placebo, whereas there are no data to support the use of PEG. For all three agents, adverse effects were relatively few, and diarrhea is perhaps the major side effect. Both linacotide and lubiprostone are costly (as are eluxadoline and plecanatide) and may involve high out-of-pocket expenses for patients.

For IBS-D, both rifaximin and alosetron received conditional recommendations based on moderate quality evidence. The latter is approved by the FDA only for women in whom all other treatments have failed. There is a very small risk (approximately 1 case/1000 patient-years) for ischemic colitis with alosetron. Although loperamide has very low-quality evidence to support its use, it can be very effective if used in a proactive fashion.

The case for TCAs and antispasmodics is based on low-quality evidence, but both agents can be very effective for abdominal pain and, in the case of TCAs, for reducing diarrhea in IBS patients.

Behavioral Therapy for IBS

For patients with unrelenting IBS symptoms, cognitive behavioral therapy (CBT) and gut-directed hypnosis have been found to be beneficial. Such therapies should be performed by experienced and well-trained behavioral specialists who are an integral part of the medical team that treats patients with functional GI disorders. The most robust data for efficacy is for CBT. One potential drawback is that these treatments are provider-intensive approaches, but recent studies suggest that CBT can be as effective when given in a shortened course as is the traditional method.

MALABSORPTION

Method of

Lawrence R. Schiller, MD

CURRENT DIAGNOSIS

- Recognize the presence of generalized malabsorption by the combination of typical symptoms: diarrhea, greasy stools, flatulence, weight loss, fatigue, edema.
- Recognize the presence of specific malabsorption by associated symptoms and those symptoms particular to deficiency states of the malabsorbed substance: flatus, diarrhea, anemia, dermatitis, glossitis, neuropathy, paresthesias, tetany, ecchymosis.
- Documentation of generalized malabsorption is best done by stool analysis demonstrating steatorrhea and acid stools (reflecting carbohydrate malabsorption). Diagnosis depends on visualization of the small bowel by endoscopy or radiography and small bowel biopsy. Additional tests may be needed.
- Documentation of specific malabsorption is best done by demonstrating low blood levels of the malabsorbed substance or by tests designed to measure absorption of that substance. Diagnosis depends on studies designed to identify the likely diagnosis for a given situation.

CURRENT THERAPY

- Once a diagnosis is reached, therapy can be directed toward that specific problem:
 - Gluten-free diet for celiac disease
 - Antibiotics for bacterial overgrowth
 - Lactose-free diet for lactase deficiency

Every day the average human being consumes 2000–3000 kcal of food, much of it in the form of polymers or other complex molecules that must be digested and absorbed by the gut. The processes of digestion and absorption are complex and are readily disturbed by pathologic processes. More than 200 conditions have been described that can adversely affect nutrient absorption.

Strictly speaking, *mal digestion* refers to impaired hydrolysis of nutrients, usually due to lack of luminal factors, such as bile acids and pancreatic enzymes, and *malabsorption* refers to impaired mucosal transport. For clinical purposes, “malabsorption” is used to describe both processes.

Malabsorption can be generalized (panmalabsorption) or limited to a specific category of nutrients. Generalized malabsorption is usually due to maldigestion or to extensive mucosal dysfunction. Specific malabsorption occurs when a single transporter is disabled.

The causes of malabsorption can be divided into three categories: impaired luminal hydrolysis, impaired mucosal function (mucosal hydrolysis, uptake, packaging, and excretion), and impaired removal of nutrients from the mucosa (Box 1).

Diagnosis

Symptoms and Signs

Most patients with panmalabsorption have changes in their stools (Box 2). Steatorrhea (excess fat in stools) is characterized by pale color, bulkiness, greasiness, and a tendency to float (probably because of incorporated gas). Occasionally patients with malabsorption present with watery stools due to the osmotic effects of unabsorbed carbohydrates and short-chain fatty acids.

Abdominal distention and excess flatus also commonly occur due to fermentation of unabsorbed carbohydrate by colonic bacteria. This can occur not only with panmalabsorption but also with specific malabsorption of carbohydrate (e.g., lactase deficiency).

BOX 1

Causes of Malabsorption or Maldigestion

- Impaired luminal hydrolysis or solubilization
 - Bile acid deficiency
 - Impaired mucosal hydrolysis, uptake, or packaging
 - Pancreatic exocrine insufficiency
 - Postgastrectomy syndrome
 - Rapid intestinal transit
 - Small bowel bacterial overgrowth
 - Zollinger-Ellison syndrome
- Brush border or metabolic disorders
 - Abetalipoproteinemia
 - Glucose-galactose malabsorption
 - Lactase deficiency
 - Sucrase-isomaltase deficiency
- Mucosal diseases
 - Amyloidosis
 - Crohn's disease
 - Celiac sprue
 - Collagenous sprue
 - Eosinophilic gastroenteritis
 - Immunoproliferative small intestinal disease (IPSID)
 - Lymphoma
 - Nongranulomatous ulcerative jejunoileitis
 - Olmesartan enteropathy
 - Radiation enteritis
 - Systemic mastocytosis
- Infectious diseases
 - AIDS enteropathy
 - *Mycobacterium avium-intracellulare*
 - Parasitic diseases
 - Small bowel bacterial overgrowth
 - Tropical sprue
 - Whipple's disease
- After intestinal resection
- Chronic mesenteric ischemia
- Impaired removal of nutrients
 - Lymphangiectasia

BOX 2

Symptoms and Signs of Malabsorption or Maldigestion

- Changes in stool characteristics
 - Floating stools
 - Pale, bulky, greasy stools
 - Watery diarrhea
- Increased colonic gas production
 - Abdominal distention
 - Borborygmi
- Vitamin and mineral deficiencies
 - Anemia
 - Cheilosis
 - Glossitis
 - Dermatitis
 - Neuropathy
 - Night blindness
 - Osteomalacia
 - Paresthesia
 - Tetany
- Ecchymosis
- Fatigue, weakness
- Edema
- Weight loss, muscle wasting

Weight loss is typical with severe panmalabsorption, but it might not be very prominent with lesser degrees of malabsorption due to compensatory hyperphagia. Weight loss is most prominent early in the course of the illness, but body weight usually stabilizes as

calorie absorption and body weight come into balance again. This is in contrast to illnesses like cancer or tuberculosis that produce continuing weight loss. If a patient with malabsorption has continuing weight loss, inflammatory bowel disease or lymphoma should be considered.

Abdominal pain is usually not present with malabsorption, although some cramping may be associated with diarrhea. Severe pain should bring chronic pancreatitis, Zollinger-Ellison syndrome, lymphoma, Crohn's disease, or mesenteric ischemia to mind.

Constitutional symptoms of fatigue and weakness commonly occur, even early in the course. In contrast, appetite is impaired only late in the course of most malabsorption states. Edema is uncommon until late in the course unless protein-losing enteropathy is present.

Vitamin and mineral deficiencies can lead to several symptoms or signs. Glossitis and cheilosis are common in patients with water-soluble vitamin deficiencies. Florid beriberi, pellagra, and scurvy are not commonly seen unless malabsorption has been particularly severe or long-lasting. Fat-soluble vitamin deficiencies also are unlikely to develop except when malabsorption has been long-standing because of substantial body stores.

Miscellaneous findings occasionally seen in patients with malabsorption can provide clues to the diagnosis. Aphthous ulcers in the mouth may be seen with celiac disease, Behçet's syndrome, or Crohn's disease. Hyperpigmentation is seen in Whipple's disease, and dermatitis herpetiformis (pruritic, blistering skin lesions) is seen in celiac disease. Scleroderma can manifest with tight skin, digital ulceration, nail changes, and Raynaud's phenomenon. Chronic sinusitis, bronchitis, and recurrent pneumonia suggest cystic fibrosis or IgA deficiency. Several systemic diseases can be associated with malabsorption syndrome (Box 3).

Tests

Routine Laboratory Tests

Routine laboratory tests (Box 4) commonly are abnormal in patients with established malabsorption syndrome. Anemia is common but not universal. Iron deficiency anemia may be the only finding in some patients with celiac disease. Microcytic anemia may be present in Whipple's disease (due to occult blood loss) and in lymphomas manifesting with malabsorption. Macrocytic anemia due to folate or vitamin B₁₂ deficiency can occur in short bowel syndrome, small bowel bacterial overgrowth, or ileal disease. Lymphopenia may be present in patients with AIDS or lymphangiectasia.

Electrolyte abnormalities may be due to a combination of poor intake and excess loss in stool. Renal function usually is well maintained in malabsorption syndrome, but blood urea nitrogen may be low due to poor protein absorption, and serum creatinine concentration may be low due to depletion of muscle mass. Serum calcium levels may be low due to malabsorption, vitamin D deficiency, or intraluminal complexing of calcium by fatty acids. Hypomagnesemia can produce hypocalcemia or hypokalemia that is resistant to intravenous repletion. Serum phosphorus, cholesterol, and triglyceride levels may be reduced due to poor intake or malabsorption. Liver tests may be abnormal due to fatty liver. Serum protein and albumin levels are well preserved in patients with malabsorption unless protein-losing enteropathy or an acute illness is present.

BOX 3

Systemic Diseases Associated with Malabsorption or Maldigestion

Endocrine Diseases

- Addison's disease
- Diabetes mellitus
- Hypoparathyroidism
- Hyperthyroidism, hypothyroidism

Collagen-Vascular and Miscellaneous Diseases

- AIDS
- Amyloidosis
- Scleroderma
- Vasculitis (systemic lupus erythematosus, polyarteritis nodosa)

BOX 4

Laboratory Tests for Evaluation of Malabsorption or Maldigestion

Complete Blood Count

- Hemoglobin/hematocrit
- Platelet count
- WBC differential count

Biochemistry Tests

- Blood urea nitrogen
- Potassium
- Prothrombin time
- Serum albumin
- Serum calcium
- Serum creatinine

Blood Levels of Potentially Malabsorbed Substances

- Serum iron, vitamin B₁₂, folate, 25-OH vitamin D, carotene

Fat absorption

- Qualitative fecal fat (Sudan stain)
- Quantitative fecal fat (Timed collection)

Protein Absorption and Protein-Losing Enteropathy

- α_1 -Antitrypsin clearance
- Fecal nitrogen excretion

Carbohydrate Absorption

- Osmotic gap in stool water
- Quantitative excretion (anthrone)
- Stool pH <5.5
- Stool reducing substances
- D-Xylose absorption test
- Oral glucose, sucrose, and lactose tolerance tests
- Breath hydrogen tests

Vitamin B₁₂ Absorption

- Serum B₁₂ level

Bile Acid Malabsorption

- ¹⁴C-glycocholic acid breath test
- Fecal bile acid excretion
- Serum 7 α -hydroxy-4-cholesten-3-one (C4)
- ⁷⁵SeHCAT retention

Small Bowel Bacterial Overgrowth

- ¹⁴C-glycocholic acid breath test
- ¹⁴C-xylose breath test
- Glucose breath hydrogen test
- Quantitative culture of jejunal aspirate

Exocrine Pancreatic Insufficiency

- Secretin/CCK test
- Stool elastase or chymotrypsin concentration

Serologic Testing for Celiac Disease

- Anti-tissue transglutaminase antibody (IgA)
- Anti-endomysial antibody (IgA)

Abbreviations: CCK = cholecystokinin; SLE = systemic lupus erythematosus; ⁷⁵SeHCAT = selenium-75-labeled taurohomocholic acid; WBC = white blood cell.

Prothrombin time is normal unless vitamin K malabsorption (typically associated with steatorrhea), anticoagulant therapy, antibiotic therapy, or colectomy is present.

Assays are available for several potentially malabsorbed substances, including iron, vitamin B₁₂, folate, 25-hydroxyvitamin D, and β -carotene. Malabsorption tends to lower blood levels, but substantial body stores of many of these can mitigate the reduction in concentration that otherwise might occur. Thus, the sensitivity and specificity of these assays for malabsorption are poor.

Tests for Malabsorption

Fat Malabsorption. The simplest test for fat malabsorption is a qualitative microscopic examination of stool using a fat-soluble stain, such as Sudan III. The finding of more than five stained

droplets per high-power field is abnormal and correlates well with quantitative measurement of fecal fat excretion. The test is subject to false-positive results with some drugs and food additives, such as mineral oil, orlistat, and olestra.

A more precise estimate of fat absorption is obtained by a quantitative analysis of a timed stool collection (48 or 72 hours). During the collection, a diary of dietary intake should be maintained so that fat excretion can be assessed as a percentage of intake. Normal fat excretion is <7% of intake when stool weight is normal, but it can be twice as high due to voluminous diarrhea without indicating defective mucosal transport of fat. Thus, fat excretion must be judged against stool weight. Stool fat concentration (grams of fat per 100 grams of stool) also is of value. Pancreatic exocrine insufficiency is associated with high fecal fat concentration (>10 g/100 g stool) because, unlike hydrolyzed fat, unhydrolyzed fat does not stimulate colonic water and electrolyte secretion that would dilute fecal fat concentration.

Protein Malabsorption. Fecal nitrogen excretion can be employed as a marker of protein malabsorption, but is not often used in clinical medicine because it adds little to the evaluation. If protein-losing enteropathy is suspected, an α_1 -antitrypsin clearance study can be done. In this study, fecal excretion of α_1 -antitrypsin, a serum protein that is relatively resistant to hydrolysis by luminal enzymes, is divided by serum concentration of α_1 -antitrypsin, and the volume of serum leaked into the lumen can be calculated. Values of more than 180 mL/day are associated with hypoalbuminemia.

Carbohydrate Malabsorption. Carbohydrate malabsorption is difficult to measure directly because fermentation of malabsorbed carbohydrate by colonic bacteria reduces the amount of intact carbohydrate that can be recovered in stool. Indirect estimates of carbohydrate malabsorption can be made by examining fecal pH (<5.5 with carbohydrate malabsorption) or fecal osmotic gap (>100 mOsm/kg with osmotic diarrhea) based on chemical analysis of stool water. Oral carbohydrate tolerance tests may be used to evaluate absorption of sugars, such as lactose or fructose. Following an oral load of a given sugar, blood glucose levels are monitored; failure of blood glucose to increase suggests malabsorption.

Another test for carbohydrate malabsorption is the D-xylose absorption test. In this test, a 25-gram dose of D-xylose is given orally; blood xylose levels are measured 1 and 3 hours later, and urinary excretion of xylose is measured for 5 hours. Failure of blood xylose to rise above 20 mg/dL at 1 hour or above 22.5 mg/dL at 3 hours or failure of urinary excretion to exceed 5 g in 5 hours suggests malabsorption. In addition, because xylose does not require pancreatic enzymes or bile acids for absorption, an abnormal D-xylose test suggests a mucosal problem as the cause for malabsorption. The results of this test can be misleading if the patient is dehydrated or has ascites, if renal function is compromised, or if bacterial overgrowth is present in the upper small bowel.

Breath hydrogen testing is another method to assess carbohydrate absorption. If substrates such as lactose or sucrose are not absorbed in the small intestine, they pass into the colon, where bacterial fermentation produces hydrogen gas. The hydrogen is absorbed into the bloodstream and then is exhaled. The concentration of hydrogen in exhaled breath can be measured easily; a rise of more than 10 to 20 ppm after ingestion of a specific substrate is consistent with malabsorption. False-positive results can be seen in patients with small bowel bacterial overgrowth, and false-negative results can be seen in patients who lack hydrogen-producing flora or who have been on antibiotics recently.

Vitamin B₁₂ Malabsorption. Although the Schilling test has been used to measure Vitamin B₁₂ absorption, commercial testing kits are no longer available in the United States. Instead, serum B₁₂ levels are measured: low levels are consistent with B₁₂ malabsorption, but normal levels do not exclude it because B₁₂ is stored in the liver and can maintain serum levels for several years.

Bile Acid Malabsorption. Tests for bile acid malabsorption are not widely available in the United States. Direct measurement of bile acid excretion has been used mainly in research studies. Retention of a radioactive taurocholic acid analogue (SeHCAT,

selenium-75-labeled taurohomocholic acid) is used in Europe to assess bile acid malabsorption. A breath test using ¹⁴C-glycocholic acid has been used for evaluating small bowel bacterial overgrowth, but it may have application for assessing bile acid malabsorption as well. Serum 7 α -hydroxy-4-cholesten-3-one (C4) reflects bile acid synthesis; higher levels reflect increased synthesis in patients with bile acid malabsorption.

Small Bowel Bacterial Overgrowth. The gold standard method used to test for small bowel bacterial overgrowth in the upper intestine is quantitative culture of jejunal fluid. The sample can be obtained during endoscopy and sent to the laboratory with instructions to quantitate the aerobic and anaerobic flora. Finding more than 10⁵ bacteria per mL confirms bacterial overgrowth. Breath tests using glucose, ¹⁴C-xylose, and lactulose also have been described for this purpose.

Pancreatic Exocrine Insufficiency. Tests for pancreatic exocrine insufficiency are not commonly used. The gold standard test is a secretin test. This study requires duodenal intubation, injection of secretin, and measurement of bicarbonate output. Measurement of fecal chymotrypsin or elastase activity is only moderately useful in predicting the presence of exocrine pancreatic insufficiency. For most situations, a therapeutic trial using a high dose of pancreatic enzymes with monitoring of the effect on steatorrhea is the best that can be done.

Evaluation of Suspected Malabsorption

When malabsorption is suspected because of the history, physical findings, and setting, the physician must decide if the malabsorption involves a specific nutrient or represents a generalized process (Figure 1). If the malabsorption seems to be specific, a diet and symptom diary, breath tests using the presumptively malabsorbed substrate, and stool pH to identify acid stools seen with carbohydrate malabsorption are reasonable diagnostic maneuvers.

Suspected generalized malabsorption requires a more intense evaluation. Steatorrhea should be confirmed with either a qualitative fecal fat test (e.g., Sudan stain) or a quantitative stool collection for measurement of fat excretion. If steatorrhea is confirmed, the small bowel should be visualized with either capsule endoscopy or radiography (small bowel follow-through examination or computed tomography) and biopsied from above by enteroscopy and from below by colonoscopy. During enteroscopy, an aspirate of small bowel contents can be obtained for quantitative culture to look for small bowel bacterial overgrowth. An alternative method to detect small bowel bacterial overgrowth is breath testing (see

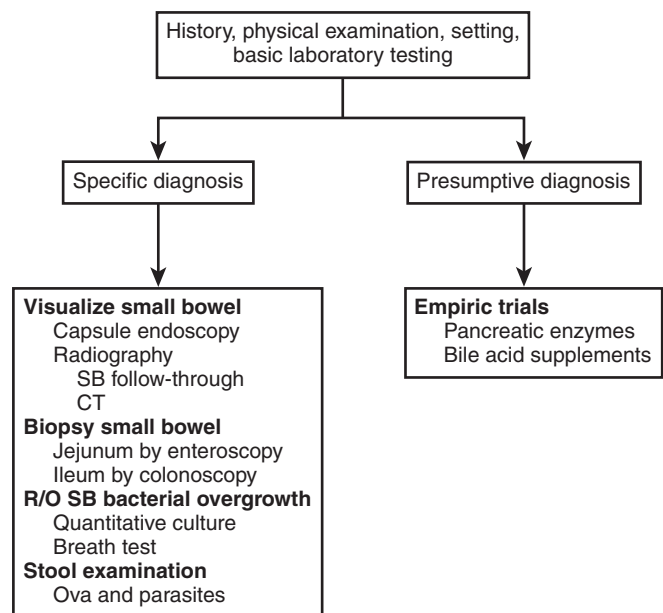

Figure 1 Flow chart for evaluation of malabsorption or maldigestion. Abbreviations: CT = computed tomography; R/O = rule out; SB = small bowel.

earlier). Stool samples also should be examined with microscopy or immunoassay for the presence of parasites that may be associated with malabsorption.

