) 1 g by mouth is the first-line treatment for gonorrhea. Ceftriaxone alone should not be used to treat gonorrhea, even when concomitant chlamydia testing is negative.
- Azithromycin is preferred as the second agent over doxycycline (Vibramycin) because of enhanced compliance and better antimicrobial activity.
- Only immunoglobulin E-mediated allergic reaction to PCN or cephalosporins (anaphylaxis, Stevens-Johnson syndrome, or toxic epidermal necrolysis) should contraindicate use of ceftriaxone.

Gonorrhea is a sexually transmitted infection caused by the gram-negative diplococcus *Neisseria gonorrhoeae*, or gonococcus (GC).

Epidemiology

Gonorrhea is the second-most common reportable human infection in the United States, with 468,514 cases of gonorrhea reported to the Centers for Disease Control and Prevention (CDC) in 2016,

Figure 3 Lymphogranuloma venereum. **A**, Small ulcerative lesion near corona of penis (arrow). **B**, Bilateral inguinal adenopathy, with developing groove sign as adenopathy expands above and below the inguinal ligament. Gonorrhea is a sexually transmitted infection caused by the gram-negative diplococcus *Neisseria gonorrhoeae*, or gonococcus (GC).

Epidemiology

Gonorrhea is the second-most common reportable human infection in the United States, with 468,514 cases of gonorrhea reported to the Centers for Disease Control and Prevention (CDC) in 2016,

an 18.5% increase from 2015. The actual number of cases is estimated to be at least double those reported because of asymptomatic cases and underreporting. Regional rates vary widely from 20 (Vermont) to 480 (District of Columbia) per 100,000 population. The estimated annual US health care costs related to GC infections is \$162 million.

Risk Factors

Risk factors for infection include unprotected intercourse, adolescent and young adult age, new/multiple sexual partners, and exchanging sex for money or drugs. Gonococcal infection is strongly associated with other sexually transmitted infections (STIs) (Figure 1). In fact, at a county population level, HIV infection rate carries the highest association with GC rates, superseding all other socioeconomic and demographic risk factors. Additional risk factors for gonorrhea include inconsistent condom use among persons who are not in mutually monogamous relationships, previous or coexisting sexually transmitted infections, and exchanging sex for money or drugs. Military recruits, incarcerated persons and persons receiving care at public STI clinics are also at high risk. A significant ethnic disparity in GC rates is seen, with rates in black men 8.9 times higher than in white men and black women and 8.4 times higher than in white women in 2016; however, these proportions have been decreasing since 2011 (Figure 2).

Pathophysiology

N gonorrhoeae infects non-cornified epithelial cells, such as the urethra, endocervix, rectum, oropharynx, and conjunctiva. The bacteria divide by binary fission every 20 to 30 minutes, thus

the rapid emergence of symptoms. *N gonorrhoeae* attaches to different types of mucus-secreting epithelial cells via a number of alterable structures located on the surface of gonococci, and additionally uses several mechanisms to counter the immune system. *N gonorrhoeae* is primarily spread by infected secretions (oral, urethral) coming into contact with mucosal surfaces. Maternal-child transmission is well established; hence, the recommendation to treat all newborns prophylactically with erythromycin (Ilotycin) 0.5% ophthalmic ointment.

Screening and Prevention

The United States Preventive Service Task Force recommends annual screening for *N gonorrhoeae* infection in all sexually active women aged <25 years and for older women at increased risk for infection (e.g., those who have a new sex partner, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has an STI); a “B” recommendation. The United States Preventive Service Task Force concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for gonorrhea in men; an “I” recommendation.

Men who have sex with men (MSM) without consistent condom use are at high risk for gonorrhea infection, and the CDC recommends screening of sexually active MSM at least annually at anatomic sites of exposure. Mucosa that is infected by GC is more susceptible to HIV, even in asymptomatic states, raising the impetus for screening and treatment. Because the bacterium is an obligate human pathogen with adult transmission only via sexual contact, avoidance of intimate contact with an infected person is the optimal mode of prevention. Male latex condoms, used cor-

Figure 1 Rates of reported cases by age group and sex, United States 2016.

Figure 2 Ethnic disparity rates per population.

rectly and consistently, are highly effective at preventing GC transmission; polyurethane male and female condoms are effective when intact but have higher breakage rates.

Clinical Manifestations

The most common symptom of genital GC infection is a mucopurulent urethritis or cervicitis. In men, genital GC typically manifests with urethral discharge and dysuria 2 to 5 days after exposure; however, approximately 30% of urethral infections are asymptomatic. About half of genitally infected women will show symptoms, most commonly vaginal discharge, dysuria, and itching, generally 5 to 10 days after exposure. The great majority of rectal and pharyngeal infections are asymptomatic. GC can also present as ocular and disseminated infection. Except for neonatal infections believed to arise from perinatal transmission, diagnosis of gonococcal infection in infants and children should trigger a sexual abuse investigation, including multisite testing.

Diagnosis

Laboratory diagnosis of GC can be made by gram staining of urethral secretions in symptomatic men, by culture of endocervical or urethral specimens, or by nucleic acid amplification testing (NAAT) of urine or the target location. Gram staining of urethral discharge showing leukocytes with intracellular gram-negative diplococci is extremely specific and sensitive. Gram staining is not sensitive enough to rule out infection in symptom-free men or in extra-urethral locations. NAAT has largely replaced culture and appears to be more than twice as sensitive as culture in extragenital locations. The increased sensitivity of NAATs is due to their ability to produce a positive test result from as little as a single copy of the target DNA. False-positive test results can occur with nucleic acid amplification testing, especially if NAAT is not cleared by the Food and Drug Administration for use with these specimens or if it is ordered too soon after treatment, because NAATs do not require viable organisms. Although this higher sensitivity has allowed the use of less invasively collected specimens, such as first-catch urine, specific site testing or pharyngeal or rectal specimens will detect up to 80% more infections than urine screening alone, highlighting the importance of a careful exposure history and consideration of multiple-site screening in high-risk populations. Recent literature has also demonstrated that approved self-collection vaginal swabs are accurate and highly acceptable to patients.

Differential diagnosis

Differential diagnosis of gonorrheal genital infections includes *Chlamydia trachomatis* (CT), *Mycoplasma genitalium*, *Trichomonas vaginalis*, and herpes simplex infection. In women, yeast vaginitis and bacterial vaginosis should be considered. Coinfection is common and cannot be ruled out on clinical grounds; therefore co-testing for CT and trichomonas should be done in all patients, and all patients should be offered testing for HIV, syphilis, and hepatitis.

Gonococcal conjunctivitis is typically purulent and unilateral but again cannot be distinguished clinically from other bacterial infections. Because gonococcal eye infections in adults generally result from autoinoculation, this diagnosis should prompt testing at other exposure sites.

Therapy

The 2015 CDC guidelines recommend ceftriaxone (Rocephin) and azithromycin (Zithromax) for the treatment of gonorrhea, even if the concomitant chlamydia testing result is negative. Ideally the dual treatment should be carried out under direct observation or at least in the same day. Unfortunately, primary care clinician awareness of recommendations for dual therapy is suboptimal, especially in clinicians who do not pursue continuing education in this area. Use of azithromycin as the second antimicrobial is preferred to doxycycline (Vibramycin) because of the convenience and compliance advantages of single-dose therapy and the substantially

higher prevalence of gonococcal resistance to tetracycline than to azithromycin among surveillance study isolates. Tetracycline resistance is associated with cefixime (Suprax) resistance, underscoring the importance of using azithromycin as the second agent if oral therapy is used.

Data are limited regarding alternative regimens for treating gonorrhea among persons who have either a cephalosporin or immunoglobulin E-mediated penicillin allergy. Potential therapeutic options are dual treatment with gemifloxacin (Factive)¹ 320 mg by mouth plus oral azithromycin 2 g (single dose of each) or dual treatment with single doses of intramuscular gentamicin (Garamycin)¹ 240 mg plus oral azithromycin 2 g. The 2-g dose³ of azithromycin has significantly higher efficacy than 1 g and can be used as solo therapy if no other options are available.

Expedited partner therapy (EPT) is a strategy of treating sex partners of patients with GC or chlamydia without examining the partner. EPT is advocated by the CDC to decrease reinfection rates, particularly where the likely alternative is no care. In 2018, all US states except Kentucky and South Carolina allowed EPT as an exception to scope of practice legislation requiring an established clinician-patient relationship. A challenge for EPT with gonorrhea is the need for parental administration of one of the components of the preferred therapy, ceftriaxone. If oral therapy seems to be the only option for a partner to be treated, cefixime (Suprax, 400 mg single-dose tablet) plus azithromycin (1- or 2-g single dose) should be used.

Treatment has been complicated by emerging resistance. In 2013 the CDC released Antibiotic Resistance Threats in the United States, which named antibiotic-resistant gonorrhea among the *three most urgent public health threats* in the country. Currently at least 30% of US isolates are resistant to at least 1 tested drug, most commonly tetracyclines, fluoroquinolones, or PCN. Resistant strains are much more frequent outside of the United States, underlining the importance of travel history, and are also more common in MSM. Cephalosporin resistance has stabilized following the recommendations for dual therapy, raising optimism that this strategy will maintain efficacy of these agents.

Monitoring

Test of cure after treatment is not recommended except for the following circumstances:

- Use of a non-preferred antibiotic regimen for treatment, especially for pharyngeal infection
- Continued intercourse <7 days after treatment of any/all partners
- Pregnant women (if treated early in pregnancy, also retest in third trimester)
- Persistent symptoms 3 weeks or more after treatment. Testing with NAAT in a shorter interval after treatment may result in false-positive test results because of the presence of DNA fragments. In this situation, testing should be repeated for CT and trichomonas to reduce the potential for false-negative initial test results. For continued symptomatic genital infections despite appropriate therapy, culture with sensitivity testing is recommended.
- Suspected internationally acquired infection
- Culture sensitivity testing showed decreased susceptibility to cephalosporins

Because of a high rate of reinfection, persons treated for gonorrhea should be retested 3 months after treatment regardless of whether they believe their sex partners were treated. If the 3-month retesting does not occur, clinicians should retest whenever the individual next presents for care within 1 year of initial treatment.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Management of Complications

In men younger than 40, GC causes about 30% of cases of epididymitis, marked by unilateral testicular pain and swelling. Uncommon male complications of *N gonorrhoeae* include inguinal lymphadenitis, penile edema, periurethral abscess or fistula, accessory gland infection (Tyson's glands), balanitis, urethral stricture, and perhaps prostatitis. Female complications of gonorrhea are more frequent and burdensome and include pelvic inflammatory disease, potentially leading to infertility or ectopic pregnancy in women. Disseminated gonococcal infections may occur in up to 2% of untreated patients. Certain gonococcal strains are more likely to cause disseminated gonococcal infections. Although patients are bacteremic, many appear nontoxic. Symptoms and signs may include fevers, myalgias, arthralgias, asymmetrical polyarthritides, and a characteristic dermatitis consisting of a small number (<30) of skin lesions on the distal extremities that begin as papules and progress to pustules and ulcerations. Rarely, meningitis and endocarditis may occur. Hospitalization and consultation with an infectious-disease specialist are recommended.

- If test results are not immediately available, patients should receive concurrent treatment for gonorrhea with ceftriaxone (Rocephin) 250 mg IM.
- Expedited partner therapy should be offered where allowed.
- Persistent symptoms in compliant patients who have not been reexposed can be treated with metronidazole (Flagyl) 2 g orally in a single dose.

Epidemiology

Chlamydia trachomatis is the most common pathogen identified in nongonococcal urethritis (NGU) in men. Other potential causes include *Mycoplasma genitalium*, *Trichomonas vaginalis*, herpes simplex virus, adenovirus, and urethral trauma. Chlamydia is the most commonly reported sexually transmitted infection (STI) in the United States. Determining the exact prevalence of *C. trachomatis* infection is difficult, because most infected individuals are asymptomatic. Additionally, although screening commonly occurs in women, empiric treatment without confirmatory testing is routinely extended to sexual partners of those who test positive. While 1,307,893 cases were reported to the CDC in 2010, the estimated prevalence is 2.8 million.

Risk Factors

C. trachomatis infection is associated with young age (less than 25 years), multiple sex partners, history of prior STI, low condom use, cervical ectopy, lower socioeconomic status, and low/intermediate education. Insertive oral sex among men who have sex with men is associated with urethritis caused by HSV or adenovirus. Posttraumatic urethritis is 10 times more likely in patients using latex catheters than silicone catheters for intermittent catheterization.

Pathophysiology

Urethritis is inflammation of the urethra caused by infection or traumatic injury. The term *nongonococcal urethritis* is typically reserved to describe an STI of the male urethra with a negative Gram stain of urethral discharge, most commonly due to *Chlamydia*. In women, urethral infection often accompanies chlamydial cervicitis.

C. trachomatis is an obligate intracellular parasite with a two-phase life cycle: an extracellular, nonreplicating, infectious elementary body; and an intracellular, replicating, noninfectious reticulate body. A cycle can take 3 to 5 days, requiring prolonged courses of treatment. Immunity to infection is relatively short-lived, contributing to reinfection or persistent infection.

Prevention

Primary prevention of NGU relies on education regarding chlamydial infection targeted at adolescents and young adults. Education should include promotion of behavioral changes aimed at reducing the risk of acquiring and transmitting STIs such as abstinence from sexual activity, delaying coitarche, reducing the number of sexual partners, and consistent and correct condom use.

Because most infections in males and females are asymptomatic, screening at-risk individuals is a cornerstone of secondary prevention. As most reproductive complications of *Chlamydia* infection occur in women, the CDC recommends annual screening of all sexually active, nonpregnant women 25 years old or younger and sexually active older women with a new partner or multiple partners. Because of the potential for maternal complications and transmission to the neonate, the CDC also recommends screening all pregnant women regardless of age. The CDC reserves screening of males for those at highest risk, including men attending STI clinics, under age 30 in the military, in correctional facilities, whose partners test positive, and who have sex with men. The United States Preventive Services Task Force recommends screening all sexually active and pregnant women age 24 or younger; recommends screening women age 25 or older only if they are

NONGONOCOCCAL URETHRITIS

Method of

Robert S. Freelove, MD

CURRENT DIAGNOSIS

- Urethritis is diagnosed by the presence of mucopurulent/purulent urethral discharge, >5 WBC/hpf on Gram stain of urethral secretions, a positive leukocyte esterase test or ≥10 WBC/hpf on microscopic examination of first-void urine.
- Testing first-void urine/urethral discharge using NAAT has replaced culture as the "gold standard" in diagnosis of chlamydial NGU.
- Test for cure is indicated in pregnant women and should wait at least 3 to 4 weeks after treatment.
- Patients with confirmed *Chlamydia* infection should be rescreened 3 to 6 months after treatment.

CURRENT THERAPY

- Treatment of choice is azithromycin (Zithromax) 1 g orally in a single dose.
- Other first-line treatment is doxycycline (Vibramycin) 100 mg orally twice a day for 7 days.

Management of Complications

In men younger than 40, GC causes about 30% of cases of epididymitis, marked by unilateral testicular pain and swelling. Uncommon male complications of *N gonorrhoeae* include inguinal lymphadenitis, penile edema, periurethral abscess or fistula, accessory gland infection (Tyson's glands), balanitis, urethral stricture, and perhaps prostatitis. Female complications of gonorrhea are more frequent and burdensome and include pelvic inflammatory disease, potentially leading to infertility or ectopic pregnancy in women. Disseminated gonococcal infections may occur in up to 2% of untreated patients. Certain gonococcal strains are more likely to cause disseminated gonococcal infections. Although patients are bacteremic, many appear nontoxic. Symptoms and signs may include fevers, myalgias, arthralgias, asymmetrical polyarthritides, and a characteristic dermatitis consisting of a small number (<30) of skin lesions on the distal extremities that begin as papules and progress to pustules and ulcerations. Rarely, meningitis and endocarditis may occur. Hospitalization and consultation with an infectious-disease specialist are recommended.

NONGONOCOCCAL URETHRITIS

Method of

Robert S. Freelove, MD

CURRENT DIAGNOSIS

- Urethritis is diagnosed by the presence of mucopurulent/purulent urethral discharge, >5 WBC/hpf on Gram stain of urethral secretions, a positive leukocyte esterase test or ≥10 WBC/hpf on microscopic examination of first-void urine.
- Testing first-void urine/urethral discharge using NAAT has replaced culture as the "gold standard" in diagnosis of chlamydial NGU.
- Test for cure is indicated in pregnant women and should wait at least 3 to 4 weeks after treatment.
- Patients with confirmed *Chlamydia* infection should be rescreened 3 to 6 months after treatment.

CURRENT THERAPY

- Treatment of choice is azithromycin (Zithromax) 1 g orally in a single dose.
- Other first-line treatment is doxycycline (Vibramycin) 100 mg orally twice a day for 7 days.

Figure 1 Mucopurulent urethral discharge in patient with NGU.

at increased risk, whether or not they are pregnant; and concludes that there is insufficient evidence to assess benefits and harms of screening in men.

Clinical Manifestations

Many patients with NGU are asymptomatic, including up to 42% of men and 75% of women. The most common complaints are of urethral discharge and/or dysuria, usually appearing 1 to 3 weeks after exposure. The discharge can be watery, mucoid, or mucopurulent (Figure 1). The dysuria is commonly described as a burning sensation. Men may also have some itching and/or redness at the urethral meatus. Symptoms appear 1 to 3 weeks after exposure. Physical examination should include inspection for inguinal lymphadenopathy, ulcers, and/or urethral discharge.

Diagnosis

Urethritis is diagnosed clinically based on the presence of mucopurulent or purulent urethral discharge, greater than 5 WBC/hpf on Gram stain of urethral secretions, a positive leukocyte esterase test on first-void urine or 10 WBC/hpf or greater on microscopic examination of first-void urine sediment. All patients who have confirmed or suspected urethritis should be tested for both gonorrhea and chlamydia, and consideration should be given to check for other STIs. *C. trachomatis* cannot be cultured on artificial media and instead requires a tissue culture. However, nucleic acid amplification techniques (NAAT) are both sensitive and specific and have replaced culture as the “gold standard” in diagnosis of chlamydial NGU. Testing can be performed on urethral specimens or on urine. Performing the testing on urine avoids invasive sampling of the urethra and may improve patient acceptance. Testing first-morning void improves detection rate.

Differential Diagnosis

The differential diagnoses include gonococcal urethritis, urinary tract infection (UTI), and urethritis caused by *M. genitalium*, HSV, and *T. vaginalis*. The incubation period for gonococcal urethritis is typically shorter and the discharge is more copious and purulent. UTIs usually cause more dysuria as well as other urinary symptoms, and bacteria can often be identified on Gram stain during urinalysis.

Therapy (or Treatment)

Treatment for chlamydial urethritis should be initiated immediately after diagnosis, ideally observed and in the health-care provider's office to ensure compliance. Recommended first-line agents are azithromycin (Zithromax) 1 g orally in a single dose or doxycycline (Vibramycin) 100 mg orally twice a day for 7 days. Alternative regimens include erythromycin base (Ery-Tab) 500 mg orally four times a day for 7 days; or erythromycin ethylsuccinate (E.E.S.) 800 mg orally four times a day for 7 days; or ofloxacin (Floxin) 300 mg orally twice a day for 7 days; or levofloxacin (Levaquin) 500 mg orally once daily for 7 days. Patients with confirmed urethritis in whom test results are not already known or immediately available should also be treated empirically for gonorrhea with ceftriaxone (Rocephin) 250 mg intramuscularly in a single dose. All sexual partners should be referred for evaluation and treatment. Alternatively, expedited partner therapy (EPT), providing prescriptions or medications to the patient to take to his/her partner, should be offered where allowed; EPT has been shown to increase partner treatment and reduce reinfection. Patients with symptoms of persistent or recurrent infection can be re-treated with the initial regimen if they were not compliant with treatment or have been reexposed to an untreated partner. If the patient was compliant and was not reexposed, he or she should be treated with metronidazole (Flagyl) 2 g orally in a single dose; or tinidazole (Tindamax) 2 g orally in a single dose plus azithromycin (Zithromax) 1 g orally in a single dose.

Monitoring

Testing for cure is not recommended except in pregnant women or those in whom therapeutic compliance is in question, and must wait for at least 3 to 4 weeks after treatment, because NAAT may be positive in the presence of dead organisms. All patients with *Chlamydia* infection should be screened again 3 to 6 months after treatment.

Complications

In men, untreated chlamydial NGU can lead to epididymitis and/or prostatitis. Reactive arthritis is an uncommon complication in men, as is Reiter syndrome (arthritis, conjunctivitis/uveitis, urethritis, mucocutaneous lesions). In women, concurrent cervicitis can lead to PID. Transmission to newborns can result in conjunctivitis or pneumonia.

SYPHILIS

Method of

Jennifer Frank, MD

CURRENT DIAGNOSIS

- Serologic testing includes both nontreponemal-specific testing (VDRL and RPR) and treponemal-specific testing (FTA-Abs [fluorescent treponemal antibody absorption] and TP-PA [*Treponema pallidum* particle agglutination]).
- Cerebrospinal fluid testing (VDRL [Venereal Disease Research Laboratory], protein, cell count) is performed to diagnose neurosyphilis.

CURRENT THERAPY

- Penicillin is first-line therapy for all types and stages of syphilis.
- Penicillin is the only recommended treatment for pregnant women and for congenital syphilis. Penicillin-allergic patients should undergo desensitization.

Epidemiology

The rate of primary and secondary syphilis reached a low point (2.1 per 100,000) in 2000 and has increased since that time, reaching a rate of 8.7 per 100,000 in 2016; this represented an 18% increase from 2015 and is the highest rate since 1993. The recent increase in rates has occurred in both men and women, in all regions, in all age groups between 15 years and older, and in all ethnicities. Men who have sex with men (MSM) have the highest rates of primary and secondary syphilis. Increased rates were also seen in men ages 20–29, in the West, and in black men. Congenital syphilis is also increasing with a rate of 15.7 cases per 100,000 live births in 2016; this represents a steady increase since 2012 and mirrors the increased rates among women.

Risk Factors

MSM and HIV-positive persons are at highest risk for primary and secondary syphilis. Other risk factors include living in the certain geographic areas in the United States or an urban area, and being born to a mother infected with syphilis.

Pathophysiology

Syphilis is caused by infection with the spirochete *Treponema pallidum* subspecies *pallidum* (Figure 1). Primary infection manifests with signs and symptoms at the site of infection; secondary and tertiary syphilis manifest with systemic signs and symptoms. Syphilis is primarily sexually transmitted but may be transmitted perinatally or through nonsexual cutaneous transmission.

Prevention

Prevention includes both avoiding initial infection and preventing disease progression through early detection and treatment. Transmission of syphilis can be reduced (although not eliminated) by using condoms. Screening for syphilis in pregnancy combined with treatment of infected women reduces perinatal transmission. Screening high-risk populations may prevent spread of infection.

Screening

The US Preventive Services Task Force recommends screening people at increased risk for syphilis. Screening HIV-infected men or MSM every 3 months increases rates of detection. All pregnant women should be screened for syphilis at the first prenatal visit.

Women at increased risk should be rescreened in the third trimester, at delivery, and after any potential exposure to an infected partner.

Clinical Manifestations

Primary syphilis manifests as a chancre at the site of inoculation. The chancre, a painless ulcer with sharp borders, is usually solitary and associated with regional lymphadenopathy. Atypical presentations include extragenital location (most commonly oral or anal) and the presence of pain or multiple lesions. Secondary syphilis characteristically manifests with a generalized rash with variable features (Figure 2). The palms and soles are affected in the majority of patients. Typically, the rash is maculopapular or papulosquamous and nonpruritic. Other clinical manifestations include highly infectious flat lesions (condyloma lata), fever, malaise, sore throat, headache, myalgias, alopecia, and, rarely, renal, bone, eye, or liver involvement. Latent syphilis, by definition, has no clinical manifestations. Ocular syphilis can occur during any stage of syphilis and has been reported in 20 states in the last few years. Patients with syphilis should be screened for any visual symptoms or eye complaints.

Tertiary syphilis, which is rare, is a late manifestation in untreated people and includes neurosyphilis, cardiovascular, and gummatous disease. Gummas are nodular lesions that vary in size and location. They can ulcerate and cause local tissue destruction. Other skin lesions include granulomas and plaque formation. Cardiovascular syphilis most commonly manifests as aortitis of the ascending aorta. The clinical manifestations of neurosyphilis are numerous and include meningitis with or without vascular involvement, dementia, tabes dorsalis (posterior column involvement with ataxia and bowel and bladder dysfunction), and ocular or otologic involvement.

Congenital syphilis has early (birth to 2 years) and late (2 to 20 years) clinical manifestations. Early signs include hepatosplenomegaly, rash, fever, neurosyphilis, pneumonitis, rhinitis, generalized lymphadenopathy, hepatitis, ascites, hematologic disease, renal disease, periostitis, and osteochondritis. Late manifestations (present in 40% of untreated patients) include skeletal deformities, neurologic disease (deafness), dental abnormalities, and ocular abnormalities.

Diagnosis

Diagnostic evaluation of syphilis depends on the stage and location of suspected infection. Darkfield microscopy or direct fluorescent antibody testing is done on tissue or exudates obtained from an ulcer or chancre (primary infection). Serologic testing is done using nontreponemal (VDRL or RPR) and treponemal testing (FTA-ABS or TP-PA) because both tests have limitations. Nontreponemal testing may be falsely positive with other medical conditions, but antibody titers correlate with disease activity and therefore can indicate response to treatment. Nontreponemal tests usually become nonreactive after successful treatment. A serofast reaction can occur in which the nontreponemal test stays reactive. Treponemal tests are specific for syphilitic infection but usually stay reactive

Figure 1 *Treponema pallidum* on darkfield microscopy.

Figure 2 Syphilis skin lesion.

TABLE 1 CDC Recommendations for Treatment of Syphilis

STAGE	RECOMMENDED PENICILLIN TREATMENT	
	PENICILLIN	DOSAGE
Primary and secondary syphilis	Benzathine penicillin G (Bicillin LA)	2.4 million U IM once
Early latent syphilis (acquired within previous 12 mo)	Benzathine penicillin G	2.4 million U IM once
Late latent syphilis	Benzathine penicillin G	2.4 million U IM weekly × 3 doses
Tertiary syphilis	Benzathine penicillin G	2.4 million units IM weekly × 3 doses
Neurosyphilis	Aqueous crystalline penicillin G	3–4 million U q4h
	or	
	Continuous infusion	18–24 U daily IV × 10–14 d (preferred)
	or	
	Procaine penicillin (Wycillin)	2.4 million U IM
	plus	
	Probenecid	500 mg PO qid
Congenital Syphilis		
Proven or highly probable disease	Aqueous crystalline penicillin G	100,000–150,000 U/kg/d (divided 50,000 U/kg/dose) IV q12h
	or	× first 7 d of life, then q8h for total of 10 d of treatment
	Procaine penicillin G	50,000 U/kg/dose IM daily × 10 d
Normal examination but mother inadequately treated	Aqueous crystalline penicillin G	100,000–150,000 U/kg/d (divided 50,000 U/kg/dose) IV q12h
	or	× first 7 d of life, then q8h for total of 10 days of treatment
	Procaine penicillin G	50,000 U/kg/dose IM daily × 10 d
	or	
	Benzathine penicillin G	50,000 U/kg/dose IM once
Normal examination, serologic titers $\leq 4 \times$ the maternal titer, and mother adequately treated during pregnancy	Benzathine penicillin G	50,000 U/kg/dose IM once

Abbreviation: CDC = Centers for Disease Control and Prevention.

regardless of treatment or disease status. Treponemal test antibody titers do not match the level of disease activity and therefore cannot be used to monitor treatment response. Reverse sequence testing has been used in which a treponemal specific test is the initial screening test, followed by a non-treponemal test. Reverse sequence testing has a higher false-positive rate with the initial screening step of testing but identifies more cases of syphilis, particularly early infection, previously treated infection, or long-standing infection. If reverse sequence screening is used, a third treponemal specific test using different antigens should be used to confirm the results.

Neurosyphilis is diagnosed based on clinical signs and symptoms using laboratory testing to support a clinical diagnosis. No single test can be used to diagnose all patients with neurosyphilis, which means that neurosyphilis is usually diagnosed by a combination of serologic testing, testing of cerebrospinal fluid (CSF), and clinical evaluation. Laboratory testing includes reactive serologic testing; cerebrospinal fluid (CSF) VDRL (Venereal Disease Research Laboratory) testing, which is specific but not sensitive; and CSF positive for white blood cells or protein, or both. The CSF FTA-Abs (fluorescent treponemal antibody absorption) test is sensitive but less specific than CSF VDRL testing. Patients with latent, tertiary, or neurosyphilis should be tested for HIV infection.

Differential Diagnosis

Syphilis, which can affect every organ system, has historically been called the great mimicker. Syphilis is on the differential diagnosis of, most commonly, conditions causing genital ulcers or lesions, conditions causing systemic rashes affecting the palms and soles, conditions causing ocular and otologic manifestations (uveitis, sudden visual changes, hearing loss), and conditions causing dementia, meningitis, or ataxia.

Treatment

Penicillin G is the preferred treatment for all stages of syphilis; other forms of penicillin (oral penicillin, combinations of benzathine and procaine [Bicillin CR]) are not effective. The stage and extent of

clinical disease determine which preparation is used, the dosage, and the length of treatment (Table 1). In penicillin-allergic patients, antibiotic alternatives exist for all types and stages of syphilis except for syphilis in pregnancy and congenital syphilis.

Neurosyphilis is ideally treated with penicillin. Alternative treatment of primary and secondary syphilis and early latent syphilis includes doxycycline (Vibramycin) 100 mg orally twice a day or tetracycline 500 mg orally four times daily for 14 days. Ceftriaxone (Rocephin)¹ 1 g daily IM or IV for 10 to 14 days is also used, although data is limited regarding optimal dose and treatment duration. Azithromycin (Zithromax)¹ 2 g orally as a single dose may be used when treatment with both penicillin and doxycycline is contraindicated, although treatment failures have been reported and azithromycin is not appropriate treatment for MSM, HIV-infected patients, or in pregnancy. Penicillin-allergic patients with late latent syphilis can be treated with doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 28 days, recognizing that there is limited data to support this treatment. Treatment of penicillin-allergic patients with tertiary syphilis should be done in consultation with a specialist. Ceftriaxone¹ 2 g given IV or IM daily for 10 to 14 days has been described for the treatment of neurosyphilis in penicillin-allergic patients.

The Jarisch-Herxheimer reaction is an acute febrile reaction (with accompanying headache, myalgias, and other symptoms) occurring within 24 hours of treatment of syphilis. It is more common in early stages of syphilis and rare in newborns.

Monitoring

No definite criteria exist for either cure of syphilis or treatment failure. It is recommended that nontreponemal antibody titers be followed every 6 months, and patients should be periodically reexamined for clinical signs or symptoms of syphilitic infection. Treatment failure is probable in patients with either persistent or

¹Not FDA approved for this indication.

recurrent clinical signs or symptoms or a sustained fourfold increase in nontreponemal antibody titer (compared to maximum titer at time of treatment). Treatment failure is possible if nontreponemal antibody titers fail to decline fourfold within 6 months after treatment. Suspected treatment failure warrants retesting for neurosyphilis and HIV infection. Patients with HIV infection, with congenital syphilis, who are pregnant, or who have neurosyphilis warrant closer and more-specific laboratory and clinical follow-up. Full recommendations can be found in the Centers for Disease Control and Prevention (CDC) treatment guidelines (<http://www.cdc.gov/std/tg2015/syphilis.htm>).

Complications

Complications of syphilis are primarily related to neurologic involvement, tertiary syphilis, or late manifestations of congenital syphilis.

ACNE VULGARIS*Method of***Daniel J. Van Durme, MD, MPH; and Lisa M. Johnson, MD****CURRENT DIAGNOSIS**

- Acne vulgaris is primarily found in teenagers and young adults and is characterized by microcomedones that develop into open and closed comedones (blackheads and whiteheads) as well as inflammatory papules and pustules, or nodules and cysts.
- Acne vulgaris lesions are primarily on the face, neck, upper arms, back, and chest.
- Acneiform lesions are typically found in various stages, with many patients having a predominant type.

**CURRENT THERAPY**

- Acne therapy targets abnormal hyperkeratinization, excess sebum production, colonization by *Propionibacterium acnes*, and inflammation. Therapy involves prevention of new lesions and control over a long period of time with response generally seen in 6 to 8 weeks.
- Numerous topical and oral medications have demonstrated efficacy for patients with acne; there is little evidence for which is best.
- Benzoyl peroxide is an excellent starting agent owing to extensive safety and efficacy studies, its demonstrated benefit in controlling *P. acnes*, and some benefits in controlling abnormal keratinization and inflammation.
- Topical retinoids should also be considered as starting agents owing to their demonstrated benefits in controlling abnormal keratinization leading to microcomedones, a primary lesion in acne.
- Topical antibiotics such as clindamycin (Cleocin-T) and erythromycin (Akne-Mycin) should be used in combination with topical retinoids for more efficacy or with benzoyl peroxide to decrease the likelihood of bacterial resistance.
- Oral antibiotics such as doxycycline (Vibramycin) should be used if acne is widespread or unresponsive to topical agents.
- Oral contraceptives have proven benefits for most types of acne.
- Oral isotretinoin (Accutane, Claravis) can be very effective and even cures many patients, but the teratogenic and other side effects are profound and mandate use with extreme caution.

Acne (or acne vulgaris) and rosacea (previously called acne rosacea and sometimes adult acne) are often thought of together. However, they actually represent different pathophysiologic processes and require different therapeutic approaches.

Epidemiology

Acne is a chronic inflammatory dermatosis that is most common in adolescents, affecting approximately 85% of teenagers with the

average age of onset being 11 to 12 years of age, peaking at ages 15 to 17, and decreasing with age. It is typically worse in male patients. The severity varies widely. Although significant physical scarring is uncommon, the psychological burden may be severe and includes depression, anxiety, social withdrawal, and suicidal ideation. More severe forms of acne are found in those with a genetic predisposition and those with earlier onset.

Prevention

Cigarette smoking raises acne risk, and the severity increases in a dose-dependent fashion. There are many myths, anecdotes, and limited (flawed) studies regarding acne and its triggers, but there is no good evidence to date to support the roles of chocolate, greasy foods, or other dietary factors in causing acne. There is some evidence that dairy products (particularly milk) might contribute to acne, but others have questioned the strength of these studies.

Pathophysiology

The pathophysiology of acne involves androgens as a major contributing factor, and thus acne starts with puberty. Four intersecting pathophysiologic processes are involved in acne, and the sequence and degree of contribution of each factor is still under study. The lesions begin with abnormal keratinization of the pilosebaceous glands that are more concentrated on the face, neck, and trunk. The keratin that lines the opening of the glands becomes more cohesive; this blocks the gland from being able to adequately excrete the sebum, and the plugged opening dilates. This leads to a closed comedone (whitehead) or open comedone (blackhead). Additional factors include the proliferation of the gram-positive *Propionibacterium acnes* (*P. acnes*) and an increase in inflammatory mediators, such as cytokines, leukotrienes, lymphocytes, and macrophages, which lead to the papules and pustules of inflammatory acne. Finally, the abnormal and excess production of sebum, particularly triggered by androgens, can play a key role as well, notably in nodulocystic acne.

Diagnosis

Diagnosis is generally straightforward, especially in teenagers. Dermatologic lesions include open and closed comedones, pustules, inflammatory papules, nodules, and cysts. Lesions are primarily found on the face, neck, upper arms, back, and chest. They are typically found in various stages, and many patients have a predominant type.

Clinical Manifestations

Clinical manifestations include open and closed comedones (blackheads and whiteheads), inflammatory papules and pustules, and in severe cases, nodules and cysts. There are several proposed classification schemes to help identify the numbers and types of lesions. Perhaps the most useful combines an estimate of the numbers of lesions with a descriptor of the lesions and location. Thus, a patient can have mild (few lesions) papulopustular acne of the face and severe (many lesions) comedonal acne on the back and shoulders. This classification helps to identify optimal treatment and provide a better description to assess response to therapy.

Differential Diagnosis

Differential diagnosis should include drug-induced acne (especially from steroids), which can be identified by seeing all lesions at nearly

the same stage of development. Rosacea should also be considered in the differential diagnosis of acne vulgaris, though the age of onset and symptomatology are usually distinguishing.

Treatment

Treatment of acne begins with careful patient education and often involves a negotiation of management with teenagers who are taking responsibility for their health for the first time. It is increasingly important to address myths and misperceptions that they might hear from others or find on the Internet (such as the use of toothpaste for acne as seen on YouTube). Additionally, it is key to set realistic expectations about how acne can be controlled with the regular use of a variety of agents and how it can take 6 to 8 weeks to see improvement. If these issues are not addressed, the likelihood of adherence and long-term improvement are low.

Medical treatment should begin with a benzoyl peroxide agent because these are available over the counter and have an extensive history of safety and efficacy. They are available in a wide range of vehicles (soaps, lotions, gels); strengths vary from 2.5% to 10%. Many patients go straight to the maximum strength and report significant irritation, so it is important to educate that higher strengths dry the skin but are otherwise no more effective against *P. acnes* than the lower strengths. Patients should be advised that this reflects the base of treatment upon which other agents are added. Benzoyl peroxide plays a key role as a combination with both topical and oral antibiotics in preventing the development of bacterial resistance. If necessary, the patient can use it every other day to develop a tolerance to any irritation and gradually work up to once- or twice-daily dosing.

Topical retinoids (tretinoin [Retin-A, Renova, Avita], adapalene [Differin], or tazarotene [Tazorac]) are all extremely effective for abnormal keratinization and comedone development and thus treat existing lesions and prevent the development of new lesions. These can be irritating and come in a variety of strengths. Patients might need to start at the lowest strength with every-other-day dosing and work up to the highest strength needed and tolerated. Some formulations of tretinoin (primarily generic products) are not photo stable and should be applied in the evening. All are contraindicated in pregnancy.

Salicylic acid preparations are comedolytic and can be used for patients who cannot tolerate either benzoyl peroxide or topical retinoids, although salicylic acid preparations have not been shown to be as effective.

For patients with moderate inflammatory and comedonal lesions, it can be appropriate to start both benzoyl peroxide and topical retinoids at the initial visit; however, the applications should be separated in time because the benzoyl peroxide will inactivate the retinoid. An effective regimen (if tolerated) is a benzoyl peroxide wash in the morning and topical retinoid at bedtime.

Antibiotics should be added if response to topical benzoyl peroxide and retinoids is inadequate at the 6- to 8-week follow-up visit. Topical clindamycin (Cleocin-T) and erythromycin (Akne-Mycin) have demonstrated efficacy and can be used twice a day at the same time as the benzoyl peroxide. There are also combination agents that conveniently add the two agents into a single preparation: clindamycin 1% plus benzoyl peroxide 5% gel (BenzaClin, Duac) and erythromycin 3% plus benzoyl peroxide 5% gel (Benzamycin). They are more expensive, however.

Oral antibiotics should be started if the acne is moderate to severe, if it is too widespread to reasonably cover with topical antibiotics, or if there is an inadequate response after 6 to 8 weeks of topical antibiotics. Effective oral agents include the tetracyclines, macrolides, and trimethoprim-sulfamethoxazole (TMP-SMX [Bactrim])¹; however, side effects of each must be considered, and bacterial resistance is an increasing issue.

Doxycycline (Vibramycin) at 100 mg/day is generally considered the optimal antibiotic despite some issues with photosensitivity. Minocycline (Minocin) at 100 mg twice daily has side effects that include pigment deposition in skin, mucous membranes, and teeth (as well as rare autoimmune hepatitis and other problems).

¹Not FDA approved for this indication.

TMP-SMX (Bactrim, Septra DS)¹ taken twice daily also has side effects to consider but can be useful when other agents are not tolerated. Macrolides, particularly erythromycin (Ery-Tab),¹ have had the most problems with bacterial resistance. For this reason, they should be reserved for pregnant patients or when other agents cannot be used and should always be used with benzoyl peroxide to minimize that resistance. All oral agents should be used in combination with benzoyl peroxide and/or a topical retinoid but not in combination with topical antibiotics. If significant improvement is noted, oral agents should be decreased after 3 to 4 months and stopped in order to attempt maintenance control with topical agents.

Oral contraceptives can be very helpful in female patients with moderate acne owing to their antiandrogenic effects, which decrease sebum production. There are currently 4 combined oral contraceptives approved by the FDA for the treatment of acne. They are ethinyl estradiol/norgestimate (Orthotricyclen), ethinyl estradiol/norethindrone acetate/ferrous fumarate (Estrostep Fe, Tilia Fe, Tri-Legest Fe), ethinyl estradiol/drospirenone (Yasmin, Yaz), and ethinyl estradiol/drospirenone/levomefolate (Beyaz, Rajani).

Several other topical agents have shown benefit for acne, including azelaic acid (Azelex, Finacea) used twice a day. It seems less effective than other agents, but can be useful when multiple types of lesions are present. It can also cause gradual hypopigmentation, which may be helpful in those with inflammatory hyperpigmentation. Topical sulfacetamide 10% (Klaron)¹ applied twice daily has also shown benefit.

Oral isotretinoin (Accutane, Claravis) has demonstrated marked benefit for patients with severe recalcitrant acne, even inducing a full remission. It is a potent teratogen and has a host of other significant side effects, including cheilitis, epistaxis, photosensitivity, and many others. Prescribed at 0.5 to 2 mg/kg per day over 20 weeks, it is like chemotherapy for acne. It is extremely tightly regulated, and both prescribers and patients must register with the iPledge program in order to write for the medicine and to receive the prescriptions. See www.ipledgeprogram.com. When all the precautions are managed, it can be an extremely effective option for the patients with the worst cases of acne.

¹Not FDA approved for this indication.

ATOPIC DERMATITIS

Method of

Peck Y. Ong, MD

CURRENT DIAGNOSIS

- Itch must be present for the diagnosis of atopic dermatitis. In addition, the diagnosis must include three or more of the following criteria (U.K. Working Party's Diagnostic Criteria for Atopic Dermatitis):
 - History of generalized dry skin
 - Visible flexural dermatitis
 - Onset of the skin condition before 2 years (not used for patients younger than 4 years)
 - History of itchy skin involving the following areas: elbows, behind knees, front of ankles, or around the neck

the same stage of development. Rosacea should also be considered in the differential diagnosis of acne vulgaris, though the age of onset and symptomatology are usually distinguishing.

Treatment

Treatment of acne begins with careful patient education and often involves a negotiation of management with teenagers who are taking responsibility for their health for the first time. ATOPIC DERMATITIS

Method of

Peck Y. Ong, MD

CURRENT DIAGNOSIS

- Itch must be present for the diagnosis of atopic dermatitis. In addition, the diagnosis must include three or more of the following criteria (U.K. Working Party's Diagnostic Criteria for Atopic Dermatitis):
 - History of generalized dry skin
 - Visible flexural dermatitis
 - Onset of the skin condition before 2 years (not used for patients younger than 4 years)
 - History of itchy skin involving the following areas: elbows, behind knees, front of ankles, or around the neck

- History of asthma or allergic rhinitis (or for children younger than 4 years, history of atopic disease in a first-degree relative)

CURRENT THERAPY

- Bathe or shower for 10 to 20 minutes daily and pat dry gently.
- Follow immediately by applying an emollient on unaffected areas and an antiinflammatory medication on affected areas.
- Use topical corticosteroids as a first-line antiinflammatory medication; alternative medications are topical calcineurin inhibitors, topical phosphodiesterase 4 inhibitor or dupilumab (Dupixent).
- Avoid environmental triggers such as extreme heat, humidity, or dryness.
- Avoid food allergens that may cause anaphylaxis. Consult an allergist regarding the interpretation of serum-specific IgE tests or food challenge.
- Treat skin infection only when clinical signs are present (e.g., oozing, impetigo).
- Severe, generalized infection or vesicular lesions may indicate herpes simplex virus infection; persistent fever may indicate invasive *S. aureus* infection.

Atopic dermatitis (AD) is a chronic inflammatory skin disease that is characterized by itch and a predilection of eczema on extensor areas in young infants or flexural areas in older children and adults. In the United States, AD affects about 15% of children and 2% of adults. For more than 85% of patients, AD begins during the first 5 years, but 50% of the children with AD improve significantly or outgrow the disease by age 7. The persistence of AD depends on various factors: early onset, severity, family history of AD, personal history of asthma, and food or inhalant allergies.

The itch associated with AD causes significant discomfort in these patients and often leads to sleep loss and to poor school or work performance. The quality of life of children with generalized AD is worse than that for children with diabetes, epilepsy, asthma, cystic fibrosis, or renal disease. The maternal stress in taking care of children with moderate to severe AD is equivalent to that associated with care of children with diabetes, Rett syndrome, profound deafness, or the need for enteral feeding.

Pathophysiology

AD is caused by a combination of genetic and environmental factors. Patients with AD have a defective skin barrier. This leads to a loss of skin hydration and susceptibility to environmental triggers. There is evidence that the skin barrier defects of AD are caused by genetic mutations. Studies have shown that many AD patients carry a genetic mutation in filaggrin, a protein with important barrier function.

Potential external triggers of AD include microbial pathogens and environmental allergens. Almost 100% of AD skin lesions are colonized by *Staphylococcus aureus*, which may produce toxins that trigger immune response in the skin. As a result, AD patients produce an increased amount of pro-allergic cytokines, such as interleukin-4 (IL-4), IL-5, and IL-13, in their skin. These cytokines lead to an increased infiltration of inflammatory T cells and eosinophils. IL-4 and IL-13 also are important for the production of serum IgE, the level of which is elevated in AD patients.

Diagnosis and Clinical Assessment

Most AD patients can be diagnosed by clinical history and physical examination. Typical presentation includes itch, dryness, flexural dermatitis, early age of onset, and atopy such as multiple food allergies. Patients with generalized eczema or adult-onset eczema can present as a diagnostic challenge. The differential diagnosis includes immunodeficiency (e.g., hyper-IgE syndrome, Omenn syndrome), malignancy (e.g., cutaneous T-cell lymphoma), zinc

TABLE 1 Differential Diagnoses of Atopic Dermatitis

DISEASE CATEGORY	DIFFERENTIAL DIAGNOSES
Dermatologic diseases	Contact dermatitis, seborrheic dermatitis, psoriasis, dyshidrotic eczema, eosinophilic pustular folliculitis, ichthyosis vulgaris
Neoplastic diseases	Cutaneous T-cell lymphoma, Langerhans cell histiocytosis
Immunodeficiencies	Hyper-IgE syndrome, severe combined immunodeficiency, Omenn syndrome, IPEX (immune dysregulation, polyendocrinopathy, enteropathy X-linked) syndrome
Infectious diseases	Scabies, cutaneous candidiasis, tinea versicolor
Nutritional deficiencies	Acrodermatitis enteropathica (zinc deficiency), essential fatty acid deficiency, biotin deficiency
Multisystemic disorders	Netherton syndrome, dermatitis herpetiformis

deficiency (i.e., acrodermatitis enteropathica), and celiac-associated dermatitis (i.e., dermatitis herpetiformis) (Table 1). AD children seldom present with failure to thrive, unless they are under severe dietary restriction. Failure to thrive should therefore prompt further investigation. Punch skin biopsies may be needed when the diagnosis is still unclear.

The prevalence of mild, moderate, and severe AD is 80%, 18%, and 2%, respectively. Most patients with mild to moderate disease have flexural, extensor, or facial involvement, whereas patients with severe disease often present with total-body involvement with or without erythroderma (Figure 1). Validated scales for assessing the severity of AD include Scoring of Atopic Dermatitis (SCORAD) and Eczema Area and Severity Index (EASI). These scoring systems or a simplified diagram documenting the extent of dermatitis are useful for more objective follow-up of the patient's progress.

Figure 1 Generalized atopic dermatitis.

Management of Atopic Dermatitis and Associated Conditions

Daily Maintenance Care

Changes in humidity can adversely affect AD symptoms. Dry conditions lead to increased transepidermal water loss and dry AD skin. Extreme heat, humidity, and sweating may lead to irritation of AD skin. AD patients are at increased risk for contact or irritant dermatitis, which may occur with over-the-counter topical skin medications that contain multiple ingredients. Wool or synthetic acrylic fabrics may also be irritating to AD skin.

To improve barrier function, AD patients should bathe or shower for 10 to 20 minutes once or twice daily, followed immediately by gently drying the skin and applying an emollient on the unaffected areas and a topical antiinflammatory medication on the affected areas. A petrolatum-based emollient is recommended in infants and young children because of its occlusive property. In older children and adults, the ointment may not be tolerated well because of its greasy feel, and another emollient or moisturizer may be chosen based on the patient's preference or experience.

Itch may continue to be a problem even if the rash has improved. The mechanisms of itch in AD are not fully understood but do not appear to be mediated solely by histamine. The use of first-generation antihistamines (diphenhydramine [Benadryl]¹ and hydroxyzine [Vistaril]) in AD largely depend on their sedative effects and are best used at bedtime. The second-generation, non-sedating antihistamines such as loratadine (Claritin)¹ and cetirizine (Zyrtec)¹ have not proved helpful in treating AD. Low-dose doxepin has been used anecdotally to treat itching in AD.

Topical and Systemic Medications

The first-line medication for AD is a topical corticosteroid (TCS). For mild AD, a TCS with group VI and VII potency (Table 2) may suffice. However, for moderate to severe AD, a TCS with at least group III to V potency is chosen to increase efficacy and to shorten the duration of need for these medications.

The use of TCS is confronted with various obstacles, including rare side effects such as skin atrophy, but mostly patients' or parents' misunderstanding of TCS. Studies have shown that twice-daily use of fluticasone propionate (Cutivate) 0.05% cream (group V) and desonide (DesOwen, Tridesilon) 0.05% ointment or aqueous gel (group V and VI, respectively) continuously up to 1 month in young children with AD results in no significant adverse effect. It is therefore important to clarify for patients or parents the safety and side effects based on the potency of the TCS.

¹Not FDA approved for this indication.

Topical calcineurin inhibitors (TCI) (pimecrolimus [Elidel] 1% cream and Protopic/tacrolimus ointment) are alternative nonsteroidal antiinflammatory medications for AD. Elidel is indicated for mild to moderate AD in patients older than 2 years, whereas 0.03% and 0.1% Protopic are indicated for moderate to severe AD in patients 2 to 15 years old and in patients 16 years old or older, respectively. Both Elidel and Protopic have an FDA black box warning saying that their long-term use may be associated with cancer risk. However, a recent large longitudinal study has failed to confirm this risk. These medications continue to be useful alternatives for skin areas that are prone to atrophy, including the face, axillae, and groins.

A third class of topical medication, phosphodiesterase 4 inhibitor (crisaborole [Eucrisa] 2% ointment), has been approved by the FDA for patients 2 years and older with mild to moderate AD. A biologic dupilumab (Dupixent), which targets IL-4 and IL-13, has also been approved by the FDA for adults with moderate to severe AD.

Wet-wrap treatment, phototherapy, and systemic immunosuppressive therapies (e.g., cyclosporine [Sandimmune, Neoral],¹ azathioprine [Imuran],¹ methotrexate [Trexall],¹ and mycophenolate mofetil [CellCept])¹ are alternatives, but not approved by FDA, for severe AD patients. Because of the potential serious adverse effects associated with these treatments, referral to an allergist or dermatologist is recommended before their initiation.

Systemic corticosteroids usually are not recommended for AD because of their known adverse effects, including stunted growth in children, adrenal suppression, osteoporosis, and cataracts. A rebound of AD symptoms is common after the medication is stopped. If a systemic corticosteroid is used, it should be tapered over a short period (e.g., a week) while topical antiinflammatory treatment is intensified.

The efficacy and side effects of the following medications have not been established in AD: intravenous immunoglobulin (IVIG),¹ anti-IgE (omalizumab [Xolair]),¹ probiotics,⁷ montelukast (Singulair),¹ Chinese medicinal herbs,⁷ and fish oils.¹

Food Allergies

At least 30% of children with moderate to severe AD have one or more food allergies, compared with 4% to 6% of the general population. Accurate diagnosis of food allergies in AD patients is crucial because it can prevent life-threatening anaphylaxis or unnecessary food restriction.

The diagnosis of food allergy involves one or more of the following: history taking, skin tests, serum-specific IgE tests, and food

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

TABLE 2 Classification of Topical Corticosteroids Based on Potency

GROUP	TOPICAL CORTICOSTEROIDS
I (most potent)	Clobetasol propionate 0.05% (Temovate) (cream, ointment, gel), betamethasone dipropionate, augmented 0.05% (Diprolene) (cream, ointment), diflorasone diacetate 0.05% (Psorcon) (ointment)
II	Amcinonide 0.1% (Cyclocort) (ointment), betamethasone dipropionate 0.05% (Diprosone) (ointment), mometasone furoate 0.1% (Elocon) (ointment), halcinonide 0.1% (Halog) (cream), fluocinonide 0.05% (Lidex) (gel, cream, ointment), desoximetasone (Topicort) (0.05% gel, 0.25% cream, 0.25% ointment)
III	Fluticasone propionate 0.005% (Cutivate) (ointment), amcinonide 0.1% (Cyclocort) (lotion, cream), diflorasone diacetate 0.05% (Florone) (cream), betamethasone valerate 0.1% (Valisone) (ointment)
IV	Flurandrenolide 0.05% (Cordran) (ointment), mometasone furoate 0.1% (Elocon) (cream), triamcinolone acetonide 0.1% (Kenalog) (cream), fluocinolone acetonide 0.025% (Synalar) (ointment), hydrocortisone valerate 0.2% (Westcort) (ointment)
V	Flurandrenolide 0.05% (Cordran) (cream), fluticasone propionate 0.05% (Cutivate) (cream), hydrocortisone butyrate 0.1% (Locoid) (cream), fluocinolone acetonide 0.025% (Synalar) (cream), desonide 0.05% (Tridesilon) (ointment), betamethasone valerate 0.1% (Valisone) (cream), hydrocortisone valerate 0.2% (Westcort) (cream), prednicarbate 0.1% (Dermatop) (cream)
VI	Alclometasone dipropionate 0.05% (Aclovate) (cream, ointment), fluocinolone acetonide 0.01% (Synalar) (solution, cream) (Derma-Smooth/FS Oil), Desonide 0.05% (Tridesilon) (cream and aqueous gel)
VII (least potent)	Hydrocortisone 1%/2.5% (lotion, cream, ointment).

Data from Stoughton RB. Vasoconstrictor assay—specific applications. In Maibach HI, Surber C, editors. *Topical Corticosteroids*. Basel, Switzerland: Karger, 1992, pp 42–53.

challenge. History taking is helpful in the diagnosis of food allergy in most patients. It is often useful to begin by asking the patients whether they have any problems or reactions with any of the seven food allergens: milk, egg, peanut, wheat, soybean, seafood, and tree nuts. These foods account for more than 90% of food allergies. Almost all food allergic reactions occur in the first hour. AD patients may complain of immediate worsening of itching after ingestion. Symptoms of anaphylactic reactions include throat-clearing, cough, shortness of breath, vomiting, dizziness, fainting, and headache, which may be attributed to hypotension. Most food allergic reactions also manifest with skin symptoms, including hives, swelling, or generalized itching.

Skin tests are useful in the context of negative test results because they have a negative predictive value of more than 95%. A positive test result has only a 50% positive predictive value.

Quantitative serum-specific IgE antibodies (ImmunoCAP, Phadia) have become useful in the diagnosis of food allergies because of their high positive predictive values (Table 3). These tests are also useful for deciding whether a food challenge is necessary to confirm the diagnosis.

Although history, skin tests, and serum-specific IgE values are useful in the diagnosis of food allergy, a double-blind, placebo-controlled food challenge remains the gold standard in diagnosing food allergy. Food challenge should be done in consultation with an allergist because of the risk of anaphylaxis.

Patients with confirmed food allergy should avoid any amount of the food allergen. Parents or patients should be instructed to read food allergen labels carefully. All packaged foods in the United States are required to label the contents of milk, eggs, peanuts, wheat, soybeans, fish, shellfish, or tree nuts. Organizations, such as the Food Allergy Research & Education, can provide patients and parents with useful information on potential hidden food allergens and alternative food sources.

AD children often have multiple food allergies, including cow's milk and soy, and the use of a hydrolyzed or amino acid-based formula can provide an alternative source of nutrition. For these patients, consultation with a dietitian can be helpful in managing food avoidance and nutrition needs.

Patients or parents of children with anaphylactic reactions should be prescribed and instructed on the use of an epinephrine autoinjector (EpiPen or Auvi-Q 0.15 mg for patients who weigh more than 15 kg but less than 30 kg; 0.3 mg for patients who weigh 30 kg or more, while Auvi-Q 0.1 mg for patients who weigh 7.5–15 kg).

Infants with severe AD who consume peanut products early have a 86% relative risk reduction in the development of peanut allergy. For any infants with AD under a year, clinicians should consider introducing peanut products early in their diet according to the guidelines of National Institute of Allergy and Infectious Disease, or consult an allergist.

Infections

Most AD patients are colonized by *S. aureus* on their skin lesions or in their nostrils. The frequency of colonization increases with AD severity. Exacerbation of AD is frequently associated with secondary *S. aureus* skin infections. Other common skin pathogens in AD include group A β -hemolytic *Streptococcus* and herpes simplex virus (HSV), which causes eczema herpeticum (Figure 2). Many reports have documented invasive *S. aureus* infections such as

Figure 2 Eczema herpeticum.

bacteremia, septic arthritis, osteomyelitis, and endocarditis in AD patients. Persistent fever or focal limb pain should alert the physician to the possibility of these infections.

The reasons for the high rate of bacterial colonization and skin infections in AD are not completely understood. A defective skin barrier and decreased cutaneous innate immunity (i.e., deficiency in natural skin antibiotics) likely contribute to the frequency of skin infections in patients with AD.

Because of the concern about increasing bacterial resistance, antibiotics are not recommended for treating *S. aureus* colonization in patients with AD. Treating AD patients with methicillin-resistant *S. aureus* (MRSA) can be challenging, due to possibly recolonization from family contacts. Decolonization may be effective but controversial.

Inhalant Allergies and Asthma

Eighty-five percent of AD infants have concurrent respiratory allergies or are at risk for allergic rhinitis or asthma. However, whether inhalant allergens lead to a worsening of AD remains controversial. Randomized, double-blind, placebo-controlled studies have shown positive and negative effects of house dust mites (HDM) as a trigger for AD symptoms. Because there is no serious side effect associated with the use of HDM-proof bed and pillow encasings, unless cost is an issue, these encasings are recommended for AD patients with HDM sensitization. Further research is needed to confirm the role of inhalant allergens, including furry pets and pollens, as triggers for AD.

Investigational Treatments for Atopic Dermatitis

Because of the concern about potential side effects associated with existing therapies of AD, several agents are being investigated for the treatment of AD. They include anti-IL-13, anti-IL-22, anti-IL-31, and Janus kinase (JAK) inhibitors. Kappa opioid receptor agonists, systemic chymase inhibitors, and cannabinoid receptor agonists are potential anti-itch medications for AD. With improved understanding of the pathophysiology of AD, treatments for AD are likely going to be personalized in the future.

TABLE 3 Predictability of ImmunoCAP-Specific IgE

REACTION*	MILK	SOY	EGG	WHEAT	PEANUT	FISH	TREE NUTS
Reaction highly probable	>15 kU/L	>60 kU/L	>7 kU/L	>80 kU/L	>14 kU/L	>20 kU/L	>15 kU/L
Reaction highly probable (young children)	>5 kU/L (<1 y)		>2 kU/L (<2 y)				

*Because of their high positive predictive values, quantitative serum-specific IgE antibodies are used in the diagnosis of food allergies.

BACTERIAL DISEASES OF THE SKIN

Method of

Dennis L. Stevens, MD, PhD

CURRENT DIAGNOSIS

- Most infections are superficial and local and not associated with systemic toxicity.
- Deeper infections may involve many layers of the soft tissues, including fascia and muscle.
- Systemic toxicity is always present in deeper infections.
- Rapid advancement of the local infection with areas of necrosis indicates more serious infections, including necrotizing and gangrenous processes.
- Streptococci and clostridial microorganisms are the cause of most gangrenous infections.
- Mixed aerobic and anaerobic microflora cause most necrotizing infections.

CURRENT THERAPY

- Local care and oral antibiotics chosen for the suspected or culture-proven pathogens are the usual treatments for most limited skin infections.
- Infections that show evidence of rapid advancement associated with bullae, blebs, crepitus, or necrosis require parenterally administered antibiotics and prompt surgical débridement.
- Morbidity and mortality rates associated with the deeper infections increase with delays in antibiotic therapy and surgical débridement.
- Antibiotic therapy should be guided by clinical presentation and changed if necessary when culture and sensitivity studies are available.

The spectrum of bacterial diseases of the skin ranges from superficial, localized, easily recognized, and treated skin eruptions to deep, aggressive, gangrenous, or necrotizing infections that may appear innocuous at first but quickly become life threatening.

The prompt recognition and treatment of these infections are paramount in limiting morbidity and mortality. A healthy respect for the aggressiveness of gangrenous and necrotizing infections of the skin and soft tissues is developed by first harboring a high index of suspicion to provide early recognition and appropriate treatment before overwhelming clinical infection occurs.

Common Infections

Impetigo

Impetigo is the most common bacterial infection of the skin. It is highly contagious and can occur at any age from infancy to adulthood, but it is most common in preschool-age children. There are two classic forms of impetigo: nonbullous and bullous. Both forms have a predominantly staphylococcal cause, but they manifest with different morphologic characteristics.

Nonbullous (crusted) impetigo can be recognized by the development of a serous, yellow-brown exudate, which dries into a golden crust. Lesions rarely elicit pain but can be associated with erythema and pruritus. They are most common on exposed areas such as the hands, feet, face, and legs and are often associated with a minor traumatic event such as an insect bite, abrasion, or laceration. Crusted impetigo is usually caused by a heavy mixed flora of staphylococci and streptococci. Streptococcal impetigo has been associated with the postinfectious sequelae of post-streptococcal glomerulonephritis.

The bullous variety usually manifests as a rapidly spreading papule, which may progress to a thin-walled vesicle if the lesion is infected with *Staphylococcus aureus*, an organism that produces an exfoliative toxin. These lesions occur most often in warm, moist areas of the body. Predisposing factors include warm ambient temperatures, humidity, poor hygiene, and crowded living conditions.

Treatment of impetigo begins with eradication of the environmental factors thought to be influential in its development. Aggressive lesion débridement with mesh gauze sponges or brushes and antibacterial soap is encouraged. Special attention to hygiene and disinfection of towels and bedding are also necessary. Topical antibiotic treatment with mupirocin (Bactroban) or bacitracin¹ has been effective in mild to moderate cases. In more extensive cases, oral antibiotic therapy with a penicillinase-resistant synthetic penicillin (oxacillin) is the treatment of choice (Table 1). However, a high percentage of methicillin-resistant strains of *S. aureus* (MRSA) are isolated in institutional and community settings. Patients should be treated for at least 5 to 7 days. If no improvement is seen, lesions should be cultured and antibiotics adjusted appropriately.

Systemic complications from impetigo are very uncommon. Cellulitis has occurred but is usually susceptible to systemic antibiotic therapy. Septicemia and staphylococcal scaled skin syndrome are rare complications of impetigo. When they occur, systemic therapy is indicated.

Folliculitis

Folliculitis is a pyoderma that arises within a hair follicle. The process is known as a furuncle (boil) when the infection extends beyond the hair follicle. These lesions occur most frequently in the moist areas of the body and in areas subject to friction and perspiration. Host factors known to predispose one to folliculitis include obesity, blood dyscrasias, defects in neutrophil function, immune deficiency states (e.g., diabetes, transplantation-related immunosuppression, acquired immunodeficiency syndrome [AIDS]), and treatment with corticosteroids or cytotoxic agents. The offending organism in most immunocompetent patients is *S. aureus*; however, when immunosuppression impairs host defenses, gram-negative organisms (*Klebsiella*, *Enterobacter*, and *Proteus* species) can be involved. *Pseudomonas* species such as *aeruginosa* or *cepacia* are associated with hot-tub folliculitis, which involves numerous hair follicles. It is usually self-limited, resolving in 7 to 10 days.

Successful treatment of folliculitis depends on correcting the predisposing factors that promote the development of this condition. For patients with localized disease, topical wound care including

TABLE 1 Suggested Antibiotic Therapy for Gram-Positive Bacterial Isolates

ISOLATE	ORAL	PARENTERAL
GABHS	Penicillin G or V Erythromycin First-generation cephalosporin	Penicillin G Ampicillin/sulbactam (Unasyn) First-generation cephalosporin
<i>Staphylococcus aureus</i> (methicillin sensitive)	Penicillinase-resistant synthetic penicillin (Oxacillin)	First-generation cephalosporin Clindamycin (Cleocin) Oxacillin
<i>Staphylococcus aureus</i> (methicillin resistant)	Linezolid (Zyvox)	Vancomycin (Vancocin) Daptomycin (Cubicin) Linezolid (Zyvox) Ceftaroline (Teflaro)
Clostridial species	Penicillin G or V Clindamycin (Cleocin) Metronidazole (Flagyl)	Penicillin G Clindamycin Metronidazole

Abbreviation: GABHS = group A β -hemolytic *Streptococcus*.

antibiotics such as mupirocin (Bactroban) is effective. Patients with furunculosis or multiple lesions with surrounding erythema of more than 2.5 cm should be treated with orally administered systemic antibiotics that are effective against *S. aureus*. Any fluctuant nodules or abscesses should be incised and drained. Patients with recurrent furunculosis should have their nares cultured for methicillin-susceptible *Staphylococcus aureus* (MSSA) or MRSA because nose rubbing and self-inoculation are the usual means of developing infection. This not only determines which type of *Staphylococcus* is causing the infection, but illustrates to the patient the importance of self-inoculation. Intranasal bacitracin or mupirocin (Bactroban) and daily baths with chlorhexidine (Hibiclens) or hexachlorophene (PHisoHex) (adults only) may break the cycle of nasal colonization and reinfection.

Cellulitis

Cellulitis is an acute infection of the skin and underlying soft tissues. It commonly begins as a hot, red, edematous, sharply defined eruption and may progress to lymphangitis, lymphadenitis, or in severe cases, necrotizing fasciitis and gangrene. Cellulitis usually occurs in local skin trauma caused by insect bites, abrasions, surgical wounds, contusions, or other cutaneous lacerations. Immunosuppressed patients are particularly susceptible to the progression of cellulitis to regional or systemic infections, and these patients should be treated aggressively with systemic antibiotics, drainage, and débridement when indicated. Cellulitis is 20-fold more common in patients with chronic venous stasis or lymphedema. Recurrent cellulitis may occur in patients at the exact site of saphenous donor site surgery.

Initial presentation is that of a rapidly expanding, tender, erythematous, indurated area of skin. An ascending lymphangitis may be present, especially in cellulitis involving an extremity often associated with regional lymphadenopathy. Systemic signs and symptoms can eventually evolve and when present, mandate hospitalization and treatment with systemic antibiotics. Offending organisms are most commonly group A β -hemolytic *Streptococcus* (GABHS), other group A species, and group C and group G streptococcal species. The IDSA guidelines suggest that *S. aureus* is associated with purulent infections (e.g., localized abscesses, furuncles, or carbuncles) and not really cellulitis which is, of course, non-purulent. The redness around an abscess is not cellulitis but merely local inflammation. This is an important consideration in selecting treatment options. In diabetic patients, cellulitis can be caused by group B *Streptococcus*.

Localized processes are treated with oral antibiotics (see Table 1). If fever, septicemia, or other signs of advancement to

deeper tissues are present, the patient should be admitted to the hospital for blood and wound cultures, parenteral antibiotics (see Table 1), and observation. If a prompt response is not observed after parenteral antibiotic treatment, surgical exploration of the involved area may be indicated to establish an etiologic diagnosis and rule out the presence of necrotic or gangrenous tissue. Immunosuppressed patients or patients with recurrent cellulitis should be extensively examined to exclude chronic sources of infection, and these patients should be treated with parenteral antibiotics until the cellulitis resolves, followed by 5 to 7 days of oral antibiotics.

Abscess

Local skin signs and symptoms such as pain (dolor), redness (rubor), warmth (calor), and swelling (tumor) often denote an abscess and, like furunculosis, is usually caused by *S. aureus*. Loss of function associated with fluctuation may also indicate abscess formation. Localization of purulent fluid necessitates surgical drainage and local wound care. The administration of oral or parenteral antibiotic therapy should not be used routinely after incision and drainage of localized abscesses. They should be administered only when clinically indicated, and antibiotic therapy should be based on culture and sensitivity testing. Some recent studies suggest that oral treatment with trimethoprim/sulfamethoxazole (Bactrim)¹ improves resolution by about 24 hours and lessens but does not prevent the recurrence of infection.

Life-Threatening Infections

Group A β -Hemolytic Streptococcal Gangrene

Group A β -hemolytic streptococcal gangrene is an extremely rapidly progressing skin and soft tissue infection commonly caused by *Streptococcus pyogenes*. These organisms secrete hemolysins and streptolysins O and S, which are cardiotoxic, leukocytic, and responsible for the characteristic hemolysis. Gangrene results when the cutaneous blood vessels thrombose, a finding that is often associated with intense local pain. The involved skin is initially erythematous and indurated and quickly evolves to hemorrhagic blebs with focal necrotic zones. The potential for extensive tissue loss and mortality exists, especially if treatment is delayed. Prompt, aggressive tissue débridement and antibiotic therapy are necessary for a favorable outcome (see Table 1).

Synergistic Necrotizing Cellulitis

Synergistic necrotizing cellulitis (SNC) is an extremely aggressive, often lethal, polymicrobial infection of the skin and soft tissues that exhibits progressive invasion superficial to fascial planes. This condition may initially begin as a benign process with scant indication of its impending severity. The initial lesion is typically an erythematous, tender pustule or abscess with a small area of necrosis. The benign appearance of this lesion belies the widespread and aggressive tissue destruction that has occurred beneath it.

Direct inspection through skin incisions reveals extensive gangrene of the superficial tissues and fat that rarely involves the underlying fascia and muscles. These lesions characteristically exude a thin, brown, malodorous discharge, which manifests mixed flora with abundant polymorphonuclear leukocytes with a Gram stain. Crepitus, which is caused by the accumulation of gas in the tissue produced by facultative or obligate anaerobes, can be palpated in 25% of patients, and it mandates immediate surgical attention.

The most common site of involvement is the perineum, which is involved in 50% of patients with SNC. Predisposing factors include perirectal abscess and ischioanal abscess, both of which may track to the deeper structures of the pelvis, leading to abscess formation and subsequent septicemia. The thigh and leg are involved in approximately 40% of patients. This infection can occur after amputation and is usually associated with diabetes mellitus (75% of cases) or peripheral vascular disease (50% of cases).

¹Not FDA approved for this indication.

The relative immunosuppression and poor circulation that accompany these significant causes of morbidity are also responsible for upper extremity and neck SNC, which account for the remaining 10% of cases.

Synergistic necrotizing cellulitis is commonly caused by mixed flora originating in the gastrointestinal tract. Coliforms are the most prevalent aerobes (*Escherichia coli*, *Klebsiella*, *Proteus*), and anaerobic flora include *Bacteroides*, *Peptostreptococcus*, *Clostridium*, and *Fusobacterium*. The primary treatment modality is aggressive débridement of nonviable skin and subcutaneous tissues. This may involve several operations and dressing changes under general anesthesia, which should be performed until all necrotic tissue is removed. Rotation or free myocutaneous flaps and split-thickness skin grafting may cover areas of tissue loss when necessary. If the perineum is involved, fecal diversion by colostomy may be necessary to facilitate healing. Empiric parenteral antibiotics effective against polymicrobial gram-positive and gram-negative aerobic and anaerobic flora are also a mainstay of therapy. However, antibiotic coverage must be modified as soon as culture and susceptibility testing reveal specific offending organisms (Table 2) to reduce the emergence of resistant organisms.

Clostridial Myonecrosis

Clostridial myonecrosis (i.e., gas gangrene) is a destructive infectious process of muscle associated with infections of the skin and soft tissues. It is often associated with local crepitus and systemic signs of toxemia, which are caused by the anaerobic, gas-forming bacilli of the *Clostridium* species. This infection most often occurs after abdominal operations on the gastrointestinal tract; penetrating trauma, such as gunshot wounds, and frostbite can also expose muscle, fascia, and subcutaneous tissues to these organisms. Common to all these conditions is an environment containing tissue necrosis, low oxygen tension, and sufficient amounts of amino acids and calcium to allow germination of clostridial spores and production of the lethal α toxin.

Clostridia are gram-positive, spore-forming, obligate anaerobes that are widely found in soil contaminated with animal excreta. They have also been isolated in the human gastrointestinal tract and skin, most importantly in the perineum and oropharynx. *Clostridium perfringens* is the most common isolate (in 80% of cases) and is among the fastest growing clostridial species, having a generation time under ideal conditions of approximately 16 minutes. This organism produces collagenases and proteases that cause widespread tissue destruction and produces α toxin, which is associated with the high mortality rate of clostridial myonecrosis. The α toxin, a phospholipase C, causes platelet-neutrophil complexes, vascular obstruction, and extensive compromised vascular perfusion, leading to necrosis of the muscle and overlying fascia, skin, and subcutaneous tissues.

TABLE 2 Suggested Parenteral Antibiotic Therapy for Mixed Infections

ORGANISMS	PRIMARY CHOICE
Aerobic (must include an agent effective against anaerobic organisms)	Amikacin (Amikin) Aztreonam (Azactam) Ceftriaxone (Rocephin) Ciprofloxacin (Cipro) Gentamicin (Garamycin) Levofloxacin (Levaquin) Tobramycin (Nebcin)
Anaerobic (must include an agent effective against aerobic organisms)	Clindamycin (Cleocin) Metronidazole (Flagyl)
Aerobic and anaerobic	Ampicillin/sulbactam (Unasyn) Imipenem/cilastatin (Primaxin) Meropenem (Merrem) Piperacillin/tazobactam (Zosyn) Tigecycline (Tygacil)

Historically, clostridial myonecrosis was a disease associated with battle injuries, but 60% of current cases occur after trauma: 50% after automobile accidents and the remainder after crush injuries, industrial accidents, and gunshot wounds. Mortality can be the result of a failure to recognize that clostridial infection is underway, which leads to a delay in the débridement of devitalized tissues. Patients often complain of a sudden onset of pain at the site of trauma or surgical wound, which increases rapidly in severity and extends beyond the original borders of the wound. The skin initially exhibits tense edema, but its pale appearance progresses to a magenta hue. Hemorrhagic bullae and a thin, watery, foul-smelling discharge are common. A Gram stain examination of wound discharge reveals abundant gram-positive rods with a paucity of leukocytes.

The diagnosis of gas gangrene is based on the appearance of the muscle on direct visualization by surgical exposure, because many changes are not apparent when inspected through a small traumatic wound. Initially, the muscle is pale, edematous, and unresponsive to stimulation. As the disease process continues, the muscle becomes frankly gangrenous, black, and extremely friable. This occurs as a late event and is often accompanied by septicemia and shock. Despite profound hypotension and impending organ failure, these patients may be remarkably alert and extremely sensitive to their surroundings. They feel their impending doom and often panic just before slipping into toxic delirium and eventually into coma.

The clinical features should arouse suspicion early in the course, so the disease can be recognized and treated with aggressive surgical débridement. Gas in the wound is a relatively late finding, and by the time crepitation is observed, the patient may be near death. Approximately 15% of blood cultures are positive, but this is also a late finding. Serum creatinine kinase levels, although relatively nonspecific, are always elevated in cases with muscle involvement.

The mortality rate for gas gangrene is as high as 60%. It is highest in cases involving the abdominal wall and lowest in those affecting the extremities. Among the signs that prognosticate a poor outcome are leukopenia, thrombocytopenia, hemolysis, and severe renal failure. Myoglobinuria is common and can contribute significantly to worsening renal function. Frank hemorrhage may also be present and indicates disseminated intravascular coagulation.

Successful treatment of this life-threatening infection depends on early recognition and débridement of devitalized and infected tissues. Hyperbaric oxygen and systemic antibiotics are important adjuncts. Surgical intervention should include wide débridement of all necrotic tissue and amputation if extremities are involved. Hyperbaric oxygen (100% O₂ at 3 atm) has been reported to reduce associated tissue loss and mortality; however, core treatment is surgical débridement, and it should never be delayed to arrange for hyperbaric oxygen treatments. In animal studies of gas gangrene, hyperbaric oxygen was not efficacious, whereas clindamycin (Cleocin) treatment had dramatic effects in reducing mortality. A parenteral antibiotic is directed toward the offending organism (see Table 1). Clindamycin¹ is the treatment of choice because of its ability to suppress toxin production. Cardiovascular collapse mandates careful monitoring of intravenous fluid resuscitation, which may require large volumes. Failure to adequately resuscitate these patients compromises therapy by limiting oxygen delivery and antibiotic distribution to the affected tissues and may promote progression to multisystem organ failure.

A less life-threatening form of this disease is known as clostridial cellulitis. In this process, the bacterial tissue invasion is primarily superficial, extending to the fascial layer without muscle involvement. Prompt recognition and treatment can reduce morbidity and mortality. Spontaneous gas gangrene caused by *Clostridium septicum* can occur in the absence of trauma in patients with gastrointestinal lesions such as carcinoma of the colon.

Necrotizing Fasciitis

Necrotizing fasciitis is an aggressive soft tissue infection involving the fascia with extensive undermining and tracking along anatomic

¹Not FDA approved for this indication.

planes. Necrotizing fasciitis is probably an incorrect designation, since tissue from the deep muscles to the epidermis is generally destroyed. A better designation would likely be necrotizing infection. This process usually occurs in patients with significant comorbidity, such as diabetes mellitus or peripheral vascular disease, but it is also seen in obese or malnourished patients and intravenous drug abusers. Cellulitis is a frequent occurrence, and progressive necrosis of subcutaneous tissue results from thrombosis of the perforating vessels. Necrotizing fasciitis can be caused by single organisms such as GABHS and staphylococci (MRSA), *Vibrio vulnificus* or *Aeromonas hydrophila*, or a combination of a variety of organisms, including aerobic streptococci, staphylococci, and coliforms, as well as anaerobic *Peptostreptococcus* and *Bacteroides*. Ninety percent of these infections have a polymicrobial cause, and it is common to culture up to five organisms from the fascial planes involved with this infection.

Polymicrobial necrotizing fasciitis most commonly evolves from a benign-appearing skin lesion (80% of cases). Minor abrasions, insect bites, injection sites, and perirectal abscesses have been implicated. Rare cases have been reported in women with Bartholin's gland abscess, from which the infection has spread to fascial planes of the perineum and thigh. The remaining 20% of patients have no visible skin lesion. Surgical procedures, especially bowel resections, and penetrating trauma can be complicated by superficial wound infections that evolve into necrotizing fasciitis. The infection commonly involves the buttocks and perineum, which results from untreated perirectal abscesses or decubitus ulcers; intravenous drug abusers commonly participate in "skin popping," which leads to infections of the upper extremities.

Fifty percent of group A streptococcal necrotizing fasciitis patients have a portal of entry such as an insect bite, slivers, surgical procedures, or burns, whereas the other 50% have no portal of entry, and the infection begins at the exact site of nonpenetrating trauma, such as a muscle strain or bruise. This idiopathic form, commonly known as spontaneous necrotizing fasciitis, is particularly dangerous because of the frequent delay in diagnosis.

For those with a portal of entry, the initial presentation is a slowly advancing cellulitis that progresses to a firm, tense, woody feel of the subcutaneous tissues. This entity may be distinguished from other aggressive anaerobic soft tissue infections (e.g., SNC) by the brawny, pale, erythematous appearance of the skin overlying subcutaneous tissues that are unyielding, making fascial planes and muscle groups indistinguishable during palpation. Often, a broad, erythematous tract along the route of the underlying fascial plane can be discerned through the skin. If an open wound exists, probing the edges with a blunt instrument permits ready dissection of the superficial fascia well beyond the wound margins, and this is the most important diagnostic feature of necrotizing fasciitis. On direct inspection, the fascia is swollen and dull gray in appearance, with stringy areas of fat necrosis. A thin, brown exudate can be expressed from the wound, but frank purulent drainage is rare. These wounds are remarkably insensate when found and mandate immediate débridement.

As with other gangrenous soft tissue infections, the most important component of the treatment plan is aggressive, total débridement of all devitalized and necrotic tissue. This often necessitates frequent operations and dressing changes. Wide débridement and parenteral antibiotics have a profound effect on survival, and limited or staged débridement has no place in the treatment of this very aggressive, life-threatening infection. Parenteral antibiotics (see Table 2) should be directed against the polymicrobial aerobic and anaerobic microorganisms isolated from these infections. Every effort should be made to quickly identify the offending organisms, and antibiotic therapy should be changed accordingly.

In patients with no defined portal of entry, severe pain at the site of previous nonpenetrating trauma is common. Early in the course, there may be no cutaneous evidence of infection. Severe pain and fever may be the only presenting symptoms. These patients usually have a slightly elevated white blood cell count with a left shift and an elevated pulse. Later, erythema, induration, and warmth occur

and may rapidly progress to violaceous skin, ecchymosis, and blister formation. A markedly elevated creatine phosphokinase level in a patient with any erythematous rash may suggest a necrotizing process. By the time these late cutaneous findings are present, most patients have evidence of shock and organ failure. Misdiagnosis and delay in diagnosis are common and associated with significant morbidity and mortality. Surgical exploration with débridement of infected and necrotic tissue in addition to systemic antibiotic therapy directed toward the aerobic *Streptococcus* organism can result in decreased morbidity and mortality (see Table 1).

Special Circumstances

Fournier's Gangrene

Fournier's gangrene is a necrotizing fasciitis that originates as a necrotic black area on the scrotum of male patients or the labia of female patients, and it most often has a cryptogenic origin. In my experience, Fournier's gangrene occurs more commonly without a predisposing event or after routine, uncomplicated hemorrhoidectomy. Less commonly, this condition has occurred after urologic manipulation or as a late complication of deep anorectal suppuration.

Fournier's gangrene is characterized by necrosis of the skin and soft tissues of the scrotum or perineum and is associated with a fulminant, painful, and severely toxic infection. Definitive diagnosis is made by identification of a necrotic black area on the scrotum associated with local and systemic signs of infection. Left untreated, death ensues from uncontrolled, severe systemic sepsis and multiple-organ failure. Prompt recognition and treatment can minimize tissue loss, especially the skin and soft tissues of the scrotum or labia and perineum, and may prevent complete loss of genitalia.

The infection is often polymicrobial, as with necrotizing fasciitis, with several species of aerobic and anaerobic bacteria predominating. Successful treatment is based on early recognition and vigorous surgical débridement, occasionally including diversion of the fecal stream. Empiric treatment is appropriate until results of culture and susceptibility testing are available (see Table 2). The therapeutic benefit of hyperbaric oxygen treatments has not been proved, and it should be used only as an adjunct to surgical débridement.

Ecthyma Gangrenosum

Occasionally, hospitalized patients with overwhelming pseudomonal septicemia develop a patchy dermal and subcutaneous necrosis. Although sepsis caused by *Pseudomonas aeruginosa* is often indistinguishable from other types of gram-negative sepsis, a characteristic skin lesion may develop with erythematous macular eruptions that quickly become bullous with central ulceration and necrosis. This lesion may resemble a decubitus ulcer with the characteristic black eschar. There are usually multiple lesions occurring in different stages of development. They may concentrate on the extremities or the gluteal region. These lesions may be distinguished from the lesions of pyoderma gangrenosum (a noninfectious dermatosis) by their association with clinical signs of infection (i.e., fever and leukocytosis) in addition to the isolation of *P. aeruginosa* from culture of the lesion.

Treatment is primarily administration of antimicrobial therapy effective against the *Pseudomonas* organism and by débridement of the multiple lesions. This may lessen the bacterial burden, perhaps allowing greater antibiotic efficacy.

Sea Water and Fresh Water Infections

Infections caused by *V. vulnificus* and *A. hydrophila* can be extremely aggressive, with necrosis often occurring within hours and necessitating rapid, wide débridement. Although infections caused by these organisms cannot be differentiated from those caused by mixed infections, a history of exposure to sea water (*V. vulnificus*) or fresh water (*A. hydrophila*) and the rapidity with which the infection spreads often suggest the cause of the infection. The antibiotics of choice for *V. vulnificus* infection are doxycycline (Vibramycin) or tetracycline and an aminoglycoside. In patients with impaired renal function, chloramphenicol (Chloromycetin)

may be used. *A. hydrophila* is susceptible to cephalosporins such as ceftazidime (Fortaz), cefuroxime (Ceftin), and fluoroquinolones such as levofloxacin (Levaquin) and ciprofloxacin (Cipro).

Conclusion

The many types of soft tissue infections caused by bacteria may be distinguished by their presenting signs, symptoms, and body location and by the time course of the pathologic processes unique to each. Early recognition is of paramount importance to an effective treatment plan, which most often includes aggressive surgical débridement and specific antimicrobial therapy. This approach can often minimize tissue damage and promote recovery.

Epidemiology

The primary lesion in bullous diseases is a vesicle or a bulla. Autoimmune bullous diseases result from immune dysregulation that increases with age, hence the incidence of autoimmune bullous diseases is higher in the elderly. This group of disorders is heterogeneous, and generalizations about the epidemiology cannot be made.

Risk Factors

In general, predisposition to autoimmune bullous diseases is genetic and manifests as loss of tolerance toward self antigens followed by a T-cell and B-cell response resulting in antibody production. Age may be a risk factor in the development of bullous pemphigoid and mucous membrane pemphigoid. Pemphigus vulgaris has a higher incidence among persons of Jewish ancestry.