This sequence of evaluation often leads to a specific diagnosis. When it does not, empiric trials of high-dose pancreatic enzyme replacement or low-dose bile acid supplementation can lead to a presumptive diagnosis of pancreatic exocrine insufficiency or bile acid deficiency. Hard endpoints (e.g., quantitative fat excretion) should be used to assess the effectiveness of these empiric trials.

Specific Disorders Associated With Malabsorption

Malabsorption of Specific Nutrients

Disaccharidase Deficiency

Ingested disaccharides such as lactose and sucrose and starch-digestion products such as maltotriose and α -limit dextrins must be hydrolyzed by brush border enzymes into monosaccharides for absorption by the mucosa. If these brush border enzymes are not active or if the brush border is damaged, malabsorption of the specific carbohydrate substrate results. This can result in gaseousness or osmotic diarrhea when those substrates are ingested. This rarely occurs on a congenital basis, but it commonly occurs as an acquired disorder.

Lactase deficiency is the most common acquired disaccharidase deficiency. Infant mammals all rely on lactose as the carbohydrate source in milk, but lactase activity is shut off after weaning in most species. Most human populations lose lactase activity during adolescence as a normal part of maturation. Members of the northern European gene pool might maintain lactase activity into adult life, but lactase activity declines gradually in many. At some point the amount of lactose ingested might exceed the ability of the remaining enzyme to hydrolyze it, resulting in lactose malabsorption and symptoms. This also can occur with acute conditions such as gastroenteritis that can disturb the mucosa and temporarily reduce lactase activity. Patients might not recognize lactose ingestion as a cause of their problem because they have not had difficulty tolerating lactose in the past. Restriction of lactose in the diet (or use of products that have predigested lactose) mitigates symptoms. Use of exogenous lactase as a tablet may only be partially effective because of incomplete hydrolysis of ingested lactose.

Transport Defects at the Brush Border

Glucose-galactose malabsorption is a rare congenital disorder resulting from an inactive hexose transporter in the brush border. Hydrolysis of lactose is intact, but transport across the apical membrane of the enterocyte fails to occur. Fructose absorption, which is mediated by a different carrier, is unaffected.

In all human beings, the ability to absorb fructose is limited by the availability of carriers in the brush border and may be overwhelmed when excess fructose is ingested. This can occur relatively easily nowadays, because high-fructose corn syrup is used frequently as a sweetener in commercial products such as soda pop. Limiting the amount of fructose ingested will reduce symptoms.

Abetalipoproteinemia is a rare condition that prevents absorption of long-chain fatty acids due to failure to form chylomicrons. Use of medium-chain triglycerides that do not require transport in chylomicrons can bypass this defect.

Pernicious anemia develops when failure to secrete intrinsic factor in the stomach prevents vitamin B₁₂ absorption by the ileal mucosa. Parenteral replacement with cyanocobalamin by injection (Cyanoject) or nasal spray (Nascobal) is necessary.

Generalized Malabsorption

Celiac Disease

Celiac disease (also known as celiac sprue) is a disorder in which the mucosa of the small bowel is damaged due to activation of the mucosal immune system by ingestion of gluten, a protein component found in wheat, barley, and rye. People who have HLA-DQ2 or DQ8 are susceptible to this condition because these specific antigen-presenting proteins produce particularly strong reactions by interacting with a unique peptide digestion product of gluten.

Tissue transglutaminase, an enzyme produced in the mucosa, is an important cofactor in pathogenesis by amplifying the immunogenicity of gluten peptide fragments and is the target of autoantibodies that are characteristic of this disease. The condition produces generalized malabsorption by destroying the villi of the small intestine, reducing the surface area available for absorption.

In addition to malabsorption syndrome with diarrhea and weight loss, celiac disease can produce a host of nonspecific symptoms, including abdominal pain, fatigue, muscle and joint pains, and headaches and seemingly unrelated problems such as iron deficiency anemia, abnormal liver tests, and osteoporosis. These protean manifestations mean that celiac disease must be considered in the differential diagnosis of many conditions. The clinical course is quite variable, with symptoms coming and going. Symptoms can develop during childhood and produce growth retardation or first become manifest in adulthood.

Testing for celiac disease has been simplified by the development of an assay for anti-tissue transglutaminase antibodies. This test largely supplants measurement of antigliadin antibodies, although these remain of some use in evaluating adherence to a gluten-free diet. IgA antibodies are the most useful for diagnosis, but IgA deficiency is common enough that an IgA level should be measured concomitantly.

Although serologic tests have high sensitivity and specificity, the implications of adhering to a gluten-free diet are so extreme that the diagnosis of celiac disease should be confirmed whenever possible by small bowel mucosal biopsy, now obtained routinely by endoscopy. An empiric trial of a gluten-free diet may be difficult to interpret because many persons with gastrointestinal symptoms improve with dietary carbohydrate restriction. Wheat starch is particularly hard to digest; ordinarily 20% of wheat starch is not digested and absorbed by the small bowel, and enters the colon.

Treatment of celiac disease at present involves strict lifetime exclusion of gluten from the diet. This is a difficult regimen that excludes most processed foods. Assistance of a dietitian is most helpful. The prognosis with effective treatment is very good. Symptoms should respond to the diet within weeks; failure to do so should prompt an examination of compliance with the diet or reconsideration of the diagnosis. Failure to respond may be seen when lymphoma or adenocarcinoma complicate the course of celiac disease or in cases of "refractory sprue" or "collagenous sprue," which can have a different autoimmune basis from classic celiac disease and which might respond to immunosuppressive drugs such as corticosteroids or azathioprine (Imuran).¹ Persistent diarrhea may be observed in patients with celiac disease who have concomitant microscopic colitis, another condition that is linked to HLA-DQ2 and HLA-DQ8.

Olmесartan (Benicar) and some other medications can produce enteropathies resembling celiac disease clinically, but which are not related to gluten ingestion. Diarrhea and malabsorption resolve with discontinuing the medication.

Inflammatory Diseases

Diseases that produce extensive mucosal damage by inflammation cause generalized malabsorption by reduction of mucosal surface area, by promotion of small bowel bacterial overgrowth, by ileal dysfunction, or by development of enteroenteral or enterocolic fistulas. Examples include jejunoileitis due to Crohn's disease, non-granulomatous ulcerative jejunoileitis, radiation enteritis, and chronic mesenteric ischemia. With Crohn's disease, previous resection can add to the problem (see later). Therapy aimed at the underlying process can improve absorption; in some cases (e.g., radiation enteritis), no effective therapy is available for the underlying problem, and symptomatic management is all that is possible. This includes use of antidiarrheal drugs to prolong contact time between luminal contents and the small bowel mucosa, ingestion of a reduced-fat diet to reduce steatorrhea, and use of vitamin and mineral supplements to prevent deficiency states.

¹Not FDA approved for this indication.

Infiltrative Disorders

Several conditions involve infiltration of the intestinal mucosa with cells or extracellular matrix that impede absorption or modify mucosal function by secretion of cytokines and other regulatory substances. These include eosinophilic gastroenteritis, systemic mastocytosis, immunoproliferative small intestinal disease (IPSID), lymphoma, and amyloidosis. These conditions are diagnosed by mucosal biopsy, but special stains might have to be employed to identify the infiltrating cells or matrix accurately.

Treatment of the underlying processes can improve absorption, but it is not uniformly effective. For eosinophilic gastroenteritis, a hypoallergenic (elimination) diet and corticosteroids may be useful. Mild systemic mastocytosis is treated with the mast cell-stabilizer sodium cromoglycate, H₁- and H₂-receptor antagonists, and low-dose aspirin.¹ More advanced disease might respond to interferon or cytotoxic chemotherapy. IPSID initially is treated with antibiotics, because small bowel bacterial overgrowth may be a causative factor. Once malignant change has occurred, it is treated like lymphoma with cytotoxic chemotherapy. Amyloidosis affecting the gut is not amenable to therapy and is usually fatal.

Infectious Diseases

Small Bowel Bacterial Overgrowth. Small bowel bacterial overgrowth in the jejunum can produce generalized malabsorption. It can occur whenever the mechanisms that reduce overgrowth are compromised. These situations include achlorhydria or hypochlorhydria, motility disorders of the small intestine (e.g., diabetes mellitus or scleroderma), and anatomic alterations (e.g., diverticulosis, gastrocolic fistula, or blind loops postoperatively). Fat malabsorption is attributed to bacterial deconjugation of bile acid. Bacterial toxins or free fatty acids can produce patchy mucosal damage, leading to less efficient carbohydrate and protein absorption. Bacteria also can compete with the mucosa for uptake of certain nutrients such as vitamin B₁₂.

Diagnosis of small bowel bacterial overgrowth can be difficult (see earlier). Treatment consists of antibiotic therapy unless a surgically correctable anatomic defect is discovered. Tetracycline is no longer uniformly effective; amoxicillin-clavulanic acid (Augmentin), cephalosporins, ciprofloxacin (Cipro), metronidazole (Flagyl), and rifaximin (Xifaxan) may be employed. Therapy should be given for 1 to 2 weeks initially and then discontinued. It should be restarted when symptoms recur. If this occurs quickly, longer treatment periods should be considered. Continuous antibiotic therapy is needed rarely.

Tropical Sprue. Tropical sprue is a progressive, chronic malabsorptive condition occurring in both the indigenous population and in visitors residing in certain tropical countries for extended periods. The prevalence of tropical sprue seems to be decreasing for uncertain reasons. The disease starts as an acute diarrheal disease that becomes a persistent diarrhea associated with substantial weight loss and typically megaloblastic anemia. Villi become shortened and thickened (partial villous atrophy), but the flat mucosa of celiac disease is not usually present. Enterocytes have disrupted brush borders and can have megaloblastic changes; the submucosa has a chronic inflammatory infiltrate. Intestinal biopsy is required for diagnosis.

Currently, tropical sprue is believed to represent a form of bacterial overgrowth with organisms that secrete enterotoxins. Most patients have evidence of excessive gram-negative bacterial colonization of the jejunum. The declining prevalence of tropical sprue may be due to improved nutrition, better sanitation, or prompt treatment of acute diarrhea with antibiotics. Treatment consists of pharmacologic doses of folic acid (folate) (5 mg daily³), injection of cyanocobalamin (if deficient), and antibiotic therapy for 1 to 6 months. Tetracycline 250 mg four times a day or sulfonamide is the treatment of choice. Newer antibiotics have not been tested extensively in this condition. Improvement

should be noted after a few weeks. The prognosis with treatment is excellent; without treatment, tropical sprue can be fatal. Recurrence can occur.

Whipple's Disease. Whipple's disease is a rare chronic bacterial infection with multisystem involvement. The small bowel typically is heavily infiltrated with foamy macrophages containing periodic acid-Schiff (PAS)-positive material, distorting the villi. Small bowel biopsy with special stains or electron microscopy or a specific polymerase chain reaction (PCR) is diagnostic. Foamy macrophages and bacteria can be found outside the intestine in lymph nodes, spleen, liver, central nervous system, heart, and synovium. Accordingly, symptoms are protean. The bacterium has been identified as *Tropheryma whippelii*, a relative of *Acinetobacter*. It does not appear to be very contagious, and no direct person-to-person transmission has been demonstrated. Presumably, differences in host resistance allow proliferation within macrophages without clearance of the bacteria.

Whipple's disease occurs mainly in older white men, but women and all ethnic groups are susceptible. Patients can present with malabsorption syndrome or with symptoms related to the extraintestinal disease (arthritis, fever, dementia, headache, or muscle weakness). Gross or occult gastrointestinal bleeding can occur. Protein-losing enteropathy may be present.

Treatment with any of several antibiotics (penicillin, erythromycin, ampicillin, tetracycline, chloramphenicol, or trimethoprim-sulfamethoxazole [TMP-SMX]) produces excellent symptomatic responses within days to weeks, but it should be continued for months to years. Even with protracted courses, relapses are common.

Other Infections. *Mycobacterium avium-intracellulare* is another chronic bacterial infection that can cause malabsorption, particularly in patients with AIDS. Mucosal biopsy with special stains to distinguish it from Whipple's disease is essential. Antibiotic therapy can reduce the intensity of infection; clearance depends on immunologic reconstitution with antiretroviral therapy. Clarithromycin (Biaxin) and ethambutol (Myambutol) are recommended as initial therapy.

Parasitic diseases can produce malabsorption by competing for nutrients and causing mechanical occlusion of the absorptive surface and epithelial damage. Protozoa that may be associated with malabsorption include *Giardia lamblia*, *Isospora belli*, *Cryptosporidium*, and *Enterocytozoon bienersi*. Tapeworms associated with malabsorption include *Taenia saginata* (beef tapeworm), *Hymenolepis nana* (dwarf tapeworm), and *Diphyllobothrium latum* (fish tapeworm).

Giardia lamblia is a cosmopolitan parasite acquired from contaminated water or from another person by fecal-oral transmission. Cysts are relatively hardy, and ingestion of as few as 10 cysts is sufficient to establish infection. Patients with dysgammaglobulinemia (especially IgA deficiency) are likely to become infected. Diagnosis depends on finding the organism (cysts or trophozoites) in stool by microscopy (sensitivity ~50% for a single specimen), or detection of giardia antigens by immunologic testing of stool (sensitivity >90%), multiplex PCR testing (sensitivity >95%), or discovery of the organism on small bowel biopsy.

Therapy consists of a single dose of tinidazole (Tindamax) (2 g), metronidazole (Flagyl)¹ (250 mg three times a day for a week), nitazoxanide (Alinia) (500 mg twice a day for three days), or quinacrine² (100 mg three times a day for a week).

Isospora belli and *Cryptosporidium* spp. are coccidia, protozoa that disrupt the epithelium by intracellular invasion (*Isospora*) or by attaching to the brush border, destroying microvilli (*Cryptosporidium*). Stool examination or small bowel biopsy can identify the organism. *Cryptosporidium* can be discovered by antigen immunoassay or multiplex PCR testing on stool with excellent sensitivity. *Isospora* can be treated with trimethoprim/sulfamethoxazole (TMP-SMX)¹ or furazolidone.² *Cryptosporidium* can be treated by nitazoxanide.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

¹Not FDA approved for this indication.

²Not available in the United States.

Microsporidia are intracellular organisms now believed to be most closely related to fungi and are implicated in diarrhea and malabsorption in patients with AIDS and other immunodeficiency states. Small bowel biopsy can show partial villous atrophy, and electron microscopy displays characteristic changes. Stool examination occasionally is helpful. No treatment is of proven value.

Tapeworms compete with their hosts for nutrients in the lumen. *Diphyllobothrium latum* can produce vitamin B₁₂ deficiency. The others can result in more extensive nutritional deficiencies. Diagnosis is based on stool examination, and treatment depends on the particular organism identified.

Luminal Problems Causing Malabsorption

Pancreatic Exocrine Insufficiency. Pancreatic exocrine insufficiency is the most common luminal problem that results in maldigestion. Patients develop symptoms of malabsorption when pancreatic enzyme secretion is reduced by >90%. There are several clinical features that distinguish pancreatic exocrine insufficiency from mucosal disorders, such as celiac disease. When fat is not digested, it is transported through the gastrointestinal tract as intact triglyceride, which can appear as oil in the stool. In contrast, if fat is digested but not absorbed, it is in the form of fatty acids that can produce secretory diarrhea in the colon, resulting in more voluminous, even watery stools. This has two important ramifications: Fecal fat concentration is lower with mucosal disease (typically <9% by weight), and hypocalcemia due to formation of soaps (calcium plus 2 fatty acids) is seen with mucosal disease but not with pancreatic exocrine insufficiency. In addition, patients with mucosal disease tend to have more problems with water-soluble vitamin deficiencies than those with pancreatic exocrine insufficiency. In some patients with pancreatic exocrine insufficiency, carbohydrate malabsorption can produce substantial bloating, flatulence, and watery diarrhea.

Tests to document pancreatic exocrine insufficiency are not widely available or are nonspecific (see earlier), and so diagnosis usually hinges on a consistent history, demonstration of anatomic problems in the pancreas (calcification or abnormal ducts), and documentation of a response of steatorrhea to empiric treatment with a large dose of exogenous enzymes.

Bile Acid Deficiency. Bile acid deficiency is a less common cause of maldigestion, and malabsorption in this setting is limited to fat and fat-soluble vitamins. The usual setting is a patient with an extensive ileal resection (see later), but this also occurs in certain cholestatic conditions in which bile acid secretion by the liver is markedly compromised, such as advanced primary biliary cirrhosis, or complete extrahepatic biliary obstruction. As with pancreatic exocrine insufficiency, stools tend to have high fat concentrations (>9% by weight) when bile acid secretion is limited by hepatic or biliary disorders.

Zollinger-Ellison Syndrome. Zollinger-Ellison syndrome produces several abnormalities that can affect absorption. High rates of gastric acid secretion produce persistently low pH in the duodenum, which precipitates bile acid and inactivates pancreatic enzymes. In addition, excess acid can damage the absorptive cells directly.

Postoperative Malabsorption

Substantial malabsorption can result from gastric surgeries. Weight loss can result from inadequate intake due to early satiety or symptoms of dumping syndrome. Malabsorption can result from impaired mechanical disruption of food, mismatching of chyme delivery and enzyme secretion, rapid transit, or small bowel bacterial overgrowth due to loss of the gastric acid barrier. In addition, gastric surgery sometimes brings out latent celiac disease.

Short intestinal resections are well tolerated, but more extensive resections produce diarrhea and malabsorption of variable severity. When these symptoms are associated with weight loss or dehydrating diarrhea, short bowel syndrome is said to exist. In general, nutrient absorptive needs can be met if at least 100 cm of jejunum are preserved, but fluid absorption will be insufficient and diarrhea may be profuse. The process of intestinal adaptation permits

improved absorption with time; it depends on exposure of the absorptive surface to nutrients. Absorption of specific substances, such as bile acids or vitamin B₁₂, is reduced permanently by resection of the terminal ileum.

Malabsorption in short bowel syndrome is not due solely to loss of absorptive surface area. Gastric acid hypersecretion, bile acid deficiency, rapid transit (due to loss of the ileal brake), and bacterial overgrowth may be present. These conditions are amenable to treatment and therapy with antisecretory drugs, exogenous bile acids, opiate antidiarrheals, or antibiotics can produce substantial improvement. Injection of teduglutide (Gattex), a glucagon-like peptide-2 intestinal growth factor, or growth hormone in combination with glutamine and a special diet have been approved as treatments for short bowel syndrome; they can reduce the volume of parenteral fluid or nutrients required. Results with small bowel transplantation are improving with the use of better immunosuppressive regimens, and it remains the only cure for select patients with postresection malabsorption.

Attention to nutrition is vital in any patient with malabsorption. If adequate nutrition cannot be maintained by oral intake, nutritional therapy is needed. Because of impaired bowel function, success with enteral nutrition may be impossible; parenteral nutrition may be needed. It is important to distinguish between the need for supplemental fluid and electrolytes and the need for nutrients; total parenteral nutrition is not a good choice for patients who only require fluids and electrolytes.

NONALCOHOLIC FATTY LIVER DISEASE

Method of

Vladimir Bakhutashvili, MD; and Adnan Said, MD, MS

CURRENT DIAGNOSIS

- Suspected in patients with steatosis noted on imaging or elevated liver enzymes (alanine aminotransferase, aspartate aminotransferase, γ -glutamyl transferase)
- Diagnosis of exclusion
 - Exclude alcohol excess by history (>21 drinks/week for men and 14 units/week for women)
 - Hepatitis C virus antibody, hepatitis B surface antigen
 - Review medications that can cause steatosis (methotrexate [Trexall], tamoxifen [Nolvadex], diltiazem [Cardizem], amiodarone [Pacerone], steroids)
 - Check serum ferritin, iron saturation (hemochromatosis)

Microsporidia are intracellular organisms now believed to be most closely related to fungi and are implicated in diarrhea and malabsorption in patients with AIDS and other immunodeficiency states. Small bowel biopsy can show partial villous atrophy, and electron microscopy displays characteristic changes. Stool examination occasionally is helpful. No treatment is of proven value.

NONALCOHOLIC FATTY LIVER DISEASE

Method of

Vladimir Bakhutashvili, MD; and Adnan Said, MD, MS

CURRENT DIAGNOSIS

- Suspected in patients with steatosis noted on imaging or elevated liver enzymes (alanine aminotransferase, aspartate aminotransferase, γ -glutamyl transferase)
- Diagnosis of exclusion
 - Exclude alcohol excess by history (>21 drinks/week for men and 14 units/week for women)
 - Hepatitis C virus antibody, hepatitis B surface antigen
 - Review medications that can cause steatosis (methotrexate [Trexall], tamoxifen [Nolvadex], diltiazem [Cardizem], amiodarone [Pacerone], steroids)
 - Check serum ferritin, iron saturation (hemochromatosis)

- Check serum ceruloplasmin and unbound copper (Wilson disease)
- Check autoantibodies (ANA, antismooth muscle antibody) (autoimmune hepatitis)
- Liver biopsy gold standard.
 - Not essential for diagnosis
 - Useful for diagnosis of nonalcoholic steatohepatitis (NASH) and fibrosis
 - Useful in excluding other conditions (if above tests raise suspicion)
- Noninvasive serum tests (more useful for diagnosis or exclusion of advanced fibrosis and potentially in decision of whom to biopsy)
 - Nonalcoholic fatty liver disease fibrosis score
 - FIB-4 index
- Noninvasive imaging tests for diagnosis of steatosis
 - Transient elastography with controlled attenuation parameter score
 - Right upper quadrant ultrasound
 - Magnetic resonance imaging of liver with proton density fat fraction
- Noninvasive imaging tests for diagnosis of fibrosis
 - Transient elastography with FibroScan
 - Magnetic resonance elastography

CURRENT THERAPY

Lifestyle Modifications Mainstay of Therapeutic Plan

- Goal is to lose 7% to 10% of body weight gradually
- Lose no more than 1 to 2 lbs/week

Dietary Modification

- Reduce calories by 30% (500 to 1000 kcal/day)
- Reduce sugars, carbohydrates, fructose-enriched foods, and sugar sweetened beverages
- Reduce consumption of processed foods and saturated fat
- Coffee consumption (>2 cups/day, avoid adding sugar, syrups) has been shown to be beneficial

Exercise

- 150 to 200 minutes per week divided over 3 to 5 days
 - Moderate to vigorous intensity (swimming, biking, jogging, playing tennis, weights)
- Pioglitazone (Actos)¹ can be used for diabetic or nondiabetic NASH but causes weight gain and does not treat fibrosis.
- Vitamin E (800 IU/day)⁷ can be used for nondiabetic NASH
- Bariatric surgery can be considered if indicated for morbid obesity, complications of metabolic syndrome

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

Nonalcoholic fatty liver disease

Nonalcoholic fatty liver disease (NAFLD) is defined as the presence of hepatic steatosis (hepatic fat accumulation), on imaging or liver biopsy, in the absence of secondary causes for the fat accumulation (such as excessive alcohol consumption, hepatitis C, certain medications). NAFLD is closely associated with metabolic comorbidities, including obesity, diabetes, dyslipidemia, and hypertension, and is the most common cause of chronic liver disease worldwide.

NAFLD comprises a spectrum of disease spanning from isolated steatosis (sometimes called *nonalcoholic fatty liver* or NAFL) to more advanced liver disease such as nonalcoholic steatohepatitis (NASH) (Figure 1). NASH signifies steatosis with inflammation and hepatocyte injury and has a higher likelihood of progress to cirrhosis, liver failure, and occasionally liver cancer. Besides liver

disease, NAFLD is also closely associated with cardiovascular disease (CVD) and malignancy.

Epidemiology of NAFLD

The global prevalence of NAFLD is estimated at 25% according to a recent systematic review, with the highest prevalence reported in South America (31%) and the Middle East (32%) followed by Asia (27%), the United States (24%), Europe (23%), and Africa (14%). The largest datasets for these prevalence studies come from North America, Asia, and Europe, with lower numbers from the Middle East, Africa, and South America.

In the United States, the prevalence of NAFLD is highest in Hispanic Americans (22% to 45%), followed by non-Hispanic whites (15% to 33%) and blacks (13% to 24%). A significant contribution to this ethnic difference can be explained by genetic differences, particularly a single nucleotide polymorphism (SNP) in a gene (PNPLA3) that is involved in triglyceride (lipid) hydrolysis in the liver, and the ethnic prevalence that mirrors the ethnic differences in the frequency of NAFLD.

NAFLD prevalence increases with age, with a range from 22% to 30% from age 30 to a peak in the sixth decade. Very few studies report on NAFLD prevalence after age 70. Pediatric NAFLD is on the rise paralleling childhood obesity trends, but population data are scant, with estimated population prevalence of 7% to 8% in the United States. An autopsy study of 742 children (ages 2 to 19) who died of unnatural causes used liver histology as the gold standard and demonstrated a NAFLD prevalence of 9.6% adjusted for age, sex, race, and ethnicity. Pediatric obesity clinic studies have shown NAFLD prevalence of 34.2% in a meta-analysis. Differences in sex prevalence also exist, with some studies reporting the prevalence of NAFLD in men as almost double that of women.

Although the prevalence of alcohol and infectious hepatitis has remained stable, the prevalence of NAFLD has been rising in the global and US adult and pediatric population, growing in parallel with the epidemic of obesity and metabolic syndrome. From 2000 to 2015, the worldwide prevalence of NAFLD progressively increased from 20% to 27%. A recent study using data from the U.S. National Health and Nutrition Examination Survey found that NAFLD prevalence doubled between the survey periods of 1988–1994 and 2005–2008 from 5.5% to 11%.

In higher-risk populations such as patients with diabetes, the prevalence of NAFLD is higher, varying from 33% to 70%. In patients with morbid obesity attending bariatric surgery clinics, the prevalence of NAFLD has been reported at 95%.

Risk Factors for NAFLD

NAFLD is a complex disease that has genetic predispositions and is affected by various environmental factors. The degree of contribution of each of the risk factors requires further study and may vary depending on the region of the world.

NAFLD is regarded as the hepatic manifestation of the metabolic syndrome (presence of at least three of the following: abdominal obesity, hypertriglyceridemia, low high-density lipoprotein levels, hypertension, and high fasting glucose levels). Obesity (defined as waist circumference >102 cm in men or >88 cm in women or simplified to body mass index (BMI) ≥ 30) and diabetes are two of the primary associated risk factors for NAFLD. Underpinning the rising prevalence of these associated conditions and NAFLD are societal and individual trends in unhealthy eating habits (proliferation of high-caloric processed foods and diets with a high content of sugar, corn syrup, and fat) and decreased physical activity levels. The industrialization of food production, as well as deficiencies in neighborhood planning with poor walkability and public transport system availability, are partly to blame for this epidemic. Being overweight in childhood and adolescence, especially weight gain during school years, is a significant risk factor for development of NAFLD by late childhood and adulthood.

Several genetic risk factors have been reported, with non-synonymous SNPs in two genes in particular, PNPLA3 (patatin-like phospholipase domain-containing protein 3) and TM6SF2 (transmembrane 6 superfamily member 2), being the most

Figure 1 Histology of NAFLD. (A) Hepatic steatosis. Arrow points to macro-vesicular steatosis in Hepatocytes. (B) NASH. Arrow points to ballooned hepatocytes. Arrowhead points to lobular inflammation. (C) NASH with cirrhosis. Arrow points to fibrosis bands (collagen) trichrome stain.

consistently validated. The prevalence of the PNPLA3 SNP is highest in the Hispanic population and leads to the higher prevalence of NAFLD in this population. I148M PNPLA3 genetic mutation has consistently been shown to be the most common genetic determinant of NAFLD and correlates with hepatic steatosis, as well as severity of liver disease and risk of cirrhosis and liver cancer in NAFLD.

Heavy alcohol intake and obesity have been shown to act synergistically in increasing the risk of liver disease. The effect of more moderate alcohol consumption on NAFLD is unclear currently and will require more study of cumulative lifetime alcohol consumption. There are population data suggesting that low levels of alcohol use (1 or fewer drinks per day), wine in particular, may be associated with lower risk for development of NAFLD compared with those who drink more or do not drink at all. NASH, which has a higher chance of progression to fibrosis and cirrhosis, is independently associated with diabetes, age, BMI, as well as genetic polymorphisms in PNPLA3.

Pathophysiology of NAFLD

The hallmark finding of NAFLD is accumulation of triglyceride in the cytoplasm of hepatocytes. This is caused by an imbalance between lipid buildup (fatty acid uptake and *de novo* lipogenesis) and removal (mitochondrial fatty acid oxidation and export as a part of very low-density lipoprotein particles). Further factors contributing to transition from a healthy liver to NAFLD include adipose tissue dysfunction, hepatic insulin resistance, dysbiosis of the gut microbiome, toxic metabolites, and genetic factors (Figure 2).

Along with storage of triglycerides, adipose tissue is involved in the secretion of hormones, cytokines, and chemokines, called *adipokines*. Overnutrition and sedentary lifestyle cause obesity and adipose tissue dysfunction, which likely plays a pivotal role in the development of insulin resistance and NAFLD. Obesity results in excess free fatty acids entering the liver through the portal

circulation, which can increase lipid synthesis and gluconeogenesis. Increased levels of circulating free fatty acids also lead to peripheral insulin resistance, along with inflammation and induction of cytokine production, thereby contributing to NAFLD. In NASH, liver cell injury occurs (ballooning hepatocytes, inflammation) along with steatosis and varying degree of fibrosis.

Clinical Manifestations of NAFLD

NAFLD patients are typically symptom free until the condition progresses to cirrhosis. Early in the course of disease, it is often found incidentally on abdominal imaging including ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) (hepatic steatosis). Hepatomegaly may be the presenting symptom in some patients. Vague right upper abdominal discomfort, malaise, or fatigue can occur in patients with NASH but is very nonspecific.

The other common presentation of NAFLD is with elevation of liver enzymes, with mild to moderate elevations in aspartate aminotransferase (AST) and alanine aminotransferase (ALT). However, even advanced NAFLD can present with normal liver enzyme levels in up to 30% of individuals.

Patients with NAFLD frequently have comorbidities including hyperlipidemia, obesity, metabolic syndrome, hypertension, and type 2 diabetes mellitus. Associated conditions also include hypothyroidism, obstructive sleep apnea, and, less commonly, hypopituitarism, hypogonadism, polycystic ovarian syndrome, pancreaticoduodenal resection, and psoriasis among others.

In a community study of more than 7 years of follow-up from Minnesota, patients with NAFLD were shown to have excessive risk of mortality compared to population-based age- and sex-matched control subjects (SMR 1.34, 1.003-1.76). Given the commonality of risk factors for NAFLD and CVD, cardiac disease is the leading cause of death in these patients. A meta-analysis of observational studies also confirmed that the

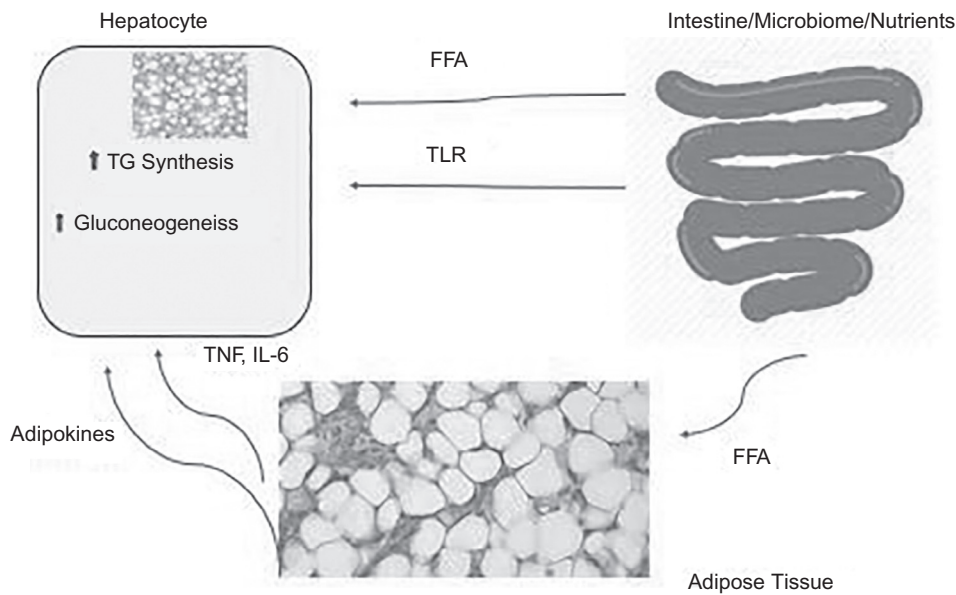

Figure 2 Pathophysiology of NAFLD. An interaction between intestine, adipose tissue and hepatocytes. *Abbreviations:* FFA = free fatty acids; TNF = tumor necrosis factor; IL = interleukin; TLR = toll-like receptor.

increased risk of CVD is NAFLD (odds ratio [OR] 1.64, 1.26–2.13) and in NASH as well (OR 2.58, 1.78–3.75). Obesity, diabetes, and metabolic syndrome are also risk factors for carcinogenesis, and a multitude of cancers are increased in patients with NAFLD, including liver cancer, breast cancer, kidney cancer, and colon cancer, among others. Liver disease mortality from cirrhosis and liver cancer is the third most common risk of death in these patients.

NAFLD is an increasingly common reason for decompensated cirrhosis and liver cancer. Over their lifetime 5% to 10% of patients with NAFLD progress to cirrhosis. Isolated hepatic steatosis without evidence of hepatocellular injury carries a minimal risk of progression to cirrhosis (<2%). NASH has a higher likelihood of progress to cirrhosis (5% to 12%), liver failure, and occasionally liver cancer. Patients who are older and have type 2 diabetes are at higher risk for progressing to NASH and fibrosis, and in these patients liver disease mortality predominates the clinical picture. Complications of cirrhosis, including variceal hemorrhage, ascites, hepatic encephalopathy and liver failure, can occur.

NAFLD is the second-most common cause of liver transplantation in the United States after chronic hepatitis C and is on track to becoming the most common indication by 2020. In the US general population NAFLD is already the most common reason for developing liver cancer, and the risk of developing liver cancer in patients with NAFLD related cirrhosis is 1% to 2% per year. Hepatocellular cancer (HCC) in NASH, as in most other chronic liver diseases, occurs predominantly in the setting of cirrhosis. Age, obesity, diabetes, and PNPLA3 I148M SNP are risk factors for HCC in these patients. NAFLD associated HCC is the third-most common cause of HCC in the United States, and the incidence of NAFLD-associated HCC is increasing the fastest by a 9% annual incidence rate compared with other causes of HCC.

Diagnosis of NAFLD (Figure 3)

The diagnosis of NAFLD is made by confirming the presence of hepatic steatosis on either imaging or liver biopsy, in the absence of alternative explanations for the steatosis. Diagnosing NAFLD based on elevated liver enzymes alone (without imaging or biopsy) is not recommended. Not *** are elevation of liver enzymes non-specific, but they are also frequently normal in patients with NAFLD including in those with advanced liver disease.

Alternate causes of steatosis that must be excluded before diagnosing NAFLD include the following:

- Alcohol excess (typically defined as greater than 21 standard drinks of alcohol per week in men and greater than 14 drinks per week in women)
- Hepatitis C infection
- Medications that cause steatosis (amiodarone [Pacerone], tamoxifen [Nolvadex], methotrexate [Trexall], diltiazem [Cardizem], prednisone)
- Hemochromatosis
- Wilson disease

These conditions are easily screened for by history and serologic studies (hepatitis C virus antibody, ferritin and iron saturation, serum ceruloplasmin and copper, and serum autoantibodies).

During serologic workup in patients with suspected NAFLD, it is common to find elevated ferritin, and this is due to NAFLD itself in the majority of cases. In patients with significantly elevated ferritin and transferrin saturation, serum testing for mutations in the hemochromatosis gene (HFE) should be performed, and if there are heterozygous or homozygous mutations in this gene, then a liver biopsy should be performed for iron quantification. It is also common to find autoantibodies in NAFLD that are often elevated in autoimmune hepatitis (ANA > 1:160, Antismooth muscle antibody > 1:40). These are often epiphenomena, but if the level of liver enzymes is significantly elevated (> 5 fold above normal), then a liver biopsy can be done to exclude autoimmune hepatitis.

NAFLD is usually diagnosed in one of two common scenarios:

- Patients with unsuspected hepatic steatosis detected on imaging done for other indications (Ultrasound or CT) or
- Patients with unexplained abnormal liver chemistries (liver enzymes). These patients should be assessed for associated metabolic risk factors (obesity, diabetes mellitus, or dyslipidemia).

Routine Screening for NAFLD in high-risk groups attending primary care, diabetes, or obesity clinics is not advised at this time, but there should be a high index of suspicion for NAFLD and NASH in patients with type 2 diabetes. This is primarily due to gaps in our knowledge regarding the natural history of NAFLD and treatment outcomes in NAFLD discovered by screening.