Pathophysiology

Autoimmune bullous diseases result from an immune response against proteins of desmosomes or the epidermal (or other epithelial) basement membrane. The pemphigus group of diseases is associated with antibodies to different desmosomal proteins. There is strong direct experimental evidence that these antibodies cause acantholysis and blister formation directly without significant participation of cellular components of the immune system. The subepidermal autoimmune bullous diseases, however, result from antibodies against one or more components of the basement membrane that activate the complement system. The latter results in chemoattraction of inflammatory cells, particularly eosinophils and neutrophils, to the basement membrane, as well as activation of local mast cells with degranulation of their cytoplasmic granules, resulting in the release of mediators that further attract inflammatory cells. Both complement and inflammatory cells are required for blister formation. Experimental animals that lack complement or leukocytes fail to develop lesions when injected with patients' serum antibodies.

Prevention

There are no methods for preventing autoimmune bullous diseases. These disorders result from genetically controlled immune dysregulation.

Clinical Manifestations

Clinical manifestations are described for each disease separately under the section on therapy.

Complications

Severe blistering can lead to extensive erosions that heal slowly, especially in the elderly and in those with nutritional deficiencies or systemic disease. Slow healing of extensive erosions predisposes patients to considerable loss of fluids and electrolytes as well as secondary bacterial infection and sepsis. Superficial erosions can become ulcers owing to increased local pressure in immobile and bedridden patients. Temperature regulation can also be compromised following loss of large areas of epidermis. Over the past several decades, mortality from bullous disease has decreased significantly. At present, the common causes of death are complications of the pharmacologic agents used in the treatment.

Diagnosis

The diagnosis of autoimmune bullous diseases requires clinical evaluation, histopathology, direct immunofluorescence, and indirect immunofluorescence. The ideal specimen for direct immunofluorescence should be from normal-appearing skin immediately adjacent to a lesion (perilesional skin). Immunofluorescence tests are usually performed in specialized immunopathology laboratories and are best interpreted by a dermatopathologist with special expertise in the area of immunofluorescence and autoimmune bullous diseases.

Differential Diagnosis

An accurate diagnosis is essential for predicting the course and prognosis of a disease as well as for choosing therapy. Autoimmune

may be used. *A. hydrophila* is susceptible to cephalosporins such as ceftazidime (Fortaz), cefuroxime (Ceftin), and fluoroquinolones such as levofloxacin (Levaquin) and ciprofloxacin (Cipro).

Conclusion

The many types of soft tissue infections caused by bacteria may be distinguished by their presenting signs, symptoms, and body location and by the time course of the pathologic processes unique to each. Early recognition is of paramount importance to an effective treatment plan, which most often includes aggressive surgical débridement and specific antimicrobial therapy. Severe blistering can lead to extensive erosions that heal slowly, especially in the elderly and in those with nutritional deficiencies or systemic disease. Slow healing of extensive erosions predisposes patients to considerable loss of fluids and electrolytes as well as secondary bacterial infection and sepsis. Superficial erosions can become ulcers owing to increased local pressure in immobile and bedridden patients. Temperature regulation can also be compromised following loss of large areas of epidermis. Over the past several decades, mortality from bullous disease has decreased significantly. At present, the common causes of death are complications of the pharmacologic agents used in the treatment.

Diagnosis

The diagnosis of autoimmune bullous diseases requires clinical evaluation, histopathology, direct immunofluorescence, and indirect immunofluorescence. The ideal specimen for direct immunofluorescence should be from normal-appearing skin immediately adjacent to a lesion (perilesional skin). Immunofluorescence tests are usually performed in specialized immunopathology laboratories and are best interpreted by a dermatopathologist with special expertise in the area of immunofluorescence and autoimmune bullous diseases.

Differential Diagnosis

An accurate diagnosis is essential for predicting the course and prognosis of a disease as well as for choosing therapy. Autoimmune

bullous diseases overlap clinically and histologically, hence the need for immunofluorescence studies. For example, epidermolysis bullosa acquisita can have clinical and histologic overlap with both bullous pemphigoid and linear IgA disease. The three diseases, however, have different courses and therapeutic responses and may be easily differentiated on the basis of immunofluorescence tests.

Treatment

Principles

Because autoimmune bullous disorders result from immune dysregulation, the principle of treatment is immune modulation. Immune modulation can be accomplished by several methods: blocking antibody production by B cells and plasma cells, eliminating antibodies from the circulation, suppressing inflammation, or inducing resistance of target epithelial cells to separation and blister formation. Antibody production by B cells and plasma cells may be blocked by destroying the B cell lineage or suppressing activation of T or B cells. The former is accomplished by the drug rituximab (Rituxan) and, to a lesser degree, cyclophosphamide (Cytoxan), and the latter may be accomplished by many immunosuppressive agents including corticosteroids, azathioprine (Imuran), cyclosporine (Neoral), cyclophosphamide, methotrexate (Trexall), and mycophenolate mofetil (Cellcept). Antibodies may be eliminated from circulation by plasmapheresis, high-dose intravenous immunoglobulin (IVIg, Gammagard), and immunoadsorption.

Inflammation that is required for blister formation, especially in subepidermal bullous diseases, may be suppressed by several agents. These include systemic and topical corticosteroids, dapsone, tetracyclines, erythromycin, nicotinamide, and etanercept (Enbrel). Although not yet available, agents that experimentally inhibit signal transduction and agents that inhibit apoptosis can induce resistance of the target epidermal or epithelial cell to separation (acantholysis) and blister formation.

The choice of agents in therapy of bullous diseases requires evaluation of both disease-specific parameters and patient-specific parameters. Disease-specific parameters include the pathophysiology of the disease and its severity; patient-specific parameters include age and concomitant illness such as diabetes, hypertension, active infection, or cancer. There are very few controlled studies that provide high-quality evidence for bullous disease therapy. This is primarily a result of the rarity of many of these disorders. Because of the relative frequency of bullous pemphigoid, some controlled studies have been performed on the disease in Europe. Most of the evidence for bullous disease therapy is available from case reports, case series, and personal experience.

Pharmacologic Treatment

Glucocorticoids

Glucocorticoids (prednisone, prednisolone) have both antiinflammatory and immunosuppressive effects. Long-term use of glucocorticoids is associated with well-known adverse effects.

Azathioprine

Azathioprine (Imuran)¹ interferes with de novo purine synthesis and hence DNA synthesis. This results in suppression of T-cell function and a decrease in B-cell antibody production. In low doses (1–2 mg/kg/day), azathioprine is usually well tolerated. In higher doses (2–4 mg/kg/day), bone marrow may be suppressed, resulting in leukopenia (most commonly) and, less commonly, thrombocytopenia and anemia. Severe bone marrow suppression can occur in patients who are homozygous deficient for the enzyme thiopurine methyltransferase. Other adverse effects include hepatotoxicity and gastrointestinal toxicity as well as pancreatitis and are all dose related. Allopurinol (Zyloprim) is contraindicated in patients receiving azathioprine because it results in an increase in the blood level of azathioprine.

¹Not FDA approved for this indication.

Mycophenolate Mofetil

Mycophenolate mofetil¹ is a purine analogue antimetabolite that inhibits inosine monophosphate dehydrogenase, resulting in suppression of purine and DNA synthesis and hence suppression of both T and B cell function. Mycophenolate mofetil is usually well tolerated.

Methotrexate

Methotrexate¹ is an antimetabolite and a folic acid analogue. Its metabolites inhibit folate-dependent enzymes of de novo purine and thymidylate synthesis. This results in the suppression of DNA and RNA synthesis, which causes decreased lymphocyte function and hence immune modulation.

Cyclophosphamide

Cyclophosphamide¹ is an alkylating agent that binds DNA, resulting in cell cycle arrest, DNA repair, and cell death. The most susceptible cells reside in rapidly proliferating tissues. The toxicity of cyclophosphamide is significantly higher than that of azathioprine, mycophenolate mofetil, and methotrexate. Acute myelosuppression is common, with a nadir at 6 to 10 days and recovery in 2 to 3 weeks. Both cellular and humoral immunity are suppressed.

Cyclosporine

Cyclosporine¹ significantly suppresses cellular immunity and preferentially inhibits antigen-triggered signal transduction in T lymphocytes, which results in decreased expression of several lymphokines. Cyclosporine forms complexes with the receptor protein cyclophilin in the cytoplasm. The complex binds and inhibits calcineurin, resulting in failure of T cells to respond to antigenic stimulation.

Several drugs can interact with cyclosporine and influence its blood level. Agents that can increase cyclosporine blood level include calcium channel antagonists (diltiazem [Cardizem], nifedipine [Cardene], and verapamil [Calan]), systemic antifungal agents (fluconazole [Diflucan], itraconazole [Sporanox], and ketoconazole [Nizoral]), antibacterials (clarithromycin [Biaxin], erythromycin), methylprednisolone (Medrol), other drugs (allopurinol [Zyloprim], bromocriptine [Parlodel], danazol [Danocrine], metoclopramide [Reglan], colchicine [Colcrys], and amiodarone [Cordarone]), and grapefruit juice.

Dapsone

Dapsone is highly effective in neutrophil-mediated conditions. The mechanism of action of dapsone is not well understood. Its clinical benefit in inflammatory conditions probably results from inhibition of neutrophil chemotaxis. Dapsone is associated with multiple potential adverse effects that include dose-related hemolysis, methemoglobinemia (which is common and may be severe in patients who are genetically predisposed), and agranulocytosis (not dose-related and usually occurs in the first 3 months of therapy).

Tetracycline

Tetracycline (Sumycin),¹ doxycycline (Vibramycin),¹ and minocycline (Minocin)¹ have been used interchangeably for the treatment of subepidermal, inflammation-mediated, bullous diseases. Their mechanism of action is not clear.

Niacinamide (Nicotinamide)

Niacinamide¹ is a vitamin whose mechanism of action in cutaneous disorders including autoimmune bullous diseases is not known.

High-Dose Intravenous Immunoglobulin

IVIg¹ is a purified human source of immunoglobulin that is given as a slow infusion over 6 to 8 hours. Treatment is repeated every 3 to 4 weeks. IVIg is highly expensive.

¹Not FDA approved for this indication.

Rituximab

Rituximab¹ is a chimeric monoclonal antibody against CD20 on the surface of pre-B, mature B, and malignant B cells and is not expressed on stem, pro-B or plasma cells. B cells are depleted primarily by antibody-dependent cellular cytotoxicity and, to a lesser degree, by complement-dependent cytotoxicity or apoptosis. Rituximab is given in different regimens, including 375 mg/m²/week (approximately 500 mg for an average-size adult) for 4 consecutive weeks, or 1000 mg once or on two occasions 2 weeks apart.

Plasmapheresis and Immunoapheresis

Plasmapheresis and immunoapheresis are procedures that aim to physically remove pathogenic antibodies. Plasmapheresis consists of withdrawing the patient's blood, filtering cellular elements from the plasma, and returning the cellular components to the patient. Immunoapheresis consists of exposing the patient's plasma to an immunoglobulin-binding matrix that contains the disease-specific antigen. Plasmapheresis and immunoapheresis are usually used in patients who are resistant to other therapies. Plasmapheresis or immunoapheresis is accompanied by immunosuppressive drugs to prevent the rebound phenomenon of excessive antibody production.

Treatment of Individual Disorders

Pemphigoid

There are three forms of pemphigoid: bullous pemphigoid (primary skin involvement); mucous membrane pemphigoid (primary mucosal disease), previously referred to as cicatricial pemphigoid; and pemphigoid gestationis (bullous pemphigoid in pregnant women), previously called herpes gestationis. The pemphigoid group of diseases shares the histology of a subepithelial vesicle with usually eosinophil-rich infiltrate, skin-bound IgG and C3 along the basement membrane, and circulating IgG antibodies against two hemidesmosomal proteins of the basement membrane.

Bullous Pemphigoid. Bullous pemphigoid affects primarily persons older than 60 years and is rarely reported in children. Lesions have a predilection for the inner thighs, groin, axillae, neck, and abdomen. The course of bullous pemphigoid is variable. The disease is self-limited within 5 years, and the mortality from the disease is low.

Because blisters in bullous pemphigoid result from an abnormal immune response that is mediated by inflammatory cells, therapy for bullous pemphigoid should suppress inflammation or the immune response. Potent topical steroids may be considered for patients with localized disease. Although potent topical steroids lead to rapid resolution of a lesion at its earliest manifestation, they are impractical for patients with generalized disease because they do not prevent new lesions. Patients with generalized bullous pemphigoid require systemic therapy. Glucocorticoids are the most commonly used agents. Prednisone (or methylprednisolone) is sufficient as the only therapy in most cases. The dose varies between 0.2 and 0.5 mg/kg/day depending on the severity of the disease, the age of the patient, and the patient's general health status. A clinical response is usually obtained within 1 to 2 weeks and is manifested by healing of existing lesions and cessation of new blister formation. The dose is then gradually decreased by relatively large amounts initially (approximately 10 mg) and smaller amounts (2.5–5 mg) subsequently. If the patient develops a flare of lesions during the tapering phase, the dose may be increased to the previous level or higher and maintained longer before further, slower tapering. In many patients, prednisone may be decreased to 5 mg every day or completely discontinued after 6 months.

For patients who require a high dose of steroid for either clearing or maintenance, adjuvant therapy with another agent should be considered in order to avoid the long-term adverse effects of corticosteroids. These drugs include azathioprine¹ (1–3 mg/kg/day in two equally divided doses), mycophenolate mofetil¹ (1000–3000 mg/day or 40 mg/kg/day in two divided doses), and

methotrexate¹ (10–15 mg/week). The dose of the second drug may be decreased a few months after clinical remission, slowly tapered, and ultimately discontinued. Dapsone¹ and sulfapyridine¹ are used less commonly and may be effective. Dapsone may be commenced at 25 to 50 mg/day and increased as needed by 25 mg every week until a beneficial effect is obtained. The maximum dose of dapsone is 250 mg/day.

Plasmapheresis and high-dose IVIg¹ are reserved for more resistant cases. Antibiotics of the tetracycline family as well as erythromycin¹ have been used alone or in combination with niacinamide¹ and have been shown to have some benefit. The dose of tetracycline¹ is 500 mg four times daily and niacinamide 500 mg three times daily. Minocycline¹ or doxycycline¹ in a dose of 100 mg twice daily may be substituted for patients who do not tolerate tetracycline. In my view, a tetracycline with niacinamide is indicated in two situations. In mild cases, the combination alone can lead to a clinical remission. In patients with extensive disease, the addition of this combination to prednisone can have a corticosteroid-sparing effect.

Mucous Membrane Pemphigoid. Therapy for mucous membrane pemphigoid varies with the disease location, extent, and severity. In limited oral disease, local therapy with topical anesthetic agents and topical glucocorticoids in addition to oral hygiene can suffice. The steroid may be applied under occlusion with a prosthetic device or may be injected intralesionally. Patients with extensive oral involvement can require systemic therapy.

Dapsone¹ is effective in some patients with oral mucous membrane pemphigoid. The drug may be started at 50 mg daily and increased gradually. Tetracyclines,¹ with or without niacinamide,¹ may be effective. In patients with severe oral disease and in patients with ocular, pharyngeal, or laryngeal involvement, systemic glucocorticoids, in combination with cyclophosphamide¹ are indicated. In my experience, most patients have an excellent response, with a prolonged remission after treatment with the combination of prednisone (1 mg/kg/day for 6 months) and cyclophosphamide (1–2 mg/kg/day for 18–24 months).

Azathioprine¹ and mycophenolate mofetil¹ are generally less effective but may be used if there are contraindications to steroid or cyclophosphamide use. High-dose IVIg¹ may be used for patients who are refractory to other therapy.

Patients with severe ocular scarring might benefit from cryotherapy ablation of eyelashes. Ocular surgery is contraindicated when the disease is active. Surgical intervention may cause severe flares of the disease.

Epidermolysis Bullosa Acquisita

Unlike bullous pemphigoid and other subepidermal autoimmune bullous diseases, epidermolysis bullosa acquisita is generally resistant to therapy. The disease waxes and wanes, with periods of exacerbation and remission. Trauma contributes to blister formation, especially in the classic form of epidermolysis bullosa acquisita. The inflammatory form of epidermolysis bullosa acquisita responds more easily to therapy than the classic form.

Because of the neutrophil predominance in the inflammatory form, patients might respond to dapsone.¹ The drug may be started at a dose of 50 mg daily and increased by 50 mg every week until clinical remission (usually 100–250 mg). The dose is maintained for several months. If the patient remains in remission, the dose may be decreased slowly and ultimately discontinued. Colchicine¹ 0.6 mg two or three times daily is variably effective. Patients who do not tolerate or do not respond to colchicine and dapsone may be treated with oral glucocorticoids such as prednisone in a dose of 0.5–1 mg/kg/day in divided doses. The response is variable. If there is no response to glucocorticoids or the patient develops adverse effects, cyclosporine¹ 4–6 mg/kg/day may be initiated and is usually associated with a rapid response. Once disease activity is controlled, the dose may be slowly decreased. Cyclosporine should be discontinued if there is no response in a few weeks.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

The duration of treatment varies with the course of the disease. The same agents used for the inflammatory form may be used for the classic form. The latter is generally more resistant to treatment. Patients who fail to respond may be treated with immunosuppressive agents such as azathioprine,¹ cyclophosphamide,¹ mycophenolate,¹ or methotrexate¹ in a manner similar to pemphigus vulgaris, bullous pemphigoid, or mucous membrane pemphigoid. Patients who are resistant to these agents may be treated with extracorporeal photochemotherapy or with IVIg¹ alone or in conjunction with plasmapheresis.

Dermatitis Herpetiformis

Dermatitis herpetiformis results from an immune response to gluten and manifests as pruritic papulovesicles over the elbows, knees, buttocks, and scalp. A gluten-free diet is extremely helpful and is often associated with a marked decrease in the requirement for pharmacologic therapy. A strict gluten-free diet can result in complete remission of the disease without requiring dapsone. Reinstitution of gluten-containing diet results in rapid recurrence of the disease.

Many patients find a strict gluten-free diet too restrictive and instead choose pharmacologic therapy. The drug of choice is dapsone. Treatment is initiated with dapsone 50 mg daily and is increased by 25 to 50 mg every week as needed and as tolerated. The average daily maintenance dose is 100 mg. Some patients require slowly increasing doses several years later, likely secondary to increased deposition of IgA in the skin that results in increased disease activity.

In patients who are intolerant or allergic to dapsone, therapy with sulfapyridine may be considered. The initial dose is 500 mg three times daily and may be increased slowly to 2 g three times daily. The response to sulfapyridine is not as predictable as that to dapsone. Patients who are allergic to dapsone often tolerate sulfapyridine.

Patients who are intolerant or allergic to dapsone and sulfapyridine may be treated with colchicine,¹ cholestyramine (Questran),¹ heparin,¹ tetracycline,¹ or nicotinamide.¹ These agents are much less effective than dapsone and sulfapyridine. Topical steroids are only minimally effective.

Linear Immunoglobulin A Disease

Linear IgA disease is mediated by neutrophils and clinically mimics bullous pemphigoid and dermatitis herpetiformis. Dapsone¹ is the first-line agent. The drug may be started at 25 to 50 mg daily and increased by 25 to 50 mg every 1 to 2 weeks until an effective dose is reached. Patients with early disease tend to respond to lower doses of dapsone.

Sulfapyridine¹ is an alternative agent for patients who cannot tolerate dapsone. The starting dose is 500 mg twice daily and may be increased by 1000 mg every 1 to 2 weeks until the disease is adequately controlled. Colchicine¹ 0.6 mg 2–3 times daily may also be used if a patient is allergic to dapsone. Glucocorticoids may be added if patients do not respond completely to these agents.

Tetracyclines in combination with niacinamide¹ have been reported to be effective. The dose of tetracycline¹ is 500 mg 4 times daily. Alternatively, doxycycline¹ or minocycline¹ 100 mg twice daily may be used. The dose of niacinamide is 500 mg three times daily. Cyclosporine¹ or high-dose IVIg¹ may be used in resistant cases.

Pemphigus

Pemphigus Vulgaris. Pemphigus vulgaris often manifests with erosions in the oral cavity that may be followed by skin blisters. Successful therapy suppresses the production of pathogenic autoantibodies. Therefore immunosuppressive drugs are used. A positive clinical response is associated with a decrease in or absence of pathogenic circulating autoantibodies in the serum and then absence of bound autoantibodies in the skin. There has been a

dramatic decrease in the mortality of pemphigus vulgaris owing to the increasing availability of immunosuppressive drugs and glucocorticoids, as well as earlier diagnosis and treatment.

Unless there is an absolute contraindication, the initial therapy of pemphigus vulgaris is systemic glucocorticoid. Prednisone is the most commonly used agent. The initial dose is 1 mg/kg/day divided into two or three doses. Most patients obtain remission within 4 to 12 weeks. The dosage is maintained for 6 to 10 weeks, then decreased by 10 to 20 mg every 2 to 4 weeks. If there is no recurrence, the patient is maintained on 5 mg daily or every other day for several years. Pulsed-steroid therapy with intravenous methylprednisolone, 1 g daily for 3 consecutive days, is reserved for severe cases. The goal of this approach is to quickly achieve the immunosuppressive effects of glucocorticoids while avoiding the long-term side effects.

If prednisone fails to induce a remission, or if the patient develops serious adverse effects, adjuvant immunosuppressive drugs should be instituted. My practice is to initiate adjuvant therapy concomitant with steroid therapy to decrease the total dose of glucocorticoid used. The glucocorticoid is tapered rapidly and the patient is maintained on the steroid-sparing agent for 24 to 36 months. The most commonly used steroid-sparing immunosuppressive drugs are azathioprine¹ and mycophenolate mofetil.¹ Cyclophosphamide¹ is used for resistant cases at a dose of 2 to 3 mg/kg/day, azathioprine at a dose of 3 to 5 mg/kg/day, and mycophenolate at a dose of 2 to 3 g daily (or 40 mg/kg/day in two divided doses). Methotrexate¹ may also be used, but it is generally less effective than other treatments.

The response of pemphigus vulgaris to cyclosporine¹ is controversial. High-dose IVIg¹ has a rapid onset of action and appears most effective when used as an adjuvant to conventional therapy, especially as a steroid-sparing agent. Plasmapheresis is used in refractory cases. To avoid the rebound phenomenon (increased production of autoantibodies), immune suppression (usually with cyclophosphamide) is used concomitantly with plasmapheresis. Rituximab¹ has been used successfully in several cases of pemphigus vulgaris and other autoimmune bullous diseases. For resistant cases, extracorporeal photochemotherapy may be considered.

Pemphigus Foliaceus. The principles and practice of managing pemphigus foliaceus are similar to those for pemphigus vulgaris.

Paraneoplastic Pemphigus. Paraneoplastic pemphigus is a unique intraepidermal blistering disease associated with antibodies against a unique set of skin and internal organ antigens. The most common associated neoplasms are lymphoproliferative. The management of paraneoplastic pemphigus consists of the treatment of the underlying neoplasm as well as immune suppression. Surgical excision of benign neoplasms such as thymoma and Castleman's disease can result in clinical and serologic improvement. In patients with malignant neoplasms, treatment of the associated neoplasm might not result in remission. Generally, skin lesions respond more rapidly than mucosal lesions.

Systemic glucocorticoids are often used as the first-line agent in a dose of 1 to 2 mg/kg/day. Patients usually have a partial response and rarely have complete resolution of lesions. Other immunosuppressive drugs have been used with variable success. These include mycophenolate mofetil,¹ azathioprine,¹ and cyclosporine.¹

Rituximab¹ has been reported to be effective in a case of paraneoplastic pemphigus associated with CD20-positive follicular lymphoma and in a case of paraneoplastic pemphigus associated with follicular non-Hodgkin's lymphoma. Immunoapheresis has been used successfully occasionally.

CANCER OF THE SKIN

Method of

Bernhard Ortel, MD; and Diana Bolotin, MD, PhD

CURRENT DIAGNOSIS

- Skin cancers are polymorphous in appearance, ranging from small papules and plaques to nodules and tumors of different colors, sizes, and consistencies.
- The surface may be smooth, scaly, ulcerated, or crusted.
- A common feature is that all of these skin neoplasms grow continuously and relapse when superficially treated.
- The distinction between skin cancers and benign neoplasms or inflammatory dermatoses may be difficult for the nondermatologist to make.

CURRENT THERAPY

- For the majority of nonmelanoma skin cancers, localized treatments are sufficient and include cryotherapy, immunotherapy, topical chemotherapy, and photodynamic therapy.
- Surgical techniques include electrodesiccation and curettage, simple excision, and Mohs' micrographic surgery, which offers

intraoperative confirmation of complete tumor removal and maximal cure rates.

- The Mohs procedure is indicated for more-aggressive tumors, for tumors in certain anatomic locations, and in immunosuppressed patients.
- Rarely, sentinel lymph node dissection and adjuvant therapies, such as radiation and chemotherapy, are warranted.

Nonmelanoma skin cancer (NMSC) is a heterogeneous group of skin malignancies that includes basal cell cancer (BCC) and squamous cell cancer (SCC). These are the most common skin cancers and NMSC in the stricter sense of the definition (Figure 1). The more-inclusive use of the term NMSC also includes malignant neoplasms of adnexal, fibrohistiocytic, and vascular origin, as well as Merkel cell carcinoma and metastatic tumors. The vast majority of NMSCs are slowly growing and locally invasive neoplasms that are often diagnosed and treated by dermatologists. Management of the more aggressive tumors often requires a team approach to diagnosis, treatment, and clinical follow-up (Table 1).

Basal Cell Carcinoma

BCC accounts for the majority of NMSC seen in the United States and is increasingly diagnosed in younger patients. Light skin complexion and history of ultraviolet (UV) light exposure are the predominant risk factors for BCC in the majority of the population. Intermittent intense UV light exposures early in life, but not cumulative UV light exposure, pose the highest risk factor for developing BCC later in life. Other risk factors for BCC include exposure to ionizing radiation, psoralen photochemotherapy, arsenic, and smoking. A history of BCC also increases one's risk for developing a subsequent BCC. Immunosuppression, especially in recipients of solid-organ transplants, presents a significant risk factor for BCC. Inherited genodermatoses such as Gorlin's, Bazex's, and Rombo's syndromes, xeroderma pigmentosum, and some forms of albinism are predisposing factors for BCC as well. Mutations in *PTCH1* that are found in Gorlin's syndrome have been shown to be an early event underlying BCC pathogenesis.

Clinically, BCC is most commonly found on the head and neck region, though any part of the body can develop this tumor. The presentation varies depending on the histologic subtype of the tumor. Although many histologic variants of BCC exist, the most

TABLE 1 Overview of Therapeutic Modalities for the Management of Skin Cancers

THERAPEUTIC MODALITY	NEOPLASM	COMMENT
Cryotherapy	AK, SCC in situ Superficial BCC Kaposi's sarcoma	Versatile, but operator dependent
Topical 5-fluorouracil (Efudex)	AK, SCC in situ Superficial BCC	Will treat preclinical AK
Topical imiquimod (Aldara)	AK Superficial BCC	Flulike adverse effects can occur
Photodynamic therapy	AK, SCC in situ Superficial BCC	SCC and BCC are off-label uses
Electrodesiccation and curettage	AK, SCC BCC	
Excision	All	
Mohs micrographic surgery	BCC, SCC MAC, sebaceous carcinoma DFSP, AFX Angiosarcoma EMPD, MCC	Preferred for certain types of invasive tumors (e.g., morpheaform BCC), on high-risk regions (e.g., nose, lip), and settings (e.g., recurrence, immunosuppressed patient)
Radiation therapy	BCC, SCC Kaposi's sarcoma, angiosarcoma MCC Inoperable tumors	Careful risk-to-benefit evaluation

Abbreviations: AFX = atypical fibroxanthoma; AK = actinic keratosis; BCC = basal cell carcinoma; DFSP = dermatofibrosarcoma protuberans; EMPD = extramammary Paget's disease; MAC = microcystic adnexal carcinoma; MCC = Merkel cell carcinoma; SCC = squamous cell carcinoma.

common subtypes are superficial, nodular and micronodular, morpheaform, and metatypic. The histologic heterogeneity results in variable clinical findings. Superficial BCC typically forms an erythematous scaly patch or plaque. Nodular BCC is the more classic-appearing lesion, a pink pearly nodule with or without central crust or ulcer. Unlike these subtypes, morpheaform BCC clinically resembles an ill-defined scar; it is the most histologically aggressive variant with a tendency for deep local invasion. Metatypic BCC is also known as basosquamous carcinoma because it has histologic features of both BCC and SCC, though it is distinguished from the latter by molecular markers. This subtype also has a tendency for more-aggressive growth.

Although it is potentially locally destructive, BCC rarely metastasizes. Successful treatment of this tumor involves its local eradication. A number of treatment options exist and depend on the histologic subtype of the tumor. For small, superficial tumors, a nonsurgical approach can suffice, though nonsurgical treatment often carries a higher risk of recurrence than surgical treatment. Nonsurgical options include topical 5-fluorouracil (Efudex 5%), topical imiquimod (Aldara 5%), liquid nitrogen cryotherapy, photodynamic therapy, and local radiation therapy.

Electrodesiccation and curettage (ED&C) is an option that has a high cure rate for small and superficial tumors (95%–98%). Standard excision with adequate margins is an appropriate surgical treatment providing good cure rates, especially for tumors with nonaggressive histologic pattern. Mohs micrographic surgery (MMS) offers the advantage of precise margin examination during excision and therefore carries the lowest overall rate of recurrence. This tissue-sparing procedure is also advantageous in terms of reconstruction on cosmetically sensitive regions. MMS is indicated to treat recurrent tumors, those in immunosuppressed patients,

aggressive histologic variants, and BCCs located on certain areas of the face known to carry a higher risk of recurrence.

Squamous Cell Carcinoma

Cutaneous squamous cell carcinoma (SCC) is the second most common skin malignancy. Its incidence is rising among both men and women in the United States. Development of SCC is intimately linked to the cumulative ultraviolet radiation exposure of the patient via a mechanism that combines DNA damage with immunosuppression. History of ionizing radiation exposure is a risk factor as well. Similar to BCC, occupational exposures such as arsenic can also predispose one to SCC. Patients with xeroderma pigmentosum or oculocutaneous albinism also are at higher risk for SCC.

Chronic inflammation or injury can predispose to epidermal malignant transformation. Examples of this phenomenon are SCC developing within scars from burns, in chronic ulcers and skin overlying osteomyelitis, and in persistent lichen sclerosus or lichen planus. These tumors have a more-aggressive behavior and higher rates of metastasis.

Human papilloma virus (HPV) predisposes to SCC. Verrucous carcinoma, a well-differentiated subtype of SCC, has a well-documented association with HPV types 6 and 11.

Transplant patients are at high risk for SCC that correlates with the degree of immunosuppression. In fact, SCC development is up to 250 times greater in the immunosuppressed compared to the general population, whereas BCC increases to a lesser extent with immunocompromise. A more common association between HPV and SCC has been noted in the immunocompromised population and might account for the disproportional increase of SCC over BCC in this population.

As with BCC, history of previous SCC has been found to be a risk factor for developing a subsequent SCC. This risk appears especially pronounced in smokers.

Unlike BCC, SCC often has a precursor lesion: actinic keratosis. Histologically, actinic keratosis demonstrates partial thickness atypia of the epidermis, and patients often describe it as waxing and waning. Full-thickness histologic atypia is seen in SCC in situ (Bowen's disease), whereas invasive SCC penetrates the basement membrane to invade underlying dermis. Histologically, the degree of differentiation of SCC tends to correlate with its clinical behavior. Well-differentiated lesions tend toward local invasion, as opposed to poorly differentiated SCC, which more commonly is infiltrative.

The typical clinical presentation of SCC is that of a hyperkeratotic pink plaque. More-advanced lesions may be nodular and can ulcerate. In most cases, SCC shows only local invasion; however, perineural invasion and rarely metastasis are more likely with SCC than BCC. The central face, temples, and scalp present high-risk zones for recurrence and metastasis.

Treatment of SCC involves modalities similar to those used for BCC. Cryotherapy is the mainstay of treatment for actinic keratosis. Topical treatment with 5-fluorouracil (Carac 0.5% cream, Fluoroplex 1% cream, Fluorouracil 2%, or 5% solution, Efudex 5% cream), imiquimod (Aldara or Zyclara), ingenol mebutate (Picato), or photodynamic therapy is often used as field therapy to depopulate large regions of the skin of actinic keratosis lesions. Continued sun protection has been shown to be of benefit to prevent progression from actinic keratosis to SCC, especially in the immunocompromised population. SCC in situ may be treated with ED&C. Excision with a clear surgical margin is often used in treatment of SCC on the trunk or extremities, but MMS yields the highest cure rates, especially in high-risk areas such as the face and scalp. Adjuvant radiotherapy may be used along with surgical excision for more-aggressive tumors. Overall, the prognosis for a patient with cutaneous SCC depends heavily on location, degree of histologic differentiation, invasion, and metastasis.

Neoplasms of Adnexal Origin

The adnexal structures of the skin include the pilosebaceous unit as well as apocrine and eccrine glands and ducts. A great number of

benign and malignant tumors of adnexal origin occur in the skin. Most of the adnexal malignancies are rare. Sebaceous carcinoma and microcystic adnexal carcinoma (MAC) are two of the more common adnexal carcinomas that have an aggressive nature and may be subtle at presentation.

Sebaceous Carcinoma

Sebaceous carcinoma is an aggressive malignancy that is most commonly found on the head and neck region. More specifically, it is one of the more common tumors of the eyelid and periocular area. Due to its nonspecific clinical presentation it is often treated as chalazion before biopsy and diagnosis. Population-based risk factors associated with development of sebaceous carcinoma include older age and European ethnicity. History of irradiation and immunosuppression predisposes to sebaceous carcinoma development, similar to BCC and SCC. Sebaceous carcinoma is one of the cutaneous neoplasms characteristic of Muir-Torre syndrome, which results from mutations in DNA mismatch repair genes and is associated with multiple sebaceous neoplasms and internal malignancy.

Clinical diagnosis of sebaceous carcinoma is difficult, and therefore progressive or nonresolving eyelid lesions require biopsy. Treatment of sebaceous carcinoma is primarily surgical. Wide local excision with 5- to 6-mm margins or MMS is indicated. A lower rate of recurrence with MMS (11.1%) has been shown as compared to local excision (32%). Close follow-up is indicated to monitor for recurrence and metastasis.

Microcystic Adnexal Carcinoma

MAC is another adnexal malignancy with predilection for the head and neck. In the United States it is most prevalent in the white population and on the left side of the body, suggesting UV irradiation as a risk factor. Although it can be seen in a wide age range of patients, older patients have a higher risk of developing MAC. The low incidence of this tumor makes it difficult to evaluate other risk factors, though cases have been reported in immunosuppressed patients and those with a history of radiation therapy.

Clinically, MAC occurs as a slowly growing, pink to flesh-colored ill-defined plaque. Paresthesia and/or numbness are common complaints and have been attributed to the high degree of perineural invasion by this tumor. MAC is a locally aggressive tumor with an unpredictable pattern of infiltrative growth. Histologically, MAC exhibits both pilar and sweat duct differentiation, deep invasion with a desmoplastic stromal response, and perineural invasion.

Surgical excision is the standard-of-care treatment for MAC, and radiation as an adjunct therapy is reported in a few cases. Because this tumor can extend for centimeters subclinically, MMS is favored as the first-line surgical treatment because it allows complete examination of the surgical margins intraoperatively and has been reported to have a lower recurrence rate than standard excision.

Fibrohistiocytic Malignancies

Fibrohistiocytic tumors of the skin are derived from the mesenchymal tissue and range from those of intermediate malignant potential to aggressive pleomorphic sarcomas. Of these overall rare malignancies, dermatofibrosarcoma protuberans (DFSP) and atypical fibroxanthoma are more frequently encountered.

Dermatofibrosarcoma Protuberans

DFSP is the most common fibrohistiocytic malignancy of the skin. It occurs at various ages ranging from infancy to older adulthood. The pathogenesis of DFSP involves a translocation between chromosomes 17 and 22 that fuses the collagen type 1 $\alpha 1$ gene (*COL1A1*) with the platelet-derived growth factor B-chain gene (*PDGFB*). This fusion gene results in overexpression of PDGFB, which acts as a potent growth stimulant for mesenchymal cells. In general slowly growing, DFSPs are locally invasive and infiltrative rather than metastatic. Therefore treatment of this tumor is primarily surgical.

A high recurrence rate has been noted in a number of studies and is attributed to the infiltrative growth of the tumor. MMS reduces recurrence rates, and is often recommended. DFSP is thought to be a radiosensitive tumor, and adjunctive radiation therapy has been successfully used both pre- and postoperatively. The discovery of *COL1A1-PDGFB* fusion has led to trials of imatinib (Gleevec) therapy as an adjunct to surgery for DFSP. So far, a limited number of clinical reports have demonstrated regression of DFSPs during treatment with imatinib. Larger studies and long-term follow-up are needed to determine whether this warrants a change to the current treatment recommendations.

Atypical Fibroxanthoma

Atypical fibroxanthoma is a low-grade sarcoma of the skin. This locally invasive tumor favors sun-damaged skin of the head and neck region in older adults. Patients with xeroderma pigmentosum have a higher risk for developing atypical fibroxanthoma. It has a nonspecific clinical presentation, and a biopsy with histopathology is needed for diagnosis. Histologically, this tumor often exhibits marked pleomorphism and frequent mitoses. Often immunohistochemical staining is necessary for definitive diagnosis. Surgery is the treatment of choice for atypical fibroxanthoma. Either wide local excision or MMS may be used, though lower recurrence rates have been reported with MMS. Despite the pleomorphic microscopic appearance, this tumor rarely metastasizes, and the prognosis with appropriate treatment is favorable.

Vascular Malignancies

Vascular neoplasms of the skin are rare. Kaposi's sarcoma (KS) and angiosarcoma, both increasingly encountered in healthy older adults as well as immunosuppressed patients, are discussed here.

Kaposi's Sarcoma

Controversy exists regarding the nature of cell proliferation seen in KS. Some regard it as a true malignancy, and others view it as a reactive proliferation. Four types of KS exist: KS of elderly men of Jewish and Mediterranean origin, African endemic KS, immunosuppression-associated KS, and AIDS-associated KS. Infection with human herpesvirus 8 (HHV 8) is involved in the pathogenesis of all types of KS. Clinical findings include non-blanching purpuric patches and plaques that can progress to nodules with ulceration. KS can be isolated to the skin or can become disseminated to the lymph nodes and viscera. Diagnosis is established with histopathology and immunostaining. Management of KS is complex owing to the varied clinical course of the four subtypes. In cases of localized lesions, surgery, cryotherapy, or laser treatment may be useful. Radiotherapy can also be used for localized disease. Patients with disseminated KS are generally treated with chemotherapy. In AIDS-associated KS, institution of HIV medications has been shown to effect resolution of KS.

Angiosarcoma

Angiosarcoma is a more rare but aggressive vascular cutaneous malignancy that tends to metastasize and carries a poor prognosis. Clinically, angiosarcoma favors the head and neck area of elderly men; it can also arise within sites of previous radiation therapy or chronic lymphedema. No association between angiosarcoma and HHV8 has been found. Patients present with an asymptomatic enlarging purpuric plaque that can eventually develop a nodular component. Angiosarcoma may have multifocal involvement that is often not appreciated clinically. The treatment for angiosarcoma involves wide local excision and postoperative radiation. The overall prognosis is poor, and distant metastasis-free 5-year survival rates range between 20% and 37%.

Other Nonmelanoma Skin Cancers

Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is a rare but often fatal NMSC that derives from cutaneous neuroendocrine cells. Fair skin and a history of exposure to UV light are risk factors for developing MCC. Like many other NMSCs, MCC favors the head and neck

and is much more common in the elderly. Immunosuppression appears to be a risk factor for MCC development because its incidence is significantly increased in patients with AIDS and recipients of organ transplants. Polyomavirus has been implicated in the pathogenesis of MCC.

This malignancy is often metastatic upon presentation. Clinically, it occurs as a nonspecific, red asymptomatic papule or nodule. A biopsy with immunohistochemical analysis is diagnostic. The therapy for MCC involves surgery with wide local excision or MMS. Sentinel lymph node biopsy can be performed for staging purposes but should be considered on a case-by-case basis. MCC is sensitive to radiation therapy, which is a recommended adjuvant treatment for patients with lymph node involvement. Palliative chemotherapy often produces a response; however, recurrence is common. Prognosis is poor for metastatic disease or lymph node involvement.

Paget's Disease

Paget's disease refers to intraepidermal spread of adenocarcinoma. Two types are seen in the skin: mammary Paget's disease and extramammary Paget's disease. Mammary Paget's disease is most commonly seen in women and has a strict association with adenocarcinoma of the breast. The lesions are usually unilateral scaly red plaques that favor the nipple. Often the underlying tumor is not clinically present but is detected through imaging. Other dermatoses of the nipple can resemble mammary Paget's disease, and therefore definitive diagnosis requires biopsy and immunohistochemistry. Surgical excision along with appropriate treatment of the breast cancer is the recommended treatment. Prognosis depends on the extent of breast cancer at diagnosis, though it appears to be worse for breast cancer patients with mammary Paget's disease than those without.

Extramammary Paget's disease consists of two types of disease: type I disease, which is associated with distant adenocarcinoma, and type II, primary cutaneous EMPD. Both are very rare but, like mammary Paget's disease, have a female predominance. Most commonly extramammary Paget's disease is found in the genital or perianal region; however, other areas of the skin can be affected less frequently. Clinically, extramammary Paget's disease manifests as a well-demarcated red plaque that can become erosive. Long-standing disease can spread from the groin to the trunk, mimicking an inflammatory dermatosis. Definitive diagnosis is based on biopsy findings, and further workup includes extensive screening for associated internal malignancy. Treatment relies on surgical excision with wide margins. MMS can be used to examine margins intraoperatively. Prognosis for type I extramammary Paget's disease depends on the extent of underlying tumor, but that for type II is favorable.

Cutaneous Metastases

Metastasis to the skin often heralds the systemic spread of an internal malignancy. Primary malignancy underlying the skin metastasis tends to differ by sex and age. In men, lung cancer is the most common source of skin metastasis, whereas breast cancer is the more common primary tumor in women. The head and neck are favored as sites of skin metastasis in men but the trunk is favored in women.

The clinical presentation of skin metastasis is varied and often nonspecific. A new, asymptomatic cutaneous or subcutaneous nodule may be the reason for a biopsy that reveals metastasis of an unknown primary tumor. Diagnosis is made by histopathology and appropriate molecular staining. Specific clinical patterns of metastasis may be encountered. Inflammatory carcinoma can be seen with cutaneous breast cancer metastases. Occasionally, neoplastic infiltration leads to localized areas of alopecia. Zosteriform distribution of skin metastasis has been reported with breast, colon, or squamous cell cancer.

Leukemia cutis refers to skin involvement with acute myelogenous leukemia, chronic myelogenous leukemia, myelodysplastic syndromes, chronic lymphocytic leukemia, or adult T-cell

lymphoproliferative diseases. In rare cases, skin involvement precedes bone marrow disease and is termed *aleukemic leukemia cutis*. In chronic leukemias, skin involvement tends to predict disease progression into the acute phase. Children appear to have a higher incidence of leukemia cutis as compared to adults but have a better overall prognosis.

Metastatic skin tumors are distinguished from primary cutaneous malignancies histologically. Treatment is always geared toward the primary malignancy. Regardless of type of neoplasm or site of metastasis, spread of an internal malignancy to the skin carries a poor prognosis.

CONTACT DERMATITIS

Method of

James A. Yiannias, MD; Genevieve L. Egnatios, MD; and Heidi E.K. Mullen, DO

CURRENT DIAGNOSIS

- Gather a detailed history on skin exposures, including the use of these items:
 - Irritants
 - Alkalis: soaps, detergents, cleansers
 - Acids
 - Hydrocarbons: petroleum, oils
 - Solvents
 - Allergens
 - Nickel sulfate
 - Balsam of Peru (*Myroxylon pereirae*, fragrance)
 - Fragrance mix
 - Quaternium-15 (formaldehyde-releasing preservative)
 - Neomycin
 - Bacitracin
 - Formaldehyde
 - Cobalt chloride (metals, personal products)
- Examine the skin for the location and pattern of eruption:
 - Eyelid: nail polish
 - Postauricular scalp: perfume
 - Perioral area: chewing gum, toothpaste
 - Trunk: dyes, clothing finish
 - Wrist: nickel, chrome
 - Waistline: rubber
 - Feet: shoes
 - Wounds: topical antibiotic ointment
- Perform patch testing:
 - T.R.U.E. TEST with 35 allergens (note: one common allergen, benzalkonium chloride, is not included in this panel)
 - Customized series with 70 or more allergens

CURRENT THERAPY

- Avoid irritants and allergens, using the prepared patient handout.
- Consult the SkinSAFE shopping list of skincare products free of top 10 most common allergens (if patch testing is not performed).
- Consult a customized SkinSAFE shopping list of skincare products free of the patient's contact allergens, based on patch test results.
- Topical corticosteroids can be applied.
- Hydrocortisone 2.5% (Hytone) can be applied twice daily on the face, neck, axillae, groin, and intertriginous areas.
- Triamcinolone 0.1% (Kenalog) can be applied twice daily on the body.
- For severe reactions, short-term, higher-potency steroids can be applied (e.g., clobetasol [Clobex] 0.05% twice daily).
- Sedating antihistamines can be taken: doxepin (Sinequan)¹ 10 to 20 mg nightly 2 hours before bed.
- Steroid-sparing topical agents can be applied: tacrolimus 0.1% (Protopic)¹, pimecrolimus 1% (Elidel)¹, crisaborole 2% (Eucrisa)¹
- For severe, acute episodes, systemic corticosteroids can be taken in a several-week, tapering course (e.g., prednisone 60 mg for 5 days, 40 mg for 5 days, and 20 mg for 5 days).
- Longer-term systemic therapy is possible for severe or recalcitrant disease.

- Phototherapy is suggested, with narrowband ultraviolet B.
- Azathioprine (Imuran)¹ can be taken 1 to 3 mg/kg daily.
- Mycophenolate mofetil (CellCept)¹ can be taken 2 to 3 g daily.
- Methotrexate¹ can be taken 10 to 25 mg weekly.
- Cyclosporine (Neoral)¹ can be taken 2.5 to 5 mg/kg daily.

¹Not FDA approved for this indication.

Dermatitis typically manifests as papules and vesicles, with weeping and oozing that can become lichenified and scaly when chronic. When this clinical picture is secondary to an exogenous substance coming into contact with the skin, it is termed *contact dermatitis*. Further delineation leads to irritant versus allergic contact dermatitis, although in practice these often overlap. Irritant contact dermatitis is not an allergic process. It represents damage to the skin from repeated and cumulative exposure to an agent. Irritants do not require prior sensitization. A decreased barrier function of the skin—for example, with frequent hand washing—can predispose or exacerbate the condition. Examples include alkalis (in soaps, detergents, and cleansers), acids (in germicides, dyes, and pigments), hydrocarbons (in petroleum and oils), and solvents.

Allergic contact dermatitis is an immunologic process classified as a type IV cell-mediated delayed hypersensitivity reaction. Poison ivy is a classic example. It requires an initial exposure to the contactant in which sensitization occurs but without outward physical effect. Subsequent exposure can elicit a striking response that is independent of the amount of the contactant.

From 1994 to 2017 the most common contact allergens have changed little. Based on studies performed by the North American Contact Dermatitis Group (NACDG) and the Mayo Clinic Contact Dermatitis Group, the allergens most consistently in the top 10 were nickel sulfate, balsam of Peru, fragrance mix, quaternium-15, neomycin, bacitracin, formaldehyde, and cobalt chloride (Box 1). However, in the last few years, the preservatives methylisothiazolinone (MI) and benzalkonium chloride have also gained prominence on these lists. Common sources of exposure to nickel include costume jewelry, snaps, zippers, and other metal objects. Balsam of Peru and fragrance mix are markers for fragrance

BOX 1 Top 10 Most Common Allergens

North American Contact Dermatitis Group

- Nickel sulfate
- Fragrance mix I
- MI
- Neomycin
- Cobalt chloride
- Bacitracin
- Balsam of Peru
- *p*-Phenylenediamine
- Formaldehyde
- MCI/MI

Mayo Clinic Contact Dermatitis Group

- Nickel sulfate
- MI
- Balsam of Peru
- Neomycin
- Cobalt chloride
- Fragrance mix
- Benzalkonium chloride
- Propolis
- Formaldehyde
- Bacitracin

From Warshaw and colleagues, 2017, and James A. Yiannias, personal communication, January 13, 2017.

sensitivity. Sources of exposure to formaldehyde include skincare products, household products, and the resins in plastics and clothing. Quaternium-15 is a formaldehyde-releasing preservative and may be found in items such as skincare products, paper, inks, and photocopier toner. Neomycin and bacitracin are topical antibiotics available alone and in combination with polymyxin (Neosporin), antifungals, and corticosteroids. Cobalt is found with other metals, including zinc, and in items such as jewelry, crayons, hair dye, and antiperspirants. MI is a common preservative found in personal care products and may be used in combination with another preservative, methylchloroisothiazolinone. Benzalkonium chloride is commonly used in the healthcare field as a cleanser, antiseptic, and preservative but is also found in personal care products such as wipes and an increasing number of skin care products.

Others less consistently in the top 10 during that period were methyl dibromo glutaronitrile, gold sodium thiosulfate, potassium dichromate, *p*-phenylenediamine, thiuram mix, methylchloroisothiazolinone/methylisothiazolinone (MCI/MI), and propolis. Methyl dibromo glutaronitrile is a preservative and can be found in healthcare and personal products. Clinically relevant sources of gold may be found in jewelry and dental appliances. Potassium dichromate is used in cement, leather, and steel surfaces. Permanent hair dyes are the usual source of *p*-phenylenediamine. Thiuram mix is in rubber and some personal products. Propolis is another marker of fragrance sensitivity.

Each year since 2000, the American Contact Dermatitis Society has designated an allergen of the year, designed to spotlight allergens, common or not, that are rising in significance. For 2018, propylene glycol was chosen. Propylene glycol is a common ingredient in personal care products, topical corticosteroids and other medications, and foods. Other designated allergens of the year have been alkyl glucosides, cobalt chloride, benzophenones, MI, acrylates, dimethyl fumarate, neomycin, mixed dialkyl thioureas, nickel, fragrance, *p*-phenylenediamine, corticosteroids, cocamidopropyl betaine, bacitracin, thimerosal, gold, and disperse blue. Alkyl glucosides are surfactants that are pervasive in consumer products including cosmetics. Benzophenones, such as oxybenzone, are chemical ultraviolet light filters that are found in sunscreens and personal care products. Artificial nails, dentures, and bone cement contain acrylates, but these substances are only allergenic when in the liquid, powder, or paste forms. Dimethyl fumarate is a biocide in furniture, shoes, and textiles. It is often placed in little paper packets with these items. Rubber products and shoe glue are common sources of mixed dialkyl thioureas. Shampoos often contain cocamidopropyl betaine as a lathering agent. Thimerosal is a preservative for medications and personal care products, including contact lens solution. Disperse blue is a fabric dye. Patients with an allergy to disperse dyes may also react to *p*-phenylenediamine.

Diagnosis

The evaluation of a patient with suspected contact dermatitis begins with the history. Specific questions directed at the patient's occupation, hobbies, and home routine will be helpful. Examination should note the location and pattern of the eruption. Although eyelid dermatitis may be seen in the atopic patient, nail polish may be the source of the offending allergen. Dyshidrotic eczema occurs as vesicles along the lateral aspects of the fingers, whereas eczematous changes along the dorsal hands are more commonly due to an allergen. Other distributions as clues include postauricular scalp (perfume), perioral area (chewing gum, toothpaste), trunk (dyes or clothing finish), wrist (nickel or chrome), waistline (rubber), feet (shoes), and history or presence of wounds (topical antibiotic ointment).

Patch testing can confirm or reveal a contact allergy. It involves placement of allergens against the skin of the patient's back for 48 hours. An initial reading is then done, with follow-up readings typically at 96 hours. Prepared series include the thin-layer,

rapid-use epicutaneous test (T.R.U.E. TEST), which consists of 35 allergens and 1 negative control (www.truetest.com); customized series, such as the NACDG Standard Series with 70 allergens and the Mayo Clinic's Standard Series with 73 allergens, must be manually assembled. Most dermatologists performing patch testing use T.R.U.E. TEST. Note that benzalkonium chloride, MCI/MI, and propolis are not included in that panel. Overall, the NACDG estimates that T.R.U.E. TEST would have missed up to 33% of allergic reactions based on their data for 2013-2014.

In addition to ascertaining degree of positivity, relevance must be determined. This involves collaborating with patients to assess the likelihood that they are currently exposed to the positive antigen.

Treatment

Ideally, the allergen(s) will be identified and avoided. Realistically, compliance is a challenge. To assist patients in avoiding antigens in skincare products, SkinSAFE was created in 1999. It includes approximately 19,132 ingredients and 27,363 individual over-the-counter and prescription skincare products. Once the patient's allergens have been identified with patch testing, they can be entered into the database, and a list of products free of those substances is generated. The patient should be reminded that even small and infrequent exposures can perpetuate the eczema.

Topical corticosteroids applied twice daily are helpful in hastening resolution and may also be used for disease control when the allergen is unknown. Low-potency corticosteroids such as 2.5% hydrocortisone (Hytone) are recommended for the thinner skin of the face, neck, axillae, groin, and intertriginous areas. Mid-potency steroids such as triamcinolone 0.1% (Kenalog) are appropriate for the thicker skin of the body. Short-term use of higher-potency steroids may be necessary if the reaction is severe. If there is significant pruritus, sedating antihistamines such as doxepin (Sinequan)¹ 10 to 20 mg taken nightly 2 hours before bedtime can provide relief. Steroid-sparing topical immunomodulators such as tacrolimus (Protopic)¹, pimecrolimus (Elidel)¹, and crisaborole (Eucrisa)¹ may be helpful adjuncts. Treatment for severe acute episodes can entail a several-week tapering course of systemic corticosteroids, especially if the eruption is widespread. Other longer-term systemic therapies for severe or resistant disease include phototherapy or systemic immunosuppressants such as azathioprine (Imuran)¹, mycophenolate mofetil (CellCept)¹, methotrexate¹, or cyclosporine (Neoral)¹.

It may take many weeks before the skin reverts to a normal appearance despite successful avoidance of antigens. A prepared handout with concrete recommendations for the patient on truly hypoallergenic skincare is beneficial. A sample of that used at Mayo Clinic Arizona is shown in Figure 1.

If patch testing is not performed, an initial approach may be to instruct the patient on avoiding the most common contact allergens via such a handout and prescribing symptomatic treatment including topical and oral therapies. SkinSAFE can generate a shopping list of products free of the top 10 allergens as identified by the NACDG and the Mayo Clinic Contact Dermatitis Group. Patients may access SkinSAFE independently (at www.skinafesafe.com, Apple App Store, or Google Play Store under "SkinSAFE") to generate this list or build customized lists free of fragrances, common preservatives, parabens, nickel, lanolin, coconut, and topical antibiotics. In 35% of patients, simply using products free of the top 10 allergens can prompt clearance. Some physicians follow these measures for several months, especially if the eruption is mild, before pursuing formal patch testing.

An excellent primer for the physician interested in learning more about contact allergy diagnosis and management is *Contact and Occupational Dermatology*.

¹Not FDA approved for this indication.

Introduction

Eczema, also known as dermatitis, is an inflammation of the skin due to dryness, irritation, or possible external allergy. Eczema/dermatitis is not contagious.

Some skin care products contain fragrance even though the package says “fragrance free” or “unscented.” Therefore, please choose the skin care products as listed below by their *exact brand name*.

Suggestions

Soaps/Cleansing

- Vanicream cleansing bar
- Free and Clear liquid cleanser
- Aveeno moisturizing bar for dry skin fragrance Free or Aveeno advanced care body wash
- Oilatum unscented soap
- Neutrogena original formula fragrance-free (bar or liquid)

Any of the shampoos listed in this brochure may be used as your hand or body soap.

- Vanicream shave cream for sensitive skin

Moisturizers

- Vanicream, Vanicream Lite
- Aveeno daily moisturizing lotion fragrance Free
- Plain Vaseline, Vaniply
- DML unscented
- Use moisturizers twice daily.
- All of the above are OK to use on the face.
- After showering, blot excess water with hands and apply cream. Do not use a towel to dry.
- Robathol bath oil

Deodorants

- Almay unscented antiperspirants
- Plain cornstarch from the grocer can be used.

Shampoo

- Free and Clear shampoo and conditioner
- DHS clear shampoo and DHS conditioner
- If you have dandruff, use DHS sal shampoo or Neutrogena T-SAL shampoo (not T-Gel).
- Conditioners can be used as “leave on” hair gel.

Hairspray

- Fragrance-free hairspray such as Free and Clear hairspray
- Caution: Hairsprays labeled as “unscented” may not be fragrance free.

Laundry and Home Care

- Unscented laundry detergents (Tide free, Cheer free and gentle, All free clear, Arm & Hammer unscented, Wisk free, Purex unscented)
- Wash all new clothes and linens five times before using.
- Old clothes and fabrics are preferred.
- Use white vinegar in rinse cycle to help remove soap.

Hand, Nail, and General Skin Care Tips

- Wear cotton gloves under rubber/vinyl gloves for any activities where hand-wetting is expected.
- Trim nails short. Long nails are dangerous to skin, especially when sleeping.

Sunscreens

- Vanicream sunscreen #30 or #60

Make-ups/cosmetics

- If you would like a list of make-ups and cosmetics that are free of the most common allergy-causing ingredients, ask your provider about a “virtual patch testing” printout from our Mayo CARD program.

Avoid

Soaps/Cleansing

- No hot water (use lukewarm).
- Avoid hot tubs.
- No rubbing alcohol.

Moisturizers

- No creams, lotions, oils or powders other than those recommended in this brochure.
- No Neosporin, triple antibiotic, or bacitracin antibiotic ointments.

Fragrances

- No perfumes, colognes, after shave, or pre-shave on any part of body/clothing.

Laundry and Home Care

- No fabric softener in washer.
- Bounce unscented fabric softener sheets in dryer if desired.
- No washing machine water softener such as Calgon (in-house water softeners are acceptable).
- White vinegar may be used as a general household cleaner.

Hand, Nail, and General Skin Care Tips

- No wetting of hands more than five times a day.
- Avoid tight-fitting clothes unless your doctor has advised you to wear a pressure garment such as support hose.
- No scrubbing! No loofah! No pumice stone!
- Do not pull off dead skin. Snip with scissors instead.

Figure 1 Sample of prepared handout (used at Mayo Clinic Arizona) with recommendations for the patient on hypoallergenic skincare products.

CUTANEOUS T-CELL LYMPHOMAS, INCLUDING MYCOSIS FUNGOIDES AND SÉZARY SYNDROME

Method of

Gary S. Wood, MD

CURRENT DIAGNOSIS

For Cutaneous T-cell Lymphomas, obtain the following:

- History: duration and pace of lesion development
- Skin examination: extent of patches, plaques, tumors, and ulcers
- Extracutaneous examination: status of lymph nodes, liver, and spleen
- Laboratory: complete blood cell count, differential, and lesional biopsy results
- Imaging: CT or fused PET/CT scans of the chest, abdomen, and pelvis (not needed for early stage mycosis fungoides)

CURRENT THERAPY

Guidelines Are Primarily for Mycosis Fungoides and Sézary Syndrome:

- Stages IA–IIA: skin-directed therapy with potent topical corticosteroids, topical mechlorethamine (Mustargen),¹ or phototherapy; radiation therapy or topical bexarotene (Targretin) in selected cases
- Stages IIB–IVB: skin-directed therapy plus one or more systemic therapies, such as interferon alfa-2b (Intron A),¹ bexarotene (Targretin), vorinostat (Zolinza), denileukin diftitox (Ontak), or methotrexate; photopheresis for erythrodermic cases
- Combination therapies are often used in intermediate- and advanced-stage disease.
- Multiagent chemotherapy is usually not an effective long-term treatment strategy.

¹Not FDA approved for this indication.

TABLE 1 Classification of Primary Cutaneous T-Cell Lymphomas

CTCL TYPE	PROPORTION OF PRIMARY CTCL (%)	5-YEAR SURVIVAL RATE (%)
MF and variants	70	85
SS	<5	<50*
CD30 ⁺ large cell	13	90
CD30 [−] large cell	7	15
Pleomorphic small/medium cell	4	60
Miscellaneous	<1	Variable

*The 5-year survival rate depends on the criteria used to define SS, and it may be as low as 10%.

Abbreviations: CTCL = cutaneous T-cell lymphoma; MF = mycosis fungoides; SS = Sézary syndrome.

T-cell lymphomas (CTCLs) recognized in the World Health Organization and European Organization for Research and Treatment of Cancer classification include mycosis fungoides (MF) and its leukemic variant, the Sézary syndrome (SS); CD30⁺ large cell lymphoma; CD30[−] large cell lymphoma; and pleomorphic CD4⁺ small or medium cell variants (Table 1). All other primary CTCLs comprise only a few percent of the total. This discussion focuses on MF and SS because they account for up to 75% of primary cutaneous cases.

Standard Diagnosis and Staging Methods

The evaluation of CTCL patients begins with a thorough clinical history and physical examination. Key elements of the history include the pace and nature of disease development, the presence or absence of spontaneous regression of lesions, prior therapy, and ingestion of drugs (e.g., anticonvulsants, antihistamines, other agents with antihistaminic properties) that have been associated with pseudolymphomatous skin eruptions that can mimic CTCLs. The review of systems should establish the presence of lymphoma-associated constitutional symptoms (e.g., fever of unknown origin, night sweats, weight loss, fatigue). In addition to general aspects, the physical examination should document the type and distribution of skin lesions and whether there is lymphadenopathy, hepatosplenomegaly, or edema of extremities (i.e., potential sign of lymphatic obstruction).

Histopathologic analysis of representative lesional skin biopsy specimens is the primary means of confirming the clinical diagnosis. Biopsy specimens should be deep enough to include the deepest portions of the cutaneous lymphoid infiltrates because these areas often exhibit the most diagnostic features. Putative extracutaneous involvement should be confirmed by biopsy if it is relevant to clinical management.

Routine blood tests include a complete blood cell count, differential review, and general chemistry panel. A “Sézary prep” is used to assess peripheral blood involvement.

Internal nodal and visceral involvement by lymphoma usually is assessed with chest radiography, computed tomography (CT), or combined positron emission tomography and CT (PET/CT) scans of the chest, abdomen, and pelvis. These radiologic studies usually are not needed for patients with early forms of MF (i.e., nontumorous skin lesions without evidence of extracutaneous involvement assessed by physical examination); however, they are usually obtained during the work-up of other types of CTCLs. The role of immunopathologic and molecular biologic assays in the diagnosis and staging of CTCLs is discussed later.

An algorithm for the diagnosis of early MF has been proposed by the International Society for Cutaneous Lymphomas (ISCL) (see Pimpinelli et al. in References). It relies on a combination of clinical, histopathologic, immunopathologic, and clonality criteria. This differs from former approaches that have been based primarily on histopathologic criteria.

Cutaneous T-Cell Lymphomas

An algorithm for the diagnosis of early MF has been proposed by the International Society for Cutaneous Lymphomas (ISCL) (see Pimpinelli et al. in References). It relies on a combination of clinical, histopathologic, immunopathologic, and clonality criteria. This differs from former approaches that have been based primarily on histopathologic criteria.

Cutaneous T-Cell Lymphomas

Classification

Virtually every subtype of T-cell lymphoma involves the skin primarily or secondarily. The principal types of primary cutaneous

Mycosis Fungoides, Sézary Syndrome, and Variants

Clinical Features

MF classically manifests as erythematous, scaly, variably pruritic, flat patches or indurated plaques, often favoring the most sun-protected areas. The patches or plaques may progress to cutaneous tumors and involvement of lymph nodes or viscera, although this usually does not occur as long as the skin lesions are reasonably well controlled by therapy. SS manifests as total-body erythema and scaling (i.e., erythroderma), generalized lymphadenopathy, hepatosplenomegaly, and leukemia. Large-plaque parapsoriasis is essentially the prediagnostic patch phase of MF. Lesions may exhibit poikiloderma (i.e., atrophy, telangiectasia, and mottled hyperpigmentation and hypopigmentation) and have then been referred to as *poikiloderma atrophicans vasculare*.

Follicular mucinosis refers to a papulonodular eruption in which hair follicles are infiltrated by T cells and contain pools of mucin. In hairy areas, this may result in alopecia. Follicular mucinosis may exist as a lesional variant of MF (i.e., follicular MF) or as a clinically benign entity (i.e., alone or associated with other lymphomas).

Granulomatous slack skin is a variant of MF that manifests with pendulous skin folds in intertriginous areas. Lesional skin biopsy specimens contain atypical T cells in a granulomatous background.

Pagetoid reticulosis manifests as a solitary or localized, often hyperkeratotic plaque containing atypical T cells that are frequently confined to a hyperplastic epidermis. Some authorities regard it as a variant of unilesional MF, whereas others think it is a distinct entity.

Other variants of MF include hypopigmented, palmoplantar, bullous, and pigmented purpuric forms. The latter form shows clinicopathologic overlap with the pigmented purpuric dermatoses. *Tumor d'emblée* MF is an outmoded concept used in the past to refer to supposed cases of MF that manifested as cutaneous tumors in the absence of patches or plaques. Most experts now prefer to classify such cases as other forms of CTCL, depending on their histopathologic features.

Histopathologic and Cytologic Features

A well-developed plaque of MF contains a bandlike, cytologically atypical lymphoid infiltrate in the upper dermis that infiltrates the epidermis as single cells and cell clusters known as Pautrier's microabscesses. The atypical lymphoid cells exhibit dense, hyperchromatic nuclei with convoluted, cerebriform nuclear contours and scant cytoplasm. The term *cerebriform* comes from the brainlike ultrastructural appearance of these nuclei. In more advanced cutaneous tumors, the infiltrate extends diffusely throughout the upper and lower dermis and may lose its epidermotropism. In the earlier patch phase of the disease, the infiltrate is sparser, and lymphoid atypia may be less pronounced. In some cases, it may be difficult to distinguish early patch-type MF from various types of chronic dermatitis. The presence of lymphoid atypia and absence of significant epidermal intercellular edema (i.e., spongiosis) help to establish the diagnosis of early MF.

Involvement of lymph nodes by MF begins in the paracortical T-cell domain and may progress to complete effacement of nodal architecture by the same types of atypical lymphoid cells that infiltrate the skin. These cells can be seen in low numbers in the peripheral blood of many MF patients; however, those with SS develop gross leukemic involvement, usually defined as at least 1000 tumor cells/mm³. These cells are known as Sézary cells, and they are traditionally detected by manual review of the peripheral blood smear (the so-called Sézary prep). They may also be defined by various immunophenotypic criteria.

Immunophenotyping

Cellular antigen expression is usually assessed by immunoperoxidase methods for tissue biopsy specimens and by flow cytometry for blood specimens. Almost all cases of MF or SS begin as phenotypically and functionally mature CD4⁺ T-cell neoplasms of skin-

associated lymphoid tissue (SALT). MF and SS express homing markers consistent with "effector memory" and "central memory" T cells, respectively. They express the SALT-associated homing molecule cutaneous lymphocyte antigen (CLA) and most mature T-cell surface antigens, with the exceptions of CD7 and CD26, which are often absent. As disease progresses, the tumor cells often dedifferentiate and lose one or more mature T-cell markers, such as CD2, CD3, or CD5.

Cases typically express the α/β form of the T-cell receptor. At least in advanced cases, the cytokine profile is consistent with the T_H2 subset of CD4⁺ T cells (i.e., production of interleukin [IL]-4, IL-5, and IL-10 rather than T_H1 cytokines such as IL-2 and interferon- γ). Expression of the high-affinity IL-2 receptor (CD25, TAC) ranges widely, with most cases showing a variable minority of lesional CD25⁺ cells. Tumor cells can be induced to express a regulatory T-cell phenotype (Treg) in vitro. MF cases that express CD8⁺ or other aberrant phenotypes occur occasionally but behave like conventional cases. They should not be confused with rare aggressive CTCLs exhibiting cytotoxic T-cell differentiation.

In addition to tumor cells, MF and SS lesions contain a minor component of immune accessory cells (i.e., Langerhans cells and macrophages) and CD8⁺ T cells with a cytolytic phenotype. This presumed host response correlates positively with survival and tends to decrease as lesions progress. A favorable response to therapy such as photopheresis appears to correlate with normal levels of circulating CD8⁺ cells.

Molecular Biology

Well-developed MF or SS is a monoclonal T-cell lymphoproliferative disorder. Southern blotting or polymerase chain reaction (PCR) assays demonstrate monoclonal T-cell receptor gene rearrangements. The greater sensitivity of PCR assays allows the demonstration of dominant clonality in many early patch-type lesions of MF. These assays sometimes detect dominant clonality in lesional skin showing only chronic dermatitis histopathologically. These cases are called *clonal dermatitis* and may represent the earliest manifestation of MF because several have progressed to histologically recognizable MF within a few years. However, some cases of clinicopathologically defined early-phase MF lack a detectable monoclonal T-cell population until later in their clinical course. Next generation high throughput T-cell receptor sequencing is emerging as a more sensitive and quantitative alternative to other molecular assays of T-cell clonality.

In addition to aiding initial diagnosis, gene rearrangement analysis has facilitated staging and prognosis. Because some patients without MF or SS can have low levels of circulating Sézary-like cells and because not all cases of peripheral blood involvement in MF or SS exhibit morphologically recognizable tumor cells, the demonstration of dominant clonality that matches the clone in lesional skin has proved to be a useful diagnostic adjunct. The same holds true for assessing lymph node involvement. T-cell receptor gene rearrangement analysis of MF and SS lymph nodes is more sensitive than histopathology and possesses at least some prognostic relevance.

TNMB Staging

Although several proposed methods have used a weighted extent approach to more accurately determine the MF or SS tumor burden, the preferred approach is the tumor-node-metastasis-blood (TNMB) system, which is detailed in [Tables 2 and 3](#). The original tumor (skin), lymph nodes, and metastasis (visceral organs) version of this system has been modified by the ISCL to incorporate the extent of blood involvement (B classification) into the staging process. [Table 2](#) shows the TNMB classification relevant to MF and SS, and [Table 3](#) shows how this information is used to determine the stage of disease. The prognostic relevance of this staging system has been supported by numerous studies, and use of the TNMB helps to guide the selection of therapies. For example, early-stage MF is the most amenable to control with topically directed treatments, whereas advanced MF or SS with extracutaneous involvement usually requires systemic therapies or topical plus systemic combinations.

³Exceeds dosage recommended by the manufacturer.

TABLE 2 TNMB Classification of Mycosis Fungoides and Sézary Syndrome

Skin (T)	
T1	Patches and/or plaques; <10% body surface area
T2	Patches and/or plaques; ≥10% body surface area
T3	Tumors with/without other skin lesions
T4	Generalized erythroderma
Lymph Nodes (N)	
N0	Not clinically enlarged; histopathology not required
N1	Clinically enlarged; histopathologically negative
N2	Clinically enlarged; histopathologically equivocal
N3	Clinically enlarged; histopathologically positive
Visceral Organs (M)	
M0	No involvement
M1	Involvement
Peripheral Blood (B)	
B0	Atypical cells ≤5% of leukocytes
B1	Atypical cells >5% of leukocytes
B2	Atypical cells ≥1000/mm ³

Modified from Olsen E, Vonderheid E, et al: Revisions to the staging and classification of mycosis fungoides and Sézary syndrome: A proposal of the International Society for Cutaneous Lymphomas (ISCL) and the cutaneous lymphoma task force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood* 2007;110(6):1713–1722.

Treatment

Treatment guidelines for CTCL published by the National Comprehensive Cancer Network can be found at www.nccn.org. Rather than cure, which is attained in less than 10% of cases, the goal of MF and SS therapy is to reduce the impact of the skin disease on quality of life. For most patients, this is achieved by reducing pain, itch, and infection and improving clinical appearance. Appearance is affected by the disfigurement of the eruption and by the profound degree of scale shedding in some patients. Because the natural history of early-stage MF predicts a virtually normal life span, the goal of treatment must be directed at quality of life. For more advanced stages, prolongation of life expectancy may be a reasonable treatment goal.

Regardless of presentation, relief of symptoms should be addressed early. For dryness and scaling, the use of emollient ointments is indicated. These include petrolatum, Aquaphor, and commercially available shortening such as Crisco (an inexpensive alternative).¹ For modest dryness, creams (e.g., Nivea, Cetaphil, Eucerin) can be adequate and more acceptable to patients. Mild superfatted soaps such as Dove and Oil of Olay are recommended. Soap substitutes such as Cetaphil are also acceptable. Pruritus can be addressed with oral agents such as hydroxyzine (Atarax) or diphenhydramine (Benadryl)¹ 2 to 5 mg/kg/day and divided into four daily doses. Antipruritics work better when used on a regular basis rather than on an as-needed basis. Nonsedating antihistamines tend to be less effective. Measures to reduce dryness also help to reduce pruritus. Secondary infection needs to be treated with appropriate antibiotics. Their selection is guided by results of skin cultures but usually involves coverage of gram-positive organisms.

Phototherapy

Two main phototherapeutic regimens are used to treat CTCLs. Ultraviolet B radiation (290–320-nm broad band or 311-nm narrow band) can be used for patients with patches but not those with well-developed plaques or tumors. Seventy percent of patients achieve total clinical remission, usually within about 3 to 5 months. Another 15% achieve partial remission. Narrow-band UVB usually is more effective than broadband UVB and achieves maximal responses more rapidly.

Psoralen–ultraviolet A (PUVA) photochemotherapy uses oral 8-methoxypsoralen (8-MOP)¹ 0.6 mg/kg as a photosensitizer before UVA (320–400 nm) exposure. Sixty-five percent of patients with patch or plaque disease achieve complete remissions, and 30% have partial responses to this modality. For most patients, maximal responses are achieved within 3 months, and after 5 months, it is unlikely that further improvement will be gained. Limitations of these modalities include actinic damage, photocarcinogenesis, retinal damage (if eyes are not protected), and the inconvenience of getting to phototherapy centers. PUVA also has the risk of nausea and a theoretical risk of cataract induction without proper eye protection.

During the clearing phase of treatment, phototherapy treatments usually are administered three times per week. After resolution of skin lesions, treatment frequency is usually tapered gradually to once weekly for UVB and once every 4 to 6 weeks for PUVA. These maintenance regimens are often continued for months to years because abrupt cessation of phototherapy is commonly associated with rapid relapse, which is probably related to the persistence of microscopic disease after clinical clearing.

Topical Therapy

Like phototherapeutic regimens, topical therapies are appropriate for disease confined to the skin (stage I). Topical corticosteroids are frequently used for CTCLs, often before diagnosis. Low-potency formulations are useful on the face and skin folds. Medium-potency preparations are appropriate for the trunk and extremities. High-potency formulations are useful for recalcitrant lesions; however, prolonged use of such potent agents can cause local atrophy and adrenal suppression. Roughly half of patients achieve complete remissions, and most others have partial remissions. Response duration varies widely with the individual pace of disease and patient compliance. Topical corticosteroids are particularly useful as a means to relatively quickly ameliorate severe signs and symptoms and as an adjuvant therapy in combination with other primary treatments.

Mechlorethamine (nitrogen mustard, HN₂, Mustargen) is applied topically in an aqueous solution or in an ointment, such as Aquaphor. Although these forms are not FDA approved for this indication, a 0.016% gel formulation (Valchlor) is now commercially available and FDA approved. The aqueous form is prepared at home and involves a daily dose totaling 10 mg

¹Not FDA approved for this indication.

in 60 mL water. The ointment form is prepared by a pharmacist in 1-pound lots at a concentration of 10 mg mechlorethamine per 100 g ointment. Only the amount of ointment needed to apply a thin layer is used. Either formulation is usually applied at bedtime to lesional skin for limited disease or to the entire skin surface (excluding the head unless it is also involved) for more extensive disease. It is then showered off every morning using soap and water. Results are similar to those from PUVA. Advantages include therapy at home and availability in all regions of the country. Disadvantages are daily preparation (aqueous form only), daily application, and possible allergic contact dermatitis (more common with the aqueous preparation). Maximal efficacy is expected within 6 months. Mild flare-ups of disease may occur during the first few months of treatment and probably represent inflammation of subclinical skin lesions, analogous to the clinical accentuation of actinic damage during topical therapy with 5-fluorouracil (Efudex). As with phototherapy, topical mechlorethamine is tapered gradually after remission is achieved in an effort to delay clinical relapse.

Carmustine (BCNU, BiCNU)¹ is applied to the total skin surface as an alcohol/aqueous solution (10–20 mg in 60 mL).⁶ Complete responses are seen in 85% of patients with stage IA disease (<10% involvement) and 50% of patients with stage IB disease (>10% involvement). Another 10% of patients obtain partial responses. Advantages include those described for nitrogen mustard and reports of success with application only to lesional skin. Disadvantages include skin irritation followed by telangiectasia formation and possible bone marrow suppression necessitating blood monitoring.

A topical gel formulation of the retinoid X receptor (RXR)–specific retinoid, bexarotene (Targretin), is useful for localized or limited skin lesions. The principal side effect is local irritation.

Radiotherapy

Conventional radiotherapy for mycosis fungoides therapy has been used for approximately 100 years. It is useful in the treatment of isolated, particularly problematic lesions such as recalcitrant tumors or ulcerated plaques. In addition to benefit from the photons delivered by radiotherapy, electron beam therapy (0.4 Gy per week for 8–9 weeks) is also useful for CTCL therapy. An approximately 85% complete response rate of skin disease with a median duration of 16 months is expected with electron beam therapy. An advantage is an excellent rate of complete response. Disadvantages include limited access to required equipment and expertise and cutaneous toxic effects, such as alopecia, sweat gland loss, radiation dermatitis, and skin cancers. As with other skin-directed therapy, the benefit for internal disease is limited. Cumulative toxicity also limits the number of courses a patient may receive. Localized electron beam therapy is also useful for treating cases of limited-extent MF and in treating selected problematic MF lesions in patients who are otherwise responding to therapy. After completion of total-skin electron beam therapy, patients require maintenance therapy such as topical mechlorethamine⁶ or phototherapy to prolong remission. Low dose radiotherapy is emerging as an effective alternative to conventional regimens.

Apheresis-Based Therapy

Leukapheresis and particularly lymphocytapheresis (6000–7000 mL of blood treated three times per week initially, then according to response) have been used in the treatment of SS patients. Benefit has been reported in several case reports and small case series; however, response rates are not possible to determine. Photopheresis (i.e., extracorporeal photochemotherapy) describes an apheresis-based therapy in which circulating lymphocytes are first exposed to a psoralen (orally or extracorporeally) and then exposed to UVA extracorporeally. In contrast to leukapheresis, in which leukocytes are discarded, all cells are returned to the patient's circulation during photopheresis. Response rates in erythrodermic patients are 33% to 50%, and median survival for

SS patients is prolonged from 30 months to more than 60 months. In recent years, extracorporeal photochemotherapy has been used increasingly in conjunction with one or more systemic therapies to enhance efficacy. The toxicity of the systemic agents is diminished because they are often used in combination at reduced doses.

Cytokine Therapy

Interferon alfa-2a (Roferon-A) or alfa-2b (Intron-A)¹ (1 to 100 × 10⁶ units) is given subcutaneously or intralesionally every other day to once weekly. A standard starting dose is 3 × 10⁶ units three times per week. Response rates are approximately 55%, with complete responses occurring in 17% of patients. Advantages include the relative ease of delivery. Disadvantages include anorexia, fever, malaise, leukopenia, and risk of cardiac dysrhythmia. Interferon alfa-2a or alfa-2b combined with narrow-band UVB or PUVA is effective for many patients with generalized skin lesions unresponsive to phototherapy alone.

Tumor-Associated Antigen-Directed Therapies

Various specific tumor-associated antigens have been targeted with antibody-based therapy. The response rate typically is low, and response durations are short. Less specific targets are CD4, CD5, and IL-2 receptors. Of this class of agent, the most promising is denileukin diftitox (Ontak, DAB389 IL-2) (9–18 µg per/kg/day IV on 5 consecutive days, every 3 weeks). This agent is a fusion protein combining IL-2 and diphtheria toxin. Cells bearing the IL-2 receptor (in the lesions of at least one half of MF patients) bind and internalize the drug. The drug also may destroy Treg cells that are CD25⁺ and suppress immune responses. Inside the cell, the toxin portion of the molecule disrupts protein synthesis, leading to cell death. Approximately 10% of patients achieve complete responses, and total response rates of near 40% have been reported. Half of responders and 20% of nonresponders experienced decreased pruritus. Adverse events include capillary leak syndrome, flulike symptoms, and allergic reactions. Combination therapy with denileukin diftitox and multiagent chemotherapy is being explored for advanced disease. Alemtuzumab (Campath)¹ is an antibody directed against CD52. It has shown benefit in advanced-stage disease. This agent can be used alone or in conjunction with multiagent chemotherapy. Brentuximab vedotin (Adcetris)¹ is an anti-CD30 antibody linked to the microtubule toxin monomethyl auristatin E. It can be effective in those cases of MF that express sufficient CD30.

Systemic Chemotherapy

Various regimens of single-agent and multiagent chemotherapy have been used in the treatment of MF and SS. Oral methotrexate, chlorambucil (Leukeran)¹ with or without prednisone,¹ and etoposide (VePesid)¹ have shown therapeutic activity. The best response has been in erythrodermic patients treated with methotrexate (5 to 125 mg weekly),³ who have shown a 58% response rate. The combination of low-dose methotrexate and interferon alfa has been reported to yield a high response rate in advanced-stage MF and SS.

The use of multiagent regimens is controversial because of the small number of patients treated with any given regimen. There is even some evidence that for some populations of CTCL patients, survival may be reduced. For individual patients with advanced disease, however, cyclophosphamide (Cytosan),¹ doxorubicin (Adriamycin),¹ vincristine (Oncovin),¹ and prednisone¹ (CHOP regimen) can provide some short-term palliation. In some cases, CHOP has successfully eradicated large cell transformation of MF and returned patients to their more clinically indolent patch or plaque baseline disease. Idarubicin (Idamycin)¹ in association with etoposide, cyclophosphamide, vincristine, prednisone, and bleomycin (Blenoxane)¹ (VICOP-B regimen) has demonstrated response rates of 80% (36% complete response rate) for patients with stage II through IV disease and 84% for MF patients, with a median duration of response longer than 8 months. Other regimens have been used with more modest success.

¹Not FDA approved for this indication.

⁶May be compounded by pharmacists.

¹Not FDA approved for this indication.

Several purine nucleoside analogues have been used for CTCL treatment, including erythrodermic variants. These include 2-chlorodeoxyadenosine (cladribine [Leustatin]),¹ with a response rate of 28%), 2-deoxycoformycin (pentostatin [Nipent]),¹ with a response rate of 39%), and fludarabine (Fludara).¹ Toxicities include pulmonary edema, bone marrow and immune suppression, and neurotoxicity.

Retinoids

Retinoids have therapeutic activity against MF and SS alone and in combination with other therapies, such as interferon alfa or PUVA (the latter combination is called Re-PUVA). Arotinoid,⁵ acitretin (Soriatane),¹ and 13-*cis*-retinoic acid (isotretinoin [Accutane])¹ have various degrees of efficacy, and they typically are used in conjunction with other modalities. A newer RXR-specific retinoid, bexarotene, has an overall response rate of about 40% and can be used alone or in combination with phototherapy and other systemic agents such as interferon alfa-2. Disadvantages of bexarotene therapy include signs of hypothyroidism and vitamin A toxicity, particularly hyperlipidemia.

Enzyme Inhibitors

Vorinostat (Zolinza) is the first histone deacetylase inhibitor to be FDA approved for MF and SS. The overall response rate approaches 40% using a standard oral dose of 400 mg/day. Side effects include gastrointestinal symptoms, thrombocytopenia, and cardiac conduction abnormalities. Romidepsin (Isotodax) is an intravenously administered histone deacetylase inhibitor recently approved by the FDA for MF and SS. Forodesine⁵ is a purine nucleoside phosphorylase inhibitor that preferentially affects T cells because they contain relatively high concentrations of this enzyme. Forodesine is undergoing clinical trials for MF and SS in the United States and appears to have a response rate of about 40%.

Miscellaneous Therapies

Various other therapies have been tried for MF and SS with modest success. Nonmyeloablative allogeneic stem cell transplantation has led to favorable responses in some patients; however, the total number treated is small. Cyclosporine (Sandimmune)¹ has been used for MF and SS. Transient improvement is followed by worsened survival due to immunosuppression, and it is not a recommended therapy. Thymopentin⁵ has given excellent results in SS patients (i.e., 40% complete response rate and 35% partial response rate, with a median duration of response of 22 months). The lack of follow-up reports in recent decades leaves the status of this therapy in question.

Selection of Therapy

Initial choices among conventional treatments for MF and SS depend on the types of lesions and the stage of disease. Disease subsets are followed by recommended initial treatments in parentheses: unilesional or localized MF (local radiation therapy), patch MF (broad- and narrow-band UVB, PUVA, mechlorethamine), patch/plaque MF (PUVA, mechlorethamine), thick plaque/tumor MF (electron beam radiation therapy, interferon alfa-2, bexarotene, histone deacetylase inhibitors), erythrodermic MF/SS (photopheresis), and nodal or visceral MF or SS (interferon alfa-2, bexarotene, histone deacetylase inhibitors, denileukin diftitox, experimental systemic therapies, systemic chemotherapy).

Second-line therapeutic choices often involve interferons, retinoids, or histone deacetylase inhibitors, usually in combination with primary modalities. Multimodality combinations, often at reduced doses, are used commonly to treat patients with stage IIB or more advanced disease. Medium-potency topical corticosteroids, such as 0.1% triamcinolone cream or ointment (Kenalog),¹ are useful adjuncts to many different therapies. The optimal use of newer therapeutic agents in various subtypes and stages of MF and SS is still being established. Evidence-based guidelines for MF and

SS therapy have been developed by the National Comprehensive Cancer Network (NCCN) (www.nccn.org).