It is essential to emphasize that a diagnosis of NAFLD includes the determination of whether progressive liver disease, NASH, and

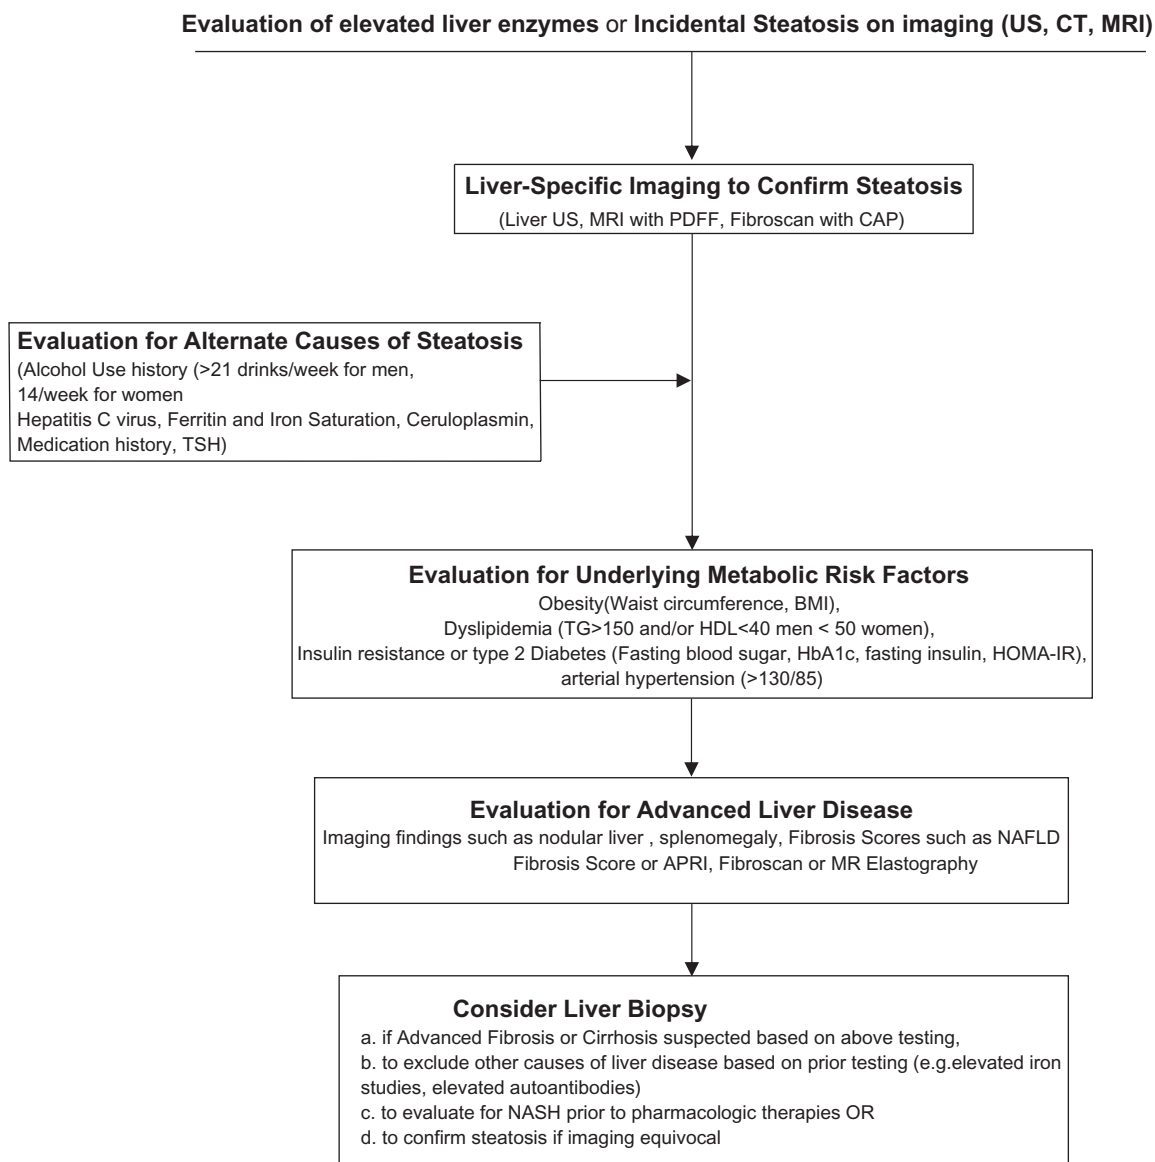

Figure 3 Diagnostic evaluation for suspected NAFLD. *Abbreviations:* US = ultrasound; PDFF = proton density fat fraction; CAP = controlled attenuation parameter; TG = triglyceride; HDL = high-density lipoprotein; HOMA-IR = homeostatic model assessment- insulin resistance; APRI = AST to platelet ratio index.

fibrosis, are present to tailor treatment and monitoring. The state of comorbidities including dyslipidemia, obesity, insulin resistance, diabetes, hypothyroidism, polycystic ovary syndrome, and sleep apnea is important to evaluate at the initial evaluation to recommend specific treatment for these associated disorders.

Role of Liver Biopsy in NAFLD

Currently, the gold standard for establishing a diagnosis of NAFLD and staging fibrosis is liver biopsy. In NAFLD liver histology typically shows steatosis graded as mild (<33% of hepatocytes involved), moderate 33% to 66% or severe (>66% steatosis). Other findings seen in NASH include lobular inflammation and hepatocyte ballooning indicative of hepatocyte injury, as well as varying degrees of fibrosis from none (stage 0) to cirrhosis (stage 4).

Although liver biopsy is not essential for diagnosing hepatic steatosis, liver biopsy should be considered in patients with NAFLD who are

At increased risk of having steatohepatitis (NASH) or advanced fibrosis because no serum or radiologic marker thus far can reliably differentiate NASH from isolated steatosis. Thus patients who are older (>50), have long-standing metabolic

syndrome, or have noninvasive scores that indicate advanced fibrosis (NAFLD or FIB-4 scores, or elevated liver stiffness measured by imaging techniques such as vibration-controlled transient elastography or MRE) may fall into this category.

Liver biopsy should also be considered when presence or severity of coexisting chronic liver diseases cannot be excluded without a liver biopsy. This may include patients with serum antibodies in whom coexistent autoimmune hepatitis cannot be excluded or patients with significantly elevated ferritin and iron saturation.

Despite the useful information obtained in some patients with NAFLD, liver biopsy has several limitations, including sampling error and intraobserver and interobserver variability in interpretation. It is costly and invasive and also carries risks including a mortality risk of up to 0.1% after the procedure, pain, intraperitoneal bleeding, bile leaks, and infection. As a result, it is not practical for screening millions of at-risk individuals or for frequent repeated assessments. Noninvasive approaches to diagnosis of NAFLD are thus widely used and include imaging of the liver, liver stiffness testing, and biological marker testing.

Noninvasive Testing in NAFLD

Hepatic Steatosis

Abnormal hepatic steatosis is defined by a liver fat content of $\geq 5\%$. The most accurate noninvasive method to quantify liver fat content is magnetic resonance spectroscopy. However, this modality requires special expertise, is time consuming to perform, and is not readily available clinically. A good alternative is MRI that uses proton density fat fraction (MRI-PDFF), which provides an accurate estimate of liver fat content, as well as spatial imaging of the liver. Conventional ultrasonography remains the most commonly used imaging modality to diagnose hepatic steatosis. It is wide availability and lower in cost than MRI, but it has limited accuracy, especially in obese individuals. It is not sensitive in detecting mild steatosis ($<33\%$) and is also less specific than MRI with fibrosis and iron, also resulting in similar findings.

Transient elastography-based techniques are increasingly used to diagnose steatosis and estimate the degree of hepatic fibrosis. Fat and fibrosis affects shear wave propagation through tissue, and this property can be used to measure liver attenuation (steatosis) and velocity (fibrosis) using a FibroScan machine. This machine uses an ultrasonic probe placed over the skin in the right upper quadrant to produce shear waves of 50 MHz that pass through the liver. Measurements of shear wave attenuation called *controlled attenuation parameter* assess for presence and grade of hepatic steatosis. Controlled attenuation parameter has been shown to be less accurate than MRI-PDFF in diagnosing steatosis, but it is cheaper and is a point-of-care quantitative modality.

Currently there are many widely available serum-based diagnostic panels for NAFLD that use a mix of serum tests and other demographic, anthropometric measures that are combined in single measurements for diagnosis of NAFLD. Examples include fatty liver index (triglycerides, BMI, γ -glutamyl transferase, waist circumference) and NAFLD Liver Fat Score (metabolic syndrome, type 2 diabetes mellitus, fasting insulin, alanine aminotransferase, aspartate aminotransferase). These panels have been found to have sensitivities and specificities in the 70% range and show reasonable accuracy for predicting steatosis. These tests are not as accurate as imaging or biopsy tests and therefore are less often used clinically and more often used as research tools in epidemiologic research.

Assessing Fibrosis

Fibrosis is highly correlated with outcomes in liver disease and a marker of worse outcomes. Fibrosis histologically is categorized (staged) as follows on liver biopsy:

- F0: no fibrosis
- F1: portal fibrosis without septa
- F2: portal fibrosis with few septa, extending outside of portal areas
- F3: bridging fibrosis or numerous septa without cirrhosis
- F4: cirrhosis

F3 and F4 are categorized as advanced fibrosis and F0-F1 are considered none-minimal fibrosis.

Clinical decision aids such as *NAFLD fibrosis score* (<https://www.mdcalc.com/nafl-d-non-alcoholic-fatty-liver-disease-fibrosis-score>) (biomarkers evaluated: age, glucose level, BMI, platelet count, albumin, and AST/ALT ratio) or *fibrosis-4 index* (<https://www.mdcalc.com/fibrosis-4-fib-4-index-liver-fibrosis>) (FIB-4: biomarkers measured include age, AST, platelet count, ALT) use a combination of serum and clinical variables to predict the presence of advanced fibrosis or cirrhosis. These tests are most useful in distinguishing patients who may have advanced fibrosis from those without fibrosis and thus may aid in clinical decision making including whether to perform a liver biopsy or make a referral to a liver specialist (in patients with test indicating advanced fibrosis).

Imaging-based techniques such as vibration-controlled transient elastography (FibroScan) or MRI-based elastography can be used to identify those at low or high risk for advanced fibrosis (bridging fibrosis or cirrhosis) with more accuracy than serum-based markers. The drawbacks to these methods include cost and

TABLE 1 Therapy of NAFLD

Assessment of steatosis versus more advanced liver disease (NASH, fibrosis)
Consider pharmacotherapy or investigational agents for more advanced liver disease in addition to lifestyle modifications

Lifestyle modifications aimed at weight loss

Goals

Lose 7% to 10% of body weight

Gradual weight loss, no more than 2 lbs per week till at goal

Diet changes

Reduce calories by 30% (750–100 kcal/day), reduce simple sugars, decrease saturated fat, reduce sugar sweetened beverages and foods including fructose enriched foods

Exercise

150–200 minutes per week spaced over 5 days; moderate to vigorous intensity (e.g., jogging, playing tennis, swimming laps, biking)

Treatment of associated metabolic factors as per best practices

Diabetes

No particular agent proven beneficial as primary treatment for NAFLD although pioglitazone (Actos)¹ may benefit histologic NASH. Causes weight gain

Metformin (Glucophage)¹ no proven benefit for NASH

Insulin can cause weight gain and insulin resistance associated with NASH

Dyslipidemia

Treat per standard guidelines

Statins are safe to use if indicated (except in decompensated cirrhosis)

Pharmacotherapy for NASH

Pioglitazone¹

Histologic benefits in diabetic and non-diabetic NASH except for fibrosis

Can cause weight gain

Vitamin E⁷

Histologic benefits in non-diabetic NASH except for fibrosis

Concerns for long term use: small risk in all-cause mortality, increase risk of prostate cancer

Investigational trials (generally for biopsy proven NASH)

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

availability (MRE) and limited utility in obesity, ascites, and acute inflammation (FibroScan). However FibroScan is increasingly available and widely used at point of care in liver clinics for fibrosis assessment.

Therapy of NAFLD (Table 1)

Treatment of NAFLD entails treatment of the liver disease, as well as of the associated metabolic syndrome (obesity, diabetes, hyperlipidemia and hypertension).

Lifestyle Modifications in NAFLD

Lifestyle modifications are integral in the treatment of NAFLD at any stage and are the principal intervention for patients with isolated steatosis and NASH without fibrosis. Patients are advised to lose $\geq 7\%$ of body weight if overweight or obese (3–5% weight loss will improve steatosis, 7–10% is needed to improve histopathologic features of NASH and fibrosis).

This weight loss is best achieved gradually (losing no more than 1 to 2 lbs per week) and sustained through a combination of diet and exercise.

Basic principles of diet include reducing calories (by at least 30% or by 750–1000 kcal/day for an average US adult) and reducing consumption of simple carbohydrates and saturated fat. Reduction of sugar-sweetened beverages and of fructose-enriched food and drinks is recommended. In general, using fresh fruits and vegetable and lean meats and minimizing processed foods is recommended. Although many different diets have been studied and shown to be beneficial (Mediterranean diet), studies have also shown that any

diet that follows the basic principle noted above and results in weight loss achieves the benefits of reversing NASH.

Significant alcohol use can exacerbate steatohepatitis, and limiting consumption of alcohol (≤ 1 drink/day for women and ≤ 2 drinks/day for men) is recommended.

A preponderance of epidemiologic data also shows that consumption of coffee (2 or more cups) per day is associated with reduced prevalence of NAFLD. If coffee is consumed, it should be caffeinated; addition of sweetened syrups, sugar, and large servings of milk/other calories may negate any beneficial effects.

Recommendations for physical activity include at least 150 to 200 minutes of moderate- to vigorous-intensity physical activity per week (examples are moderate jogging, weight training, sports such as tennis, swimming, or biking). For patients who do not exercise, a gradual buildup to this level is recommended. Limited data suggest that the combination of diet and exercise may be more beneficial than either in isolation.

Pharmacotherapeutics in NAFLD

Currently there are no pharmacologic agents that have an FDA indication specifically for NAFLD or NASH. There are, however, pharmacologic treatments aimed at different components of metabolic syndrome that can be used off label for NAFLD-related liver disease based on controlled trials studies and published guidelines. These agents, when used for NAFLD, should generally be limited to those with biopsy-proven NASH and fibrosis.

Pioglitazone (Actos)¹ is an insulin-sensitizing agent used in diabetes (PPAR Gamma agonist) and can be used to treat patients with and without type 2 diabetes with biopsy-proven NASH. It has been shown to improve histologic changes in NASH, including steatosis, ballooning, and inflammation but not fibrosis. For nondiabetic adults with biopsy-proven NASH, vitamin E² administered at a daily dose of 800 IU/day can be used as well and can cause similar histologic improvements as pioglitazone.

It must be noted that trials of these agents in NASH were generally limited to 24 months or less, and longer-term benefits are not known. Consideration to side effects must also be given; pioglitazone can cause weight gain, has been associated with osteoporosis, and has been known to exacerbate heart failure in susceptible individuals. Vitamin E has some concerns regarding increased all-cause mortality, potentially small increased risk of hemorrhagic stroke, and, in a large trial, increased risk of prostate cancer.

Patients with NAFLD are at high risk for cardiovascular morbidity and mortality, and aggressive modification of CVD risk factors should be considered in all patients with NAFLD. Statins can be used to treat dyslipidemia in patients with NAFLD, NASH, and NASH cirrhosis, but they should be avoided in patients with decompensated cirrhosis.

Currently, the following drugs are not recommended as specific treatment for NAFLD because they have shown no specific benefit for NASH: metformin (Glucophage) and GLP-1 agonists are agents that can be used for diabetes, including in patients with NAFLD; however, they have no beneficial effects specifically on NASH, although trials with GLP-1 agonists are ongoing; ursodeoxycholic acid (ursodiol [Actigall])³ and omega-3 fatty acids⁴ (can consider for hypertriglyceridemia concurrent with NAFLD) do not specifically improve NAFLD.

There are numerous pharmacologic agents in phase 1 and phase 2 trials and a few in phase 3 trials for NAFLD. Some of these agents work on glucose or lipid metabolism in the liver, whereas others are antifibrotic or antioxidant. Obeticholic acid (Ocaliva)⁵ and elafibranor⁶ are two compounds that show promise and are undergoing phase 3 registration trials. More safety and efficacy data are needed before they can be recommended.

Foregut bariatric surgery can be considered in otherwise eligible obese individuals with NAFLD or NASH, although it is not an established option to treat NASH specifically. Case series have shown improvement in histologic markers of NASH in patients after bariatric surgery.

Prevention of NAFLD

Prevention of NAFLD is imperative and is a societal challenge that should focus on reducing obesity and the metabolic syndrome. Early education and focus on healthy nutrition and childhood physical activity are key initiatives, as are neighborhood planning for improving access to healthy foods and healthy spaces.

Monitoring of NAFLD

Patients with NASH, especially those with significant fibrosis, are at the greatest risk for increased progression to cirrhosis and mortality. Patients with NASH and F0 or F1 fibrosis are monitored annually for liver disease progression via blood work (liver enzymes and function tests, platelet counts) and physical examinations. Evaluation of fibrosis progression in these patients through repeat liver biopsy or noninvasive testing such as FibroScan or MR elastography can be done approximately 5 years after diagnosis; however, with high interindividual variation in fibrosis progression, the timeline of testing is tailored to each individual.

For patients with more advanced fibrosis (F2 or higher) at NASH diagnosis, severity of the fibrosis governs the management. Once F3 or F4 fibrosis occurs, the risk of liver-related illness and death increases significantly, making closer follow-up appropriate.

Patients with NASH cirrhosis should be screened for gastroesophageal varices (upper endoscopy) and considered for hepatocellular carcinoma screening (guidelines from the American Association for the Study of Liver Diseases recommend ultrasound of the liver and serum alpha-fetoprotein measurements every 6 months).

PANCREATIC CANCER

Method of

Robert S. Freelove, MD

Epidemiology

Cancer of the exocrine pancreas is the fourth-leading cause of cancer death in both men and women in the United States in spite of being only the 12th-leading cause of cancer. This is primarily because the majority of pancreatic cancers are diagnosed at an advanced stage, with a 5-year survival rate of only 3%. The incidence increases steeply with age but rarely occurs in people younger than 45. It affects men 1.3 times more than women and is seen more in black patients than in other races.

¹Not FDA approved for this indication.

PANCREATIC CANCER

Method of

Robert S. Freelove, MD

Epidemiology

Cancer of the exocrine pancreas is the fourth-leading cause of cancer death in both men and women in the United States in spite of being only the 12th-leading cause of cancer. This is primarily because the majority of pancreatic cancers are diagnosed at an advanced stage, with a 5-year survival rate of only 3%. The incidence increases steeply with age but rarely occurs in people younger than 45. It affects men 1.3 times more than women and is seen more in black patients than in other races.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

⁷Available as a dietary supplement.

Risk Factors

Risk factors can be divided into hereditary and nonhereditary categories. The defined hereditary syndromes that increase risk include hereditary pancreatitis, Peutz-Jeghers syndrome, hereditary nonpolyposis colon cancer, familial atypical multiple mole melanoma syndrome, and carrying BRCA1, BRCA2, or both genes. Non-O blood types are at increased risk for developing pancreatic cancer. Pancreatic cancer in a first-degree relative also increases risk, although a genetic basis has not been determined. Risk increases significantly with each first-degree relative affected, and familial pancreatic cancer occurs when pancreatic cancer is diagnosed in more than one first-degree relative.

Nonhereditary risk factors include chronic pancreatitis, diabetes mellitus, cigarette smoking, obesity, and physical inactivity; all independently increase the risk of developing pancreatic cancer.

Screening

No effective screening mechanism exists for early diagnosis of pancreatic cancer in asymptomatic adults at average risk. The United States Preventive Services Task Force gives screening for pancreatic cancer a grade D recommendation, recommending specifically against screening symptom-free adults using palpation, ultrasonography, or serologic markers. Although it is believed that adults with significant hereditary risk factors should receive screening, there is no clear guidance on when to initiate screening or the interval at which to perform repeat screening. There is also no strong evidence for which modality to use, although most experts suggest screening should be done with either endoscopic ultrasound scanning or magnetic resonance cholangiopancreatography (MRCP).

Clinical Presentation

Overall, the most common clinical findings at diagnosis are jaundice, vague abdominal pain, weight loss, and hepatomegaly. Other signs and symptoms that can be present include back pain, diarrhea, steatorrhea, vomiting, right upper quadrant or epigastric mass, ascites, weakness, malaise, fatigue, and dark urine. Migratory thrombophlebitis (Trousseau's sign) and presence of a nontender, palpably distended gallbladder (Courvoisier's sign) occur less commonly but are strongly linked to pancreatic cancer when present.

Tumor size and location within the pancreas, as well as existence and location of metastases determine which of those clinical features mentioned above are present. Approximately 70% of pancreatic cancers arise in the head of the pancreas, causing biliary obstruction and leading to jaundice from conjugated hyperbilirubinemia, weight loss, steatorrhea, and dark urine. Another 25% of tumors occur in the body or tail, and the remaining 5% involve the entire pancreas. These tumors are insidious and usually present with only nonspecific findings such as unintentional weight loss, anorexia, fatigue, generalized weakness, nausea, and dyspepsia.

Diagnosis

A thorough history and physical examination are insufficient for diagnosing pancreatic cancer but can raise suspicion and influence further workup. The imaging modality of choice is a triphasic, contrast-enhanced helical computed tomography (CT) scanning of the abdomen and should be the preferred initial imaging test for patients presenting with abdominal pain and weight loss. A transabdominal ultrasound scan may be ordered initially based on the patient's presentation. In those patients strongly suspected of having pancreatic cancer, CT scanning is indicated if the ultrasound scan is negative. Endoscopic ultrasound-guided fine-needle aspiration can usually be used for a histologic diagnosis. There are no specific serologic tests that are helpful in diagnosing pancreatic cancer, but general serologic testing appropriate for the patient's presentation should be undertaken. The serum tumor marker carbohydrate antigen 19-9 (CA 19-9) can be used for monitoring response to treatment but has no diagnostic value.

Staging

Staging of pancreatic cancer can generally be accomplished through CT scanning. Endoscopic ultrasound scanning may provide more information for smaller tumors in the head of the pancreas and in predicting vascular invasion if not clear on CT. If metastasis is strongly suspected but not confirmed by imaging studies, staging laparoscopy can be performed.

Staging of pancreatic cancer categorizes tumors as resectable or unresectable. Extensive vascular involvement, direct invasion into adjacent organs, and distal metastasis all make tumors unresectable.

Treatment

The only potentially curative treatment for pancreatic cancer is surgical resection. Only 15% to 20% of patients diagnosed with pancreatic cancer are candidates for resection, which has a 10% to 30% 5-year survival rate. Factors that influence postresection survival rates include histology, tumor size, adequacy of the resection, and presence of positive lymph nodes. Pancreaticoduodenectomy (Whipple procedure) is still performed on tumors of the head and neck of the pancreas. Variations in surgical technique meant to have less morbidity have not shown a significant difference in outcome. Once plagued with high death rate, the perioperative mortality rate has declined significantly to only 4% as outcomes have improved at centers where surgeons perform a higher volume of procedures. Distal pancreatectomy and splenectomy is performed for resectable lesions in the body or tail of the pancreas. The addition of postoperative adjuvant chemotherapy has been shown to add a few months to survival.

Treatment of unresectable pancreatic cancer may improve survival slightly but is primarily aimed at palliation. There is no curative treatment for unresectable lesions, and treatment decisions must be weighed against patient preferences, symptoms, and goals of care. If a patient with unresectable disease desires treatment, enrollment in a clinical trial of chemotherapeutic agents is preferred. For those not able to be enrolled in a clinical trial, there are chemotherapy protocols for both locally advanced disease and metastatic disease. The choice of which regimen depends on functional status, comorbid conditions, and serum bilirubin levels.

Palliative Care

Given the high mortality and likelihood of developing significant complications, physicians should perform a full assessment of psychological status, end-of-life care wishes, symptom burden, and existing social support systems for all patients with a new diagnosis of pancreatic cancer. Early intervention with palliative services should occur, as evidence shows an improved quality of life and a reduction in aggressiveness of end-of-life care as measured by provision of chemotherapy within 14 days of death, admission to the intensive care unit or hospital near death, and visits to the emergency department. Hospice services should be discussed with patients soon after the diagnosis, and consultation should be made as soon as appropriate to maximize the hospice benefit.

Pain is one of the most common symptoms that needs to be addressed in patients with advanced pancreatic cancer. Opioid analgesics are commonly used, and the type and nature of the pain should be clearly assessed to determine whether adjuvant medications for neuropathic pain could be helpful. Radiation therapy can be beneficial for pain, especially from bony metastases. Celiac plexus neurolysis performed percutaneously, during surgery, or under endoscopic ultrasound guidance can be more effective than pharmacologic therapy and avoids opioid-related complications such as sedation and constipation.

Biliary obstruction and resultant jaundice occurs commonly. Palliation of jaundice is primarily accomplished through endoscopic placement of a bare metal stent because it is less invasive than surgical intervention. However, surgical bypass of the biliary obstruction can be performed if endoscopic intervention is

technically impossible. Gastric outlet obstruction also can occur and is treated in similar fashion with either expandable metal stents or surgical bypass.

Weight loss and malnutrition can be severe. In addition to managing gastric outlet and biliary obstruction, physicians must address pancreatic exocrine insufficiency, as it is another significant contributor. Oral pancreatic enzyme replacement should be initiated empirically with doses of 10,000 international units of pancreatic lipase (Creon)¹ taken at the beginning, middle, and end of each meal. High-calorie or calorie-dense diets and nutritional supplements should be recommended over appetite stimulants because the stimulants increase risk for thromboembolic disease.

Patients with pancreatic cancer have a higher incidence of venous thromboembolism (VTE) than other cancers, and patients should know the signs and symptoms. Primary prophylaxis in ambulatory patients is not recommended, but low-molecular-weight heparin prophylaxis should be provided to hospitalized patients who are not at increased risk of bleeding complications. Long-term treatment with low-molecular-weight heparin in patients with pancreatic cancer and VTE has been shown to reduce incidence of VTE with no difference in survival or bleeding outcomes over warfarin (Coumadin). As such, long-term low-molecular-weight heparin should be considered over warfarin as treatment for VTE, especially if the patient is on drugs that affect warfarin metabolism.

¹Not FDA approved for this indication.

TUMORS OF THE COLON AND RECTUM

Method of

Pinckney J. Maxwell, IV, MD; and Gerald A. Isenberg, MD

CURRENT DIAGNOSIS

- Screening of asymptomatic, average-risk patients should begin at 50 years of age.
- Colonoscopy should be performed if any screening test result is positive.
- Colonoscopy should be performed for any patient with signs or symptoms of colorectal cancer.
- Screening of high-risk patients—those with inflammatory bowel disease, familial adenomatous polyposis, or hereditary nonpolyposis colorectal cancer) and those with a significant positive family history—should begin at an earlier age and occur more frequently.

CURRENT THERAPY

- Patients with familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer should undergo early, prophylactic colon resection.
- Colon tumors should be treated with segmental laparoscopic or open resection.
- Chemotherapy is offered for colon cancers with locally advanced, nodal (stage III), or metastatic (stage IV) disease.
- Rectal tumors that are small (<3 cm), involve <25% of the rectal circumference, are superficial (Tis or T1), lack nodal involvement, and have favorable pathologic characteristics should be removed by transanal techniques.
- Rectal tumors that are larger, are locally invasive, or have nodal involvement should be removed by formal open resection, with sphincter preservation if possible.
- Combination chemotherapy and radiation therapy is offered for advanced (stage II), nodal (stage III), or metastatic (stage IV) rectal cancer.
- Postoperative surveillance includes frequent office evaluations, measurements of carcinoembryonic antigen, endoscopy, and imaging.

Background, Epidemiology, and Etiology

Colorectal cancer is the third most common cancer in men and women, after prostate and lung/bronchus cancer in men and breast and lung/bronchus cancer in women. The American Cancer Society estimates that there will be 102,900 new diagnoses of colon cancer and 39,670 new diagnoses of rectal cancer in the United States in 2010. The incidence of colorectal cancer has been decreasing since the mid-1980s, with a more dramatic decrease occurring in the most recent decade. This decrease is likely related to an increase in screening with removal of precancerous polyps. The American Cancer Society expects an estimated 51,370 deaths from colorectal cancer in 2010, accounting for 9% of all cancer deaths. The mortality rate of colorectal cancer has similarly decreased since the mid-1980s, again with a sharper decline in the past decade most likely related to improved screening. Colorectal cancer is a highly treatable and frequently curable malignancy when it is detected early, highlighting the need for better screening.

The development of colorectal cancer is related to a number of factors, including age, diet, activity, environmental exposures, family history, and genetics. Ninety percent of colorectal cancers are diagnosed after the age of 50 years, and fewer than 5% of cases are diagnosed before the age of 40. The peak incidence of diagnosis is in the seventh decade of life. Dietary factors play a role in carcinogenesis. Western diets, containing high fat and low fiber, have been associated with increased rates of colorectal cancer, as has the intake of red or processed meats and alcohol. It is likely that the low-fiber Western diet slows transit time, leading to increased exposure to carcinogens. Activity level also can play a role in carcinogenesis: studies have shown an increase in cancer among those with sedentary jobs and a decreased incidence among those who exercise regularly. Exposure to cigarette smoke increases the risk of colorectal adenomas and cancers. The American Cancer Society Cancer Prevention Study II revealed that 12% of colorectal cancer deaths in the general U.S. population can be attributed to smoking. Family history and genetics also play a significant role in carcinogenesis, because approximately 10% of patients diagnosed have a first-degree relative with colorectal cancer.

Adenomatous Polyps

The progression from normal mucosa to an adenomatous polyp and then to an invasive colorectal cancer proceeds through a well-defined process over many years. Aberrant crypt foci develop into microadenomas and then into adenomatous polyps. Dysplastic cells develop within the polyp, continue to multiply, become a tumor and then break through the subepithelial barrier and invade

technically impossible. Gastric outlet obstruction also can occur and is treated in similar fashion with either expandable metal stents or surgical bypass.

Weight loss and malnutrition can be severe. In addition to managing gastric outlet and biliary obstruction, physicians must address pancreatic exocrine insufficiency, as it is another significant contributor. Oral pancreatic enzyme replacement should be initiated empirically with doses of 10,000 international units of pancreatic lipase (Creon)¹ taken at the beginning, middle, and end of each meal. High-calorie or calorie-dense diets and nutritional supplements should be recommended over appetite stimulants because the stimulants increase risk for thromboembolic disease.

Patients with pancreatic cancer have a higher incidence of venous thromboembolism (VTE) than other cancers, and patients should know the signs and symptoms. Primary prophylaxis in ambulatory patients is not recommended, but low-molecular-weight heparin prophylaxis should be provided to hospitalized patients who are not at increased risk of bleeding complications. Long-term treatment with low-molecular-weight heparin in patients with pancreatic cancer and VTE has been shown to reduce incidence of VTE with no difference in survival or bleeding outcomes over warfarin (Coumadin). As such, long-term low-molecular-weight heparin should be considered over warfarin as treatment for VTE, especially if the patient is on drugs that affect warfarin metabolism.

¹Not FDA approved for this indication.

TUMORS OF THE COLON AND RECTUM

Method of

Pinckney J. Maxwell, IV, MD; and Gerald A. Isenberg, MD

CURRENT DIAGNOSIS

- Screening of asymptomatic, average-risk patients should begin at 50 years of age.
- Colonoscopy should be performed if any screening test result is positive.
- Colonoscopy should be performed for any patient with signs or symptoms of colorectal cancer.
- Screening of high-risk patients—those with inflammatory bowel disease, familial adenomatous polyposis, or hereditary nonpolyposis colorectal cancer) and those with a significant positive family history—should begin at an earlier age and occur more frequently.

CURRENT THERAPY

- Patients with familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer should undergo early, prophylactic colon resection.
- Colon tumors should be treated with segmental laparoscopic or open resection.
- Chemotherapy is offered for colon cancers with locally advanced, nodal (stage III), or metastatic (stage IV) disease.
- Rectal tumors that are small (<3 cm), involve <25% of the rectal circumference, are superficial (Tis or T1), lack nodal involvement, and have favorable pathologic characteristics should be removed by transanal techniques.
- Rectal tumors that are larger, are locally invasive, or have nodal involvement should be removed by formal open resection, with sphincter preservation if possible.
- Combination chemotherapy and radiation therapy is offered for advanced (stage II), nodal (stage III), or metastatic (stage IV) rectal cancer.
- Postoperative surveillance includes frequent office evaluations, measurements of carcinoembryonic antigen, endoscopy, and imaging.

Background, Epidemiology, and Etiology

Colorectal cancer is the third most common cancer in men and women, after prostate and lung/bronchus cancer in men and breast and lung/bronchus cancer in women. The American Cancer Society estimates that there will be 102,900 new diagnoses of colon cancer and 39,670 new diagnoses of rectal cancer in the United States in 2010. The incidence of colorectal cancer has been decreasing since the mid-1980s, with a more dramatic decrease occurring in the most recent decade. This decrease is likely related to an increase in screening with removal of precancerous polyps. The American Cancer Society expects an estimated 51,370 deaths from colorectal cancer in 2010, accounting for 9% of all cancer deaths. The mortality rate of colorectal cancer has similarly decreased since the mid-1980s, again with a sharper decline in the past decade most likely related to improved screening. Colorectal cancer is a highly treatable and frequently curable malignancy when it is detected early, highlighting the need for better screening.

The development of colorectal cancer is related to a number of factors, including age, diet, activity, environmental exposures, family history, and genetics. Ninety percent of colorectal cancers are diagnosed after the age of 50 years, and fewer than 5% of cases are diagnosed before the age of 40. The peak incidence of diagnosis is in the seventh decade of life. Dietary factors play a role in carcinogenesis. Western diets, containing high fat and low fiber, have been associated with increased rates of colorectal cancer, as has the intake of red or processed meats and alcohol. It is likely that the low-fiber Western diet slows transit time, leading to increased exposure to carcinogens. Activity level also can play a role in carcinogenesis: studies have shown an increase in cancer among those with sedentary jobs and a decreased incidence among those who exercise regularly. Exposure to cigarette smoke increases the risk of colorectal adenomas and cancers. The American Cancer Society Cancer Prevention Study II revealed that 12% of colorectal cancer deaths in the general U.S. population can be attributed to smoking. Family history and genetics also play a significant role in carcinogenesis, because approximately 10% of patients diagnosed have a first-degree relative with colorectal cancer.

Adenomatous Polyps

The progression from normal mucosa to an adenomatous polyp and then to an invasive colorectal cancer proceeds through a well-defined process over many years. Aberrant crypt foci develop into microadenomas and then into adenomatous polyps. Dysplastic cells develop within the polyp, continue to multiply, become a tumor and then break through the subepithelial barrier and invade

Figure 1 Sequence of progression from adenoma to carcinoma.

the layers of the bowel wall, eventually spreading to pericolic tissues or to lymph nodes and distant sites. A number of genes have been implicated in carcinogenesis, including protooncogenes (*KRAS*, *SRC*, *MYC*), tumor-suppressor genes (*APC*, *DCC*, *TP53*, *MCC*, *DPC4*), and DNA-mismatch repair genes (*HMSH2*, *MLH1*, *PMS1*, *PMS2*, *GTBP*). Sporadic colorectal cancers develop as a result of several cumulative genetic insults involving these genes (Figure 1).

Familial Colorectal Cancer Syndromes

Familial adenomatous polyposis (FAP) is an inherited, non-sex-linked, mendelian dominant disease that accounts for approximately 1% of all colorectal cancers. The high penetrance of FAP means that there is a 50% chance of development of colorectal cancer among members of affected families. However, 20% of FAP patients have no family history, and their cases most likely represent new, spontaneous mutations. The disorder is caused by mutations in the tumor-suppressor *APC* gene, which is located on chromosome 5 (5q21–q22), or in the *MUTYH* gene, which is located on chromosome 1 (1p34.3–p32.1). FAP is characterized by the progressive development of hundreds or thousands of adenomatous polyps located throughout the entire colon. The clinical diagnosis is based on histologic confirmation of at least 100 adenomas. All patients eventually develop colorectal cancer. The adenomas typically appear by the mid-twenties, and cancers by the late thirties.

An attenuated form of FAP is recognized in which fewer adenomas (20–100) are identified. Adenomas and cancers develop somewhat later, at average ages of 44 and 56 years, respectively. FAP also exhibits extracolonic manifestations, including gastric, duodenal, and small-bowel polyps; osteomas and desmoid tumors (Gardner's syndrome); eye lesions (congenital hypertrophy of retinal pigment epithelium [CHRPE]); epidermoid cysts; and brain neoplasms (Turcot's syndrome).

Hereditary nonpolyposis colon cancer (HNPCC), also called Lynch syndrome, is an inherited, non-sex-linked, mendelian dominant disease with virtually complete penetrance. HNPCC is caused by a defect in any of a number of DNA-mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS1*, *PMS2*) that leads to high-level microsatellite instability (MSI-H). A number of criteria have been generated for the diagnosis of HNPCC, including the Amsterdam I and II criteria and the Bethesda guidelines (Box 1). According to the EPICOLON study, the revised Bethesda guidelines are the most discriminating set of clinical parameters for diagnosis of HNPCC.

HNPCC is subdivided into Lynch syndrome types I and II. Lynch type I refers to site-specific nonpolyposis colon cancer, and Lynch type II (formerly called familial cancer syndrome) refers to cancers that develop in the colon and related organs such as the endometrium, ovaries, stomach, pancreas, and proximal urinary tract, among others. Lynch syndrome differs from sporadic colorectal cancer in a number of important ways. It has an autosomal dominant inheritance, a predominance of proximal lesions (75% are found in the right colon), an excess of multiple primary colorectal cancers (18%), an early age at onset (average, 44 years), a significantly improved survival rate with right-sided lesions (53% at 5 years, compared with 35% for distal colorectal cancer in family members), and an increased risk for development of metachronous lesions (24%). Patients and family members of those diagnosed with HNPCC or FAP should undergo genetic testing to help improve future diagnosis and treatment options.

BOX 1

Diagnosis of Hereditary Nonpolyposis Colon Cancer (HNPCC)

Amsterdam I Criteria, 1990

- Three or more family members with histologically verified colorectal cancer, one of whom is a first-degree relative (parent, child, sibling) of the other two
- Two successive affected generations
- One or more colon cancers diagnosed before age 50 years
- Familial adenomatous polyposis has been excluded.

Amsterdam II Criteria, 1999

- Three or more family members with histologically verified HNPCC-related cancers (endometrium, ovary, stomach, small intestine, hepatobiliary, upper urinary tract, brain, or skin), one of whom is a first-degree relative (parent, child, sibling) of the other two
- Two successive affected generations
- One or more colon cancers diagnosed before age 50 years
- Familial adenomatous polyposis has been excluded.

Revised Bethesda Guidelines, 2002

- Colorectal cancer diagnosed in a patient who is younger than 50 years of age
- Presence of a synchronous, metachronous colorectal or other HNPCC-related malignancy, regardless of age
- Colorectal cancer with the high-level microsatellite instability (MSI-H) histology diagnosed in a patient who is younger than 60 years of age
 - Presence of carcinoma infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern
 - No general consensus based on this age
- Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related neoplasm
 - With one or more neoplasms being diagnosed before age 50 years
- Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related malignancies, regardless of age

Inflammatory Bowel Disease

Both Crohn's disease and ulcerative colitis are associated with an increased risk of colorectal cancer; with the latter conferring approximately double the risk of the former. The duration and severity of Crohn's disease and the duration and extent (left-sided colitis versus pancolitis) of ulcerative colitis contribute to cancer risk in patients with inflammatory bowel disease. Cancer in Crohn's disease typically occurs in a stricture or bypassed segment. Neoplasia in ulcerative colitis does not follow the adenoma-carcinoma development sequence seen in sporadic colorectal cancer, and this has important screening and treatment implications.