Lymphoproliferative Disorders Associated with Mycosis Fungoides and Sézary Syndrome

Types and Clinical Features

Patients with MF or SS are at increased risk for large T-cell lymphomas, lymphomatoid papulosis, and Hodgkin's disease. Molecular biologic analysis has shown that these disorders and MF often share the same clonal T-cell receptor gene rearrangement when they arise in the same individual. As a consequence, they are considered to be subclones of the original MF tumor clone. The development of large T-cell lymphoma in a patient with MF or SS is referred to as *large cell transformation of MF*. This occurs in up to 20% of cases in some series and is associated with a median survival of only 1 to 2 years. One half of these large T-cell lymphomas are CD30⁺; however, the generally favorable prognosis of primary cutaneous CD30⁺ anaplastic large cell lymphoma does not extend to these secondary forms of CD30⁺ lymphoma. These patients are usually treated with systemic chemotherapy such as CHOP or with experimental systemic therapies appropriate for advanced-stage CTCL.

Lymphomatoid papulosis manifests as recurrent, usually generalized crops of spontaneously regressing, erythematous papules that can exhibit crusting or vesiculation before resolution. It is the clinically benign end of a disease continuum that has primary cutaneous CD30⁺ anaplastic large cell lymphoma at its other extreme. Intermediate forms of disease can occur. Histopathologically, lesions contain a mixed-cell infiltrate, including large, atypical T cells that resemble Reed-Sternberg cells and their mononuclear variants (so-called type A) or large MF-type cells (so-called type B). Type A cells are CD30⁺. A type C form is also recognized. It has sheets of type A cells histologically mimicking CD30⁺ large T-cell lymphoma but is different from it clinically. A type D variant containing CD8⁺ CD30⁺ large atypical cells has also been described recently. All types of lymphomatoid papulosis behave similarly. Patients with lymphomatoid papulosis sometimes respond to tetracycline or erythromycin (500 mg PO bid), presumably on the basis of antiinflammatory activity. Most cases improve within 1 month with low-dose methotrexate (10–20 mg PO every week). PUVA and narrow-band UVB given three times per week are other therapeutic options.

Treatment

In most cases, non-MF/SS CTCLs are treated with radiation therapy (with or without complete surgical excision) if they are localized or with various multiagent systemic chemotherapy regimens if they are generalized. The roles of other agents remain to be defined, except that studies have proved that methotrexate (10–40 mg PO every week) is effective therapy for most cases of primary cutaneous CD30⁺ anaplastic large cell lymphoma. Therapies being investigated for this lymphoma include anti-CD30 antibodies, alone or conjugated to toxins. One of these antibody conjugates (brentuximab vedotin) is FDA approved for systemic CD30⁺ lymphomas and Hodgkin's disease. Denileukin diftitox has been reported to be effective against some subcutaneous panniculitic T-cell lymphomas.

CUTANEOUS VASCULITIS

Method of

Molly Hinshaw, MD; and Susan Lawrence-Hylland, MD

CURRENT DIAGNOSIS

- Cutaneous vasculitis can be limited to skin (leukocytoclastic vasculitis) or associated with systemic disease.
- Perform punch biopsy of intact, nonulcerated skin lesion.
- "Vasculitis" on skin biopsy describes vessel appearance and is not a clinical diagnosis.
- Thorough review of systems and physical examination are necessary to evaluate for systemic vasculitis.

CURRENT THERAPY

Leukocytoclastic Vasculitis

- First identify instigating factors: infection, medications.
- Care is symptomatic. Lesions typically remit without treatment.
- If needed, short course of prednisone may be given and tapered over 3 to 6 weeks.

All Forms of Vasculitis

- Treat underlying systemic vasculitis.

Vasculitis is an inflammatory-mediated destruction of blood vessels. The systemic vasculitides have historically been differentiated by their involvement of small, medium, or large blood vessels. Names used to describe isolated cutaneous vasculitis have included hypersensitivity vasculitis and leukocytoclastic vasculitis (LCV). In 1990, the American College of Rheumatology proposed five criteria for the classification of hypersensitivity vasculitis: age older than 16 years, possible drug trigger, palpable purpura, maculopapular rash, and skin biopsy showing neutrophils around vessel. At least three out of five criteria yield a sensitivity of 71% and specificity of 84%. In 1994, a new nomenclature proposed at the Chapel Hill International Consensus Conference in North Carolina further classified vasculitis ([Box 1](#)). The term "hypersensitivity vasculitis" was not used, because most vasculitides that would have previously been in this category fall into either microscopic polyangiitis or cutaneous LCV. LCV is vasculitis restricted to the skin without involvement of vessels in other organs. Cutaneous vasculitis may be a clue to systemic vasculitis and guides the clinician to a comprehensive evaluation ([Table 1](#)).

BOX 1

Chapel Hill Consensus 1994 Classification of Vasculitis

Large-Vessel Vasculitis

Giant cell arteritis
Takayasu's arteritis

Medium-Vessel Vasculitis

Classic polyarteritis nodosa
Kawasaki's disease

Small-Vessel Vasculitis

Churg-Strauss syndrome
Cutaneous leukocytoclastic vasculitis
Essential cryoglobulinemia
Henoch-Schönlein purpura
Microscopic polyangiitis (polyarteritis)
Wegener's granulomatosis

Vasculitis can affect almost any organ, and once affected, end organs can become dysfunctional. Such dysfunction may be as innocuous as cutaneous, tender, transient papules or as devastating as a stroke. A thorough evaluation of the patient with a complete review of systems, physical examination, laboratory evaluation, and clinical follow-up allows a distinction to be made between the different forms of vasculitis.

Leukocytoclastic Vasculitis

Epidemiology

LCV is common. The incidence and prevalence are unknown. Mean age of onset ranges from 34 to 49 years of age. The female-to-male ratio ranges from approximately 2:1 to 3:1.

Risk Factors

LCV is often secondary to a known trigger including infection, drug ingestion, or malignancy. LCV can also be a presenting feature of autoimmune disease.

Pathophysiology

LCV is best characterized as immune complex-mediated inflammatory destruction of the postcapillary venules of any organ. The exact mechanisms of vascular destruction is unknown.

Clinical Manifestations

LCV typically manifests as nonblanchable macules that evolve to papules or, less commonly, pustules and ulcers ([Figure 1](#)). Clues to the diagnosis include a monomorphous, ruddy-brown appearance owing to leakage of hemosiderin pigment from vessels. Lesions measure a few millimeters to a few centimeters in diameter. LCV is often localized to the lower extremities but may be diffuse. Pruritus, pain, or burning of the skin lesions are indicators that the patient might have a vasculitis extending beyond LCV.

Diagnosis

To confirm a clinical impression of LCV, perform a punch biopsy in the center of a nonulcerated cutaneous lesion that is less than 24 to 48 hours old and submit the sample in 10% formalin (standard medium). It is important to biopsy an intact, nonulcerated active lesion ([Figure 2](#)) because ulcers can show histologic features simulating vasculitis regardless of whether the patient has true vasculitis or not.

Pathology reveals a mononuclear or polymorphonuclear inflammation of the small blood vessels (called LCV), most prominent in the postcapillary venules. The appearance may be necrotizing or non-necrotizing.

Differential Diagnosis

LCV manifests as erythematous papules or occasionally as papulopustules that can simulate a variety of entities (see [Table 1](#)). The review of systems and physical examination should be directed to evaluate for diseases that have cutaneous vasculitis as a component of their presentation (see [Table 1](#)). All patients with LCV should have a urinalysis to evaluate for hematuria as a sign of kidney involvement, with subsequent evaluation and management if identified.

Treatment

The primary goal in the management of LCV is to identify and treat instigating factors, including infection and medications. Supportive treatment includes resting, elevating legs, and wearing support hose. When review of systems, physical examination, and urinalysis do not reveal associated systemic diseases, treatment of LCV is generally not necessary. Lesions typically remit without treatment. In rare patients with symptomatic, extensively pustular, or progressive lesions, a short course of prednisone¹ dosed at 1 mg/kg/day initially and tapered over 3 to 6 weeks may be used, although no controlled trials have been performed using oral corticosteroids

¹Not FDA approved for this indication.

TABLE 1 Diseases with Cutaneous Vasculitis as a Component of Their Presentation

DISEASE	SKIN LESIONS	CLUES AND CONFIRMATION
Urticarial vasculitis	Individual lesions look like urticaria but last >24 h; typical urticaria last a few hours, always <24 h Pruritus, burning of skin lesions	May be associated with connective tissue disease, medications, low complement, viral infections (e.g., hep B, hep C, EBV) Skin biopsy
Henoch-Schönlein purpura	Wheals progress to petechia, ecchymoses and palpable purpura Lesions are in gravity-dependent or pressure-dependent areas such as legs or the buttocks in toddlers	Arthralgia or arthritis, hematuria, abdominal pain, melena Skin biopsy and DIF for IgA
Essential mixed cryoglobulinemia	Palpable purpura	Peripheral neuropathy, GN Hep C positive Serum cryoglobulins
Wegener's granulomatosis	Palpable purpura, hemorrhagic lesions, petechiae, skin ulcers	c-ANCA >80% Pulmonary hemorrhage, GN Biopsy affected organ
Churg-Strauss syndrome	Maculopapular rash, palpable purpura, hemorrhagic lesions, subcutaneous nodules, livedo reticularis or Raynaud's disease	ANCA (50%) Asthma, allergic rhinitis Eosinophilia $>1.5 \times 10^9/L$ Pulmonary infiltrates, pulmonary neuropathy Biopsy affected organ
Microscopic polyangiitis	Palpable purpura, hemorrhagic lesions, petechiae, skin ulcers, splinter hemorrhages	p-ANCA >60% Pulmonary hemorrhage, GN Biopsy affected organ
Polyarteritis nodosa	Livedo reticularis, tender nodules, skin ulcers, bullae or vesicles	Hypertension, elevated creatinine, abdominal pain, constitutional symptoms (fever) Abnormal angiogram Biopsy affected organ

Abbreviations: c-ANCA = classic antineutrophil cytoplasmic antibody; DIF = direct immunofluorescence; EBV = Epstein-Barr virus; GN = glomerulonephritis; hep = hepatitis; Ig = immunoglobulin; p-ANCA = protoplasmic-staining antineutrophil cytoplasmic antibody.

Figure 1 Leukocytoclastic vasculitis: palpable, purpuric, nonblanching, erythematous to ruddy-brown thin papules. Additional secondary changes include small pustules (pustular vasculitis) or shallow, small ulcerations.

for isolated LCV. Rapid steroid taper can lead to rebound. Systematic evaluation of the use of other medications, such as colchicine¹ or dapsone,¹ to treat isolated LCV has not been performed.

Monitoring

Patients with LCV are at risk for recurrent or chronic vasculitis. In addition, apparent LCV can occur as a systemic disease that is not recognizable at the first episode. Patients with persistent or recurrent LCV require follow-up to ensure disease clearance, to monitor for medication side effects, and to evaluate for evolving disorders known to be associated with cutaneous vasculitis (see Table 1).

Complications

Isolated LCV generally resolves without sequelae. However, pustular or ulcerative LCV may be complicated by local sequelae such as cutaneous ulcerations and scars.

Figure 2 Biopsy of intact clinical lesion of leukocytoclastic vasculitis. Histology shows destruction of postcapillary venules with fibrin deposition, degenerate inflammatory cells, and extravasated erythrocytes.

Cutaneous Vasculitis Associated with Systemic Vasculitis

Cutaneous vasculitis may be a component of the presentation of multiple diseases (see Table 1). When a clinician reads a pathology report from a biopsy of a skin lesion that states “vasculitis,” it is important to realize that this term is a descriptor of the histopathology. It is the clinician’s challenge to determine whether “vasculitis” is as potentially innocuous as LCV or part of a more severe systemic disease. Symptoms that are clues to a systemic process can include fever, arthralgias, myalgias, anorexia, abdominal pain, pulmonary abnormalities, or neurologic symptoms.

Skin biopsy may aid in the diagnosis of a systemic vasculitis (Henoch-Schönlein purpura), but biopsy of an affected end organ may be necessary to confirm a diagnosis. Pathology focuses on the confirmation of vasculitis in a small, medium, or large vessel.

Aside from Henoch-Schönlein purpura, treatment of systemic vasculitis is typically much more aggressive than treatment of LCV and should be pursued in conjunction with involvement of a rheumatologist, nephrologist, or pulmonologist. Systemic disease leads to severe complications including renal failure, pulmonary damage, permanent vascular disease, or neurologic insult depending on the viscera affected.

DISEASES OF THE HAIR

Method of

Dirk M. Elston, MD

CURRENT DIAGNOSIS

- A sudden increase in shedding most commonly represents telogen effluvium.
- Hair thinning is more likely to represent pattern alopecia.
- Scarring alopecia generally requires a biopsy for diagnosis.
- Most medically significant hirsutism results from polycystic ovarian syndrome.
- New-onset virilization suggests the possibility of a tumor.

CURRENT THERAPY

- Pattern alopecia in men is treated with oral finasteride (Propecia), topical minoxidil (Rogaine for Men), or both.
- Pattern alopecia in women is treated with antiandrogens (such as spironolactone [Aldactone]¹), topical minoxidil (Women's Rogaine), or both. Platelet-rich plasma injections may be of benefit in both men and women.
- Alopecia areata can require intralesional corticosteroid injections, topical immunotherapy, or therapy with agents such as methotrexate (Trexall)¹ or Janus kinase (JAK) inhibitors.
- A scalp biopsy is critical to guide therapy in scarring alopecia.
- Hirsutism may be treated with laser epilation or systemic antiandrogens. Topical eflornithine (Vaniqa) can slow regrowth of facial hair.

¹Not FDA approved for this indication.

Epidemiology

Hair disorders are common, with more than half of the population affected by pattern alopecia and the prevalence of hirsutism varying significantly by ethnicity.

Risk Factors

Most causes of alopecia and hirsutism are genetically determined.

Pathophysiology

Pattern alopecia relates to increased sensitivity to dihydrotestosterone. Telogen effluvium relates to an alteration in the normal hair cycle, with many hairs shedding synchronously. Alopecia areata represents an inflammatory insult directed against melanocytes in the hair bulb. There is strong evidence that the disease is mediated by T_H1 lymphocytes. Polycystic ovarian syndrome is an insulin-resistance syndrome resulting in excess production of androgens.

Prevention

Little can be done to prevent hair disorders, so the focus is generally on diagnosis and treatment.

Clinical Manifestations

Pattern alopecia manifests with apical scalp thinning. In men, receding of the hairline at the temples is typical, whereas women demonstrate widening of the part but retain the anterior hairline. Telogen effluvium manifests with diffuse shedding of telogen hairs (hairs with a nonpigmented bulb). Alopecia areata typically occurs with patchy hair loss. Shed hairs demonstrate tapered fracture at the base. Syphilitic alopecia resembles alopecia areata but often affects smaller areas, with only partial hair loss, resulting in a moth-eaten appearance. Scarring alopecia shows permanent areas of smooth alopecia lacking follicular openings.

Polycystic ovarian syndrome manifests with evidence of anovulation and excess androgen production. Signs of virilization suggesting a possible tumor include new onset of hirsutism, deepening of the voice, change in body habitus, and clitoromegaly.

Diagnosis

Alopecia

The first step is to determine if a hair shaft abnormality exists (Box 1). This is particularly important in black patients, in whom trichorrhexis nodosa is a common cause of hair loss. Trichorrhexis nodosa results from overprocessing of the hair. Hair density is normal at the level of the scalp, but hairs break off, leaving patches of short hair.

The next step is to determine if telogen effluvium exists. Telogen effluvium manifests with increased shedding of hairs with a blunt nonpigmented bulb (Figure 1), and it commonly follows an illness, surgery, delivery, or crash diet by 3 to 5 months. Hairs can often be easily extracted with a gentle hair pull or 1 minute of combing. The presence of tapered fracture suggests alopecia areata, syphilis, or heavy metal poisoning. Alopecia areata can result in diffuse hair loss, but it more commonly manifests with well-defined round patches of hair loss. The skin is either normal or salmon pink. Syphilis more often shows a moth-eaten pattern of alopecia (Figure 2).

Most patients with hair loss need only limited laboratory testing or none at all. Thyroid disorders and iron deficiency are common, and testing for them is relatively inexpensive. I recommend them when telogen effluvium is present. Their presence can also accelerate the course of pattern alopecia, and it is reasonable to test for them in women with this disorder. Thyroid-stimulating hormone is the best screen for thyroid disorders. The role of iron deficiency in telogen hair loss is controversial, but iron deficiency is common, easily established, and inexpensive to correct. Iron status also serves as an indicator of overall nutritional status. Although a low ferritin level proves iron deficiency, ferritin behaves as an acute phase reactant and a normal level does not rule out iron deficiency. Therefore I recommend measurement of ferritin, serum iron, iron binding capacity, and saturation.

A scalp biopsy is required in any patient with scarring alopecia. It may also be necessary in other patients if history and physical examination do not establish a diagnosis and the alopecia is progressive. The scalp biopsy should be performed with a 4-mm biopsy punch oriented parallel to the direction of hair growth. Collagen hemostatic sponge (Gelfoam and others) can be placed into

Skin biopsy may aid in the diagnosis of a systemic vasculitis (Henoch-Schönlein purpura), but biopsy of an affected end organ may be necessary to confirm a diagnosis. Pathology focuses on the confirmation of vasculitis in a small, medium, or large vessel.

Aside from Henoch-Schönlein purpura, treatment of systemic vasculitis is typically much more aggressive than treatment of LCV and should be pursued in conjunction with involvement of a rheumatologist, nephrologist, or pulmonologist. Systemic disease leads to severe complications including renal failure, pulmonary damage, permanent vascular disease, or neurologic insult depending on the viscera affected.

Polycystic ovarian syndrome manifests with evidence of anovulation and excess androgen production. Signs of virilization suggesting a possible tumor include new onset of hirsutism, deepening of the voice, change in body habitus, and clitoromegaly.

Diagnosis

Alopecia

The first step is to determine if a hair shaft abnormality exists (Box 1). This is particularly important in black patients, in whom trichorrhexis nodosa is a common cause of hair loss. Trichorrhexis nodosa results from overprocessing of the hair. Hair density is normal at the level of the scalp, but hairs break off, leaving patches of short hair.

The next step is to determine if telogen effluvium exists. Telogen effluvium manifests with increased shedding of hairs with a blunt nonpigmented bulb (Figure 1), and it commonly follows an illness, surgery, delivery, or crash diet by 3 to 5 months. Hairs can often be easily extracted with a gentle hair pull or 1 minute of combing. The presence of tapered fracture suggests alopecia areata, syphilis, or heavy metal poisoning. Alopecia areata can result in diffuse hair loss, but it more commonly manifests with well-defined round patches of hair loss. The skin is either normal or salmon pink. Syphilis more often shows a moth-eaten pattern of alopecia (Figure 2).

Most patients with hair loss need only limited laboratory testing or none at all. Thyroid disorders and iron deficiency are common, and testing for them is relatively inexpensive. I recommend them when telogen effluvium is present. Their presence can also accelerate the course of pattern alopecia, and it is reasonable to test for them in women with this disorder. Thyroid-stimulating hormone is the best screen for thyroid disorders. The role of iron deficiency in telogen hair loss is controversial, but iron deficiency is common, easily established, and inexpensive to correct. Iron status also serves as an indicator of overall nutritional status. Although a low ferritin level proves iron deficiency, ferritin behaves as an acute phase reactant and a normal level does not rule out iron deficiency. Therefore I recommend measurement of ferritin, serum iron, iron binding capacity, and saturation.

A scalp biopsy is required in any patient with scarring alopecia. It may also be necessary in other patients if history and physical examination do not establish a diagnosis and the alopecia is progressive. The scalp biopsy should be performed with a 4-mm biopsy punch oriented parallel to the direction of hair growth. Collagen hemostatic sponge (Gelfoam and others) can be placed into

the resulting hole to stop bleeding and eliminate the need for sutures. The biopsy should be done in a well-established but still active area of inflammation if one can be identified. A combination of vertical and transverse sections increases the diagnostic yield and is usually recommended. In patients with scarring alopecia, half of the vertically bisected specimen should be sent for direct immunofluorescence. An additional biopsy of an end-stage scarred area can demonstrate characteristic patterns of scarring with an elastic tissue stain. This can help distinguish among causes of scarring alopecia such as lupus erythematosus (Figure 3), lichen planopilaris, pseudopelade, and folliculitis decalvans.

Hirsutism

Patients with *new-onset* virilization should be evaluated to rule out an ovarian or adrenal tumor. Ovarian and adrenal imaging studies and a total testosterone level are the best screens. A total testosterone more than 200 ng/dL or dehydroepiandrosteredione sulfate (DHEAS) more than 8000 ng/dL suggests tumor. In patients with physical signs of Cushing's disease, a 24-hour urine cortisol should be obtained. Most patients with *chronic* medically significant hirsutism have polycystic ovarian syndrome (PCOS). The diagnosis is

established by means of history and physical examination, and the most important laboratory tests are serum lipids and fasting glucose to establish associated cardiac risk factors. A clinical diagnosis of PCOS requires the presence of hirsutism, acne or pattern alopecia, and evidence of anovulation (fewer than 9 periods per year or cycles longer than 40 days). Ratios of luteinizing hormone (LH) to follicle-stimulating hormone (FSH) have poor sensitivity and specificity for diagnosing PCOS. Imaging for ovarian cysts seldom affects management.

Differential Diagnosis

Syphilis can mimic alopecia areata, and serologic testing should be performed in any sexually active patient with a new diagnosis of alopecia areata. Correct diagnosis of scarring alopecia depends of a thorough examination for other cutaneous signs of lupus erythematosus or lichen planus as well as the results of a skin biopsy.

Tinea capitis can occur as inflammatory boggy areas with hair loss (kerion) or with subtle seborrheic-type scale and black-dot areas of hair loss. A potassium hydroxide (KOH) examination can be performed by rubbing the affected area with moist gauze and examining broken hairs that cling to the gauze.

Hirsutism should be distinguished from hypertrichosis. Hirsutism is a male pattern of hair growth occurring in a woman and is hormonal in nature. Hypertrichosis is excess hair growth that occurs outside of an androgen-dependent distribution. It can be found in metabolic disorders such as porphyria or may be a sign of internal malignancy (Figure 4).

Non-classic 21-hydroxylase deficiency accounts for up to 10% of patients with medically significant hirsutism. Screening with a baseline morning 17-OH-progesterone is associated with many false positive results. A stimulated 17-OH-progesterone is more specific, but the results of testing seldom affect management because outcomes with dexamethasone (Decadron)¹ are no better than with spironolactone (Aldactone)¹.

Treatment

Alopecia

Telogen effluvium commonly resolves spontaneously once the cause has been eliminated. Poor diet and papulosquamous diseases of the scalp such as seborrheic dermatitis and psoriasis can perpetuate a telogen effluvium and should be treated. The importance of a diet containing adequate protein and trace minerals should be emphasized. Seborrheic dermatitis responds to topical corticosteroids. Medicated shampoos containing selenium sulfide (Selsun

Blue) or zinc pyrithione (T-gel Daily Control) can be helpful. Scalp psoriasis can require more potent topical steroids such as fluocinonide solution (Lidex) and calcipotriene (Dovonex) applied on weekends or daily. Systemic agents such as methotrexate (Trexall)¹ at doses of 7.5 to 20 mg once weekly may be required to control severe scalp psoriasis.

Pattern alopecia in men is mediated by dihydrotestosterone (DHT). Men with pattern alopecia may be treated with daily topical minoxidil 2% to 5% (Rogaine for Men) or oral finasteride (Propecia) at a dose of 1 mg daily. In women, the pathogenesis is complex, and adrenal androgens may play a larger role. Finasteride is of little benefit in the majority of women with pattern alopecia. Spironolactone¹ 100 mg twice daily can be helpful. In women of childbearing potential, spironolactone should always be used in conjunction with an oral contraceptive. Side effects are uncommon but can include urinary frequency, irregular periods, dyspareunia, and nausea. Most patients demonstrate a minor increase in serum potassium. Those with kidney failure are at risk for life-threatening potassium retention. Topical 2% minoxidil (Women's Rogaine) can also be of benefit, and some women derive added benefit from the 5% formulation. All patients with pattern alopecia should be evaluated for superimposed causes of telogen effluvium such as inadequate diet and seborrheic dermatitis.

Tinea capitis is often overlooked in adults and black children, in whom the manifestations of inflammation can be subtle. Black dot and seborrheic tinea are common in black children. Patchy hair loss is an important clue to the diagnosis. Treatment is summarized in Table 1.

Localized patches of alopecia areata respond to intralesional injections of triamcinolone hexacetonide (Aristospan) (2.5–5 mg/mL) given once per month. Approximately 0.1 mL/cm² is injected to a maximum of 3 mL during any one session. Minoxidil¹ solution produces slow regrowth in some patients who cannot tolerate other treatments. Anthralin (Dritho-Scalp 0.5%)¹ is sometimes used in children. It is applied 30 minutes before showering. It can stain skin and anything else it touches.

Topical immunotherapy with dinitrochlorobenzene (DNCB)¹, squaric acid dibutylester (SADBE)¹ or diphenylcyclopropenone (DPCP)¹ is more effective than either minoxidil or anthralin. DNCB is mutagenic in the Ames assay and none of the topical immunotherapies are currently approved for human use. A 2% solution of the sensitizer is applied to the arm in acetone to induce initial sensitization. Subsequently, diluted solutions, starting at about 0.001%, are applied weekly to the scalp with a cotton-tipped

TABLE 1 Treatment of Tinea Capitis

ANTIFUNGAL AGENT	DOSAGE	USUAL DURATION OF THERAPY
Griseofulvin (Fulvicin U/F)	Required dosages are often higher than reflected in the product label; 4–10 mg/kg/d is a good starting dosage	1 mo or more
Fluconazole (Diflucan) ¹	5–6 mg/kg/d	1 mo or more
Itraconazole (Sporanox) ¹	3–5 mg/kg/d	1 wk, repeated monthly until cured
Terbinafine (Lamisil)	Patient <20 kg: 62.5 mg/d Patient 20–40 kg: 125 mg/d Patient >40 kg: 250 mg/d	1 mo or more

¹Not FDA approved for this indication.

applicator. Roughly 20% to 60% of patients have responded to this regimen in various studies.

Biologic agents have been disappointing, but methotrexate¹ in psoriatic doses (7.5–20 mg weekly for an adult) can be effective. Sulfasalazine (Azulfidine)¹ is sometimes effective in doses ranging from 500 to 1500 mg three times a day.³ Tofacitinib (Xeljanz)¹ and other Janus kinase (JAK) inhibitors can be effective in patients with refractory alopecia areata. Patients should be encouraged to read about new therapies on the National Alopecia Areata Foundation website (www.naaf.org).

Early, aggressive therapy for discoid lupus erythematosus is recommended to prevent permanent scarring. Topical corticosteroids are rarely sufficient. Intralesional injections are performed in a manner similar to that described above. Initial control of severe disease can be achieved with a single 3-week tapered course of oral prednisone at a dose of 60 mg daily for the first week, 40 mg daily for the second week, and 20 mg daily for the third week. Intralesional steroid injections or a systemic steroid-sparing agent are required for maintenance therapy. Systemic agents that can be effective include antimalarials, dapsone¹, methotrexate¹, mycophenolate mofetil (CellCept)¹, and thalidomide (Thalomid)¹. I generally begin treatment with hydroxychloroquine (Plaquenil)¹ at a dose of 400 mg daily for an adult. Dapsone is used at a dose of 100 mg daily for an adult. Thalidomide has been used effectively at doses of 50 to 100 mg daily, but peripheral neuropathy and teratogenicity limit its use. Mycophenolate mofetil is used at a dose of 1 gram twice daily, and methotrexate is used at doses of 7.5 to 20 mg weekly.

End-stage cicatricial alopecia is best treated by scalp reduction and hair transplantation. The disease can flare up in response to surgery, and it is best to plan a 3-week tapered course of prednisone¹ as described to help prevent the flare.

Lichen planopilaris is treated in a manner similar to lupus, except that hydroxychloroquine¹ is of less benefit and oral retinoids (Soriatane¹ at doses of 25 to 50 mg daily) are more likely to be successful. Topical calcineurin inhibitors can be effective in achieving and maintaining remission. A few months of pioglitazone (Actos)¹ can induce remission in a subset of patients and the frontal fibrosing alopecia variant can respond to dutasteride (Avodart)¹. Patients should be aware of the risks associated with each of these treatments, including bladder cancer and hypospadias in a male fetus. Mycophenolate mofetil¹ 1 g twice daily is often effective when other treatments fail, and excimer laser can also be effective for lichen planopilaris. It is contraindicated in lupus erythematosus.

Folliculitis decalvans manifests with crops of pustules that result in permanent scarring. Patients respond to weekend applications of clobetasol (Clobex, Olux) together with prolonged use of antistaphylococcal antibiotics such as doxycycline (Doryx)¹ 100 mg twice daily.

Hirsutism

Treatment options include laser epilation, eflornithine (Vaniqa) cream to reduce the rate of hair growth, or spironolactone¹ at a starting dose of 100 mg twice daily as described for pattern alopecia. Cyproterone acetate is used in some countries but is not available in the United States. Other options that are less commonly used include insulin sensitizers, flutamide (Eulexin)¹, metformin (Glucophage)¹, and leuprolide (Lupron)¹ plus estrogen.

Monitoring

Patients treated with topical or intralesional corticosteroids should be monitored for cutaneous atrophy. Those on hydroxychloroquine should be monitored for ocular toxicity, including corneal deposits and retinal damage, although these are very rare at usual doses. They should also be monitored periodically for thrombocytopenia, agranulocytosis, and hepatitis. Patients beginning

dapsone therapy should be screened for G6PD deficiency. Potential side effects include hemolysis, methemoglobinemia, and neuropathy. Monitoring includes periodic blood count assessment and measurement of strength and sensation. Mycophenolate mofetil can produce pancytopenia, and blood counts should be monitored. Methotrexate is cleared by the kidneys, and kidney function should be assessed at baseline. Periodic assessment of liver function tests and blood count is warranted, as is a yearly chest radiograph. I also monitor procollagen 3 terminal peptide levels quarterly to assess the risk of hepatic fibrosis. Patients on antiandrogen therapy should be monitored for dyspareunia resulting from vulvar atrophy.

Complications

Patients with pattern alopecia and polycystic ovarian syndrome have a greater risk of metabolic syndrome with cardiac complications. They should be evaluated for lipid abnormalities and glucose intolerance and treated appropriately.

DISEASES OF THE MOUTH

Method of

Wendy S. Hupp, DMD

CURRENT DIAGNOSIS

High-Risk Conditions

- Obvious soft tissue enlargement that could lead to trismus or airway compromise: acute exacerbation of odontogenic infections; rapid onset, swelling, purulence, broken or decayed teeth.
- Suspicion of oral cancer: mucosal surface color change, slowly progressing enlargement, asymptomatic or with nonhealing ulcer, incidental finding, use of tobacco and alcohol.

Opportunistic Infections

- Necrotizing ulcerative gingivitis (trench mouth): compromised host resistance, generalized dental pain, usually acute onset, bleeding gums, fetid odor.
- Oral candidiasis: compromised host resistance, chronic or recurring course, bad taste, generalized burning sensation, superficial change in mucosal appearance (white or red).

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

DISEASES OF THE MOUTH

Method of

Wendy S. Hupp, DMD

CURRENT DIAGNOSIS

High-Risk Conditions

- Obvious soft tissue enlargement that could lead to trismus or airway compromise: acute exacerbation of odontogenic infections; rapid onset, swelling, purulence, broken or decayed teeth.
- Suspicion of oral cancer: mucosal surface color change, slowly progressing enlargement, asymptomatic or with nonhealing ulcer, incidental finding, use of tobacco and alcohol.

Opportunistic Infections

- Necrotizing ulcerative gingivitis (trench mouth): compromised host resistance, generalized dental pain, usually acute onset, bleeding gums, fetid odor.
- Oral candidiasis: compromised host resistance, chronic or recurring course, bad taste, generalized burning sensation, superficial change in mucosal appearance (white or red).

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Dry Mouth

- Salivary dysfunction (xerostomia): patient's perception of dry mouth, difficulty swallowing or speaking, tooth sensitivity as a result of new decay or receding gums; related to medication use or autoimmune gland dysfunction.

Acute-Onset Oral Ulcers

- Aphthous stomatitis: recurring episodes, formation of one or more superficial oral ulcers, located on nonbound mucosa, healing in approximately 7 to 10 days.
- Primary herpetic gingivostomatitis: acute onset of systemic viral infection features, including fever, and multiple oral vesicles, degenerating into ulcers; resolution in 7 to 10 days.
- Recurrent herpes: recurring episodes, acute formation of vesicles collapsing to ulcers, located on exposed lip, or bound mucosa; healing in 7 to 10 days.
- Erythema multiforme: acute onset of oral ulcers, triggering event, mild systemic features such as fever, characteristic skin lesions; resolution in 2 to 4 weeks.

Chronic Oral Ulcers

- Erosive lichen planus and lichenoid reaction: reticular appearance at periphery of ulcers, buccal mucosa affected, may cause desquamative gingivitis, skin lesions possible.
- Mucous membrane pemphigoid: typically desquamative gingivitis presentation, possible eye and genital ulcers, skin lesions unlikely.
- Pemphigus vulgaris: ulcers of irregular shape and jagged peripheral contour, possible skin lesions.

Osteonecrosis of the Jaw

- Radiation related: resulting from treatment of oral or head and neck cancer.
- Medication related: secondary to antiresorptives used to treat osteoporosis or bone metastases in cancer patients; bisphosphonates, antiangiogenics, receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitors.
- More common in the mandible: exposed bone that persists for more than 8 weeks; may be asymptomatic with localized soft tissue irritation, rough edges of necrotic bone may be irritating; can progress to osteomyelitis and physiologic fractures.

- Methylprednisolone 4 mg tablets (Medrol Pak)¹ are used to control ulcers, taken with tapered doses, then topical corticosteroid should be titrated to maintain control of ulcers.

Management of Osteonecrosis of the Jaw

- Antibiotics if purulent exudate is present.
- Pain medication as needed.
- Conservative resection of hard tissue may be necessary (referred to oral surgeon).

Management of Dry Mouth

- Saliva substitute, sugarless mints or gum, ice chips as needed.
- Cholinergic agonist, e.g., pilocarpine (Salagen) 5 to 10 mg by mouth 30 minutes before meals, not to exceed 30 mg per day.

¹Not FDA approved for this indication.

Patients often consult the physician with problems in the orofacial region, including those that are clearly dental in nature. For these problems, the intervention may simply be to treat the pain and/or infection until definitive treatment can be provided by a dentist. These problems may include a broken tooth or restoration with sharp edges that causes soft tissue injury; infected or traumatized nerves with spontaneous pain; or focal infections that cause swelling (likely to be less painful) or acute pain when the pressure of the purulent exudate is trapped within the bone at the apex of the root of the tooth.

Oral manifestations of systemic disease, such as pyostomatitis vegetans (Crohn disease), or mucosal petechiae (idiopathic thrombocytopenic purpura) are uncommon, and can pose difficult diagnostic challenges. Similarly, adverse oral reactions to therapeutic medications are inconsistent and may be unavoidable, for example, xerostomia, dysgeusia, and gingival overgrowth. These issues may best be handled in concert with the patient's dentist. Regional conditions, such as headache, cranial neuralgia, or sinusitis, may cause oral complaints, and vice versa. The diagnosis and treatment of these conditions is not discussed in this chapter.

Nevertheless, there are a few orofacial conditions that have serious implications and should be addressed by the physician rather than referred to the dentist. These conditions are addressed in the Current Diagnosis box. The Current Therapy box includes recommended treatment; if resolution does not occur in a reasonable amount of time, for example 2 weeks, the diagnosis must be questioned. For biopsy confirmation of potential oral neoplasms and autoimmune disorders, an oral pathologist is preferred.

Odontogenic Infection

With few exceptions, disseminated bacterial infections of odontogenic origin represent a dramatic, acute exacerbation of a chronic, asymptomatic infection. A variety of dental conditions are possible causes, such as a periodontal abscess, an abscess within the supportive bone resulting from the pulpal necrosis of a carious tooth, or an infection of the gingiva surrounding a partially erupted third molar. The patient often describes a history of one or more prior acute episodes of bacterial infection symptoms from the site, followed by resolution. The degree of swelling, lymphadenopathy, pain, and fever is proportional to the risk of potential complications such as septicemia. Of particular concern is evidence of the rapid progression of diffuse swelling into the floor of the mouth and neck because of the risk of respiratory distress (i.e., Ludwig angina), or superiorly from the anterior portion of the maxilla because of the possibility of cavernous sinus thrombosis.

Definitive dental treatment to eliminate the underlying infectious source is the treatment goal after the acute, disseminated infection has been controlled. Penicillin is still considered the empiric antibiotic choice for disseminated odontogenic bacterial infections in individuals with no history of adverse reaction, and clindamycin (Cleocin) is used for those hypersensitive to penicillin. Many patients mistakenly assume that empiric antibiotic treatment can eliminate the infection in the same sense that antibiotic treatment can cure bacterial sinusitis or pharyngitis. The patient should be

**CURRENT THERAPY****Topical Management of Oral Ulcerations**

- Ice chips as needed to help with pain.
- Diphenhydramine (Benadryl)¹ liquid 12.5 mg/5 mL (50/50 mix) with liquid antacid¹ (Maalox, Kaopectate, etc.), rinse with 1 to 2 teaspoons every 2 hours then spit; for pain.
- Triamcinolone acetonide 0.1% in oral paste (Oralene): dab a small amount on the lesion to provide a protective film, 2 to 4 times a day until ulcers are healed.
- Dexamethasone (Decadron)¹ elixir 0.5 mg/5 mL: rinse with 1 teaspoon for 2 minutes and spit out after meals and at bedtime until ulcers are healed.

Management of Resistant Ulcers With Topical Ultrapotent Corticosteroid Preparations

- Clobetasol propionate (Temovate)¹ 0.05%: apply a thin film to affected area after meals and at bedtime until healed.
- Halobetasol propionate (Ultravate)¹ 0.05%.

Management of Ulcers That Cannot Be Controlled With Topical Preparations

- Prednisone¹ 5- to 20-mg tablets; take 60 mg per day by mouth as needed to control ulcers; no taper indicated if less than 2 weeks of daily use; topical corticosteroid should be titrated to maintain control of ulcers.

informed that improvement of an acute odontogenic infection after antibiotic treatment is not curative and that dental care to eliminate the underlying cause is necessary. One or more courses of antibiotics without elimination of the source increase the probability of the emergence of more virulent, antibiotic-resistant pathogens. More aggressive treatment, including intravenous antibiotics and surgical drainage in a hospital setting, must be considered in cases of rapid progression or extensive swelling, particularly if the anterior maxilla or submandibular areas are involved and in instances of compromised host resistance.

Suspicion of Oral Cancer

About 90% of oral cancers are squamous cell carcinoma (SCC), but sarcoma, adenoma, and metastatic tumors of solid organs are also found. Although the 5-year survival rate of oral SCC has improved over the past decade, it still hovers about 50%. Many patients deny the presence of a lump or mass until it becomes painful, and even then first seek care from a physician instead of a dentist or oral surgeon. Routine oral examination is still the best weapon against morbidity and mortality, as there are no diagnostic tests that are satisfactory.

Oral cancer has been called the great imitator, for it can appear as many different oral conditions. It can be red, white or pigmented, exophytic, nodular, or ulcerative, smooth-surface or verrucous, and occur in any location of the oral cavity. The greatest suspicion is associated with an older patient, likely male, who uses tobacco and alcohol. The most common sites are the floor of the mouth and the lateral borders of the tongue, with the great majority being unilateral. Recently an increase in younger patients (less than 40 years old) has been tied to the presence of human papilloma virus, although no etiology has been confirmed.

Biopsy is indicated for lesions that show induration, are tied to underlying structures, are nontender, slow-growing, and especially if simple treatment of ulceration or infection has not eliminated the problem. The decision to obtain a biopsy of an oral lesion should be made with consideration of the substantial positive impact that early detection has on a disease with an otherwise unfavorable prognosis.

Necrotizing Ulcerative Gingivitis

Necrotizing ulcerative gingivitis (NUG) is a characteristic, potentially destructive infection of the dental supportive tissues caused by a predominance of fusiform bacteria and spirochetes. Some combination of psychologic stress, compromised immune function, malnutrition, or other condition of diminished host resistance dramatically increases the risk of NUG. This is suggested by the colloquial phrase *trench mouth* used to refer to this infection, because it was frequently observed among debilitated soldiers during World War I. It has also been called Vincent infection and acute NUG (ANUG).

Acute onset of poorly localized, severe dental pain, and a putrid taste are typically the patient's chief complaints. Onset usually corresponds with a significant alteration in the general health or emotional status, although a more chronic course of variably pronounced symptoms can be expected with protracted conditions, such as acquired immunodeficiency syndrome (AIDS). Visual features of NUG include necrotic deterioration of the gingiva with pronounced peripheral erythema and a superficial pseudomembrane. The tissue around the mandibular anterior teeth is most severely affected in most cases, and the gingiva often appears "punched out" from between the teeth. The gingival necrosis produces the characteristic fetid breath that is far more pungent than that caused by typical gingivitis. The putrid odor in combination with the acute onset and poor localization of pain is usually a more reliable basis for diagnosis than visual findings. Additional features, such as fever and cervical lymphadenopathy, are proportional to the severity of the oral findings.

Treatment of NUG consists of the combination of supportive care, antimicrobial measures, and improvement in the underlying compromising health conditions. Supportive care is nonspecific and includes rest, fluid intake, and a soft but nutritious diet. Warm

saline, dilute hydrogen peroxide, and chlorhexidine gluconate (Peridex) are effective antimicrobial rinses. Penicillin and metronidazole (Flagyl) are the empiric systemic antibiotics of choice. Ultimately the most effective antimicrobial treatment is the combination of thorough dental cleaning of the teeth, with debridement of the necrotic soft tissue, and improved oral hygiene. Resolution of NUG, including complete healing of the gingival tissue, is strikingly rapid in most instances if this is accomplished, and underlying health status improves. Persistence or recurrence of NUG after debridement suggests the possibility of human immunodeficiency virus (HIV) infection or another undiagnosed compromising condition.

Oral Candidiasis

Oral candidiasis is a superficial fungal infection of the oral mucosa that is clinically similar to vaginal candidiasis in many respects. With isolated exceptions, the infection is caused by the fungus *Candida albicans*, which can be identified in the mouths of approximately 50% of healthy adults. The risk of oral candidiasis is increased by one or more factors of compromised host resistance: decreased local resistance, compromised immune function, or uncontrolled systemic disease. Frequently encountered examples of decreased local resistance include poor oral hygiene, xerostomia, wearing dentures that provide an organism reservoir or limit hygiene, and recent antibiotic therapy that has altered the normally competitive oral bacteria. The combination of one or more of these local factors with a systemic condition that causes compromised immune status or constitutional compromise dramatically increases the risk of clinical apparent infection. Common examples include AIDS, corticosteroid therapy, severe anemia, and poorly controlled diabetes mellitus.