Evaluation

Screening Average-Risk Patients

Patients with no personal history of colorectal polyps or cancers, no personal history of inflammatory bowel disease, no symptoms suspicious for colorectal cancer, no family history of colorectal polyps or cancers, and no evidence of a familial or genetic

syndrome may be screened as having average risk. The two main categories of screening tests are those that detect adenomatous polyps and cancers (flexible sigmoidoscopy, colonoscopy, double-contrast barium enema, and computed tomographic [CT] colonography) and those that primarily detect cancer (fecal occult blood testing, fecal immunohistochemical testing, and stool DNA testing). The goal of screening is to reduce mortality rates by reducing the incidence of advanced disease. It seems intuitive that tests that detect polyps, the premalignant phase of colorectal cancer, would be preferred to tests that detect only cancers. However, testing for polyps and cancers is usually procedure related, whereas testing for only cancers can be conducted on stool samples alone. Screening with simple stool samples has the potential to more easily increase overall screening.

Regardless of the method used, testing in the average-risk, symptom-patient should begin at age 50 years. A total colonoscopy is required only every 10 years but involves oral bowel preparation and carries a small risk of perforation (approximately 1/1000). A flexible sigmoidoscopy is required every 5 years, in combination with annual fecal occult blood testing. Flexible sigmoidoscopy requires only enemas for preparation and carries a lower risk of perforation. Air-contrast barium enemas may be used for screening every 5 years, but they also require oral bowel preparation and are only diagnostic. CT colonography is an evolving method for screening every 5 years and offers the opportunity for more accessible screening; however, the procedure is limited in regard to identification of polyps smaller than 1 cm, also requires oral bowel preparation, and is only diagnostic. Fecal occult blood testing and fecal immunohistochemical testing are done annually. The interval for stool DNA testing is uncertain, and it tests only for a limited number of mutations. The most complete screening test, which

allows removal of any precancerous lesions that are identified, remains the total colonoscopy.

Screening High-Risk Patients

High-risk patients include those with a personal history of colorectal polyps or cancers, a family history of colorectal cancer in a first-degree relative, Crohn's disease or ulcerative colitis, or a personal or family history of FAP or HNPCC. Screening in these patients has been adjusted for changes in incidence and age at onset of neoplasia (Table 1).

Symptoms and Diagnosis

Symptoms of colorectal cancer include bleeding (85%), a change in bowel habits, abdominal pain, malaise, and obstruction. Frequently, anemia is the only sign a patient exhibits. Patients with symptoms suspicious for colorectal cancer should undergo a colonoscopy. An anorectal source of bleeding should not preclude a complete colonic evaluation.

Management

Preoperative Management

Before operative intervention is undertaken, a complete evaluation should occur, including a careful history and physical examination, routine laboratory testing, and measurement of the level of carcinoembryonic antigen. A complete evaluation of the colon is essential, including colonoscopy with biopsy, or barium enema or CT colonography if colonoscopy is incomplete. Bowel preparation is no longer indicated as a routine preoperative measure for colonic surgery.

Preoperative staging should be undertaken for colorectal cancers. CT scanning of the abdomen and pelvis are indicated to aid

TABLE 1 Screening High-Risk Patients for Colorectal Cancer

RISK CATEGORY	AGE TO BEGIN	RECOMMENDED TEST	COMMENT
Personal history of <3 adenomas with low-grade dysplasia	5–10 y after the initial polypectomy	Colonoscopy	Examination interval should be based on other clinical factors, such as prior findings, family history, or endoscopist or patient preference.
Personal history of 3–10 adenomas, or 1 adenoma >1 cm, or any adenoma with villous features or high-grade dysplasia	3 y after the initial polypectomy	Colonoscopy	Adenomas require complete excision. If the follow-up is normal, the next examination should be in 5 y. Presence of >10 adenomas should raise suspicion of a familial syndrome.
Personal history of colorectal cancer	1 y after resection	Colonoscopy	Patients should undergo high-quality preoperative clearance. Follow-up after normal examinations should be extended to 3 y and then to 5 y.
Family history of adenomas or cancer in a first-degree relative <60 y of age or in 2 first-degree relatives at any age	Age 40 y, or 10 y before the age at onset of youngest affected family member	Colonoscopy	Every 5 y
Family history of adenomas or cancer in a first-degree relative >60 y of age or in 2 second-degree relatives with cancer	Age 40 y	Colonoscopy	Screening should be initiated at an earlier age. Intervals are based on findings or on the average-risk patient.
FAP or suspected FAP	Age 10–12 y	Annual FS, counseling for genetic testing if showing polyps	Colectomy should be considered for positive genetic testing.
HNPCC or risk for HNPCC	Age 20–25 y, or 10 y before the age at onset of youngest affected family member	Colonoscopy, counseling for genetic testing	Every 1–2 y. Genetic testing should be offered to first-degree relatives of persons with a known DNA-mismatch repair gene defect or with 1 of the first 3 Bethesda criteria.
IBD, Crohn's disease, or chronic UC	8 y after the onset of pancolitis, or 12–15 y after the onset of left-sided colitis	Colonoscopies with random four-quadrant biopsies every 10 cm for dysplasia	Screening should be offered every 1–2 y, and patients are best referred to a center with experience in the surveillance and management of IBD.

Abbreviations: FAP = familial adenomatous polyposis; FS = flexible sigmoidoscopy; HNPCC = hereditary nonpolyposis colorectal cancer; IBD = inflammatory bowel disease.

in evaluating the extent of localized or metastatic disease and the presence of enlarged lymph nodes. Staging of rectal cancers includes determining the distance from the anal verge, frequently with the use of a rigid proctoscope; the depth of invasion; and the presence of enlarged lymph nodes, using endorectal ultrasound or endoanal coil magnetic resonance imaging. Metastatic disease mandates neoadjuvant chemotherapy in the absence of acute symptoms of obstruction or exsanguination. Rectal cancers with evidence of local invasion into perirectal fat or adjacent structures or evidence of enlarged metastatic lymph nodes may benefit from neoadjuvant chemotherapy and irradiation. Preoperative staging allows for the application of neoadjuvant therapy in selected candidates, which can downstage and downsize tumors and can decrease rates of local recurrence in rectal cancer. Neoadjuvant therapy can also allow for sphincter-preserving procedures in patients with previously bulky or very low rectal tumors.

Surgery for Colonic Tumors

The primary therapy for tumors of the colon is operative. The basic principles of surgery for colon cancer are the following:

- Exploration: adequate visual, tactile, and potentially intraoperative hepatic ultrasound staging at the time of primary resection
- Removal of the entire cancer with enough proximal and distal bowel to encompass the possibility of submucosal lymphatic tumor spread
- Removal of the regional mesenteric pedicle, including draining lymphatics, based on the predictable lymphatic spread of the disease and the potential for regional mesenteric involvement without concurrent distant involvement
- En bloc resection of involved structures (T4 tumors)

Segmental colonic resections (right, transverse, left, or sigmoid colectomy) are undertaken based on the tumor location and blood supply with lymphatic drainage, specifically the ileocolic, middle colic, and left colic arteries. These arteries define a convenient anatomic boundary for standard colonic resection and also provide for adequate regional lymph node clearance, because the major draining lymphatics follow these blood vessels in the mesentery. Locally invasive tumors (T4) require en bloc resection of involved structures. Metastatic colonic tumors (M1) may require neoadjuvant chemotherapy before resection or palliation.

Numerous studies have verified that laparoscopic surgery is appropriate, and perhaps preferred, for colon cancer in experienced hands. The landmark Clinical Outcomes of Surgical Therapy (COST) trial in 2004 established that laparoscopic resection is equivalent to open resection for colon cancer.

Surgery for Rectal Tumors

Two approaches for rectal tumors are local excision and formal rectal resection. Local excision is the treatment of choice for a select, small group (3%–5% of all patients diagnosed with rectal cancer). Tumors amenable to transanal excision are small (<3 cm), involve less than 25% of the rectal circumference, are confined to the mucosa or submucosa (Tis or T1), lack nodal involvement by preoperative imaging, and have favorable pathologic characteristics (well or moderately differentiated with no lymphovascular invasion). Tumors in the lower or middle third of the rectum are accessible by simple transanal excision, but tumors of the upper rectum require the use of transanal endoscopic microsurgery (TEMs) techniques for resection. Local excision requires a 1-cm normal margin, but the defect usually does not require closure.

Tumors staged at T2 or greater require a formal resection, the type of which depends on the location of the tumor. Upper and middle rectal tumors can usually be managed with a low or very low anterior resection. Lower rectal tumors frequently require a proctectomy with coloanal anastomosis or an abdominoperineal resection. The goal of resection is to obtain a 5-cm distal margin, but lower tumors can be managed with a 2-cm distal margin. Very low tumors and those involving the sphincter mechanism require an abdominoperineal resection.

Rectal tumors with greater depth of rectal wall invasion (T3), evidence of fixation or local invasion (T4), or evidence of lymph

nodal (N1–2) or metastatic (M1) disease mandates neoadjuvant chemoradiation therapy. Proctectomy requires a specimen-appropriate total mesorectal excision. This involves complete excision of all mesorectal tissue located behind the rectum with no carcinoma at the lateral or circumferential margins. The goal is to remove all malignant tissue, so as to reduce or eliminate the possibility of locally recurrent disease.

Locally advanced rectal tumors may preclude an effective or safe resection. Some indications for likely inoperability include extensive pelvic disease, invasion of ileofemoral vessels, extensive lymphatic involvement or significant lower extremity lymphedema, bony involvement, and life expectancy less than 3 to 6 months.

Laparoscopy is being performed for rectal malignancies in advanced centers, and studies are under way to verify the efficacy and safety of laparoscopic rectal resection in comparison with traditional open resection.

Complicated Disease

Colorectal tumors may manifest with complications such as obstruction, perforation, or significant bleeding. These presentations are generally related to more advanced disease and may preclude a complete staging workup or potential neoadjuvant therapy. Unless patients are unstable or critically ill or the tumor is unresectable, the tumor should be appropriately resected. An ostomy is usually performed, whether as an end ostomy or as a proximal loop diversion for a primary anastomosis. Colonic stenting is an attractive option for obstructing lesions as palliation or as a bridge to resection after medical stabilization and staging for potential neoadjuvant therapy.

Surgery for High-Risk Conditions

High-risk conditions for the development of colorectal malignancies include FAP, HNPCC, and chronic ulcerative colitis. Surgical management may be prophylactic or possibly therapeutic after a malignancy has been diagnosed. The mainstay of operative management in FAP and chronic ulcerative colitis is a total proctocolectomy. Reconstructive options include an ileal pouch–anal anastomosis, a continent ileostomy (Kock pouch), or an end ileostomy. A total abdominal colectomy with ileorectal anastomosis may be performed for temporary preservation of rectal function in selected cases of chronic ulcerative colitis with rectal sparing and FAP with few rectal polyps, but this requires aggressive surveillance of the remaining rectal mucosa because of the risk of malignancy. Patients with HNPCC should also undergo subtotal colectomy with ileorectal anastomosis; because of the prevalence of associated gynecological malignancies, a total hysterectomy with bilateral salpingo-oophorectomy should be offered to women as well.

Pathologic Staging and Adjuvant Therapy

Excellent pathologic sampling and review of the operative specimen provide important prognostic and therapeutic information. Current standards recommend that at least 12 lymph nodes be removed for adequate staging of colon cancer. The decision for adjuvant chemotherapy or radiation therapy or both is based on the pathologic staging. This information also provides prognostic information in terms of survival for the patient and family. A number of staging systems have been developed, but the tumor-node-metastasis (TNM) system is the one most commonly used in the United States (Table 2).

Chemotherapy is offered for patients who have colorectal cancers with locally advanced, nodal (stage III), or metastatic (stage IV) disease. The combination of chemotherapy and radiation therapy for advanced rectal cancer (stage II–IV) has decreased local recurrence and increased survival. Numerous protocols are available for treatment, with the standard of care being FOLFOX: oxaliplatin (Eloxatin), 5-fluorouracil (5-FU [Adrucil]), and leucovorin. Elderly patients and those with multiple comorbidities who may not be able to tolerate full-dose chemotherapy may be candidates for capecitabine (Xeloda) or 5-FU and leucovorin. Numerous study protocols are available at specialized centers evaluating other

TABLE 2 Pathologic Staging Systems for Colorectal Cancer

PATHOLOGIC FEATURES	STAGE	TNM	DUKES	ASTLER-COLLER	5-YR SURVIVAL (%)
Depth of Invasion					
Lamina propria, muscularis mucosa	0	T0/Tis	A		>90
Submucosa	I	T1	A	B1	
Muscularis propria	I	T2	A	B1	
Subserosa, pericolic fat	II	T3	B	B1	70–85
Adjacent organs, perforation	II	T4	B	B2	55–65
Lymph nodal involvement

1–3 nodes	III	N1	C	C1, C2	45–55
>3 nodes	III	N2	C	C1, C2	20–30
Distant metastatic disease					
Absent		M0			
Present	IV	M1	D		<5

Abbreviation: TNM = tumor-node-metastasis system.

medications. Newer technologies continue to evolve, such as anti-angiogenesis agents and immunomodulatory agents.

Metastatic Disease

Surgical therapy is also available for metastatic disease in certain situations. Metastatic liver lesions amenable to resection can be addressed at the time of colon resection or after the patient has healed from colectomy. The lesions could be resected or treated with radiofrequency ablation, a newer technology that allows in situ destruction of liver lesions. Similarly, selected pulmonary metastases can be resected, possibly with the use of minimally invasive thorascopic techniques.

Surveillance

Surveillance for colon and rectal cancer is a lifelong process. Patients are seen and examined in the office every 3 months for 2 years, then every 6 months for 3 years, and then yearly for 5 years. Levels of carcinoembryonic antigen are measured at each office visit, but current literature recommends obtaining levels every 3 months for 3 years as a marker for tumor recurrence in stage II–III patients. Colonoscopy should be performed at 1 year postoperatively, assuming a high-quality preoperative study has cleared the rest of the colon. A normal colonoscopy at 1 year postoperatively would allow the next surveillance colonoscopy to be performed 3 years later. If that one is normal, subsequent examinations should be performed every 5 years. After the examination at 1 year postoperatively, the subsequent intervals should be shortened if there is evidence of HNPCC or if additional adenomas are found. As an addition to formal colonoscopies, flexible sigmoidoscopies are performed with each office visit for patients with rectal cancer. Routine imaging utilizing CT scans of the chest, abdomen, and pelvis is performed annually for 3 years in patients with colorectal cancer. Patients with increased or rising CEA levels, as noted by routine surveillance checks, or evidence of recurrent disease, as noted by history and physical examinations or routine surveillance imaging studies, can be evaluated with the use of positron emission tomography (PET), an emerging sensitive test for tumor recurrence.

Scott A. Hundahl, MD

CURRENT DIAGNOSIS

- Intestinal metaplasia, which predisposes to cancer, results from chronic *Helicobacter pylori* infection.

TABLE 2 Pathologic Staging Systems for Colorectal Cancer

PATHOLOGIC FEATURES	STAGE	TNM	DUKES	ASTLER-COLLER	5-YR SURVIVAL (%)
Depth of Invasion					
Lamina propria, muscularis mucosa	0	T0/Tis	A		>90
Submucosa	I	T1	A	B1	
Muscularis propria	I	T2	A	B1	
Subserosa, pericolic fat	II	T3	B	B1	70–85
Adjacent organs, perforation	II	T4	B	B2	55–65
Lymph nodal involvement					
None		N0			
1–3 nodes	III	N1	C	C1, C2	45–55
>3 nodes	III	N2	C	C1, C2	20–30
Distant metastatic disease					
Absent		M0			
Present	IV	M1	D		<5

Abbreviation: TNM = tumor-node-metastasis system.

medications. Newer technologies continue to evolve, such as anti-angiogenesis agents and immunomodulatory agents.

Metastatic Disease

Surgical therapy is also available for metastatic disease in certain situations. Metastatic liver lesions amenable to resection can be addressed at the time of colon resection or after the patient has healed from colectomy. The lesions could be resected or treated with radiofrequency ablation, a newer technology that allows in situ destruction of liver lesions. Similarly, selected pulmonary metastases can be resected, possibly with the use of minimally invasive thorascopic techniques.

Surveillance

Surveillance for colon and rectal cancer is a lifelong process. Patients are seen and examined in the office every 3 months for 2 years, then every 6 months for 3 years, and then yearly for 5 years. Levels of carcinoembryonic antigen are measured at each office visit, but current literature recommends obtaining levels every 3 months for 3 years as a marker for tumor recurrence in stage II–III patients. Colonoscopy should be performed at 1 year postoperatively, assuming a high-quality preoperative study has cleared the rest of the colon. A normal colonoscopy at 1 year postoperatively would allow the next surveillance colonoscopy to be performed 3 years later. If that one is normal, subsequent examinations should be performed every 5 years. After the examination at 1 year postoperatively, the subsequent intervals should be shortened if there is evidence of HNPCC or if additional adenomas are found. As an addition to formal colonoscopies, flexible sigmoidoscopies are performed with each office visit for patients with rectal cancer. Routine imaging utilizing CT scans of the chest, abdomen, and pelvis is performed annually for 3 years in patients with colorectal cancer. Patients with increased or rising CEA levels, as noted by routine surveillance checks, or evidence of recurrent disease, as noted by history and physical examinations or routine surveillance imaging studies, can be evaluated with the use of positron emission tomography (PET), an emerging sensitive test for tumor recurrence.

TUMORS OF THE STOMACH

Method of

Scott A. Hundahl, MD

CURRENT DIAGNOSIS

- Intestinal metaplasia, which predisposes to cancer, results from chronic *Helicobacter pylori* infection.

- In the United States, screening studies are reserved for those with definite risk factors.
- Pretreatment staging drives subsequent treatment and involves endoscopy, endoscopic ultrasound, helical computed tomography, and often laparoscopy or mini-laparotomy.
- Mucosal abnormalities can be largely absent in early gastrointestinal stromal tumors, small carcinoids, and even diffuse-type linitis plastica. Deep endoscopic biopsies are required.

CURRENT THERAPY

Adenocarcinoma

- To ensure complete surgical resection, resection should be customized (e.g., gross margin, use of endoscopic mucosal resection for certain mucosal tumors).
- For tumors beyond mucosal depth, survival is maximized with either computer-guided "low Maruyama Index surgery," or an JGCA-defined "D-2" operation
- Adjuvant therapy options include preoperative chemotherapy (\pm postoperative treatment), or postoperative chemoradiation

Gastrointestinal Stromal Tumors

- Node dissection is not indicated.

Gastric Lymphoma

- For aggressive diffuse-type lymphomas, chemotherapy with or without radiation therapy is now the mainstay of treatment. Surgery is reserved for complications such as acute perforation.
- Superficial mucosa-associated lymphoid tissue tumors can sometimes be treated by simply eliminating *Helicobacter pylori* infection. It comes back if reinfection occurs, however.

Gastric Adenocarcinoma

Thanks to happy accident rather than specific planning, over the past 80 years, gastric adenocarcinoma has changed from the most-common solid organ malignancy in the United States to a relatively uncommon disease. Worldwide, however, it remains a scourge second only to lung cancer.

Classification and Epidemiology

Several classification schemes exist. Two are commonly used. Borrmann's morphologic classification relies on gross characteristics of the tumor. The histologic classification of Lauren, first described by Jarvi and Lauren in 1951, divides gastric adenocarcinomas into intestinal (gland-forming) and diffuse (discohesive) types, based on their microscopic appearance. Several other classification schemes have been proposed, including Broder's classification of differentiation, the World Health Organization (WHO) classification, the Nagayo-Komagome classification, the Ming classification, and the Goseki classification, but none eclipses the Lauren classification.

Epidemiologically, three patterns of disease can be discerned, with *Helicobacter pylori* infection playing an important role in the first two patterns: intestinal-type tumors arising from the lesser curve and distal stomach, related to *H pylori*-associated atrophic gastritis and intestinal metaplasia; diffuse-type tumors involving the body of the stomach, often associated with intense *H pylori*-associated inflammation but not associated with significant intestinal metaplasia; and intestinal-type tumors of the gastroesophageal junction.

In high-incidence regions of the world, such as Japan and Korea, up to two thirds of gastric adenocarcinomas are of the first type and are strongly associated with chronic multifocal atrophic gastritis and intestinal metaplasia from chronic *H pylori* infection. The process usually begins at the antrum-corpus junction along the lesser curvature and predisposes to cancers of the intestinal type occurring in the sixth or seventh decades of life. The second type of gastric adenocarcinoma, also associated with *H pylori*, afflicts

younger persons in the fourth and fifth decades of life. The last type, seen in lower-incidence regions of the world such as the United States, is associated with chronic gastroesophageal reflux and Barrett's esophagitis.

Epidemiologists and public health experts estimate that more than 40% of gastric adenocarcinomas worldwide can be attributed to chronic *H pylori* infection. Strains containing the *cagA* gene appear more dangerous. The infection usually starts by the second or third decade, and unless it is successfully treated, it gives rise to chronic inflammation, atrophic gastritis, and eventually intestinal metaplasia, which is a premalignant histologic condition. Dietary factors such as high salt and high nitrates can accentuate this progression as well as the march to cancer. As the condition progresses, acid-producing oxyntic mucosa is progressively wiped out, gastric pH increases, and bacterial overgrowth with non-*H pylori* bacteria is facilitated. The original *H pylori*, which requires an acid environment to thrive, often disappears at this point.

Once intestinal metaplasia is established, dietary factors become particularly important in mitigating the risk of cancer development. Protective factors include intake of vitamin C, fresh fruits and vegetables, and antioxidants. The association of *H pylori* infection with the development of intestinal metaplasia suggests that early detection and elimination of this infection might prevent gastric cancer. Unfortunately, in high-incidence areas, reinfection from contaminated water supply and other sources is common, thus undermining the strategy. Also, in prevention trials to date, benefit appears restricted to the subgroups without preexisting intestinal metaplasia.

Risk Factors

Risk factors other than *H pylori* infection include low socioeconomic status, smoking, a diet deficient in fresh fruits and vegetables or high in salt-preserved high-nitrate foods, previous gastric ulcer, ionizing radiation, family history, and previous gastric resection. Blood group A is associated with higher risk of developing a diffuse-type tumor. Predisposing genetic conditions include Lynch's syndrome (hereditary nonpolyposis colorectal cancer [HNPCC], a condition with microsatellite instability due to deficient DNA repair enzymes), as well as dominantly inherited germline mutations in the E-cadherin gene.

Diagnosis

In Western populations, by the time gastric cancer causes symptoms, the disease is often relatively advanced. In a large National Cancer Data Base survey of US patients, presenting ascribable symptoms included weight loss (62%), abdominal or epigastric pain (52%), nausea (34%), anorexia (32%), early satiety (32%), dysphagia (26%), and melena (18%).

Mass screening combining upper GI series, endoscopy, and serum pepsinogen I/II ratio have proved beneficial in high-incidence areas such as Japan, but they cannot be justified in the United States, where incidence is low. However, for defined risk groups, such as those with established atrophic gastritis and established intestinal metaplasia, strong family history, and those with HNPCC syndrome, surveillance screening should definitely be considered. For those with hereditary E-cadherin mutations associated with gastric cancer, prophylactic total gastrectomy is recommended.

In the United States, diagnosis is usually made by upper endoscopy. One should be aware that diffuse-type cancers manifesting as linitis plastica are often associated with minimal visible mucosal changes, and deep biopsies are often required for establishing the diagnosis. Furthermore, small, early gastric cancers (defined by the Japanese as in-situ and T1 cancers, with or without node involvement) can be associated with particularly subtle mucosal changes, presenting a challenge for even the most experienced endoscopist. Chromo-endoscopy and other sophisticated mucosal imaging techniques have been used to identify such changes but are not yet standard.

Extent-of-disease studies for gastric adenocarcinoma include endoscopic ultrasound (good for estimating depth of tumor and visualizing immediately adjacent nodes), and helical CT scanning,

which is good for evaluating extraluminal extent of disease, intraabdominal or mediastinal extension or spread, and liver or lung metastases. Because even high-resolution CT scanning can miss small peritoneal implants, extraregional nodal spread, and small liver metastases, staging laparoscopy or minilaparotomy are valuable adjuncts and should be considered mandatory if any preoperative chemotherapy is considered.

Staging

Eighth Edition American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) staging, to be applied to cases diagnosed after January 1, 2018, classifies any tumor whose epicenter is in the proximal 2 cm of the stomach and proximally crosses the esophagogastric junction as an esophageal cancer. Tumors whose epicenter is distal to the proximal 2 cm are deemed a stomach cancer. Gastric cancer staging continues to harmonize the T-category designations with colon sites. T1 tumors, which involve mucosa or submucosa, are now subcategorized T1a or T1b accordingly. T2 tumors involve the muscularis propria. T3 tumors penetrate to subserosal connective tissue without breaching the visceral peritoneum. T4 tumors breach the serosa (T4a) or invade adjacent structures (T4b). Nodal categories specify N1 as reflecting 1 to 2 nodes involved, N2 as 3 to 6 nodes involved, and N3 designating 7 or more nodes involved. In the overall TNM staging matrix, stage IV is now restricted to patients with documented peritoneal (including positive peritoneal washing cytology), distant-organ, or extraregional nodal metastases.

Treatment

Curative treatment of gastric cancer involves, as main therapy, complete negative-margin surgical resection of disease. For select tumors, such resection sometimes follows up-front chemotherapy. For localized in situ and select T1 tumors, endoscopic mucosal resection and minimally invasive techniques have been successfully employed. Unfortunately, most tumors in the United States are discovered at a stage where formal open surgery is required.

To secure a histologically negative mural margin of resection, a gross margin of 2 cm is usually adequate for exophytic, noninfiltrating tumors, and a margin of at least 5 to 6 cm of grossly normal tissue is recommended for ulcerated or infiltrating tumors or diffuse histology. Closest mural margins are generally checked by frozen section at the time of surgery to confirm adequacy of resection. Total gastrectomy is not indicated as a routine procedure, except in diffuse-type tumors involving most of the stomach (linitis plastica), but it is warranted whenever required for a negative-margin resection.

Routine splenectomy in the treatment of gastric cancer, as well as routine distal pancreatectomy (performed in the past to clear splenic nodes), should be avoided unless definitely required for complete resection of visible or palpable disease.

The optimal extent of lymph node dissection in this disease has generated—and continues to generate—international controversy. Although several prospective randomized trials to date in non-Asian populations—none perfect—fail to demonstrate that routine extensive lymphadenectomy increases survival, it has also been shown that insufficient lymphadenectomy definitely compromises survival. A prospective randomized single-institution trial in Taipei has documented survival benefit associated with radical lymph node dissection. The adequacy of lymphadenectomy for a given case can be quantified using the Maruyama Index of Unresected Disease. In both a large US adjuvant chemoradiation trial and in a blinded reanalysis of a large Dutch surgical trial, low Maruyama Index score independently correlates with survival. Moreover, a dose-response effect is seen for the extent of surgical clearance of node groups at risk. Using the Maruyama computer program to predict the extent of nodal spread for a given cancer case before surgery is one way to facilitate a low Maruyama Index operation. A JGCA-defined “D-2” operation will also generate such a result.

Sentinel node biopsy, an established technique in the treatment of other cancers, has largely failed to win support in cancer of

the stomach owing to the organ's lymphatic complexity and relatively high reported false-negative rates.

A large North American prospective randomized trial of postoperative adjuvant 5-fluorouracil-based chemoradiation in completely resected gastric cancer revealed a significant increase in disease-free and overall survival with this treatment. The postoperative nature of this trial thwarted implementation of surgical guidelines, and the extent of node dissection for most patients in the trial was suboptimal. Practitioners in some countries, such as Japan, dismiss the necessity of adjuvant postoperative adjuvant chemoradiation with the argument that this is only a salvage technique for inadequate surgery. A separate Korean chemoradiation series has shown benefit even for radically treated cases, however. For patients with good postoperative performance status, good organ function, and adequate nutrition, postoperative adjuvant chemoradiation therapy remains standard in North America for those who received up-front surgery.

A UK study of preoperative plus postoperative ECF (epirubicin [Ellence], ¹*cis*-platinum¹, and continuous-infusion 5-fluorouracil [Adrucil]) chemotherapy versus surgery alone has shown encouraging results for ECF, with a significant improvement in survival. Previous preoperative chemotherapy trials, using other regimens, have been negative, however. Preoperative chemotherapy is now recommended by some, and this is especially the case for localized advanced tumors considered borderline resectable.

In Korea, a positive trial of adjuvant perioperative intraperitoneal chemotherapy has been reported. Considerable morbidity and mortality are associated with this adjuvant treatment, however, and it is unlikely it will be implemented without refinement and successful independent duplication of results.

For localized disease deemed not resectable to negative margins, both chemotherapy and chemoradiation have been used to convert such tumors to potentially resectable status. With successful negative-margin resection, some of these patients indeed survive free of disease long term. When localized unresected disease is documented to exist, administering chemoradiation with 5-fluorouracil as a radiation sensitizer can also result in some degree of 5-year survival (per reports, >10%).

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) manifest as submucosal spindle cell tumors in the sarcoma family. In contrast to leiomyosarcomas and other spindle cell sarcomas, they express the antigen CD117, and most (>80%) tumors have activating mutations of *c-KIT*. Formerly considered rare, approximately 5000 of these tumors per year are now diagnosed in the United States. Owing to pattern of growth in the gastric wall, deep to the mucosa, early symptoms are unusual, and these tumors often grow to massive size before mucosal ulceration and hemorrhage (or other major symptoms) finally develop. GISTs are classified as sarcomas. Even low-risk GISTs (<5 cm and <1 mitosis per 10 high-power fields) can metastasize, and no GIST can be considered truly benign.

Treatment of localized primary GISTs consists of complete surgical resection, and a 2-cm margin of grossly normal tissue usually accomplishes this. Specific lymph node dissection is not indicated for this histology. Surgical series indicate that approximately 50% of primary gastric tumors metastasize and recur within 5 years. For patients with widespread metastases, generally located in the peritoneal cavity or the liver, first-line therapy is now a well-tolerated oral agent, imatinib mesylate (Gleevec or STI-571) at an initial dose of 400 mg daily, which generates partial responses in more than 50% of cases and stable disease in an additional 25% of cases. Side effects are minimal, and 1-year survival in treated patients is approximately 85%. On the basis of a completed American College of Surgeons Oncology Group (ACOSOG) trial, patients who have all disease completely resected should receive postoperative adjuvant therapy for at least 1 year.

¹Not FDA approved for this indication.

For tumors resistant to imatinib, SU11248, sunitinib malate (Sutent), is now used as effective second-line therapy. Additional targeted biologic agents are under active investigation.

Carcinoid Tumors

The term “carcinoid” is reserved for a low-intermediate grade neuroendocrine tumor. In contrast, high-grade tumors are classified as “neuroendocrine carcinomas.” In the stomach, the most common carcinoid (type I) is smaller (<2 cm in size), often multiple, and associated with chronic elevation of gastrin caused by either atrophic gastritis or gastrinoma. Behavior is generally benign, and such tumors have been shown to regress if gastrin levels can be normalized. In contrast, so-called “sporadic carcinoids” are usually >2 cm and unassociated with gastrin elevation. They are often aggressive and can spread to lymph nodes or liver. Complete, negative-margin resection with lymphadenectomy is recommended. When metastatic to the liver or other organs, surgical cytoreduction (or other means of tumor ablation) can offer considerable palliation to those with carcinoid syndrome, and this should always be considered. Octreotide (Sandostatin) therapy is now a palliative mainstay in all patients with carcinoid syndrome.

Gastric Lymphomas

Gastric lymphomas encompass most of the lymphoma subtypes, but low-grade, mucosa-associated B-cell lymphomas (B-cell MALT lymphomas) deserve special mention because they are strongly associated with *H pylori* infection. Indeed, localized cases can be controlled simply by treating the *H pylori* infection. In such cases,

molecular studies indicate persistence of the offending lymphoid clone in about one half of cases. However, and, particularly if *H pylori* infection recurs, the lymphoma in such cases returns.

Aggressive, high-grade, diffuse-type B-cell gastric lymphomas, stage IE and IIE, once treated with multimodal therapy, are now treated with chemotherapy alone as the primary treatment, with or without radiotherapy. Surgical intervention is now reserved for emergencies, such as perforation.

For further information on this and other gastrointestinal lymphomas, please see the chapter on lymphoma.

ACROMEGALY

Method of

Moises Mercado, MD

CURRENT DIAGNOSIS

Clinical

- Headaches, visual field defects
- Coarse features, increased size of hands (rings) and feet (shoes)
- Thick, oily skin, skin tags, acanthosis nigricans
- Arthralgias, osteoarthritis
- Paresthesias, carpal tunnel syndrome
- Hypertension, arrhythmia, heart failure
- Glucose intolerance, diabetes, hypertriglyceridemia
- Snoring, sleep apnea
- Risk of colon polyps or colon cancer
- Risk of thyroid cancer

Biochemical

- Glucose-suppressed growth hormone >0.4 ng/mL by ultrasensitive assays or >1 ng/mL by old radioimmunoassays
- Elevated age-adjusted insulin-like growth factor 1

Imaging

- Magnetic resonance imaging

CURRENT THERAPY

- If a pituitary surgeon is available: Transsphenoidal surgery for microadenomas, intrasellar macroadenomas, and debulking or decompressing surgery in invasive macroadenomas
- Depot Somatostatin analogues (lanreotide autogel [Somatuline Depot] or octreotide LAR [Sandostatin LAR Depot]) as secondary treatment for patients failing surgery or waiting for radiotherapy effect to occur and as a primary treatment for patients with inaccessible lesions, contraindications for surgery, or preference
- Dopamine agonists: Cabergoline (DOSTINEX)¹ is effective alone or in combination with somatostatin analogues in 15% to 30% of patients
- Growth hormone receptor antagonists: Pegvisomant (Somavert) for patients resistant or intolerant to somatostatin analogues and who have tumors >5 mm from the optic chiasm
- Radiotherapy for patients resistant or intolerant to pharmacologic therapy, with clinically and biochemically active disease and a tumor remnant on MRI

¹Not FDA approved for this indication.

Physiology, Biochemistry, and Regulation of the GH/IGF-1 Axis

GH secretion is regulated at the hypothalamus (Figure 1). The pulsatile secretion of GH-releasing hormone (GHRH) stimulates somatotroph proliferation and GH gene transcription, whereas somatostatin, which is secreted tonically, inhibits GH synthesis. These two hypothalamic signals result in the pulsatile secretion of pituitary GH, with most pulses occurring during the night. GH is also stimulated by ghrelin, a hypothalamic and gastrointestinal orexigenic hormone that binds specific receptors in the somatotroph known as GH-secretagogue receptors. GH exerts its actions through a specific membrane receptor located predominantly in the liver and cartilage, but ubiquitously present in all tissues. One molecule of GH interacts with two molecules of GH receptor, resulting in functional dimerization and conformational changes that lead to the phosphorylation of several kinases and eventually the interaction with target genes such as the insulin-like growth factor (IGF)-1 gene.

IGF-1 is closely related to proinsulin and circulates in plasma bound to six binding proteins (IGFBPs) that are synthesized and released by the liver. IGFBP3 is the most important of these binding proteins and is also GH dependent; it forms a heterotrimeric complex composed of BP3, IGF-1, and the acid-labile subunit (ALS). IGF-1 is responsible for most of the trophic and growth-promoting effects of GH. Blood levels of IGF-1 are increased during puberty, coinciding with the acceleration of somatic growth, and decline with aging. Malnutrition, poorly controlled type 1 diabetes, hypothyroidism, and liver failure all result in diminished IGF-1 concentrations. IGF-1 is the main player in GH negative feedback regulation and it acts at both the pituitary and the hypothalamic levels. Glucose regulates GH release by increasing (hyperglycemia) or decreasing (hypoglycemia) somatostatin synthesis in the hypothalamus. Exercise and amino acids such as arginine also stimulate GH secretion.

Etiopathogenesis of Growth Hormone–Secreting Tumors

The molecular pathogenesis of pituitary tumors includes the inactivation of tumor suppressor genes, the activation of oncogenes, and the trophic effect of factors such as the hypothalamic releasing hormones. Approximately 40% of GH-producing tumors in whites harbor somatic point mutations of the α subunit stimulatory G protein coupled to the GHRH receptor (GSP α mutations). This molecular alteration causes constitutive activation of the GHRH receptor, resulting in an increased transcription of the GH gene and the promotion of somatotroph proliferation. Acromegalic patients whose tumors harbor GSP α mutations usually have a more benign clinical course and appear to be more susceptible to management with somatostatin analogues. Nonwhite acromegalic populations, including persons of Japanese, Korean, and Mexican heritage, have a much lower prevalence of GSP α mutations.

Other molecular events should be present in GSP α -negative somatotrophinomas. Menin is a protein encoded by a tumor suppressor gene located on the short arm of chromosome 11. Inactivating mutations of menin are the molecular basis of type 1 multiple endocrine neoplasia (MEN1); however, GH-secreting tumors occurring out of this context do not have such genetic abnormalities. Inactivating mutations of other putative tumor-

Acromegaly is a disorder resulting from an excessive secretion of growth hormone (GH), with a prevalence of 40 to 60 cases per million and an annual incidence of 3 to 4 per million.