Oral candidiasis lesions can have four distinct appearances. The most characteristic form is the pseudomembranous, curdlike plaques of thrush that wipe off with cotton gauze leaving a sore, erythematous mucosal surface. The erythematous or atrophic form of oral candidiasis produces a thin, "beefy" appearance often affecting the dorsum of the tongue or mucosa that supports a denture. The third type of lesion is the formation of fissures similar to those of tinea pedis that usually are at the corners of the mouth and are referred to as angular cheilitis. The fourth is a hyperplastic form that produces a patchy, white thickening of the surface epithelium that does not rub off and that appears similar to the hyperkeratosis of chronic frictional irritation. Oral candidiasis often produces more than one lesion form simultaneously in different areas of the mouth, which may be a confirmational finding. Patients often describe only a little discomfort or a mild burning sensation from affected sites, and also bad taste.

The clinical course of the infection may be acute, chronic, or cyclic in severity, depending on the nature of the underlying causes. The combination of clinical appearance, suspected compromised host status, and improvement after empiric treatment provides an adequate basis for the diagnosis. Exfoliative cytology provides definitive evidence of the infection in more equivocal situations.

Antifungal treatment eliminates oral candidiasis in most instances, but recurrences or a chronic, subclinical course can be expected if the predisposing condition remains unchanged. This implies that treatment of superficial oral candidiasis may not be justified in such instances, if the affected individual is asymptomatic, because the only realistic treatment goal is elimination of symptoms. That decision must be weighed against the possibility of spread to the esophagus.

Options for routine topical treatment of oral candidiasis include clotrimazole (Mycellex) troches, or nystatin (Mycostatin pastilles),⁶ and use should continue for 1 week after resolution of symptoms. Several considerations can complicate effectiveness. Patients with xerostomia have difficulty dissolving the troches or pastilles and prefer a nystatin rinse. Concurrent management of the dry mouth (discussed later) increases the effectiveness of topical antifungal

⁶May be compounded by pharmacists.

treatment for candidiasis. Limiting the *Candida* organism reservoir in the denture acrylic can be accomplished for those who wear dentures, by soaking them overnight in most commercial denture soaking solutions, mouthwashes such as Listerine, or chlorhexidine gluconate (Peridex). These products are adequately fungicidal, and keeping the denture out overnight disrupts adherence and colonization of candidal organisms. Some patients are more compliant about managing the denture problem by applying a thin layer of nystatin ointment¹ or clotrimazole cream (Lotrimin)¹ to the denture before wearing. Direct application of these preparations also promotes rapid resolution of angular cheilitis. Systemic administration of ketoconazole (Nizoral)¹ or fluconazole (Diflucan)¹ is an alternative for patients who cannot manage topical treatment, or for severely immunocompromised individuals in the interest of controlling oral symptoms and minimizing the risk of spread to the esophagus.

Xerostomia

Xerostomia is defined by the patient's subjective perception of "dry mouth" rather than by any objective parameter. The amount of saliva is decreased, and its character typically is altered to a more viscous, ropery consistency. The condition is common because salivary function is adversely affected by so many routinely encountered influences, including many frequently prescribed medications, smoking, methamphetamine abuse, several common systemic diseases, and radiation exposure for cancer treatment in the orofacial region. In addition to these influences, primary Sjögren syndrome is characterized by chronic dry eyes and dry mouth caused by autoimmune-mediated acinar degeneration. Secondary Sjögren syndrome is defined as oral and ocular dryness concurrent with an autoimmune connective tissue disorder such as rheumatoid arthritis.

The subjective response of different individuals to a mild or moderate degree of oral dryness varies considerably. Many patients who appear to produce adequate saliva complain of dryness, whereas others who seem unusually dry during oral examination have no complaints. Most patients with an advanced degree of dryness find the continual "cotton mouth" sensation and other consequences to be a significant quality-of-life issue. Decreased saliva production causes difficulty speaking, chewing, and swallowing, in addition to painful abrasion of the mucosa by coarse foods. Beyond the physical irritation, limited saliva alters the sense of taste and the enjoyment of food. Saliva contributes to oral health by providing antimicrobial components such as lactoperoxidase and IgA antibodies, and it has a significant flushing and cleansing function. Xerostomia causes a rampant and rapidly progressive pattern of dental decay that is particularly destructive, even for previously caries-resistant individuals. This is compounded if the patient compensates for the dryness by drinking sucrose-rich soft drinks or sucking on hard candy. Similarly, periodontitis tends to progress rapidly, despite normally effective treatment, if saliva production is limited. Xerostomia is also associated with complaints of generalized soreness of the mouth caused by frequent and persistent episodes of oral candidiasis.

Management of xerostomia is challenging and often frustrating for the patient and the clinician. The treatment for severe, irreversible xerostomia, as in cases of head and neck radiotherapy, is essentially symptomatic. Different patients prefer different combinations of compensation methods. Sipping water throughout the day is the single most effective and simplest way to counter loss of saliva. Some patients report additional improvement with the use of commercially available saliva substitutes, although many do as well with water and ice chips. Most patients soon learn to avoid abrasive foods, irritating commercial mouth rinses that contain alcohol, and highly flavored toothpastes in favor of less irritating alternatives. Use of a humidifier at night is often beneficial. Comprehensive dental treatment should be recommended to limit the progression and severity of dental caries and periodontitis. Smoking and compensation by drinking sucrose-rich soft drinks, sports drinks, drinks that contain caffeine, and highly acidic citric juices should be discouraged.

¹Not FDA approved for this indication.

Additional options beyond the previous recommendations are available for those who have some residual salivary function. Drinking ample water moistens the mucosa and maintains general hydration, which maximizes the residual saliva production. Sugar-free gum or hard candy significantly stimulates saliva flow. Alternative medications that are equally effective therapeutically but less likely to cause xerostomia may be substituted in some cases to treat conditions such as hypertension.

Several cholinergic agonists are available, including cevimeline (Evoxac), pilocarpine (Salagen), and bethanechol (Urecholine)¹. Titration of dosage is usually necessary to optimize saliva flow while minimizing frequent adverse effects such as excessive sweating and gastritis. Many patients discontinue treatment because of these and less common side effects that become more troublesome than the xerostomia. Contraindications such as glaucoma and the risk of serious complications such as arrhythmia must also be considered.

Aphthous Stomatitis

Recurrent aphthous stomatitis, colloquially known as *canker sores*, is a common condition of complex immune-mediated pathogenesis. Patients describe recurring episodes of painful ulcers that often follow triggering events such as minor tissue abrasion, eating certain foods, or episodes of emotional stress. The phrase *minor aphthous stomatitis* differentiates the most common, mild form of the disease from the more severe major and herpetiform variations. Most authorities believe these categorizations are somewhat artificial distinctions within a continuum of a single process. Similar ulcers are a feature of Behçet syndrome, but are of minor diagnostic and treatment significance compared with the other manifestations of this rare, multisystem condition.

The clinical features of minor recurrent aphthous stomatitis are characteristic. One or more painful ulcers develop soon after a short prodromal period of burning or itching at the affected site. The round or oval superficial ulcers exhibit a uniform, yellowish white, pseudomembranous surface with an erythematous peripheral halo at the sharply delineated ulcer margin. Typical size is less than 10 mm in diameter, and lesions affect only unbound oral mucosal surfaces of the lips, cheeks, floor of the mouth, or soft palate. This distribution specifically excludes the bound surfaces of the gingiva, hard palate, and the dorsum of the tongue. This feature is valuable for differentiating aphthous stomatitis from the intraoral recurrent herpetic lesions (discussed later) that affect only bound surfaces.

Aphthous lesions typically heal within 7 to 10 days, and most patients describe a long clinical course of symptom-free periods of various durations interrupted by episodes of ulcer formation. Lesion-free periods of weeks, months, or even years typically distinguish recurrent aphthous stomatitis from autoimmune conditions such as erosive lichen planus (discussed later) that produce a continuous course of oral ulcers.

The major form of recurrent aphthous stomatitis produces ulcers of similar appearance, but the lesions are larger, require a longer healing time, often heal with scarring, and form so frequently that at least one ulcer is usually present. The herpetiform variant is characterized by a cluster of numerous smaller (1 to 3 mm) ulcers that often coalesce into a single, large lesion, and the ulcers are described as exceptionally painful.¹ The clustering distribution explains the somewhat misleading herpetiform designation for this nonviral condition. This form of aphthous stomatitis may affect keratinized and nonkeratinized surfaces, which in addition to the clustering distribution may lead to confusion with recurrent herpes simplex lesions.

Minor recurrent aphthous stomatitis is more irritating than serious, and treatment beyond symptomatic management is usually not justified. Patients soon learn to avoid their particular trigger event as much as possible, and many find relief during outbreaks from over-the-counter preparations such as Orabase with benzocaine 20%, or by rinsing with soothing, coating products such as bismuth subsalicylate (Kaopectate).¹ Rinses containing a variety

¹Not FDA approved for this indication.

of ingredients, such as diphenhydramine¹, tetracycline¹, aloe,⁷ and chlorhexidine gluconate (Peridex)¹, have been reported to promote ulcer healing in some cases. Treatment with corticosteroids (see Current Therapy box), however, is more consistently effective, and is justified for major and herpetiform variants, as well as for particularly severe or frequent outbreaks of minor aphthous lesions.

Orofacial Herpes Simplex Infection

Most herpes simplex infections of the oral mucosa are caused by herpes simplex virus type 1 (HSV-1). A much smaller proportion of oral cases results from the type 2 herpes simplex virus that typically causes genital lesions. Transmission occurs by direct contact or contaminated saliva, and serologic studies demonstrate that as much as 90% of the population has been infected by age 50.

The initial infection, referred to as acute herpetic gingivostomatitis or primary herpes, usually affects children and causes acute onset of cervical lymphadenopathy, chills, and fever similar to many acute viral infections. The distinguishing manifestation is the formation of multiple, painful oral vesicles that rapidly rupture. The resulting ulcers most prominently affect the gingiva, lips, and tongue but may occur on any oral surface. Primary herpes in adults is more likely to cause complaints of pharyngitis rather than oral ulcers, which makes distinguishing it from other systemic viral infections unlikely. The severity of primary herpes varies from virtually subclinical or indistinguishable from nonspecific viral infections, to debilitating. The distinguishing oral lesions are probably seen only in severe cases, because relatively few seropositive individuals recall the oral ulcers of the primary infection when questioned. Symptoms resolve within 5 days to 2 weeks, depending on the severity of the manifestations, and significant complications such as encephalitis or keratoconjunctivitis are rare.

The HSV-1 virus becomes latent within the sensory neurons that supply the primary infection site. Episodes of recurrent lesions may develop after the primary infection, a pattern similar to the recurring genital lesions caused by HSV-2. The frequency, severity, and course of these outbreaks vary widely among individuals, and at least one-half of HSV-1 seropositive individuals rarely or never suffer recurrent lesions. Those who do often associate occurrence with causative events, such as sun exposure of the exposed lip, abrasion of the surface, or an illness such as a nonspecific viral infection. This explains the colloquial terms *cold sore* and *fever blister* used to describe the most common presentation affecting the exposed lip, which is referred to as herpes labialis.

The typical episode begins with a prodromal sensation of burning or itching at the site near the vermillion border, followed by formation of one or more vesicles within 24 hours. The vesicles soon rupture, forming a coalesced crust that heals after 7 to 10 days. A few individuals suffer similar recurrent herpes lesions of the intraoral mucosa. Intraoral herpes lesions produce features of pain, onset, recurrent course, and healing time that are similar to those for aphthous stomatitis, which may present some differential diagnostic uncertainty. The diagnosis can be made in most cases based on the affected surface. Aphthous lesions are usually limited to the unbound mucosa of the lips, cheeks, soft palate, and floor of the mouth, whereas the intraoral ulcers of recurrent herpes simplex infection are limited to the bound mucosa of the gingiva and hard palate.

Treatment of primary herpes simplex infection for immunocompetent individuals is supportive and symptomatic, as for any acute systemic viral infection. In cases of significant oral discomfort, a rinse consisting of a 1:1 mixture of diphenhydramine (Benadryl)¹ elixir 12.5 mg/5 mL and a liquid antacid, or bismuth subsalicylate (Pepto-Bismol)¹ used as needed, provides some relief by coating the ulcers. The use of systemic antiviral medication such as acyclovir (Zovirax) and valacyclovir (Valtrex) is not recommended for primary infections, except for immunocompromised patients to reduce the risk of systemic dissemination.

Most individuals affected by secondary herpes lesions suffer relatively few episodes, and no treatment is warranted. Patients prone to frequent lip lesions after sun exposure soon learn the preventive value of sunscreen lip balms, but the advice may be helpful to those who have not made the association. For patients who experience numerous secondary herpetic episodes, the systemic administration of valacyclovir (Valtrex) can be used therapeutically during the prodromal stage or prophylactically. The one-day dosing is 2 g by mouth 12 hours apart. For immunocompromised patients, valacyclovir 1 g twice a day¹ or famciclovir (Famvir) 500 mg twice a day are recommended for 10 days.

Erythema Multiforme

Erythema multiforme, which is discussed in greater detail elsewhere in this textbook, is characterized by shallow oral ulcers and characteristic “target” skin lesions. Outbreaks of secondary herpetic lesions have been implicated as a frequent trigger for erythema multiforme. A prodrome of mild fever, malaise, sore throat, and headache may precede the appearance of the oral ulcers and skin lesions. The shallow oral ulcers usually affect the lips, tongue, or soft palate and are less likely to develop on the gingiva or hard palate. Ulcers gradually heal after 2 to 4 weeks, and approximately 20% of affected individuals experience multiple episodes. Certain medications, especially antibiotics, have also been implicated as triggers for erythema multiforme. Medication exposure is the typical stimulus for the onset of Stevens-Johnson syndrome and toxic epidermal necrolysis, which by similar allergic mechanisms produce much more extensive, generalized epithelial sloughing.

Treatment of the oral lesions of erythema multiforme is somewhat controversial. Topical and systemic corticosteroids have been recommended in the past based largely on the presumed pathogenesis of the lesions. However, little evidence exists to demonstrate the effectiveness of this approach. Supportive care usually is adequate and includes a less abrasive diet, maintaining hydration, use of analgesics, and use of a soothing, coating rinse (1:1 mixture of Benadryl¹ elixir and Kaopectate¹).⁶ Patients who experience recurring episodes may benefit from herpes simplex virus suppression with acyclovir or valacyclovir. More extensive epithelial sloughing or rapid progression suggesting Stevens-Johnson syndrome or toxic epidermal necrolysis requires hospitalization and systemic corticosteroids.

Erosive Lichen Planus and Similar Autoimmune Ulcerative Conditions of the Oral Mucosa

Several diseases cause oral ulcers by autoimmune-mediated degeneration at or near the epithelial-connective tissue interface. In some patients, painful oral ulceration is the only presenting feature of the disease. For other patients, the oral pain is only an occasional or secondary complaint. However, with few exceptions, a chronic course of oral pain for months or years without complete remission is described by the patient. The location and severity may change over time with cyclic formation of new ulcers and concurrent healing of others, but the dominant trend is a chronic, protracted, or progressive course with little or no complete relief. This continuous course distinguishes the ulcers caused by autoimmune diseases from those of other conditions, such as aphthous stomatitis, which characteristically have an episodic pattern of occurrence. As with autoimmune diseases in general, the demographic pattern tends toward middle-aged women. Definitive diagnosis typically relies on biopsy results, but the differential diagnosis is often narrowed by the appreciation of additional findings, such as lesions of the skin or other mucous membranes, and by laboratory tests, such as obtaining an antinuclear antibody (ANA) titer. Lichenoid drug reactions can occur in any patient at anytime during the administration of a medication, although onset of ulcers associated with a new prescription is often indicative of a causative agent.

Distinguishing between chronic oral ulcers from four conditions—erosive lichen planus (ELP), lichenoid drug reaction,

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

⁶May be compounded by pharmacists.

mucous membrane pemphigoid (MMP), or pemphigus vulgaris (PV)—can be assisted by reviewing the location and appearance of the ulcers, and the history of the condition.

ELP is relatively common, and oral lesions may occur before the characteristic skin lesions in many patients. In the mouth, the none-rosive lichen planus is characterized by a reticular white lacy expression on the buccal mucosa that may be visualized more easily by drying the tissue with a gauze. Erosions may be related to stressful experiences or exposure to certain foods or dental materials. The erosive lesions of ELP and the lichenoid drug reaction are indistinguishable, so history is helpful relating the chronologic onset of a medication. Many medications are implicated in the etiology of lichenoid drug reactions, including commonly prescribed thiazide diuretics, nonsteroidal antiinflammatory drugs, and penicillins.

Mucous membrane pemphigoid (MMP) has also been referred to as *cicatricial pemphigoid* and *benign MMP*. The typical presentation of MMP is a chronic course of primarily gingival vesicles and bullae that rapidly degenerate into ulcers, usually occurring on the gingival tissue, although any intraoral area may be affected. The patient may also have genital and conjunctival mucous membrane lesions. The incidence of the eye lesions approaches nearly 25% of affected individuals during the protracted disease course, and these lesions may cause blindness in severe cases.

Of the four characteristic forms of pemphigus, only PV causes oral lesions to any clinically significant degree. Approximately one-half of patients develop oral ulcers before the appearance of skin lesions. Most PV oral lesions are found on the marginal gingiva in the upper and lower premolar regions. They appear as bands of beefy red ulceration about 2 mm wide that bleed very easily and are painful when the patient attempts to brush or floss. Initial vesicle or bulla formation is unusual with oral PV, in contrast to MMP, and the peripheral striations described with ELP are absent. The oral ulcers caused by PV tend to show slow progression without healing over time, in contrast to the cyclic variation of concurrent healing and lesion formation characteristic of ELP and MMP.

The oral ulcers caused by all of the conditions in this group respond to corticosteroid medications in the recommended therapeutic approach as described in the Current Therapy box. Several pivotal issues about these conditions and treatment with corticosteroids are important for successful management:

- Ulcers from infectious diseases (fungal or viral) should not be treated with corticosteroids as this may worsen the condition.
- Most patients will not be cured, but the erosive nature of these ulcers will be controlled and therefore the pain will be reduced.
- Oral candidiasis is a frequent complication of corticosteroid treatment, and this risk is increased with any concurrent condition such as xerostomia. Candidiasis can be detected early with periodic recall evaluation and by exfoliative cytology in suspected situations. Understanding the typical oral candidiasis symptoms increases the patient's awareness of the need to return for treatment.
- Empiric topical corticosteroid treatment should be discontinued for 2 weeks if a biopsy becomes necessary for a definitive diagnosis.

Every effort should be made to identify and discontinue use of causative or irritating agents. Examples such as the link of acidic foods with aphthous ulcers are obvious to the patient, but many are more subtle. One example is cinnamon flavoring agents in many foods, mouthwashes, and toothpastes. Others are irritating to the mucosa but are mistakenly perceived as beneficial. Hydrogen peroxide, phenol preparations, and alcohol-based mouth rinses that “seem to be doing some good” because they are painful and consequently assumed to be killing bacteria are examples that should be avoided by patients with oral ulcers.

Corticosteroid Treatment of Immune-Mediated Oral Ulcers

Corticosteroid management of oral ulcers is similar to the approach for immune-mediated skin lesions. The therapeutic goal is lesion and symptom control, because disease cure or

spontaneous remission is unlikely. This should be understood by the patient to avoid unreasonable expectations. Healing of ulcers should be achieved with as little corticosteroid medication as possible. Topical corticosteroids should be tried first, limiting systemic administration to “bursts” as needed to control outbreaks of refractory ulcers followed by maintenance with topical treatment. Long-term systemic corticosteroid administration should be considered only as a last resort. The severity of lesions in these conditions typically varies with time, which means that the need for treatment beyond topical control also varies. Understanding several issues unique to the oral cavity can increase treatment effectiveness:

- Application of the topical corticosteroid after eating and at bedtime and avoiding frequent snacks promote adherence, absorption, and effectiveness.
- Low- and intermediate-potency topical corticosteroid preparations such as triamcinolone (Kenalog) and dexamethasone (Decadron) tend to be less than optimally effective in the oral environment. Initial trial with a higher-potency preparation is justifiable because significant systemic absorption through the oral mucosa is minimal. The use of ultrapotent topical corticosteroids is reserved for persistent ulcers if some systemic absorption is acceptable.
- Titration of a topical steroid should be explained to the patient so that the least amount of steroid to keep the lesions from recurring can be found by experimenting with the interval of use.

Osteonecrosis of the Jaw

Due to the limited blood supply in the mandible, there is a greater risk of osteonecrosis of the jaw (ONJ) than in the maxilla. Many patients who have received radiation to treat head and neck or oral cancer may have an increased risk of ONJ due to the proximity of the mandible to the field of treatment. Secondary to the use of bisphosphonates and other antiresorptive drugs such as denosumab (Prolia), a small number of patients will develop an area of necrotic bone that persists for 8 weeks or more. Often the patient will first complain of an area that feels rough to the tongue on the medial side of the mandible. This is difficult to see because the tongue is in the way, but physicians who prescribe the medications for osteoporosis or metastatic tumors to the bone should be aware of the risk and use a tongue depressor to better visualize the area during examination. Some patients on these medications will have spontaneous development of the condition due to the forces put on the bone during each bite. Others will need dental surgery and the nonhealing area will appear after a tooth is extracted.

While some studies show that a drug holiday from these medications reduces the risk, there appears to be no way to evaluate this. The blood tests that show bone turnover by measuring c-telopeptide (CTX) activity are not specific, and although these tests correlate to improvement in osteoporosis, there has not been any evidence that predicts which patient will develop ONJ.

Treatment is to prescribe systemic antibiotics when there is purulent exudate, with the use of pain medication as needed. Antimicrobial mouthwash such as chlorhexidine gluconate (Peridex) is helpful to eliminate plaque when it is uncomfortable to brush. For extensive areas of necrotic bone, the oral surgeon should be consulted for conservative resection of the affected bone.

DISEASES OF THE NAILS

Method of

David de Berker, MRCP

Anatomy

The nail plate arises from the nail matrix and grows out attached to the nail bed (Figure 1). The plate is inert and physiologically comparable to the stratum corneum as a structure composed of modified corneocytes containing a high proportion of keratins specific to the hair and nail differentiation that provide the hard and flexible characteristics of the appendage. The matrix is clinically visible as the lunula or half moon in the radial digits, particularly in the thumb. It usually is concealed by the proximal nail fold in digits further round to the little finger and in the toes. The proximal nail fold is a flap of skin that provides a cover to the base of the nail and is adherent to it, with a seal at the distal edge of the nail fold in the form of the cuticle. The lateral nail folds provide a soft tissue boundary to the nail sides. Distally, the nail is firmly attached to the nail bed, with a specialized configuration of epidermis that serves the purpose of minimizing the risk of separation of the nail from the nail bed. Such lifting is called *onycholysis* and is seen in a range of inflammatory and traumatic diseases. Once established, onycholysis can result in pain and loss of function of the digit.

Physiology

Fingernails grow at approximately 3 mm a month, with a faster rate on the dominant hand, on larger digits, in men, in pregnant women, and possibly in warmer weather. The rate diminishes with age from about 45 years. It is slower in toenails, with a rate of approximately 1 mm a month, which can mean that it takes 12 months or more for a big toenail to grow out fully. This has significance for the assessment of the outcome of treatment interventions. It can take several months before a result can be assessed, and in the instance of treatment of onychomycosis it can mean that the treatment has been stopped before the benefits have been fully appreciated.

Function

Fine manipulation, picking up small objects, or scratching an itch or a sticky label are all common uses of a nail. All these functions can be lost in nail disease. Where many nail diseases are associated

with soft tissue inflammation of the digit tip or nail fold, there can also be pain that limits function further.

Diseases

Onychomycosis

Onychomycosis is the infection of the nail plate and nail bed with fungus. Pathogenic fungi can damage the nail plate and its attachments. Fungus can also be present in an altered nail but not be the cause of the altered appearance in that it is biologically normal for fungus to occupy cracks in a damp space where there is organic material. Dermatophyte fungi (e.g., *Trichophyton* sp.) are more likely to be pathogenic than nondermatophytes, also referred to as molds (e.g., *Fusarium* sp.). *Candida* sp. also commonly colonizes rather than gives rise to an active onychomycosis with nail changes. However, when a nondermatophyte becomes established as a pathogen, it is often more difficult to eradicate than a dermatophyte and may well manifest with associated biological or occupational factors in the patient (e.g., working with soil, wet work).

CURRENT DIAGNOSIS: ONYCHOMYCOSIS

- Make an objective diagnosis with KOH, culture, or clipping for periodic acid–Schiff.
- Onychomycosis is much more common on the toenails than the fingernails.
- The most common organisms are *Trichophyton rubrum* and *Trichophyton mentagrophytes*.
- *Candida* only rarely causes onychomycosis. It is primarily a colonizer where the local environment is conducive.
- Nondermatophyte molds (e.g., *Aspergillus* and *Fusarium* spp.) are unusual causes of onychomycosis in the United States. Repeat tests showing the same organisms and ruling out other causes are required before initiating treatment.

Clinical Features and Diagnosis

Fungal invasion of nail alters the color and integrity of the nail. It may also alter attachment to the nail bed and the shape of the nail. The main color change is the development of shades of yellow or cream that are not transparent, in contrast with the normal color of the nail. Patterns of onychomycosis are described according to the dominant aspect of the infection.

Distal or distolateral onychomycosis is the most common, with the patient's history revealing the progress of a yellow discoloration that has extended gradually over many months or years from the free edge proximally up the nail bed or up one margin. This is usually associated with debris beneath the nail: subungual hyperkeratosis. Diagnosis relies on laboratory confirmation by obtaining a sample of nail and subungual debris for microscopy and mycological culture to provide the identity of the fungus, from which its role and likely sensitivities can be determined. Nail plate histology and polymerase chain reaction assay can be used as second-line tests.

Superficial white onychomycosis can manifest as small white powdery islands within the surface of the nail plate or as larger confluent areas. Scraping with a semisharp blade can demonstrate that it is limited to the dorsal aspect of the nail, and this sample can be sent to mycology for confirmation of the pathogen. It is a form of onychomycosis more common in children, who as a rule do not often suffer from onychomycosis.

Proximal white subungual onychomycosis is a variant of onychomycosis seen relatively more often on the fingernails and in people with immunosuppression, either through medication or as part of disease such as HIV. The infection manifests as a white appearance arising proximal to the rim of the proximal nail fold and beneath the nail plate. With time, as the nail grows out, there may be

It usually is concealed by the proximal nail fold in digits further round to the little finger and in the toes. The proximal nail fold is a flap of skin that provides a cover to the base of the nail and is adherent to it, with a seal at the distal edge of the nail fold in the form of the cuticle. The lateral nail folds provide a soft tissue boundary to the nail sides. Distally, the nail is firmly attached to the nail bed, with a specialized configuration of epidermis that serves the purpose of minimizing the risk of separation of the nail from the nail bed. Such lifting is called *onycholysis* and is seen in a range of inflammatory and traumatic diseases. Once established, onycholysis can result in pain and loss of function of the digit.

Physiology

Fingernails grow at approximately 3 mm a month, with a faster rate on the dominant hand, on larger digits, in men, in pregnant women, and possibly in warmer weather. The rate diminishes with age from about 45 years. It is slower in toenails, with a rate of approximately 1 mm a month, which can mean that it takes 12 months or more for a big toenail to grow out fully. This has significance for the assessment of the outcome of treatment interventions. It can take several months before a result can be assessed, and in the instance of treatment of onychomycosis it can mean that the treatment has been stopped before the benefits have been fully appreciated.

Function

Fine manipulation, picking up small objects, or scratching an itch or a sticky label are all common uses of a nail. All these functions can be lost in nail disease. Where many nail diseases are associated

with soft tissue inflammation of the digit tip or nail fold, there can also be pain that limits function further.

Diseases

Onychomycosis

Onychomycosis is the infection of the nail plate and nail bed with fungus. Pathogenic fungi can damage the nail plate and its attachments. Fungus can also be present in an altered nail but not be the cause of the altered appearance in that it is biologically normal for fungus to occupy cracks in a damp space where there is organic material. Dermatophyte fungi (e.g., *Trichophyton* sp.) are more likely to be pathogenic than nondermatophytes, also referred to as molds (e.g., *Fusarium* sp.). *Candida* sp. also commonly colonizes rather than gives rise to an active onychomycosis with nail changes. However, when a nondermatophyte becomes established as a pathogen, it is often more difficult to eradicate than a dermatophyte and may well manifest with associated biological or occupational factors in the patient (e.g., working with soil, wet work).

CURRENT DIAGNOSIS: ONYCHOMYCOSIS

- Make an objective diagnosis with KOH, culture, or clipping for periodic acid–Schiff.
- Onychomycosis is much more common on the toenails than the fingernails.
- The most common organisms are *Trichophyton rubrum* and *Trichophyton mentagrophytes*.
- *Candida* only rarely causes onychomycosis. It is primarily a colonizer where the local environment is conducive.
- Nondermatophyte molds (e.g., *Aspergillus* and *Fusarium* spp.) are unusual causes of onychomycosis in the United States. Repeat tests showing the same organisms and ruling out other causes are required before initiating treatment.

Clinical Features and Diagnosis

Fungal invasion of nail alters the color and integrity of the nail. It may also alter attachment to the nail bed and the shape of the nail. The main color change is the development of shades of yellow or cream that are not transparent, in contrast with the normal color of the nail. Patterns of onychomycosis are described according to the dominant aspect of the infection.

Distal or distolateral onychomycosis is the most common, with the patient's history revealing the progress of a yellow discoloration that has extended gradually over many months or years from the free edge proximally up the nail bed or up one margin. This is usually associated with debris beneath the nail: subungual hyperkeratosis. Diagnosis relies on laboratory confirmation by obtaining a sample of nail and subungual debris for microscopy and mycological culture to provide the identity of the fungus, from which its role and likely sensitivities can be determined. Nail plate histology and polymerase chain reaction assay can be used as second-line tests.

Superficial white onychomycosis can manifest as small white powdery islands within the surface of the nail plate or as larger confluent areas. Scraping with a semisharp blade can demonstrate that it is limited to the dorsal aspect of the nail, and this sample can be sent to mycology for confirmation of the pathogen. It is a form of onychomycosis more common in children, who as a rule do not often suffer from onychomycosis.

Proximal white subungual onychomycosis is a variant of onychomycosis seen relatively more often on the fingernails and in people with immunosuppression, either through medication or as part of disease such as HIV. The infection manifests as a white appearance arising proximal to the rim of the proximal nail fold and beneath the nail plate. With time, as the nail grows out, there may be

Figure 1 Surface anatomy of the nail.

disturbance of the dorsal nail plate, and disease may progress to the distal free edge with nail destruction.

Dermoscopy can enhance clinical diagnosis with spikes, dots, or jagged borders of nail plate discoloration.

All forms of infection can combine or progress to result in a nail that is almost or entirely overtaken with fungal infection, creating a variant known as *total dystrophic onychomycosis*.

CURRENT THERAPY: ONYCHOMYCOSIS

- Oral treatment should be reserved for patients with mycological confirmation, with emphasis on those at risk for complications (diabetics, immunosuppressed patients, those at risk for secondary bacterial cellulitis).
- Topical treatment is disappointing when used in isolation, except in cases of superficial white onychomycosis. When used in combination with oral therapy, it can increase the cure rate by about 10%.
- Oral treatment is more successful than topical treatment. Terbinafine (Lamisil) 250 mg PO once a day for 6 weeks for a fingernail and 3 months for a toenail in adults is the first-line treatment. Itraconazole (Sporanox), dosed 200 mg daily or 200 mg twice daily pulsed 1 week per month, is the next most successful agent. Additional caution is needed for those on concurrent medication or who have liver disease.
- Newer antifungals are not established, and laser treatment is not fully evaluated.
- Nondermatophytes are not always pathogenic, but when they are, they can be difficult to effectively treat.
- Patients are at high risk for recurrence. Post-treatment prevention of tinea pedis is important to prevent reinfection.

Treatment

All national guidelines on the management of onychomycosis require that the clinical diagnosis be confirmed by microscopy of the nail for fungi and preferably also by mycological culture before commencing systemic treatment. It is common to see patients who have been treated for nonfungal disease with antifungal treatment, which wastes patients' time and money and puts them at needless risk of serious adverse effects if they take oral therapy. Polymerase chain reaction assays are available as an alternative to routine mycology but remain unable to determine the difference between a pathogenic and saprophytic role.

The main oral treatment for dermatophyte fungi is terbinafine (Lamisil). Itraconazole (Sporanox) is the main alternative. The concomitant treatment with a topical antifungal agent such as amorolfine 5% (Curanail, Loceryl)² or ciclopirox 8% (Penlac) can increase the rate of success, which in a trial environment is between 50% and 80% depending on accepted end points. Treatment of co-existent tinea pedis can almost double the efficacy of efinaconazole 10% solution (Jublia) when used topically on nail. There is a significant relapse or reinfection rate in the following 5 years. Ongoing intermittent management of tinea pedis is likely to help prevent this and some patients choose to use a topical therapy intermittently on the nail.

Topical therapy alone has a smaller chance of success in dermatophytes, but it can be effective, especially if combined with thorough debridement by the dermatologist or with the help of a podiatrist with a nail burr and curette. Topical therapy can also be undertaken in combination with surgical or chemical avulsion (50% urea paste in yellow soft paraffin), and this is of value in non-dermatophytes, where the fungi are less susceptible to common oral treatments. Voriconazole (Vfend)¹ and other emerging systemic antifungals might have a place in complex nondermatophyte

onychomycosis, and normally they would be used in collaboration with a clinical microbiologist. Laser therapy remains under evaluation.

Candidal onychomycosis responds to both of the main oral agents, but it is very prone to relapse if the circumstances that gave rise to the infection remain in place.

Psoriasis

Nail involvement in psoriasis is seen in 80% of psoriasis patients at some point in the course of their disease. In those with significant involvement, it results in pain and loss of function in more than 50%. Nail disease usually is in tandem with skin involvement and in particular with arthropathy of the distal interphalangeal joint, where the inflammation of the joint contributes to a zone of disease that alters matrix function.

Clinical Features and Diagnosis

A personal or family history of psoriasis assists in interpretation of the signs. Sometimes, nail psoriasis occurs in isolation, and clinical signs alone provide the diagnosis or may be supported by a nail unit biopsy. The presence of fungus does not rule out an underlying diagnosis of psoriasis, especially on a big toenail, where fungus has been noted in 27% of psoriatic nails. Nail psoriasis has features that reflect the focus of disease within the nail unit.

Treatment

Treatment requires close attention to hand care, which entails avoiding manicure or work practices that are likely to exacerbate the problem. Typical issues are the clearance of debris from beneath the nail with a sharp instrument that elicits the isomorphic reaction with further psoriasis. Manipulation of the cuticle does the same, and having long nails results in leverage on the nail plate with minor trauma to exacerbate onycholysis. So the rules are:

- No clearance of debris except with a gentle soft nail brush
- No trimming or manipulation of the cuticle
- All nails to be as short as possible.
- General hand care with protection from solvents and wet work and use of plenty of emollient

Where potent topical steroid is to be used (Table 1), it is best applied at night only and for 2 to 3 months. Nail steroid injections have the theoretical risk of rupture of the tendon of the distal interphalangeal joint if undertaken frequently and so are usually done up to several months apart; my practice is to provide a ceiling of four injections per digit. As a rule, all systemic agents work, including biologicals, but their use is rarely justified by nail disease alone. It can be argued that cyclosporine (Sandimmune) in 3-month pulses is good for younger people with no kidney problems, methotrexate (Trexall) might suit older people, and acitretin (Soriatane) may suit those with hypertrophic nail disease. But most choices will be determined by the additional characteristics of the patient and the psoriasis elsewhere.

Idiopathic Onycholysis

Onycholysis is the separation of the nail from the nail bed, with a cleavage that commences at the free edge and progresses proximally.

CURRENT DIAGNOSIS: ONYCHOLYSIS

- Primary onycholysis and chronic paronychia are diagnoses of exclusion.
- Onychomycosis, psoriasis, lichen planus, and drug reactions all must be ruled out before diagnosis.
- Primary onycholysis and chronic paronychia are more common on the fingernails than the toenails, in women, in adults, in those who use nail cosmetics, and in those who have recurrent exposure to moisture or chemicals.

¹Not FDA approved for this indication.

²Not available in the United States.

TABLE 1 Nail Psoriasis: Clinical Features and Diagnosis

CLINICAL FEATURE	FOCUS OF DISEASE	TREATMENT MODALITY	OPTIONS
Pitting	Proximal matrix	Potent topical steroid to nail fold	Clobetasone dipropionate ²
		Tazarotene (Tazorac) ¹ to nail fold	
		Steroid injection	Triamcinolone acetonide (10 mg/mL)
Onycholysis	Nail bed	Clip back and treat topically	Steroid and or vitamin D analogues
		Antiseptic finger soaks for secondary infection (e.g., <i>Candida</i> and <i>Pseudomonas</i>)	
		Systemic therapy	Cyclosporine (Sandimmune), methotrexate (Trexall), fumaric acid esters, ² acitretin (Soriatane), biologicals
Salmon patch or oily patch		No topical therapy	
Transverse ridging and undulations	Proximal nail fold	Potent topical steroid, vitamin D analogues	See pitting
		Steroid injection	Triamcinolone acetonide (10 mg/mL)
Subungual hyperkeratosis	Nail bed	Steroid injection	Triamcinolone acetonide (10 mg/mL)
		Systemic therapy	Cyclosporine, methotrexate, fumaric acid esters, acitretin, biologicals
Nail shedding	Matrix and nail bed	Systemic therapy	Cyclosporine, methotrexate, fumaric acid esters, acitretin, biologicals

¹Not FDA approved for this indication.²Not available in the United States.

- Both primary onycholysis and chronic paronychia represent breakdown in the normal barrier of the nail apparatus.
- Onycholysis results from breakdown of the onychocorneal band or nail bed–nail plate connection. Chronic paronychia is associated with loss of cuticle and inflammation of the nail folds.
- In both scenarios, moisture, contact irritants, contact allergens, colonizing yeast, and bacteria invade the exposed nail apparatus and contribute to a cycle of inflammation.

Clinical Features and Diagnosis

Most patients with onycholysis also have psoriasis. However, for some with problems of nail attachment, the cause is multifactorial and it might not be possible to provide a unifying diagnosis. A subtype of onycholysis occurs in people who undertake manicure vigorously and have long nails. Such people are troubled by the debris beneath a nail and significantly damage the area by scraping material out with a sharp object. This then creates more pathology, a bigger split, and the accumulation of more debris managed by physical manipulation. It is common for people with such cosmetic sensibilities to have long nails, which then exacerbates the onycholysis further through the mechanics of creating a large lever represented by the overhanging margin of the nail. The principle is shared with the wrench in your tool set: The longer the arm on the wrench, the easier it is to exert a torsion force on the point of contact. In this instance the contact is the margin of attachment with the nail bed.

Clipping for mycology is usually undertaken and sometimes reveals *Candida* sp. This is not causal, but is a colonizing microbe in the warm onycholytic space.

CURRENT THERAPY: ONYCHOLYSIS

- It is important not to misdiagnose the presence of yeast (especially *Candida*) as a primary infection or pathogen.

- It almost always represents a colonizer. Treatment of the yeast is therefore secondary.
- Avoidance is the mainstay of treatment. Avoid all wet work and exposure to acids, bases, and chemicals by wearing cotton gloves under heavy-duty vinyl gloves.
- Avoid nail manipulation except for regular plate trimming. No nail salon. Keep the plate trimmed to its proximal-most attachment point. Avoid obvious triggers and traumas to the nail apparatus.
- Where an allergic reaction to nail lacquer is ruled out, some people may find the concealing effect of a colored lacquer helpful.
- Use a potent topical steroid, sometimes under occlusion for paronychia in the first month.
- It can take up to 6 months for the nail apparatus to normalize.

Treatment

Treatment principles are shared with psoriasis (see earlier). The presence of *Candida* sp. on mycology might tempt the clinician to try itraconazole (Sporanox)¹ systemically. However, it rarely helps, although the removal of one factor in the pathology can help other treatments to improve the situation. Success mainly requires avoidance of all physical exacerbating factors and clipping back the separated nail to treat the exposed nail bed with moderate-potency topical steroid. Antiseptic soaks can help if clipping back is not an option or there is significant microbial colonization.

Lichen planus

Lichen planus of the nail has features in common with psoriasis in that it can involve all the different structures of the nail unit and give rise to a range of features accordingly. The area of greatest concern is when it manifests with features of scarring, which can cause permanent loss or splits in nails, with considerable cosmetic and physical handicap.

¹Not FDA approved for this indication.

Clinical Features and Diagnosis

In common with its presentation on the skin, nail lichen planus can be hypertrophic, with thickened nails, or it can be atrophic, with patterns of pronounced pitting that coalesce and eventually fragment the nail. In some instances the disease is very focal and the matrix pathology results in complete loss of nail production, with scarring sequelae. If this occurs with normal matrix remaining on either side, a pterygium may be the outcome, with a scar and nail split being bordered by viable nail spurs like wings. This is normally irreversible, and any suggestion of this pattern of disease should prompt rapid and usually systemic treatment. The potential for side effects with systemic therapy, which may be prolonged, means that I favor a diagnostic biopsy when there is any doubt or when presentation is with nail disease alone. Sometimes, clinical corroboration with mucosal, skin, or scalp disease allows certainty without a biopsy. Biopsy is best taken of nail bed, matrix, and nail fold to ensure it is representative and does not miss the diagnosis.

Treatment

The general protective and topical steroid therapies used in psoriasis can apply in lichen planus. If systemic therapy is needed, oral or intramuscular steroid injection can be used and represent flexible and effective therapy. The duration of the treatment means that monitoring of blood pressure, glucose, and weight may be indicated and bone protection might be needed. Regimens¹ vary, but oral prednisolone¹ 0.25 to 0.5 mg/kg for 4 to 6 weeks, tapering in the 2 weeks following, normally reverses active disease. It also allows assessment of what may be the irreversible scarred element, although nail growth rate means that this judgment should wait until a further 4 to 6 weeks after the end of treatment. Acitretin (Soriatane)¹ and cyclosporine (Sandimmune)¹ also can be used in lichen planus and may be better where patient morbidity does not allow prolonged or repeated oral steroids. Locally injected steroids may be used to address areas of focal scarring but seldom result in full cure.

Eczema

Eczema of the nail folds or nail bed may be associated with eczema elsewhere on the hand or foot and can cause nail unit disturbance in a manner similar to psoriasis. Special patterns of eczema can be relevant for allergic contact sensitivity.

Clinical Features and Diagnosis

The most common pattern of nail changes in eczema is where the nail fold is inflamed as part of an irritant hand eczema or as part of atopic eczema. This acts as a focus of inflammation that in turn disturbs matrix function owing to their adjacency. The nail then suffers transverse ridges and alterations of color, which reflect the fluctuating inflammation. Where the eczema is more directed at the digit tip, the nail bed is more likely to be involved, which in turn results in onycholysis. Both patterns often manifest most in the dominant hand because trauma, or simply use, increases the likelihood of pathology.

Occupational factors can be important both for analysis of the cause and for helping patients manage the global situation because they can suffer degrees of incapacitation. Where the occupation plays a part in the pathology, such as irritants in a health care or food-preparation worker, it may be necessary to review career choices. Hairdressers, beauticians, and engineers in certain fields come into contact with a wide range of contact sensitizers. The use of nail cosmetics alone can be relevant. Consider patch testing.

Treatment

Treatment is as for eczema elsewhere and shares many of the points made for managing psoriasis of the nail unit:

- Avoidance of irritants, trauma, nail manipulation, and frequent wetting
- Use of copious thick emollient
- Topical steroid tailored to severity
- Hand protection

Infective and chronic paronychia can be a complicating factor in nail unit eczema and requires additional systemic antibiotics in some instances.

Paronychia

Paronychia means inflammation of the proximal or lateral nail folds. There can be an infective component, and there is often a traumatic or eczematous background pathology.

Clinical Features and Diagnosis

An acute paronychia manifests as a focus of redness, pain, and sometimes a point of purulent collection and discharge in the nail fold. There may be a history of preceding trauma or, in children, of nail biting.

Chronic paronychia is seen with a raised, bolstered proximal nail fold, loss of cuticle, and transverse ridges in the nail extending up the nail plate, indicating many months of fluctuating inflammation. There is an account of episodic pain and sometimes discharge of pus. Antibiotics or antifungals alone do not settle the pathology.

Treatment

Acute paronychia is primarily infective and will subside after management of the bacterial infection and the associated wound or inflamed focus. Chronic paronychia has substantial crossover with an irritant hand eczema, and management is as for hand eczema. The low level of infection is secondary to the loss of cuticle and loss of barrier function in a digit that has substantial exposure to microbes. Where wet work is a factor, *Candida* sp. may be found, but short-term eradication with systemic therapy does not resolve the chronic problem. Management is with a potent steroid, sometimes under tape occlusion. Evening (10 minutes) antiseptic soaks can help diminish the risk of infective exacerbation, but once a cuticle has re-formed and the nail fold is flat, the risk greatly reduces.

If there is a failure to respond to this regimen, the diagnosis might need challenging. Periungual squamous cell carcinoma can manifest in this manner and requires nail or nail fold biopsy for assessment.

Ingrown Toenail

An ingrown nail represents a conflict between the shape of the nail and the soft tissues surrounding it. This conflict can be highlighted by an episode or period of trauma such as sport or new shoes, or may be a sustained anatomical state. It is compounded by cutting the nail short at the distolateral corner such that the nail fold overlaps the end of the nail. Symptoms arise through the soft tissue inflammation, which can sometimes be complicated by bleeding or infection. Treatment is directed at the acute inflammation and subsequently at the anatomy if needed.

CURRENT DIAGNOSIS: INGROWN TOENAIL

- Common risk factors include incorrect nail cutting, wide feet, narrow-toed shoes, lateral plate malalignment, and lateral nail fold hypertrophy.
- Neonates and infants demonstrate distal nail ingrowing, which is separate in pathogenesis and treatment from the disease in adolescents and adults.
- Ingrown nails can be graded on a scale from I to III, with I being erythema and swelling with drainage from the nail fold and III being associated with exuberant overgrowth of granulation tissue over and around the ingrown nail plate.

¹Not FDA approved for this indication.

Clinical Features and Diagnosis

Ingrowing can occur at any nail margin, with the most common site being the lateral nail fold in the big toe of someone in the second or third decade of life. At this site, it is the angle of the distal and lateral nail that becomes embedded in the lateral nail fold to create a puncture wound. The inflammation that follows creates a more bulky lateral nail fold and a positive feedback loop such that resolution typically requires medical intervention.

In a newborn or in a nail regrowing after loss, ingrowing can occur at the free edge as it meets the distal digit pulp. Proximally, an incompletely shed nail may be displaced upwards to embed into the ventral aspect of the proximal nail fold, with a pattern of pain and inflammation that matches ingrowing at other sites. This is called *retronychia*. All variants can evolve to create a mass resembling a pyogenic granuloma coupled with ooze and potential for secondary infection and local cellulitis.

CURRENT THERAPY: INGROWN TOENAIL

- Infantile disease should be treated with warm soaks with antiseptic followed by massage of the nail and distal phalangeal tuft.
- Adolescent and adult disease should be addressed with correct nail plate cutting and shoes. For mild disease, twice daily antiseptic soaks, topical steroids, 20% to 40% topical urea cream (Keralac, Carmol), and cotton wisps or dental floss under the aggravating part of the lateral nail plate will decrease inflammation, improve symptoms, and normalize the nail plate without surgery.
- For more advanced cases, use twice-daily warm soaks and oral antibiotics (with signs of infection), followed by lateral plate avulsion and lateral matricectomy (either chemical or surgical).

Treatment

Mild acute ingrowing can be treated with antiseptic soaks, potent topical steroid, and oral antibiotic if infection is suspected. Causal footwear or activities should be avoided and shoes with a high toe box to accommodate the tips of the toes should be worn. It may be possible to insert a pledget of cotton, wool, or similar substance between the embedding edge of nail and the damaged soft tissue. Advice on square end nail cutting to avoid an overshoot nail is important.

If this conservative approach does not work, surgery is indicated. This is normally ablation of the lateral 3 to 4 mm of nail matrix and can be done with 85% aqueous phenol to create a chemical burn or with excision. The latter requires considerable skill for a reliable outcome because the apex of the horn of the matrix is difficult to access, and a remnant, if left, results in a spicule of nail regrowth that will continue to cause problems. Phenol, however, tends to find the entire exposed matrix because it is a liquid flowing into a crevice and does not need precise placement.

Distal embedding normally settles with conservative measures, and proximal ingrowing with *retronychia* requires avulsion. Avulsion is not the treatment for lateral or distal ingrowing because it results in recurrence of the problem as the nail regrows in most instances.

Single Digit Dystrophy

Dystrophy of a single nail is relatively common.

CURRENT DIAGNOSIS: SINGLE DIGIT DYSTROPHY

- Nail dystrophy on a single digit represents a risk factor for squamous cell carcinoma or melanoma of the nail unit.
- This is more common on a finger than a toe, where trauma is more often the explanation on a toe.

- When history, examination, and investigations do not provide a clear diagnosis, then a nail unit biopsy is indicated to exclude neoplasm and direct definitive treatment.

Clinical Features and Diagnosis

Dystrophy in a single digit can have any appearance, but the important thing for the clinician is that single-digit dystrophies include the uncommon but significant category of skin cancer. The most common of these is in situ squamous cell carcinoma (SCC), but the main other diagnosis is melanoma, either with a longitudinal melanonychia or as amelanotic melanoma with a lesion resembling a pyogenic granuloma. Both SCC and melanoma are infamous for having a late diagnosis in the digit, and the reason for this is lack of awareness shared by patient and clinician.

Following exclusion of inflammatory dermatoses by history and body examination and of onychomycosis by multiple clippings, the area should be biopsied for histology of matrix and nail bed. The classic biopsy is the lateral longitudinal biopsy, although this should be tailored to the perceived focus of pathology. It is best undertaken by someone familiar with nail pathology and the procedure, because there is a further risk of false reassurance of a negative biopsy if the sample is too small or directed at the wrong area of the nail unit.

CURRENT THERAPY: SINGLE DIGIT DYSTROPHY

- Once a biopsy has been obtained it is possible to pursue one of the three avenues of definitive treatment: antimicrobial, immunosuppressive, or surgical. Each option is directed at infection, inflammation, or neoplasm, respectively, and each is counterproductive for management of either of the other two diagnostic groupings.

Treatment

Where malignancy is detected, treatment is normally surgery. Topical therapy for in situ SCC does not work well owing to obstruction of the involved surfaces beneath the nail. The crevices created by the nail folds make photodynamic therapy ineffective.

ERYTHEMA MULTIFORME

Method of

Gabriel P. Currie, MD; and Jose A. Plaza, MD

CURRENT DIAGNOSIS

- Acute, symmetrical, primarily extensor surfaces of acral surfaces.
- Target-like papules, plaques, and bullae.
- Mucosal lesions can be present.
- Young adults, female preponderance.
- Often preceded by herpes simplex infection.

Clinical Features and Diagnosis

Ingrowing can occur at any nail margin, with the most common site being the lateral nail fold in the big toe of someone in the second or third decade of life. At this site, it is the angle of the distal and lateral nail that becomes embedded in the lateral nail fold to create a puncture wound. The inflammation that follows creates a more bulky lateral nail fold and a positive feedback loop such that resolution typically requires medical intervention.

In a newborn or in a nail regrowing after loss, ingrowing can occur at the free edge as it meets the distal digit pulp. Proximally, an incompletely shed nail may be displaced upwards to embed into the ventral aspect of the proximal nail fold, with a pattern of pain and inflammation that matches ingrowing at other sites. This is called *retronychia*. All variants can evolve to create a mass resembling a pyogenic granuloma coupled with ooze and potential for secondary infection and local cellulitis.

ERYTHEMA MULTIFORME

Method of

Gabriel P. Currie, MD; and Jose A. Plaza, MD

CURRENT DIAGNOSIS

- Acute, symmetrical, primarily extensor surfaces of acral surfaces.
- Target-like papules, plaques, and bullae.
- Mucosal lesions can be present.
- Young adults, female preponderance.
- Often preceded by herpes simplex infection.

CURRENT THERAPY

- First episode: symptomatic care (oral antihistamines, topical corticosteroids).
- Recurrent episodes: prophylaxis with antivirals.
- Persistent: cyclosporine (Neoral, Sandimmune),¹ prednisone, azathioprine (Imuran),¹ dapsone,¹ and antimalarials.

¹Not FDA approved for this indication.

Epidemiology

Erythema multiforme (EM) is an uncommon, acute, self-limited immune-mediated mucocutaneous disorder. The exact incidence of EM is unknown, but estimated to be far less than 1% but possibly greater than 0.01%. The disorder occurs predominantly in young adults between ages 20 and 40, but as many as 20% may be seen in children and adolescents. There is a slight female predominance and the disease affects all races equally.

Risk Factors

EM has been associated with infections, medication use, malignancy, autoimmune disease, radiation, immunization, and menstruation. However, of these, infection represents approximately 90% of cases, the most common of which is herpes simplex virus (HSV) infection. Other infectious associations include mycoplasma, histoplasmosis, *Yersinia*, and tuberculosis. Approximately 10% of cases are drug associated, most often sulfonamide induced.

Pathophysiology

Studies of the pathophysiology of EM have been based on the study of herpes-associated EM. It has been postulated that peripheral blood mononuclear cells transport HSV DNA to lesional skin, where a subsequent virus-specific response occurs. CD4+ T helper type 1 (TH1) cells release interferon-gamma (IFN-gamma), leading to a nonspecific inflammatory amplification through autoreactive T cells and subsequent keratinocyte destruction. In drug-induced EM, tumor necrosis factor- α , perforin, and granzyme B cause the epidermal destruction.

Prevention

To date, there is no known preventive strategy. However, as the fields of pharmacogenomics advance, new human leukocyte polymorphisms that predispose to EM may be identified.

Clinical Manifestations and Diagnosis

Erythema multiforme is generally a self-limited illness that lasts 1 to 4 weeks. In approximately one-third of cases, the cutaneous lesions are preceded by a prodrome of fever, headache, sore throat, cough, rhinorrhea, and malaise. Although the skin lesions may vary between individual patients, the earliest lesions are usually round, erythematous, edematous papules surrounded by areas of blanching. The lesions evolve to target-like papules and plaques with a central portion of epidermal necrosis that appear dusky and can form central bullae (Figures 1 and 2). The lesions are symmetrically distributed on extensor surfaces of the extremities.

Differential Diagnosis

The clinician must consider urticaria, fixed drug eruption, bullous pemphigoid, paraneoplastic pemphigus (PNP), Sweet's syndrome, Rowell's syndrome, and polymorphous light eruption (PMLE), as well as the more serious Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN) spectrum of disorders.

Treatment

Although generally EM is a self-limited condition, the recurrent or persistent nature of the disease in some patients has led to a variety

Figure 1 Typical target lesions with three zones of coloration and one central bulla on the palm. (Photo courtesy of Sheila Galbraith, MD.)

Figure 2 Erosions with extensive crusting on the vermilion and mucosal lip. (Photo courtesy of Sheila Galbraith, MD.)

of potential treatments. Of utmost importance is discontinuation of all provocative factors, including potential medications. Although HSV induces the majority of cases, anti-HSV treatments do not alter the clinical course. However, in recurrent HSV-associated disease, suppressive therapy can provide relief. With mild disease, symptomatic treatment with oral antihistamines (diphenhydramine [Benadryl] 25–50 mg PO every 6 hours as needed, hydroxyzine [Atarax, Vistaril] 25–100 mg PO every 6 hours as needed) and midpotency topical corticosteroids (triamcinolone 0.1% ointment [Triderm] applied to affected skin twice daily) will suffice. In more problematic mucosal disease, as well as recurrent EM, cyclosporine (Neoral, Sandimmune),¹ prednisone, azathioprine (Imuran),¹ dapsone,¹ and antimalarials have all been used with varying degrees of success.

Monitoring and Complications

EM is a self-limiting disease. As a rule, lesions do not lead to scarring. However, postinflammatory hyperpigmentation may take months to resolve. Patients with ocular involvement can develop scarring without ophthalmologic intervention.

¹Not FDA approved for this indication.

FUNGAL INFECTIONS OF THE SKIN

Method of

Therese Holguin, MD; and Kriti Mishra, MS

CURRENT DIAGNOSIS

- Dermatophyte infections
 - Non-hair-bearing (glabrous) skin diagnostic techniques are scraping of leading edge of scale with glass slide onto glass slide, cover slip, and apply 10% potassium hydroxide (KOH) to edge of coverslip. Heat the bottom of slide slightly, clean off with tissue, and view under microscope without condenser. Counterstain with chlorazol black E or Parker blue-black ink may help visualize hyphae.
 - Hair-bearing skin may require a tissue biopsy with special fungal stains to confirm diagnosis.
 - Culture of scale, hair, and nail fragments sent to laboratory in a sterile urine cup and clearly marked “for dermatophyte culture” is an additional testing method. Nail fragments can be sent in formalin for periodic acid-Schiff (PAS) staining (a quick-turnaround test).
- Tinea versicolor
 - Stratum corneum removal with a glass slide against a glass slide and KOH examination as above is done for diagnosis. Cultures require a special media and lab needs notification this is the organism suspected.
- Candida cutaneous infections
 - Unroofing a pustule by scraping gently with a 15 blade and spreading contents onto a glass slide for KOH evaluation will review the characteristic yeast and pseudohyphae. Culture is usually not necessary.

CURRENT THERAPY

- Dermatophyte infections
 - Non-hair-bearing skin mild infections are treated with topical agents if severe and widespread; systemic and topical agents together will provide higher cure rate. Prevent reinfection of feet by wearing sandals when possible, especially in public places, alternating shoes, and keeping feet dry. For groin infections, dry well after showering and put socks on before underwear.
 - Hair-bearing skin and hair infections require systemic therapy for cure. Nail infections may be cured with newer topical agents.
- Tinea versicolor
 - Topical treatment with topical agents such as selenium sulfide lotion applied for 10 minutes for 2 weeks, neck to knees, is a

cheap and effective treatment. Systemic agents may be needed for resistant cases. Prevention may require maintenance therapy with topical agents during warm and humid months.

- Candida cutaneous infections
 - Topical agents such as nystatin or ketoconazole cream are an effective choice. Prevention of intertrigo is somewhat successful if care to dry thoroughly after showering in body fold areas is done routinely. Zinc-talc shake lotion may be used once or twice daily.

Dermatophyte (tinea) infections are a group of filamentous fungal infections of the skin, hair, and nails and can be noninflammatory or inflammatory. The route of acquisition for dermatophytes is either person to person (anthropophilic), or from animals (zoo-philic). Geophilic dermatophytes grow in soil and are a rare source of infection in humans. The causative organisms are of three genera: *Microsporum*, *Trichophyton*, and *Epidermophyton*.

Dermatophytoses are the most common fungal infections worldwide, affecting 20% to 25% of the world population. The predominant agents have changed over time by geography and population based on migration of populations, hygiene practices, and therapeutic breakthroughs (griseofulvin [Gris-PEG]). Clinical classification is based on site of infection. Tinea pedis refers to infection of the feet, tinea manuum the hands, tinea cruris the groin, and tinea corporis the skin excluding already mentioned sites plus scalp and nails. Tinea unguium (onychomycosis) refers to nail infection, tinea barbae to beard area, tinea faciei the face, and tinea capitis the scalp and hair. Virulence of the infection is dependent on underlying factors suppressing immunity (diabetes, cancer, HIV infection). Dissemination can be seen in the immunosuppressed.

Superficial infections of the skin and mucous membranes caused by yeasts are caused by *Candida* species. Also common are infections due to lipophilic yeast fungus *Malassezia*.

Superficial Mycoses Dermatophytes

Tinea Capitis

The populations most at risk are children, with boys more commonly than girls. The onset of puberty and change in the relative composition of unsaturated fatty acids in sebum is protective. African Americans and Hispanics have an increased incidence of *Trichophyton tonsurans*. Pet exposure is associated with infections of *Microsporum canis*. Infection with *Trichophyton schoenleinii* (favus), still seen in less well-developed countries, is of characteristic cup-shaped crusts, scutula.

The usual presentation of tinea capitis is of scale and itch on the scalp with broken-off hairs with a “black dot” appearance (Figure 1) or an inflamed boggy plaque, referred to as a *kerion*. Inflammatory

Figure 1 Black dot tinea.

TABLE 1 Treatment

INFECTION	CHILDREN	ADULTS	TOPICAL	COMMENTS
Tinea capitis	Terbinafine (Lamisil granules) ² first-line Age 4+ 4–6 weeks (granules can be added to nonacidic food) <25 kg 125 mg/d 25–35 kg 165.5mg/d >35 kg 250 mg/d Griseofulvin second line Ultramicrosize (Gris-PEG) Age 2+ 8 weeks (can sprinkle on apple sauce) 5–15 mg/kg/d, single or 2 divided doses, max 750 mg/d Fluconazole (Diflucan) ¹ Age >14 days 3–6 mg/kg PO/IV q24h × 6 weeks; Alt: 6 mg/kg PO/IV qweek × 8–12 weeks Itraconazole (Sporanox) ¹ 4–6 weeks 3–5 mg/kg/day (with full meal) or pulse regimen with capsules (5 mg/kg/d for 1 wk times 3 pulses 3 wk apart), and with oral solution (3 mg/kg/d for 1 wk times 3 pulses, ie, 1 wk per mo)	Terbinafine (Lamisil tab) ¹ 4–6 weeks 250 mg/d Fluconazole (Diflucan) ¹ 50 mg/d (4–7 weeks) or 150 mg/week (4 weeks) Itraconazole (Sporanox) ¹ 4 weeks 100–200 mg/d	Antifungal shampoos: selenium sulfide (antidandruff), ciclopirox (Loprox), and zinc pyrithione (Head & Shoulders) (twice-weekly with systemic treatment)	Systemic therapy: baseline CBC and Liver function tests. Repeat if >6 weeks. Griseofulvin contraindicated in pregnancy and restrictions for becoming or fathering after course. Avoid alcohol during treatment. Itraconazole has negative inotropic effect and can prolong Q-T interval. Ketoconazole has risks of fatal liver damage and adrenal insufficiency (not recommended)
Tinea corporis, Tinea cruris, Tinea pedis, Tinea mannum, Tinea faciei, Tinea barbae	Terbinafine ¹ Age 2+ 2 weeks <20 kg 62.5 mg/d 20–40 kg 125 mg/d >40 kg 250 mg/d Itraconazole ¹ 2 weeks 5 mg/kg/day divided qd-BID Griseofulvin ultramicrosize Age 2+ 2–8 weeks 5–15 mg/kg/day divided qd-BID; Max: 750 mg/day	Terbinafine ¹ 2–4 weeks 250 mg/d Itraconazole ¹ 1 week 200 mg/d Fluconazole ¹ 2–4 weeks 150–300 mg/week	Terbinafine (Lamisil) Butenafine (Lotrimin-Ultra) Naftifine (Naftin) Clotrimazole (Lotrimin) Econazole (Spectazole) Ketoconazole (Nizoral) Sertaconazole (Ertaczo) Luliconazole (Luzu) Eberconazole (Ebernet) 2–6 weeks once or twice daily	Systemic treatment is reserved for widespread, resistant, or severe disease. Monitor for drug interactions and adverse effects.
Tinea unguium	Children may respond completely to antifungal topical lacquer or solutions without systemic therapy. Terbinafine Age 2+ 6 weeks fingernails 12 weeks toenails <20 kg 62.5 mg/d 20–40 kg 125 mg/d >40 kg 250 mg/d Itraconazole 1week of each month for 3–5 months, 2 pulses for fingernails and 3 for toenails 5 mg/kg/d Fluconazole ¹ Age >14 d 6 mg/kg PO/IV/wk × 12–16 weeks for fingernails and 18–26 for toenails Griseofulvin Not considered as useful as would have to have daily dosing for 6–12 months. Cure rate poor.	Terbinafine 250 mg/d (fingernails for 6 weeks 12 weeks for toenails) or 250 mg/d for 4 weeks off 4 weeks for 2 pulses for toenails Itraconazole 200 mg/d 12 weeks or 200 mg BID for 1 week off 3 weeks (2 × for fingernails and 3 × for toenails) pulse therapy Fluconazole ¹ 150–300 mg/week (6–9 months fingernails 9–18 months toenails)	Lacquers: Amorolfine (Curanail, Loceryl, Locetar, Odenil) ² and Ciclopirox (Penlac) Hydrolacquer: Cicloprox Solution: Efinaconazole (Jublia) and Tavaborole (Kerydin) 48–60 weeks	Lacquers are debrided and reapplied daily. Hydrolacquers are removable with washing and reapplied daily. Conventional oral therapy followed by topical for maintenance may help prevent recurrence. Lasers and photodynamic therapy if available are considered third-line options. Surgical options include chemical (40%–50% urea compound), or surgical nail avulsion.

Abbreviations: BID = two times daily; CBC = complete blood count; IV = intravenous; PO = orally.

¹Not FDA approved for this indication.²Not available in the United States.

Figure 2 Tinea corporis.

presentations are most often seen in zoophilic infections. Patches of alopecia are common.

Tools for diagnosis include potassium hydroxide (KOH) preparation of scale or hair tweezed from affected patch to be examined microscopically. The Wood's light will show fluorescence with ectothrix infections (organism on outside of shaft) but not endothrix infections (spores on inside of shaft). Samples for culture are obtained by rubbing a wet cotton-tipped applicator over the affected area and applying this or pulled hairs onto the dermatophyte test medium or other medium if species identification is required in resistant cases. The differential diagnosis includes seborrheic dermatitis, psoriasis, folliculitis, pediculosis, secondary syphilis, discoid lupus erythematosus, lichen planus, lichen simplex chronicus, trichotillomania, alopecia areata, and other inflammatory follicular conditions.

Tinea Faciei and Barbae

Frequently misdiagnosed, infection of the face or beard is rare. Beard infections (tinea sycosis or barber's itch) can be deep and inflammatory and are seen in agricultural workers, especially those working with farm animals. Discoid lupus is a commonly mistaken diagnosis, and biopsies are sometimes required to differentiate.

Tinea Corporis

"Ringworm" is a layman's descriptive term of the characteristic clinical findings of dermatophyte infections. The term accurately portrays the appearance of an erythematous annular plaque with a scaly, raised, leading edge (Figure 2). Severe infections may herald new HIV infection or be secondary to topical immunosuppressant such as calcineurin inhibitors or, more commonly, steroids. KOH examination sampling should be taken from the leading edge. The differential diagnosis includes pityriasis rosea, impetigo, inflammatory dermatoses such as psoriasis and seborrheic dermatitis, and syphilis.

Tinea Cruris

More common in men and when humidity is high, "jock itch" or "crotch itch" involves the upper thigh, intertriginous area, and peripheral spread into the perineum and perianal areas. The scrotum is rarely involved. The usually well-defined border may display scale, papules, or pustules.

The differential diagnosis includes a bacterial infection, erythrasma, candidiasis, intertrigo, psoriasis, and dermatitis. Morphology of the rash and expected involvement of other cutaneous sites is useful to eliminate these possible diagnoses. The origin of the infection is believed to be autoinoculation from tinea pedis or onychomycosis.

Tinea Manuum and Pedis

A classic finding of "one hand and two feet" involvement is useful to lead one to consider tinea manuum (Figure 3). The organism

Figure 3 Tinea manuum.

involved in the infection determines the amount of inflammation resultant. Whereas *Trichophyton rubrum* produces a dry scale with erythema of hands and feet (moccasin-type), *Trichophyton interdigitale* (previously known as *Trichophyton mentagrophytes*) often leads to a painful, itchy, blistering eruption of the feet. Other signs of *T interdigitale* include interdigital maceration and superficial infection of the toenails with a distinct white appearance (white superficial onychomycosis). Toe-web infection with gram-negative bacteria may be consequential. Hyperhidrosis is often a precursor to this type of infection. An idiopathic reaction "dermatophytid" is a fairly common pruritic rash of small blisters involving the palms and sometimes the sides of the feet.

Onychomycosis

Fungal infections of the nail are caused by dermatophytes (tinea unguium), yeasts, and nondermatophytic molds. It is common in the general population, accounting for 50% of skin fungal infections. Risk factors include advanced age, diabetes, circulatory disorders, and family history. There are three major subtypes of onychomycosis: distal lateral subungual onychomycosis, white superficial onychomycosis, and proximal subungual onychomycosis. Distal lateral subungual onychomycosis is the most common subtype and is caused by the anthropophilic dermatophytic fungus, *T rubrum*. Symptoms include an initial discoloration of the distal corner of the nail that may be white, gray, or brown caused by accumulation of keratinous debris under the nail that eventually spreads to involve the entire nail. Other common features are onycholysis, or splitting of the nail from the bed, nail thickening, and impaired nail growth. The diagnosis typically involves KOH, mycologic laboratory confirmation (culture), and biopsy. Yeast onychomycosis is most commonly caused by *Candida albicans* and typically involves fingernails of hands frequently exposed to moisture. Nondermatophytic molds primarily involve toenails. Though not life threatening, onychomycosis can significantly impair an individual's quality of life with concerns such as issues cutting the nails and cosmetic disfigurement.

Pityriasis Versicolor

This superficial fungal infection of the skin is caused by a dimorphic lipophilic fungus, *Malassezia* species, which is part of the physiological skin flora. Certain environmental, genetic, and immunologic factors can predispose the fungus to convert to its

pathogenic hyphal form and development of disease. It grows best in warm, humid climates; thus there has been a higher prevalence reported in tropical climates. Furthermore, potential hormonal changes during adolescence can increase sebum production and allow for *Malassezia* to thrive, and the prevalence is even further increased in active adolescents. The pathophysiology may also be related to an impaired immune system.

The diagnosis is usually made clinically, but the presentation may vary; it classically consists of a well-demarcated rash with fine scale and thin plaques. The rash may be hyperpigmented, hypopigmented, or erythematous. Typically, the rash appears on the torso but may become widespread. The lesions may be mildly pruritic or asymptomatic. If KOH is performed on skin scrapings, numerous spores and hyphae can be visualized (“spaghetti and meatball” appearance). Treatment options include topical antifungals, including azoles and terbinafine, selenium sulfide (antidandruff), and zinc pyrithione (Head & Shoulders). Oral azole antifungals can be used; systemic treatment is not first-line therapy because of side effects.

Candidiasis

A dimorphic commensal fungus inhabiting skin, mouth, and reproductive tract, candidiasis, is found in up to 70% of healthy individuals. *Candida* infection of the skin usually involves moist or occluded areas such as the groin, axillae, and diaper area in the young. Candidal intertrigo classically presents as erythematous and macerated plaques with peripheral scaling. Satellite lesions help differentiate candidal lesions from other conditions. Skin lesions are typically nontender but may develop central pallor or become hemorrhagic in patients with thrombocytopenia. Primary treatment is topical azole and polyene (nystatin) antifungals that are well tolerated. Adjunct therapy with low-dose topical corticosteroids may be used for associated pruritis and pain. Systemic antifungal therapy is rarely used but may be used for refractory disease.

KELOIDS

Method of

Leslie A. Greenberg, MD

CURRENT DIAGNOSIS

- Clinical characteristics: firm, raised, papular, plaque-like, nodular, and tumorous scar tissue that extends beyond the initial wound borders. May be painful or pruritic and disfiguring.
- Location: more commonly found on ears, upper back and chest, and upper arms.
- Cause: results from an abnormal healing process after skin trauma or inflammation.

- Histologic characteristics: abnormally functioning dermal fibroblasts and overproduction of extracellular matrix result in markedly thickened bundles of hyalinized collagen arranged in a haphazard fashion.

CURRENT THERAPY

Medical Therapies

- Intralesional corticosteroids (triamcinolone acetonide [Kenalog])
- Interferon alfa (IFN-alfa2b [Intron A])¹
- Intralesional fluorouracil (5-FU, Aducil)¹

Surgical Therapies

- Cryotherapy
- Primary excision

Physical Modalities

- Pressure therapy
- Radiation therapy
- Laser therapy

Miscellaneous Therapies

- Silicone gel sheeting or gel

¹Not FDA approved for this indication.

Keloids are common, benign fibroproliferative lesions resulting from altered wound healing caused by abnormalities of fibroblast function and extracellular matrix overproduction. Lesions may be painful and severely disfiguring—at times limiting range of motion. Histologically, keloids are foci of brightly eosinophilic-staining collagen bundles laid haphazardly.

Keloids may be papular, plaque-like, nodular, or tumorous. The term *keloid* is derived from the Greek word meaning “tumor-like.” A keloid extends beyond the site of injury. Keloids tend to shrink over time, but rarely resolve.

Epidemiology

Keloids occur more commonly in people of African and Asian descent. There may be a familial or genetic contribution to keloid development as an autosomal dominant inheritance with incomplete penetrance. Keloids may be intentionally induced for cosmetic purposes. For example, the ancient Olmec of Mexico in pre-Columbian times are one ethnic group which has used keloid scarification as an intentional means of decoration.

Pathophysiology

Unlike scars, keloids are made up of markedly thickened bundles of collagen that are arranged in a haphazard fashion. Normal scar tissue formation, in contrast, consists of fibrillary bundles of collagen that are aligned parallel to the skin surface.

The pathogenesis of keloid formation is unknown. Fibroblast proliferation and increased collagen synthesis are due to overexpression of growth factors. Growth factor production fails to self-regulate and does not turn off once the wound is well healed. Alteration of programmed fibroblast apoptosis has been implicated. It has been suggested that keloid fibroblasts fail to undergo physiologically programmed cell death and thereby produce extra connective tissue. Genetic factors are likely involved, and studies have identified four susceptibility loci.

Keloids represent the end stage of an inflammatory process that starts after a traumatic disruption of skin integrity. Over a period of weeks, abnormally functioning fibroblasts replace the granulation tissue associated with the early stages of healing. At that point, a distinctive morphologic scar or keloid may be noticeable. After a keloid is fully formed, it may look the same for years or it may enlarge over time.

pathogenic hyphal form and development of disease. It grows best in warm, humid climates; thus there has been a higher prevalence reported in tropical climates. Furthermore, potential hormonal changes during adolescence can increase sebum production and allow for *Malassezia* to thrive, and the prevalence is even further increased in active adolescents. The pathophysiology may also be related to an impaired immune system.

The diagnosis is usually made clinically, but the presentation may vary; it classically consists of a well-demarcated rash with fine scale and thin plaques. The rash may be hyperpigmented, hypopigmented, or erythematous. Typically, the rash appears on the torso but may become widespread. The lesions may be mildly pruritic or asymptomatic. If KOH is performed on skin scrapings, numerous spores and hyphae can be visualized (“spaghetti and meatball” appearance). Treatment options include topical antifungals, including azoles and terbinafine, selenium sulfide (antidandruff), and zinc pyrithione (Head & Shoulders). Oral azole antifungals can be used; systemic treatment is not first-line therapy because of side effects.

Candidiasis

A dimorphic commensal fungus inhabiting skin, mouth, and reproductive tract, candidiasis, is found in up to 70% of healthy individuals. *Candida* infection of the skin usually involves moist or occluded areas such as the groin, axillae, and diaper area in the young. Candidal intertrigo classically presents as erythematous and macerated plaques with peripheral scaling. Satellite lesions help differentiate candidal lesions from other conditions. Skin lesions are typically nontender but may develop central pallor or become hemorrhagic in patients with thrombocytopenia. Primary treatment is topical azole and polyene (nystatin) antifungals that are well tolerated. Adjunct therapy with low-dose topical corticosteroids may be used for associated pruritis and pain. Systemic antifungal therapy is rarely used but may be used for refractory disease.

KELOIDS

Method of

Leslie A. Greenberg, MD

CURRENT DIAGNOSIS

- Clinical characteristics: firm, raised, papular, plaque-like, nodular, and tumorous scar tissue that extends beyond the initial wound borders. May be painful or pruritic and disfiguring.
- Location: more commonly found on ears, upper back and chest, and upper arms.
- Cause: results from an abnormal healing process after skin trauma or inflammation.

- Histologic characteristics: abnormally functioning dermal fibroblasts and overproduction of extracellular matrix result in markedly thickened bundles of hyalinized collagen arranged in a haphazard fashion.

CURRENT THERAPY

Medical Therapies

- Intralesional corticosteroids (triamcinolone acetonide [Kenalog])
- Interferon alfa (IFN-alfa2b [Intron A])¹
- Intralesional fluorouracil (5-FU, Aducil)¹

Surgical Therapies

- Cryotherapy
- Primary excision

Physical Modalities

- Pressure therapy
- Radiation therapy
- Laser therapy

Miscellaneous Therapies

- Silicone gel sheeting or gel

¹Not FDA approved for this indication.

Keloids are common, benign fibroproliferative lesions resulting from altered wound healing caused by abnormalities of fibroblast function and extracellular matrix overproduction. Lesions may be painful and severely disfiguring—at times limiting range of motion. Histologically, keloids are foci of brightly eosinophilic-staining collagen bundles laid haphazardly.

Keloids may be papular, plaque-like, nodular, or tumorous. The term *keloid* is derived from the Greek word meaning “tumor-like.” A keloid extends beyond the site of injury. Keloids tend to shrink over time, but rarely resolve.

Epidemiology

Keloids occur more commonly in people of African and Asian descent. There may be a familial or genetic contribution to keloid development as an autosomal dominant inheritance with incomplete penetrance. Keloids may be intentionally induced for cosmetic purposes. For example, the ancient Olmec of Mexico in pre-Columbian times are one ethnic group which has used keloid scarification as an intentional means of decoration.

Pathophysiology

Unlike scars, keloids are made up of markedly thickened bundles of collagen that are arranged in a haphazard fashion. Normal scar tissue formation, in contrast, consists of fibrillary bundles of collagen that are aligned parallel to the skin surface.

The pathogenesis of keloid formation is unknown. Fibroblast proliferation and increased collagen synthesis are due to overexpression of growth factors. Growth factor production fails to self-regulate and does not turn off once the wound is well healed. Alteration of programmed fibroblast apoptosis has been implicated. It has been suggested that keloid fibroblasts fail to undergo physiologically programmed cell death and thereby produce extra connective tissue. Genetic factors are likely involved, and studies have identified four susceptibility loci.

Keloids represent the end stage of an inflammatory process that starts after a traumatic disruption of skin integrity. Over a period of weeks, abnormally functioning fibroblasts replace the granulation tissue associated with the early stages of healing. At that point, a distinctive morphologic scar or keloid may be noticeable. After a keloid is fully formed, it may look the same for years or it may enlarge over time.

Risk Factors

Certain populations are at higher risk to develop keloids. Dark-skinned individuals such as those of Asian, African, and Hispanic descent have a 15-fold increased risk to develop keloids compared to light-skinned individuals. Skin insults such as lacerations, secondarily infected skin lesions, surgery, or ear piercings challenge the body's healing processes and may result in keloids, although keloids may also form without an inciting trauma. Keloids are more commonly found on the ears, upper back and chest, and upper arms. Ongoing tension or movement across the wound healing site may predispose to keloid formation. Genetics are a factor, as there are reports of familial cases with varied modes of inheritance, indicating multiple genetic disorders that may influence keloid formation. Patients with specific rare inherited conditions like Goeminne syndrome and Rubinstein-Taybi syndrome are at increased risk of keloid formation. Age affects propensity to make a keloid with the highest incidence in individuals age 10 to 20 years. Keloids are rarely found in newborns or the elderly.

Prevention

The best treatment is prevention of unnecessary trauma or surgery, including ear piercing and elective cosmetic surgery. Early treatment of acne helps decrease inflamed pustules and papule formation, which, when located at the posterior neck, may become acne keloidalis nuchae. Patients with acne keloidalis nuchae should avoid shaving the neck region and instead should use scissors to trim hair no shorter than one-eighth of an inch. Consider varicella vaccination (Varivax)¹ to decrease keloid risk of chickenpox lesions. Lack of ultraviolet (UV) B light may increase risk of keloid formation. In fact, using UV A1 phototherapy may be a promising treatment of keloids. Other environmental preventive measures are to keep the wound moist, as well as avoid sun exposure and tension on the wound.

Clinical Manifestations

Keloids are firm, rubbery, raised, papular, plaque-like, nodular, and tumorous scar tissue that extends beyond the initial wound borders. Frequently lesions are pruritic, are tender to palpation, and may be the source of sharp, shooting pains. Location is more often on the ears, jaw, neck, shoulders, upper back, and presternal chest. Keloids may be disfiguring and, in rare instances (e.g., location over a joint), may impair function.

Diagnosis

The clinical diagnosis of a keloid is usually apparent. Rarely is histologic confirmation necessary. Lesions may continue to grow for weeks to months. Keloids on the ears, neck, and abdomen tend to be pedunculated whereas those on the central chest and extremities are usually raised with a flat surface. Most keloids are round, oval, or oblong with regular margins; however, some have a claw-like configuration with irregular borders.

Differential Diagnosis

Hypertrophic scars appear different than keloids because the wound healing is linear, stays within the boundaries of the original wound site, and may be transiently indurated or tender to palpation. Hypertrophic scars are as prevalent in light- or dark-skinned individuals and as a rule tend to flatten significantly over time without treatment.

Giant cell fibroblastoma is a low-grade sarcoma considered a juvenile form of dermatofibrosarcoma protuberans. It is uncommon and locally aggressive. Histology shows multinucleated cells with hyperchromatic nuclei and infiltrating sheets of spindle-shaped fibroblasts.

Lobomycosis is a chronic fungal infection occurring in tropical areas of Latin America. It appears as localized slow-growing nodules in exposed skin.

Dermatofibrosarcoma protuberans is an uncommon, locally aggressive cutaneous soft tissue sarcoma that may present as a plaque-like area of cutaneous thickening that may be violet-red or blue at the margins. Rarely, this may arise within a preexisting scar or tattoo. Definitive diagnosis usually requires a core needle or incisional biopsy.

Treatment

Goals of therapy should be discussed with the patient. Often goals are cosmetic and functional improvement, reduction of scar volume and relief of pain and itching at the site.

Intralesional Corticosteroid. Injections of intralesional corticosteroids are considered first-line therapy for keloids. A systematic review showed that up to 70% of cases respond with flattening of lesions, though the recurrence rate is up to 50% at 5 years. For local anesthesia, apply liquid nitrogen for 10 to 15 seconds or lidocaine-prilocaine cream (EMLA) under occlusion for 1.5 hours before injection. Do not use liquid nitrogen for more than 30 seconds, or permanent hypopigmentation may result. Use triamcinolone acetonide (Kenalog) 10 mg/mL. Space injections approximately 0.5 to 1.0 cm apart. Use a ½-inch, 30-gauge Luer-Lok (twist-on) needle with bevel directed up toward the skin and a tuberculin syringe to allow injection under pressure. Wear a face shield to avoid contact with back-pressure spray. Inject within the bulk of the lesion with enough triamcinolone to make the keloid blanch, usually 0.1 to 0.5 mL. Multiple injections may be needed. Injections may be given monthly until the desired degree of involution and/or symptomatic relief is achieved. If no change occurs after one injection with triamcinolone acetonide 10 mg/mL, increase the strength to 40 mg/mL (Figure 1). If no change occurs after three or four injections, consider referral to a plastic surgeon or dermatologist for surgical excision.

Surgical Excision. Surgical excision of a keloid may help aesthetically and symptomatically, though lesions tend to recur and may result in more extensive scarring. After excision, immediately inject the base of the surgical site in multiple sites with triamcinolone

Figure 1 A, A keloid on the back. B, The scar after four intralesional injections of corticosteroid 10 mg/mL at 4 weeks apart. Note side effects of skin atrophy and hypopigmentation. (Reprinted with permission from Manuskiatti W: Current management of hypertrophic scars and keloids. *Siriraj Hosp Gaz* 2003;55:249–258.)

¹Not FDA approved for this indication.

acetonide 20 mg/mL. Use a 30-gauge needle and then occlude the excision site with a pressure dressing such as Elastoplast. Corticosteroid injections should then be repeated at 2-week intervals over a course of 3 to 4 months.

Silicon Gel Sheeting. The use of silicon sheeting may be effective for treatment of symptoms such as pain and itching for established keloids. It may also be used early in wound healing to prevent keloids at the site of new injuries. In some trials, silicone sheeting was effective in 70% to 80% of cases to avoid keloid formation. Sheeting is placed on top of the keloid, taped into place, and left on for 12 to 24 hours per day. The sheet is washed daily and replaced every 10 to 14 days. Consider effectiveness after 2 to 6 months of therapy. Over-the-counter and prescription self-drying silicone gel formulations are an alternative for exposed or larger areas.

Cryosurgery. Cryotherapy can be used in conjunction with intralesional corticosteroids. This is widely available, is effective, and has an excellent safety profile. A 10- to 30-second freeze-thaw cycle can be repeated up to three times per treatment session and repeated every 4 to 6 weeks until response occurs. One major permanent side effect is hypopigmentation, which may be most apparent in darker-skinned patients.

Pressure Therapy. When pressure (to an area of possible keloid formation) is applied early in the healing process, it may decrease keloid formation. This is thought to occur due to decrease in oxygen tension of the wound by occluding small blood vessels and decreasing fibroblast proliferation. The optimal pressure should be 20–30 mm Hg for 12–24 hours per day for 6–12 months. Zimmer splints are inexpensive, molded earring-like pressure therapy that may be effective treatment for keloids following ear piercing.

Radiation Therapy. It is the biologically effective dose (BED) that influences the effectiveness in preventing recurrence. Differing amounts of BED are delivered depending on the radiation source used. Long-term risks of radiation such as malignancy are under investigation. Radiation therapy is effective in reducing keloid recurrence with improvement rates of 70% to 90% when used after surgical excision. Recurrence rates of keloids after radiation therapy are 13% to 33%.

Intralesional 5-Fluorouracil (5-FU). Intralesional 5-FU has been used for scars that do not respond to intralesional corticosteroids. Schedule intralesional injections of 5-FU (Adrucil)¹ 50 mg/mL with a volume of 0.5 to 2.0 mL per session for every four weeks up to 12 weeks. Intralesional 5-FU has been shown to improve keloids by 50% and is considered to work best on small keloids. Injections may be painful and may cause hyperpigmentation. 5-FU is can be mixed with triamcinolone acetonide for keloids resistant to triamcinolone alone: 0.1 mL of triamcinolone acetonide 40 mg/mL can be mixed with 0.9 mL of 5-FU 50 mg/mL and injected weekly for 8 weeks. Pulsed dye laser has been used in combination with intralesional injection of a mixture of 5-FU and steroid with cumulative beneficial effect.

Pulsed Dye Laser. Pulsed dye laser therapy and neodymium-yttrium-aluminum-garnet (Nd: YAG) laser may minimize the erythema and telangiectasias of keloids. One study showed effectiveness of treatment with a combination of pulsed dye laser and intralesional steroid on recalcitrant keloid scars (Figure 2). These patients noted a 60% decrease in height of keloid, 40% improvement in erythema, and 75% decrease in pain and itching. Presternal scars may not benefit appreciably. It is speculated that the laser helped make the scar edematous and softer so that the intralesional steroid could work better.

Monitoring. Surveillance of scars during wound healing is important to alert the provider that keloids may be forming. Appropriate, focused, and timed treatment can then be performed. In a patient with keloid history, using prophylactic therapy may be instituted when a new wound is incurred. Close follow-up monitoring is vital during immediate and aggressive treatment.

Complications. Patients should be advised that keloids can be recalcitrant to all types of therapy. If a keloid recurs (especially if

Figure 2 A, A scar developing after cesarean section. B, The scar after two pulsed dye laser treatments 8 weeks apart.

ablative methods such as electrosurgery are used), it may be more disfiguring than the original lesion. Trauma to the keloid may predispose the lesion to erosion and localized bacterial infection.

MELANOMA

Method of

Vesna Petronic-Rosic, MD, MSC

CURRENT DIAGNOSIS

- ABCDEs:
 - Asymmetry of lesion.
 - Border irregularity, bleeding, or crusting.
 - Color change or variegation.
 - Diameter larger than 6 mm or growing lesion.
 - Evolving: Surface changes or symptomatic.

¹Not FDA approved for this indication.

- The “ugly duckling” sign: A mole that looks or feels different compared to surrounding moles.
- Total-body photography and dermoscopy.
- Excisional biopsy with narrow margins.
- Interpretation by physician experienced in the microscopic diagnosis of pigmented lesions.
- Molecular analyses (rarely).
- Appropriate staging workup.
- Genetic testing when appropriate (rarely).

CURRENT THERAPY

- Early diagnosis and appropriate surgical therapy is the gold standard.
- Complete excision must be achieved with appropriate margins based on tumor thickness.
- Sentinel lymph node biopsy may be offered to patients with melanoma 1 to 4 mm thick, with clinically unaffected regional nodes, and without distant metastases.
- Dissection of the lymph node basin may be offered to patients with micronodal or macronodal metastases.
- Adjuvant therapy may be considered for stage III disease.
- Stage IV treatment depends on location and extent of metastatic disease and may include surgical resection, chemotherapy, biological therapy, or radiation therapy.

Melanoma is a malignancy of pigment-producing cells (melanocytes). Melanocytes are located predominantly in the skin but are also found in the eyes, ears, gastrointestinal tract, leptomeninges, and oral and genital mucous membranes.

Epidemiology

Even though melanoma accounts for less than 5% of skin cancer cases, it causes most skin cancer deaths. U.S. incidence figures estimate that there were about 108,230 new cases of melanoma in 2007: 48,290 in situ (noninvasive) and 59,940 invasive (33,910 in men and 26,030 in women). The American Cancer Society's most recent estimates for melanoma in the United States for 2017 are 87,110 new cases with 9730 deaths. The prevalence of melanoma in the United States has doubled over the three decades from 1982 to 2011, from 11.2 per 100,000 population to 22.7 per 100,000. In 2011, the melanoma incidence rate was 19.7 per 100,000, and the death rate was 2.7 per 100,000. Overall, the lifetime risk for developing melanoma is about 1 in 50 for whites, 1 in 1000 for blacks, and 1 in 200 for Latin Americans. At current rates, 1 in 63 Americans will develop an invasive melanoma over a lifetime.

Risk Factors

A large number of nevi is the strongest risk factor for melanoma in persons of European ancestry. Atypical mole syndrome is another risk factor. Exposure to ultraviolet light is a major risk factor, especially in persons who have fair hair and skin, who have solar damage, who had sunburns and short sharp bursts of sun exposure in childhood, and who used tanning beds. Tanning beds appear more detrimental when used before the age of 20 years. The International Agency for Research on cancer has classified indoor tanning devices as “carcinogenic to humans” based on extensive review of scientific evidence. Familial risk factors include mutations in *CDKN2A*(p16INK4a), which are associated with increased risks for both melanoma and pancreatic cancer; they are transmitted in an autosomal dominant fashion and account for approximately 20% to 50% of familial melanoma cases. In recent years, mutations in *BRCA1*-associated protein 1 (BAP1), shelterin complex, microphthalmia-associated transcription factor (MITF), and phosphatase and tensin homolog (PTEN) have also been associated with melanoma and internal organ cancers. Organ transplant

recipients have an increased risk for melanoma. Genodermatoses with a defect in DNA repair (such as xeroderma pigmentosum) increase risk for melanoma.

Pathophysiology

Transformation of normal melanocytes into melanoma cells likely involves a multistep process of progressive genetic mutations that alter cell proliferation, differentiation, and death and affect susceptibility to the carcinogenic effects of ultraviolet radiation. Primary cutaneous melanoma can develop in preexisting melanocytic nevi, but more than 60% of cases likely appear de novo.

Melanomas arising in skin that is chronically sun damaged show molecular features that distinguish them from melanomas arising in skin that is not sun damaged. These features might determine tumor behavior and potential response to new targeted drugs. About 70% of melanomas arising in skin that is not sun damaged carry *BRAF* mutations. Genetic studies have shown that 50% of familial melanomas and 25% of sporadic melanomas may be due to mutations in the tumor suppressor gene *p16*. Linkage studies have identified chromosome 9p21 as the site of the familial melanoma gene.

Prevention

Early detection of thin cutaneous melanoma is the best means of reducing mortality. Patients with a history of melanoma should be educated regarding sun-protective clothing and sunscreens, skin self-examinations for new primary melanoma, possible recurrence within the surgical scar, and screening of first-degree relatives, particularly if they have a history of atypical moles.

Clinical Manifestations

Early signs of melanoma include the ABCDEs:

- Asymmetry of lesion
- Border irregularity, bleeding, or crusting
- Color change or variegation
- Diameter larger than 6 mm or growing lesion
- Evolving: Surface changes or symptomatic

The “ugly duckling” sign is also useful to recognize lesions that look or feel different compared to surrounding moles.

Lentigo maligna (melanoma in situ) begins as an irregular tan-brown macule that slowly expands on sun-damaged skin of elderly persons. Long-term cumulative sun exposure confers the greatest risk. Progression to invasive lentigo maligna melanoma is estimated to be 30% to 50%.

Superficial spreading melanoma, the most common type in light skin, represents approximately 70% of all melanomas. Peak incidence is in the fourth and fifth decade. Superficial spreading melanoma can arise in a preexisting melanocytic nevus that slowly changes over several years; it most commonly affects intermittently sun-exposed areas with the greatest nevus density (upper backs of men and women and lower legs of women). Pigment varies from black and blue-gray to pink or gray-white, and the borders are irregular. Absence of pigmentation often represents regression.

Nodular melanoma represents 15% of all melanomas. The median age at onset is 53 years. Clinically, a uniform blue-black, blue-red, or red nodule usually begins de novo and grows rapidly. About 5% are amelanotic. The most common sites are the trunk, head, and neck.

Acral lentiginous melanoma accounts for 10% of melanomas overall but is the most common type among Japanese, African Americans, Latin Americans, and Native Americans. The median age is 65 years, with equal gender distribution. It occurs on the palms or soles or under the nails and is on average 3 cm in diameter at diagnosis. Clinically, the lesion is a tan, brown-to-black, flat macule with color variegation and irregular borders. It does not appear to be linked to sun exposure.

Diagnosis

Excisional biopsy with narrow margins is recommended for diagnosis. Incisional biopsy is acceptable when suspicion for melanoma is low, the lesion is large, or it is impractical to

perform a complete excision. It is believed not to be detrimental if subsequent therapeutic surgery is performed within 4 to 6 weeks. Dermoscopy and total body photography are adjunctive noninvasive diagnostic techniques. Routine laboratory tests and imaging studies are not required for asymptomatic patients with primary cutaneous melanoma 4 mm or less in thickness for initial staging or routine follow-up. Indications for such studies are directed by a thorough medical history and complete physical examination.

Histologic interpretation should be performed by a physician experienced in the microscopic diagnosis of pigmented lesions. Molecular analyses for evidence of gene mutations, DNA copy-number abnormalities, or changed protein expression are useful adjunctive tools in the assessment of histologically ambiguous primary melanocytic tumors. It is now known that melanomas from sun-damaged skin, non-sun-damaged skin, or mucosal or acral surfaces harbor distinct molecular phenotypes. Specifically, activating mutations in BRAF are present in approximately 40% to 60% of advanced melanomas, especially those arising from non-sun-damaged skin, and result in activation of the RAS/RAF/MEK/ERK pathway, providing a constitutive growth signal.

The new revised American Joint Committee on Cancer (AJCC) staging system was published in 2017 (Tables 1 and 2). Key changes in the eighth edition of the AJCC Cancer Staging Manual include: 1) tumor thickness measurements to be recorded to the nearest 0.1 mm, not 0.01 mm; 2) definitions of T1a and T1b are revised (T1a, <0.8 mm without ulceration; T1b, 0.8–1.0 mm with or without ulceration or <0.8 mm with ulceration), with mitotic rate no longer a T category criterion; 3) pathological (but not clinical) stage IA is revised to include T1b N0 M0 (formerly pathologic stage IB); 4) the N category descriptors “microscopic” and “macroscopic” for regional node metastasis are redefined as “clinically occult” and “clinically apparent”; 5) prognostic stage III groupings are based on N category criteria and T category criteria (i.e., primary tumor thickness and ulceration) and increased from three to four subgroups (stages IIIA–IIID); 6) definitions of N subcategories are revised, with the presence of micrometastases, satellites, or in-transit metastases now categorized as N1c, N2c, or N3c based on the number of tumor involved regional lymph nodes, if any; 7) descriptors are added to each M1 subcategory designation for lactate dehydrogenase (LDH) level (LDH elevation no longer upstages to M1c); and 8) a new M1d designation is added for central nervous system metastases. This evidence-based revision of the AJCC melanoma staging system will guide patient treatment, provide better prognostic estimates, and refine stratification of patients entering clinical trials.

Five-year and 10-year survival rates based on the TNM classification range from 99% and 98% for patients with T1a N0 M0 melanomas to 82% and 75%, respectively, for patients with T4b N0 M0 melanomas.

Differential Diagnosis

The differential diagnosis includes melanocytic nevus, angioma, pigmented basal cell carcinoma, pyogenic granuloma, seborrheic keratosis, Kaposi's sarcoma, and hematoma (especially for acral lentiginous melanoma).

Treatment

Early diagnosis combined with appropriate surgical therapy is currently the only curative treatment. For melanoma in situ, wide excision with 0.5 to 1.0 cm margins is recommended; lentigo maligna histologic subtype may require >0.5 cm margins to achieve histologically negative margins because of characteristically broad sub-clinical extension. Surgical margins for invasive melanoma should be at least 1 cm and up to 2 cm clinically measured around the primary tumor; clinically measured surgical margins do not need to correlate with histologically negative margins. Margins may be modified to accommodate individual anatomic or functional considerations. The recommended margins are

Tumor thickness	Clinically measured surgical margin	Strength of recommendation	Level of evidence
In situ	0.5–1.0 cm	C	III
≤ 1.0 mm	1 cm	A	I
1.01–2.0 mm	1–2 cm	A	I
≥ 2.0 mm	2 cm	B	I,II,III

TABLE 1 Tumor, Node, and Metastasis (TNM) Staging Categories for Cutaneous Melanoma

Tumor (T)

Classification	Thickness (mm)	Ulceration Status
TX: Primary tumor thickness cannot be assessed (e.g., diagnosis by curettage)	Not applicable	Not applicable
T0: No evidence of a primary tumor or the site of the primary tumor is unknown (e.g., in a patient who presents with an axillary metastasis with no known primary tumor)	Not applicable	Not applicable
Tis	Not applicable	Not applicable
T1	≤1.0 mm	Unknown or unspecified
T1a	<0.8 mm	Without ulceration
T1b	<0.8 mm 0.8–1.0 mm	With ulceration With or without ulceration
T2	>1.0–2.0 mm	Unknown or unspecified
T2a	>1.0–2.0 mm	Without ulceration
T2b	>1.0–2.0 mm	With ulceration
T3	>2.0–4.0 mm	Unknown or unspecified
T3a	>2.0–4.0 mm	Without ulceration
T3b	>2.0–4.0 mm	With ulceration
T4	>4.0 mm	Unknown or unspecified
T4a	>4.0 mm	Without ulceration
T4b	>4.0 mm	With ulceration

Nodes (N)

Classification	Number of Metastatic Nodes	Nodal Metastatic Burden
NX	Regional nodes not assessed (e.g., sentinel lymph node [SLN] biopsy not performed, regional nodes previously

Strength of Recommendations: A,B,C Level of Evidence: I,II,II (<https://www.aad.org/practicecenter/quality/clinical-guidelines/melanoma/surgical-management>, accessed 04.08.2018)

The recommended deep margin is muscle fascia. Wider margins and Mohs' micrographic surgery can reduce the risk of contiguous subclinical spread for the desmoplastic variant of melanoma.

Sentinel lymph node biopsy (SLNB) provides accurate staging information for patients with clinically unaffected regional nodes and without distant metastases. The status of SLN is the most important prognostic indicator for disease-specific survival in patients with primary cutaneous melanoma; the impact of SLNB on overall survival remains unclear. Candidates for SLNB include patients with newly diagnosed primary cutaneous melanoma who are clinically node-negative and, based on primary tumor characteristics, are predicted to be at intermediate risk or high risk of harboring occult nodal disease. In cases of positive SLNB or clinically detected regional nodal metastases (palpable, positive cytology, or histopathology), radical removal of lymph nodes of the involved basin is indicated. There is clinical trial evidence suggesting that the survival outcome for patients who are sentinel node-positive is improved if an immediate regional lymphadenectomy is done.

Pathology staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial (i.e., sentinel node biopsy) or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes. Adapted from Balch et al. (2009) and Gershenwals et al. (2017)
<http://onlinelibrary.wiley.com/doi/10.3322/caac.21409/full>

For resectable local or in-transit recurrences, excision with a clear margin is recommended. For numerous or unresectable in-transit metastases of the extremities, isolated limb perfusion or infusion with melphalan may be considered.

Radiotherapy is indicated in select patients with lentigo maligna melanoma, as an adjuvant in select patients where re-resection is not feasible, with regional metastatic disease, and for palliation, especially in bone and brain metastases.

Numerous adjuvant therapies have been investigated for the treatment of localized cutaneous melanoma following complete surgical removal. Adjuvant interferon (IFN) alfa-2b (Intron A) is the only adjuvant therapy approved by the FDA for high-risk melanoma that affects outcome after surgery. No survival benefit has been demonstrated for adjuvant chemotherapy, nonspecific (passive) immunotherapy, radiation therapy, retinoid therapy, vitamin therapy, or biologic therapy.

Various experimental melanoma vaccines show promise in the adjuvant setting, although caution is needed because four phase III trials (E1694, MMAIT-III [Canvaxin], MMAIT-IV, and EORTC 18961) showed a deleterious effect of the experimental vaccine compared with control intervention. Considerable effort is now being focused on selecting patients on the basis of molecular profiling and on combining agents targeting melanoma-specific aberrations in signaling and apoptotic pathways to overcome the many resistance mechanisms in melanoma cells.

Metastatic melanoma is an aggressive, immunogenic, and molecularly heterogeneous disease. In the last two decades, treatment of

melanoma took a dramatic turn with the discovery of targeted therapy aimed at the mutations in the mitogen-activated protein kinase (MAPK) pathway and immune checkpoint inhibitors. In 2011, US Food and Drug Administration (FDA) approved ipilimumab (Yervoy), an anti-cytotoxic T-lymphocyte antigen-4 (CTLA-4) antibody for metastatic melanoma therapy. Since then, novel drugs including antibodies to programmed cell death 1 (PD-1) such as pembrolizumab (Keytruda) and nivolumab (Opdivo), both approved in 2014; selective BRAF inhibitors such as vemurafenib (Zelboraf), approved in 2011; dabrafenib (Tafinlar), approved in 2013; and MEK inhibitor trametinib (Mekinist), approved in 2013; have greatly extended the potential of immunotherapy and molecular targeted therapy for advanced melanoma. Despite showing initial promise, resistance and poor duration of response have limited their effectiveness as monotherapies. Combining BRAF inhibitors with MEK inhibitors such as trametinib delays the development of resistance. The greatest survival improvement was observed with the combination of BRAF plus MEK inhibitors as well as with PD1 blockers with or without CTLA-4 blockers, respectively, with these two treatment strategies showing similar survival outcomes. For first-line therapy, averaged survival proportions of patients alive at 12 months were 74.5% with BRAF plus MEK inhibitor treatment versus 71.9% with PD-1 blockade. The use of combination immunotherapy may provide improved outcomes in patients over single-agent checkpoint blockade. On October 1, 2015, the FDA announced accelerated approval of a combination of immunotherapy drugs for the frontline treatment of advanced melanoma. The drugs, ipilimumab and nivolumab, are two immune checkpoint inhibitors that “release the brakes” on the immune system, allowing it to mount a stronger and more effective attack against cancer. The FDA based its approval on results from a clinical trial showing that patients who received the combination had better responses than those who received ipilimumab alone. In 2017, The FDA granted accelerated approval to pembrolizumab as a second-line treatment for all metastatic solid tumor types classified as MSI-hi (high microsatellite instability) or dMMR (deficient DNA mismatch repair). This was the first time the FDA has ever approved any treatment based on a biomarker rather than an organ-specific tumor type.

Although melanoma has traditionally been regarded as a uniformly fatal malignancy, personalized treatment of this cancer relies on the recognition of its genetic heterogeneity and our ability to pharmacologically target these specific and recurrent changes. Recent advances in the treatment of melanoma have come from the understanding that melanoma is a large family of molecularly distinct diseases. Emerging evidence suggests that different melanoma subtypes may each be driven by diverse mechanisms of progression, associated with differing mechanisms of tumor escape and specific immunosuppression, innate immune cell activation, and altered T-cell trafficking into tumor sites that in turn modulate response to immunotherapies.

Monitoring

Most metastases occur in the first 1 to 3 years after treatment of the primary tumor, and an estimated 4% to 8% of patients with a history of melanoma develop another primary melanoma, usually within the first 3 to 5 years following diagnosis. The risk of new primary melanoma increases in the presence of multiple dysplastic nevi and family history of melanoma. Consider cancer genetics consultation in patients with three or more melanomas in aggregate in first-degree or second-degree relatives on the same side of the family, families with three or more cases of melanoma or pancreatic cancer on the same side of the family, and (in low-incidence countries) patients with three or more primary melanomas.

The frequency of monitoring is as follows: For patients with melanoma smaller than 1 mm: every 3 months for 1 year, then every 6 to 12 months for 4 years, then annual examinations thereafter. For patients with melanoma larger than 1 mm: every 3 months for 1 to 2 years, then every 6 months until the fifth year, then annual examinations thereafter.

Follow-up visits for all patients should include a thorough history, review of systems, complete skin examination, and examination of lymph nodes. In patients at high risk for metastatic disease or with an abnormal examination, appropriate imaging studies, laboratory studies, or biopsies may be indicated. Evidence to support the use of routine imaging and laboratory studies in asymptomatic patients with a normal physical examination remains controversial and is left to the discretion of the physician.

Complications

Metastasis may occur locally in the regional lymph node basins, or it can occur distally in the skin (away from the melanoma scar), the remote lymph node(s), the viscera, and skeletal and central nervous system sites.

NEVI

Method of

Jane M. Grant-Kels, MD; and Michael Murphy, MD

CURRENT DIAGNOSIS

Benign Melanocytic Lesions

- Symmetrical
- Sharply demarcated border
- Uniform color
- Diameter usually 6 mm or less and stable

Malignant Melanocytic Lesions

- Asymmetrical
- Poorly circumscribed border
- Variegated in color
- Diameter often >6 mm and increasing (changing or evolving)

CURRENT THERAPY

- Acquired melanocytic nevus: No treatment is required unless the lesion is asymmetrical or has an irregular border, change or variegation in color, or change in diameter. Symptomatic lesions should be biopsied.
- Recurrent melanocytic nevus: No treatment required if the original biopsy was benign.
- Halo melanocytic nevus: No treatment, but excision is recommended if atypical clinical features are identified.
- Congenital melanocytic nevus: Removal based on melanoma risk, cosmetics, and functional outcome. If not excised, routine follow-up with the use of photography, dermoscopy, and computer assistance is recommended.
- Blue nevus: No treatment, but excision is recommended if atypical clinical features are identified.
- Spitz nevus: If clinically unusual, a complete excisional biopsy is recommended.
- Dysplastic nevus: If only one lesion is present, excision may be considered. Patients with many dysplastic nevi require close surveillance, with removal of any lesion suspicious for melanoma.

Melanocytic nevi, or moles, are benign neoplasms composed of melanocytes. Melanocytic nevus cells are derived from melanocytes. Compared with melanocytes, nevus cells are not dendritic, are larger, and contain more abundant cytoplasm, often with coarse melanin granules. Nevus cells tend to aggregate into groups or nests. Melanocytic nevi are extremely common and can be found on almost everyone, anywhere on the cutaneous surface. This article discusses the most common types of melanocytic nevi: acquired melanocytic nevi, recurrent melanocytic nevi, halo melanocytic nevi, congenital melanocytic nevi (CMN), blue nevi, Spitz nevi, and dysplastic melanocytic nevi.

Melanocytic nevi demonstrate both heterogeneous clinical and molecular characteristics, but share common “driver” mutations with melanoma. Acquired melanocytic nevi and dysplastic nevi commonly harbor oncogenic mutations in BRAF, which is the predominant oncogene in melanoma. Congenital melanocytic nevi and blue nevi frequently exhibit NRAS mutations and GNAQ mutations, respectively. Spitz nevi and atypical Spitz tumors often show HRAS and BAP1 alterations, in addition to rearrangements in other kinase genes. These early “driver” mutations are believed to initiate the development of benign melanocytic nevi.

Acquired Melanocytic Nevi

Acquired melanocytic nevi are subdivided into junctional, compound, and intradermal types based on the location of the nevus cells. By definition, these lesions are not present at birth but can begin to appear in early childhood, usually after 6 to 12 months of age. Peak ages of appearance of melanocytic nevi are 2 to 3 years of age in children and 11 to 18 years in adolescents. Although nevi can appear at any age, it is relatively unusual for new melanocytic nevi to develop in middle-aged or older adults. With time, nevi can spontaneously regress. Consequently, patients in their ninth decade of life usually demonstrate few melanocytic nevi. An average white adult has 10 to 40 melanocytic nevi, but African Americans have far fewer, averaging only 2 to 8.

The number and location of melanocytic nevi have been shown to be associated with sun exposure, immunologic factors, and genetics. Consequently, melanocytic nevi are most numerous on the sun-exposed skin of the head, neck, trunk, and extremities, but they are only rarely found on covered areas such as the buttocks, female breasts, and scalp. Evidence suggests that patients with an increased number of melanocytic nevi (>50) might have an increased risk of melanoma.

Melanocytic nevi appear in a sequential fashion. Junctional melanocytic nevi arise during childhood as flat, dark macules.

Histologically, an increase in single or nested melanocytes is located at the dermoepidermal junction. With time, some of the junctional nests of melanocytes migrate into the dermis (compound melanocytic nevi). Clinically, compound melanocytic nevi are elevated and less heavily pigmented than junctional melanocytic nevi. Ultimately, all of the nevus cells migrate into the dermis (intradermal melanocytic nevi), resulting in the development of a tan or skin-colored dome-shaped papule. Melanocytic nevi can be flat or elevated and even polypoid, papillomatous, or verrucous and can demonstrate a range of color from skin-tone to black, but they are characteristically uniform in color, symmetrical, well marginated, and usually smaller than 6 mm in diameter.

All melanocytic lesions of clinical concern should be examined with a dermatoscope, a hand held instrument with a magnified lens and a light source similar to an ophthalmoscope. This instrument allows evaluation of colors and microstructures not visible to the naked eye, helps determine whether pigmented lesions are melanocytic or nonmelanocytic, and aids in distinguishing whether melanocytic pigmented lesions are likely to be malignant. Used by an experienced physician with proper training, the dermatoscope improves diagnostic accuracy by 20% to 30%. Another useful technology is reflectance confocal microscopy (RCM), as it safely offers noninvasive imaging of skin lesions at cellular-level magnification and is reported to reduce unnecessary biopsies by 50-60%. RCM utilizes a low-energy laser light that focuses on a specific area of tissue; the magnitude of back-scattering of light depends on the differences in refractive indices of various structures in the skin. The horizontal images of the skin afford review of a lesion up to 8mm x 8mm in diameter and extend 200-300 um into the skin.

It is unnecessary to surgically remove all melanocytic nevi because they are benign neoplasms of melanocytes. However, indications for removal include ABCDE (*asymmetry, irregular border, variegation or change in color, change in diameter, or evolving*), symptoms (e.g., pruritus), evidence of inflammation or irritation, cosmetic issues, and patient anxiety. Melanocytic nevi on acral, genital, or scalp skin that appear benign do not require surgical removal. Shave biopsies are appropriate therapy for lesions considered clinically benign. However, if a lesion is being removed because of concern regarding the possibility of malignancy, an excisional biopsy (biopsy of choice) or incisional biopsy (including a deep scoop) that extends to the subcutaneous tissue is indicated. All melanocytic lesions should be submitted to a dermatopathologist for histologic review. A history of recent sun exposure or trauma should be conveyed to the dermatopathologist because such external trauma can induce reactive atypical histologic findings.

Recurrent Melanocytic Nevi

Recurrent melanocytic nevi are melanocytic nevi that have previously been incompletely removed (either iatrogenically or traumatically) and have recurred weeks to months later. Irregular brown pigmentation is clinically noted within the scar site. If the original biopsy demonstrated a benign melanocytic nevus, re-treatment is unnecessary unless the aforementioned indications are present. However, these nevi can demonstrate pseudomelanomatous histologic features. Therefore if the repigmented area is excised, the dermatopathologist should be notified of the clinical history and, if possible, the slides from the original biopsy should be obtained and reviewed to ensure that the lesion is not histologically misdiagnosed.

Halo (Melanocytic) Nevi

Halo (melanocytic) nevi are melanocytic nevi in which a white rim or halo has developed. This phenomenon most commonly occurs around compound or intradermal nevi and is histologically associated with a dense, bandlike inflammatory infiltrate. The white halo area is histologically characterized by diminished or absent melanocytes and melanin. Approximately 20% of patients with halo nevi also exhibit vitiligo.

Although a halo can develop around many lesions in the skin, the most important differential diagnosis is between a halo nevus and melanoma with a halo. The halo and the central melanocytic proliferation of halo nevi are symmetrical, round or oval, and sharply

demarcated. Halo nevi most commonly occur in adolescence as an isolated event, but approximately 25% to 50% of affected persons have two or more.

The clinical course of halo nevi is variable. With time, the halo can repigment while the central nevus persists. Alternatively, the melanocytic nevus can regress completely and leave a depigmented macule that can persist or repigment over months or years.

Halo nevi do not require surgical excision unless atypical clinical features suggest the possibility of an atypical melanocytic lesion. It is advisable (particularly in adults, in whom halo nevi are less common) to perform a complete cutaneous examination with and without the aid of a Wood's lamp to rule out any associated atypical pigmented or regressed lesions. All patients should be advised to use sunscreens or protective clothing because of the increased risk of sunburn in the depigmented halo region.

Congenital Melanocytic Nevus

By definition, CMN are present at birth. Arbitrarily, they have been classified into small (<1.5 cm), medium (1.5–20 cm), and large (>20 cm) lesions. Terms such as *bathing trunk* or *garment-type* nevi refer to CMN that cover a significant portion of the cutaneous surface.

The approximate incidence of small congenital nevi is 1% of all live births. Large congenital nevi are rare and reported in only 1 in 20,000 births. Histologically, some congenital nevi have distinguishing histologic features (melanocytic nevus cells that extend into the deeper dermis as well as the subcutis and melanocytic nevus cells arranged periadnexally, angiocentrically, within nerves, and interposed between collagen bundles). However, these features have been identified in some acquired melanocytic nevi and are absent in some congenital nevi (especially small ones). In addition, the history obtained from the patient or their parents is often inaccurate. Consequently, it can be very difficult in some cases to distinguish a small congenital nevus from an acquired nevus.

Congenital nevi can give rise to dermal or subcutaneous nodular melanocytic proliferations. The vast majority of these lesions, particularly in the neonatal period, are biologically benign, despite a worrisome clinical presentation and atypical histologic features. Genetic analysis has shown that benign melanocytic proliferations within congenital nevi harbor aberrations qualitatively and quantitatively different from those seen in melanoma.

Patients with multiple CMN (two or more, of any site or size) are at risk for extracutaneous (i.e., endocrine, metabolic, neurological) manifestations, termed *CMN syndrome*. The primary significance of congenital nevi is related to the potential risk for progression to melanoma. Essentially, the larger the nevus, particularly if accompanied by multiple small CMN, the greater the risk of progression to melanoma. Historically, even small nevi were estimated to exhibit a lifetime melanoma risk of 5%. However, recent prospective studies suggest that small and medium congenital nevi are associated with a low risk that may approximate the risk of acquired nevi. Conversely, large congenital nevi have a lifetime risk of melanomatous progression of approximately 6.3%. Up to two-thirds of melanomas that arise within these giant congenital nevi have a nonepidermal origin (arising mainly in the deep dermis and subcutis with high Breslow thickness on presentation), thus making clinical observation for malignant change difficult. Approximately 50% of these melanomas occur in the first 5 years of life, 60% in the first decade, and 70% before 20 years of age. Patients with large congenital nevi, especially those that involve posterior axial locations (head, neck, back, or buttocks) and are associated with satellite congenital nevi, are at increased risk for neurocutaneous melanosis (melanosis of the leptomeninges) and primary central nervous system (CNS) melanoma. Recent data suggests that, in up to one-third of these patients, the primary melanoma develops within the CNS rather than the skin. The risk of melanoma appears to be higher in those with congenital abnormalities of the CNS (12% vs. 1–2% without CNS changes).

For large congenital nevi that involve a posterior axial location, screening magnetic resonance imaging (MRI) is indicated to characterize congenital disease, if any, and act as a baseline should the

child present with new neurological symptoms at a later stage. If clinical symptoms or MRI indicate neurocutaneous melanosis, excision of the large nevus should be postponed until 2 years of age (the median age of neurologic symptoms). Patients with neurocutaneous melanosis have a greater than 50% mortality rate within 3 years. The risk and morbidity of multiple, staged excisions of a large CMN is not appropriate in patients with symptomatic neurocutaneous melanosis. All other large CMN are candidates for excision as soon as general anesthesia is considered a relatively safe risk. Other issues that need to be considered before undertaking staged excisions include cosmetic issues, functional outcome, and psychosocial issues. The staged excisions are usually started after 6 months of age for nevi on the trunk and extremities and later for those on the scalp to allow closure of the fontanelle. If removal is not undertaken, follow-up with monthly self-examination, photography, dermoscopy, confocal laser microscopy, and computer assistance are recommended.

For small congenital nevi, routine excision is not always recommended because the risk of melanoma is lower, and if it occurs, it usually arises within the epidermis after puberty. If the lesions are not excised, follow-up by alternating visits to a dermatologist and primary care physician along with serial photography are indicated. Inasmuch as small congenital nevi typically enlarge with the growth of the child and can change in appearance with time, educating families on benign, predictable changes in contradistinction to potentially alarming changes is extremely important. If a lesion enlarges or changes suddenly or if parental anxiety or cosmetic issues arise, excision should then be contemplated for even small congenital nevi. Elective excision is best done when the patient is approximately 8 years old. With the use of topical anesthetic cream EMLA (eutectic mixture of local anesthetics: 2.5% lidocaine plus 2.5% prilocaine) or topical 4% lidocaine (ELA-Max), children of this age are usually cooperative and unscathed by the procedure.

Blue Nevus

Blue nevi occur primarily on the face and scalp, in addition to the dorsal surfaces of the hands and feet, as well-circumscribed, slightly raised or dome-shaped bluish papules that are usually less than 1 cm in diameter. Although these lesions are usually acquired in childhood and adolescence, rare congenital lesions have been reported. Histologically, blue nevi demonstrate a combination of intradermal spindle or dendritic melanin-pigmented melanocytes and melanophages with dermal fibrosis. The blue appearance of these lesions is a function of both the depth of the melanin in the dermis and the Tyndall phenomenon: longer wavelengths of light penetrate the deep dermis and are absorbed by the lesional melanin, and shorter wavelengths (e.g., blue) are reflected back. Blue nevi that are clinically stable and that do not demonstrate atypical features do not require removal.

Spitz Nevus

Nevi of large spindle and epithelioid cells (Spitz nevi) are relatively uncommon. In Australia, an annual incidence of 1.4 per 100,000 people has been recorded. Most Spitz nevi are noted in children and adolescents: One-third occur before the age of 10 years, one-third between the ages 10 to 20 years, and one-third past the age of 20 years. Rarely, lesions can occur in patients older than 40 years. Seven percent of Spitz nevi have been reported as congenital.

Four clinical types of Spitz nevi are recognized: light-colored soft Spitz nevi that can resemble a pyogenic granuloma; light-colored hard Spitz nevi that can resemble a dermatofibroma; dark Spitz nevi that must be distinguished from other melanocytic lesions, including melanoma; and disseminated or agminated Spitz nevi. Spitz nevi are typically smaller than 6 mm in diameter and dome shaped, with a smooth pink or tan surface and sharp borders. Although they can occur anywhere on the cutaneous surface except mucosal or palmoplantar areas, they are most commonly seen on the face (especially in children) and legs (especially in women).

Spitz nevi in adults are usually more heavily melanized than those in children.

Dermatoscopy or epiluminescent microscopy (examination of lesions with enhanced light and a dermatoscope) helps magnify the images in vivo and can assist in establishing the clinical diagnosis of some Spitz nevi. Histologically, the lesion can demonstrate features similar to those of melanoma, which earned the lesion its original designation by Sophie Spitz as a melanoma of childhood. Because Spitz nevi can be histologically difficult to distinguish from melanoma, if a biopsy is performed on a lesion because of parental, cosmetic, or transitional concern, complete excision with clear margins is recommended. Spitz nevi show fundamental genomic differences compared with melanoma, consistent with the generally benign behavior of these lesions. Spitz nevi typically demonstrate no or only a very restricted set of chromosomal aberrations (i.e., 11p gain in a subset of Spitz nevi). A distinct subset of atypical Spitz tumors is characterized by BRAF mutation and loss of BAP1 expression.

Dysplastic Melanocytic Nevi

Dysplastic melanocytic nevi, or Clark's nevi, or nevi with architectural disorder and cytologic atypia can occur sporadically as an isolated lesion or lesions or as part of a familial autosomal dominant syndrome. When such lesions occur sporadically, they are considered a marker for a patient who is at increased risk of melanoma (6% risk versus an approximate 0.6% risk in the normal white population in the United States). In association with a family history or personal past medical history of melanoma, patients with dysplastic melanocytic nevi should be considered to have a significant risk of melanoma. One first-degree family member with melanoma is associated with a lifetime risk of melanoma of 15% for the patient with dysplastic melanocytic nevi. Two or more first-degree family members with melanoma place a patient with dysplastic melanocytic nevi at a lifetime risk of developing melanoma that approaches 100%. Less commonly, dysplastic melanocytic nevi can progress to melanoma. Such progression has been documented by serial photography. However, these data are confounded by the fact that clinically and histologically dysplastic melanocytic nevi may be difficult to distinguish from an early melanoma.

Dysplastic melanocytic nevi are clinically distinguished from common acquired melanocytic nevi by a diameter usually larger than 6 mm, irregular border, asymmetry, and variable color with possible shades of brown, red, pink and black; dysplastic melanocytic nevi can be flat, with or without a raised center (fried egg appearance). The lesions begin to appear in mid-childhood and early adolescence. New lesions can appear throughout the patient's life. In addition to the back and extremities, these lesions can occur on sun-protected areas, including the scalp, buttocks, and female breasts. Dysplastic melanocytic nevi can be few or numerous, with hundreds of lesions.

Histologically, dysplastic melanocytic nevi show both architectural disorder: extension of the junctional component beyond the dermal component (shouldering); bridging of nests between adjacent rete ridges; papillary dermal concentric and lamellar fibroplasia; and a variable lymphocytic infiltrate with vascular ectasias. They also show cytologic atypia of melanocytes: increased nuclear size, hyperchromasia, dispersion or variation of nuclear chromatin patterns, and presence of nucleoli. Although there is some discordance in the histologic grading of dysplastic melanocytic nevi among expert dermatopathologists, there is some evidence to support the use in clinical practice of a two-tier grading system: Grade A are dysplastic melanocytic nevi with mild or moderate cytologic atypia, and grade B are dysplastic melanocytic nevi with severe cytologic atypia. The probability of having a personal history of melanoma in any given patient with dysplastic melanocytic nevi correlates with the grade of cytologic atypia in melanocytic nevi cells. In addition, the presence of severe cytologic atypia in dysplastic melanocytic nevi correlates with a significantly greater risk of melanoma development (19.7%) compared with moderate (8.1%) or mild (5.7%) cytologic atypia.

Management of these patients is difficult. Dysplastic melanocytic nevi are not uncommon. Reportedly, as many as 4.6 million people in the United States have one or more sporadic dysplastic melanocytic nevi. Familial dysplastic melanocytic nevi are estimated to involve 50,000 patients in the United States. The risk of melanoma for these patients is probably on a continuum and correlated with their family history of melanoma or dysplastic melanocytic nevi, personal history of melanoma, number of acquired and dysplastic melanocytic lesions, and history of sun exposure. Removal of all dysplastic melanocytic nevi is inappropriate inasmuch as the chance of any single lesion becoming malignant is small and, in addition, the melanoma can arise de novo.

Management includes patient education and total body photography for comparison at future skin examinations. Patients should avoid the sun and use sunscreens and protective clothing. These patients should have regular biannual or quarterly examinations of the entire integument, including the oral, genital, and perianal mucosa, the scalp, and an ophthalmologic examination. Comparison with the previous total body photographs and use of the dermatoscope can be helpful. Any lesions that are suspicious for melanoma should be excised. Examination of first-degree family members (parents, siblings, and children) of patients with melanoma or dysplastic melanocytic nevi is recommended to identify other persons at high risk.

PAPULOSQUAMOUS ERUPTIONS

Method of

Tam T. Nguyen, MD

CURRENT DIAGNOSIS

- Psoriasis can be clinically described as erythematous plaques with silvery white scales.
- Severity is rated as mild (< 5% body surface area [BSA]), moderate (5%–10% BSA), or severe (>10% BSA).

Spitz nevi in adults are usually more heavily melanized than those in children.

Dermatoscopy or epiluminescent microscopy (examination of lesions with enhanced light and a dermatoscope) helps magnify the images in vivo and can assist in establishing the clinical diagnosis of some Spitz nevi. Histologically, the lesion can demonstrate features similar to those of melanoma, which earned the lesion its original designation by Sophie Spitz as a melanoma of childhood. Because Spitz nevi can be histologically difficult to distinguish from melanoma, if a biopsy is performed on a lesion because of parental, cosmetic, or transitional concern, complete excision with clear margins is recommended. Spitz nevi show fundamental genomic differences compared with melanoma, consistent with the generally benign behavior of these lesions. Spitz nevi typically demonstrate no or only a very restricted set of chromosomal aberrations (i.e., 11p gain in a subset of Spitz nevi). A distinct subset of atypical Spitz tumors is characterized by BRAF mutation and loss of BAP1 expression.

Dysplastic Melanocytic Nevi

Dysplastic melanocytic nevi, or Clark's nevi, or nevi with architectural disorder and cytologic atypia can occur sporadically as an isolated lesion or lesions or as part of a familial autosomal dominant syndrome. When such lesions occur sporadically, they are considered a marker for a patient who is at increased risk of melanoma (6% risk versus an approximate 0.6% risk in the normal white population in the United States). In association with a family history or personal past medical history of melanoma, patients with dysplastic melanocytic nevi should be considered to have a significant risk of melanoma. One first-degree family member with melanoma is associated with a lifetime risk of melanoma of 15% for the patient with dysplastic melanocytic nevi. Two or more first-degree family members with melanoma place a patient with dysplastic melanocytic nevi at a lifetime risk of developing melanoma that approaches 100%. Less commonly, dysplastic melanocytic nevi can progress to melanoma. Such progression has been documented by serial photography. However, these data are confounded by the fact that clinically and histologically dysplastic melanocytic nevi may be difficult to distinguish from an early melanoma.

Dysplastic melanocytic nevi are clinically distinguished from common acquired melanocytic nevi by a diameter usually larger than 6 mm, irregular border, asymmetry, and variable color with possible shades of brown, red, pink and black; dysplastic melanocytic nevi can be flat, with or without a raised center (fried egg appearance). The lesions begin to appear in mid-childhood and early adolescence. New lesions can appear throughout the patient's life. In addition to the back and extremities, these lesions can occur on sun-protected areas, including the scalp, buttocks, and female breasts. Dysplastic melanocytic nevi can be few or numerous, with hundreds of lesions.

Histologically, dysplastic melanocytic nevi show both architectural disorder: extension of the junctional component beyond the dermal component (shouldering); bridging of nests between adjacent rete ridges; papillary dermal concentric and lamellar fibroplasia; and a variable lymphocytic infiltrate with vascular ectasias. They also show cytologic atypia of melanocytes: increased nuclear size, hyperchromasia, dispersion or variation of nuclear chromatin patterns, and presence of nucleoli. Although there is some discordance in the histologic grading of dysplastic melanocytic nevi among expert dermatopathologists, there is some evidence to support the use in clinical practice of a two-tier grading system: Grade A are dysplastic melanocytic nevi with mild or moderate cytologic atypia, and grade B are dysplastic melanocytic nevi with severe cytologic atypia. The probability of having a personal history of melanoma in any given patient with dysplastic melanocytic nevi correlates with the grade of cytologic atypia in melanocytic nevi cells. In addition, the presence of severe cytologic atypia in dysplastic melanocytic nevi correlates with a significantly greater risk of melanoma development (19.7%) compared with moderate (8.1%) or mild (5.7%) cytologic atypia.

Management of these patients is difficult. Dysplastic melanocytic nevi are not uncommon. Reportedly, as many as 4.6 million people in the United States have one or more sporadic dysplastic melanocytic nevi. Familial dysplastic melanocytic nevi are estimated to involve 50,000 patients in the United States. The risk of melanoma for these patients is probably on a continuum and correlated with their family history of melanoma or dysplastic melanocytic nevi, personal history of melanoma, number of acquired and dysplastic melanocytic lesions, and history of sun exposure. Removal of all dysplastic melanocytic nevi is inappropriate inasmuch as the chance of any single lesion becoming malignant is small and, in addition, the melanoma can arise de novo.