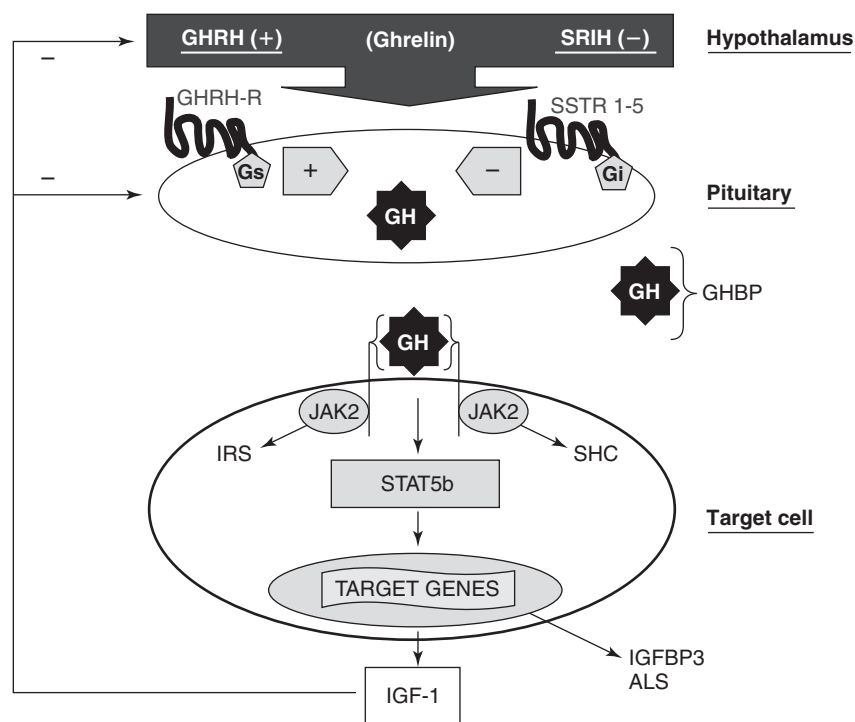

Figure 1 GH is regulated positively by GHRH and negatively by somatostatin. Fifty percent of circulating GH is bound to the GH binding protein, which represents the extracellular portion of the GH receptor. One molecule of GH dimerizes two molecules of GH receptor, and the ensuing signal transduction results in IGF-1 synthesis and secretion, which exerts negative feedback on GH secretion at the hypothalamic and pituitary levels. *Abbreviations:* ALS = acid-labile subunit; GH = growth hormone; GHRH = growth hormone-releasing hormone; IGF = insulin-like growth factor; IGFBP3 = insulin-like growth factor binding protein 3; IRS = insulin receptor S; JAK2 = Janus kinase 2; SRIH = somatostatin; SSTR = somatostatin receptor.

suppressor genes located relatively close to the *menin* locus have been described in several kindreds with familial acromegaly; however, they do not seem to play an important oncogenic role in the sporadic form of the disease. Other genetic alterations such as underexpression of *GADD 45γ* (growth arrest and DNA damage-inducible protein) and overexpression of the securing molecule *PTTG* (pituitary tumor transforming gene) have also been shown to be involved in the molecular pathogenesis of acromegaly. Although hereditary acromegaly is rare (less than 2% of the cases), familial somatotrophinomas account for 30% of the tumors seen in the syndrome of familial isolated pituitary adenomas. Patients with isolated familial somatotrophinomas are younger and usually have more aggressive tumors than subjects with sporadic acromegaly. Affected members do not show any molecular alterations in the *MEN1* gene. However, 15% of 73 tested families harbor inactivating, germline mutations of the *AIP* (aryl hydrocarbon interacting protein) gene located on chromosome 11q13.3.

In more than 90% of cases, acromegaly is caused by a sporadic pituitary adenoma. In approximately 70% of these patients, these benign epithelial neoplasms are larger than 1 cm in diameter and are known as *macroadenomas*, whereas one-third of the patients harbor lesions smaller than 1 cm or *microadenomas*. One-third of the patients have tumors that cosecrete GH and prolactin (PRL) (mammotroph cell adenomas). Real pituitary GH-secreting carcinomas, with documented metastasis as the irrefutable malignancy criterion, are exceedingly rare. On rare occasions, acromegaly results from GHRH-secreting neuroendocrine tumors, usually located in the lungs, thymus, or endocrine pancreas. In this scenario, the ectopically produced GHRH leads to hyperplasia of the somatotroph, with the consequent excessive production of GH. Even less common are GH-secreting tumors arising in ectopic pituitary tissue, usually located in the sphenoid sinus. A case of GH-secreting lymphoma has been reported.

Clinical Manifestations

Acromegaly develops insidiously over many years. An 8- to 10-year delay in diagnosis has been estimated from the beginning of the first symptom. Clinical characteristics are often attributed to aging. Symptoms and signs can be divided into those resulting from the compressive effects of the pituitary tumor and those that are a consequence of the GH and IGF-1 excess.

Local Tumor Effects

Headache results from an increase in intracranial pressure and from the effects of GH itself; it is usually described as a dull pain that persists throughout the day. Occasionally, large tumors invading laterally into the cavernous sinuses give rise to cranial nerve syndromes, usually third and sixth. Visual field defects are relatively common with macroadenomas extending superiorly and compressing the optic chiasm. This usually results in different combinations of bitemporal homonymous hemianopia or quadrontopia.

Consequences of the GH/IGF-1 Excess

Skeletal Growth and Skin Changes

A GH excess developing before the pubertal closure of epiphyseal bone leads to an acceleration of linear growth, and this results in gigantism. Once the patient is in adulthood, the GH/IGF-1 excess results in acral enlargement, which is manifested by increases in ring and shoe sizes as well as enlargement of the nose, supraciliary arches, frontal bones, and mandible. There is thickening of soft tissues of the hands and feet; hands are fleshy and bulky and the heel pad is increased. The skin is thickened due to the deposition of glycosaminoglycans and excessive collagen production. Hyperhidrosis and seborrhea occur in 60% of patients; skin tags (previously associated with colon cancer) and acanthosis nigricans are common.

Musculoskeletal System

Generalized arthralgias are present in the majority (80%) of patients. Degenerative osteoarthritis is more common than in the general population. Paresthesias of the hands and feet and a proximal painful myopathy are often reported. Nerve entrapment syndromes such as the carpal tunnel syndrome occur in nearly half of patients.

Cardiovascular System

Arterial hypertension is found in 30% of patients, and when associated with diabetes, it contributes to the increased mortality rate of the disease. Hyperaldosteronism with low renin levels and the resulting sodium retention play an important role in the pathogenesis of hypertension, but other contributors such as an increased sympathetic tone are also present. Echocardiographic findings include left ventricular and septal hypertrophy with varying

degrees of diastolic dysfunction. Symptomatic cardiac disease develops in 15% of patients and is usually due to coronary artery disease, heart failure, and arrhythmias. Although the existence of an acromegalic cardiomyopathy is still controversial, there are patients without hypertension and with angiographically normal coronaries, who develop severe congestive heart failure, in whom histologic evidence of subendocardial, subepicardial, and myocardial fibrosis and necrosis has been documented.

Respiratory Abnormalities

The majority of patients with acromegaly are affected by loud snoring. A significant fraction of these have sleep apnea (with both central and obstructive components) with significant drops in oxygen saturation, which can be complicated by arrhythmias, daytime somnolence, and chronic fatigue.

Abnormalities in Glucose Metabolism

Chronic GH hypersecretion creates a state of insulin resistance, and glucose intolerance has been reported in 30% to 50% of patients with acromegaly; the percentage with fasting hyperglycemia can be close to 30%, depending on the population. Hyperglycemia has correlated with GH concentrations in some studies and with IGF-1 levels in others. Although successful treatment of acromegaly, be it by surgical, pharmacological, or radiotherapeutic interventions, results in significant improvements in metabolic control, the prevalence of diabetes remains higher than in the general population.

Abnormalities in Lipid Metabolism

The classic lipid profile consists of diminished total cholesterol, along with elevated triglyceride concentrations. Intermediate-density lipoprotein (IDL) particles and lipoprotein(a) might also be elevated, and there is a higher percentage of the more atherogenic type II low-density lipoprotein (LDL).

Bone and Calcium Metabolism

Acromegaly is associated with hypercalciuria and hyperphosphatemia. High serum 25-hydroxyvitamin D₃ and urinary levels of hydroxyproline can be found, reflecting a state of increased bone turnover. Cortical bone mineral density is elevated, whereas trabecular bone mass is diminished.

Neoplasia

Retrospective studies suggested that colonic adenomatous polyps and adenocarcinoma were more frequent in acromegalic patients than in the general population. Prospective studies have demonstrated that the risk, albeit smaller than previously thought, is real and probably justifies screening colonoscopy in these patients. Patients with uncontrolled acromegaly have a higher risk of recurrence of premalignant polyps and a higher mortality rate from colon cancer compared with subjects with biochemically controlled disease and the general population. Recently, an increased incidence of well-differentiated thyroid carcinoma has been documented.

Associated Endocrine Abnormalities

A euthyroid goiter is often found but seldom requires specific treatment. Hypopituitarism occurs variably, depending on the size and extension of the tumor and whether the patient has undergone surgery or radiation therapy. Hypogonadotropic hypogonadism is the most common pituitary deficiency, occurring in 20% of patients. A decreased libido is a common presenting complaint in both male and female patients with acromegaly; women often have menstrual and ovulatory disturbances and men complain of impotence.

Although an elevated PRL is common, it does not always reflect cosecretion of this hormone by the somatotrophinoma, but rather an interruption of the descending dopaminergic tone by the tumor compressing the pituitary stalk. Central hypocortisolism and hypothyroidism are less common.

GH-secreting pituitary adenomas are the second, after prolactinomas, pituitary tumor occurring in the context of MEN1 (multiple parathyroid adenomas, pituitary adenoma, and pancreatic islet

cell tumors). Acromegaly can also develop in patients with the McCune-Albright syndrome (polyostotic fibrous dysplasia, café au lait spots, and endocrinopathies such as sexual precocity and autonomous thyroid nodules), and occurs in the context of the Carney complex.

Mortality

Life expectancy in patients with acromegaly is decreased by about 10 to 15 years, and the standardized mortality ratio is 1.5 to 2. Most patients die of cardiovascular causes, followed by cerebrovascular events, respiratory abnormalities, and neoplastic diseases. Hormonal control has a definite impact on survival. Lowering serum GH to less than 2.5 ng/mL results in reduction of the mortality rate to levels comparable with the general population. These safe GH levels were obtained using old radioimmunoassays, and there are no equivalent studies using ultrasensitive GH assays. IGF-1 levels have not been as good as GH as independent predictors of mortality. Other factors associated with an increased mortality include advanced age and the presence of hypertension and diabetes. Mortality rate in acromegaly can be reduced to that seen on the general population when patients are treated using a multidisciplinary approach not only aiming at controlling the GH and IGF-1 levels but also focusing on the management of comorbidities.

Biochemical Diagnosis

Due to the pulsatile nature of GH secretion, random determinations of this hormone are not useful in the diagnosis of acromegaly. The gold standard for the diagnosis is the measurement of GH after an oral glucose load of 75 g; current guidelines state that suppression to less than 0.4 ng/mL (using ultrasensitive assays) reliably excludes the diagnosis. Situations associated with decreased suppression of GH by glucose include puberty, pregnancy, use of oral contraceptives, uncontrolled diabetes, and renal and hepatic insufficiency.

IGF-1 levels reflect the integrated concentrations over 24 hours of GH and correlate well with clinical activity. Blood IGF-1 concentrations decrease with age, reflecting the parallel decline of the somatotrophic axis. There is a gender difference in IGF-1 (premenopausal women have lower levels than age-matched male subjects). Other conditions that lower IGF-1 levels include malnutrition, uncontrolled diabetes, and hepatic and renal failure. Normal ranges for IGF-1 should be established in each particular center based on age. The determination of other GH-dependent peptides such as IGFBP3 and ALS has not proved to be superior to IGF-1.

Imaging

Pituitary magnetic resonance imaging (MRI) with gadolinium enhancement allows visualization of lesions as small as 2 or 3 mm in diameter. High-resolution computed tomography (CT) is a reasonable alternative, although it is much less sensitive. An ectopic source of GHRH should be suspected when the MRI is completely normal. In these rare cases, serum GHRH should be measured and the ectopic tumor should be sought, usually with high-resolution CT of the chest and abdomen.

Treatment

The decision as to what therapeutic modality should be used has to take into account medical issues (cardiopulmonary comorbidities, size, and extension of the tumor) as well as the local characteristics of the treating center. The latter refers to the availability of pituitary surgeons and radiotherapeutic technologies as well as the economic feasibility of pharmacologic therapy.

Surgery

Transsphenoidal surgery has been the traditional treatment for acromegaly and achieves biochemical cure (achievement of a post-glucose GH <1 ng/mL and normalization of IGF-1) in 80% to 90% of microadenomas. According to the latest published acromegaly consensus, biochemical cure is defined as a

glucose-suppressed GH of 0.4 ng/mL as well as a normal age-adjusted IGF-1. Cure rates for macroadenomas are much lower (40%–50%), and invasive lesions have a very slight chance (<10%) of being cured by surgery. Even though surgery often fails to achieve a full biochemical cure, debulking the pituitary adenoma relieves optic chiasm compression and can result in a sufficient decrement of tumor mass (and therefore of GH production) to allow better results with either pharmacologic or radiotherapeutic regimens.

Pharmacologic Therapy

Somatostatin analogues are the most commonly used medical treatment for acromegaly. Somatostatin inhibits GH secretion and somatotroph cell growth via its interaction with five different somatostatin receptor (SSTR) subtypes. The development of long-acting somatostatin analogues such as octreotide (Sandostatin) and lanreotide (Somatuline) overcame the pharmacologic difficulties of native somatostatin (short half-life, rebound GH secretion, and need for IV administration) and resulted in a more potent inhibition of GH secretion. The most commonly used preparations are intramuscular octreotide LAR (long-acting repeatable) (Sandostatin LAR Depot) and subcutaneous lanreotide autogel (Somatuline Depot), which are administered every 4 weeks. Doses of octreotide-LAR range from 10 to 40 mg and those of lanreotide autogel from 60 to 120 mg, both administered every 4 weeks, although in specific patients the interval of injection can be increased to every 6 or even 8 weeks, thus diminishing the cost of therapy. Octreotide and lanreotide have very high affinities for SSTR-2 and to a lesser extent SSTR-5, which are precisely the most commonly expressed somatostatin receptors in GH-secreting adenomas.

When used after surgery has failed, somatostatin analogues can achieve a safe and a normal IGF-1 in 25% to 35% of patients. Primary treatment with somatostatin analogues is increasingly being used in patients with invasive tumors, when cardiopulmonary contraindications are present, and more recently as a result of the patient's or treating physician's preference. In these settings, biochemical success rates (achievement of a GH <2.5 ng/mL and normalization of IGF-1) have ranged between 30% and 80%, and more than 80% report significant relief of symptoms. More recent trials performed in unselected populations reveal that the real success rate lies between 25% and 35%. Tumor shrinkage occurs in 70% of primarily treated patients. Overall, treatment success is directly related to the abundance of SSTR-2 and SSTR-5 in the tumor. Lower pretreatment GH levels are also associated with a better response to somatostatin analogues. Side effects of somatostatin analogues, including nausea, abdominal pain, alopecia, and biliary sludge, occur in 20% of subjects. The currently recommended biochemical targets when treating patients with somatostatin analogues are the achievement of a GH of 1 ng/mL and an IGF-1 level within the normal age-adjusted range patients with somatostatin analogues is 1 ng/mL.

Pegvisomant (Somavert) is a GH mutant that prevents functional dimerization of the GH receptor, thus acting as an antagonist. Its use results in normalization of IGF-1 in more than 70% of patients, while increasing GH levels. Concern about adenoma growth due to the abolition of IGF-1 negative feedback on the tumoral somatotroph prevents its use in patients with very large lesions in close proximity to the optic chiasm. Transient elevations of liver aminotransferases can occur, although this seldom requires drug discontinuation. Pegvisomant does not compromise insulin secretion, as somatostatin analogues do. GH-receptor antagonists are expensive and should not be used as primary treatment; they are currently indicated in patients who are intolerant or have failed somatostatin analogue therapy.

Few patients respond marginally to difficult-to-tolerate large doses of bromocriptine. Newer dopamine agonists, such as cabergoline,¹ are better tolerated and achieve biochemical control in 20% to 30% of patients. Combination treatment with cabergoline

and octreotide appears to be promising in cases resistant to somatostatin analogues.

Radiation Therapy

Both external-beam radiotherapy and radiosurgery are indicated in patients with persistent disease and a demonstrable tumor remnant who are either intolerant or resistant to pharmacologic treatment. Biochemical success occurs in 20% to 60% and requires many years to become apparent. Hypopituitarism, involving at least two axes, develops in more than 50% of patients within 10 years. Serious adverse effects such as brain necrosis and optic nerve damage seldom occur with the currently used techniques that minimize radiation to the normal surrounding tissues.

Novel pharmacologic therapies are being developed, some of which will likely become useful particularly in patients who do not respond to current somatostatin analogues. These include the so-called “universal” somatostatin analogue pasireotide (Signifor LAR), which is capable of interacting not only with the SSTRs 2 and 5, but also with subtypes 1 and 3. Pasireotide seems to be slightly more effective than octreotide in achieving GH and IGF-1 targets; however, its major drawback is the worsening of hyperglycemia. Dopastatin⁵ is a recently developed chimeric compound that behaves both as an analog and as a dopamine agonist; clinical trials had to be discontinued at early stages due to lack of efficacy. Oral octreotide, known as octreolin,⁵ is a new preparation of octreotide acetate attached to a transient permeability enhancer, which selectively allows the translocation of the somatostatin analog through the paracellular tight junctions. Recently tested in a phase III trial its efficacy is almost equivalent as that of parenteral octreotide but it has not been approved by the FDA.

⁵Investigational drug in the United States.

¹Not FDA approved for this indication.

CURRENT DIAGNOSIS

- Initial diagnosis of adrenocortical insufficiency (AI) is based in most cases on a morning cortisol level, measured at 8–9 AM in patients with a normal circadian rhythm.
- A morning cortisol level less than 5 µg/dL supports diagnosis, and a value greater than 15 µg/dL effectively rules out AI.
- To confirm diagnosis, especially in cases with intermediate cortisol values, a high-dose (250 µg) cosyntropin (Cortrosyn) stimulation test is suggested with a normal cutoff peak cortisol greater than 18 to 20 µg/dL at 30 or 60 minutes.
- Primary AI is characterized by elevated endogenous adrenocorticotrophic hormone (ACTH) levels and absence of mineralocorticoid hormones in addition to glucocorticoid deficiency; antibody screening and/or adrenal imaging is indicated.
- Secondary AI is characterized by an inappropriately normal or low endogenous ACTH level and low cortisol with preserved mineralocorticoid hormones. If exogenous glucocorticoid use is ruled out, magnetic resonance imaging (MRI) of the pituitary sella is appropriate.

CURRENT THERAPY

- Oral hydrocortisone (Cortef) is the preferred form of steroid to attain physiologic replacement. Doses are usually 15 to 20 mg divided into two or three daily doses, with the highest dose in the morning.
- In case of physiologic stress, such as fever, severe infection, or minor surgery, doses should be doubled or tripled (depending on the type of stress or procedure) for the duration of the event.
- In patients with primary AI, fludrocortisone (Florinef), a mineralocorticoid, should be added to the treatment regimen, with a typical dose between 0.05 and 0.1 mg daily.
- For adrenal crisis in patients with known AI, administer hydrocortisone injection (Solu-Cortef) 50 to 100 mg IV every 6 to 8 hours along with generous volumes of saline.
- Patients should wear a medical alert bracelet or necklace and have frequent education regarding AI and treatment and prevention of adrenal crisis.

Epidemiology

Primary AI, also known as Addison disease when of autoimmune cause, has a prevalence of 100 to 140 cases per million persons. More than 90% of Addison disease in the developed world is secondary to autoimmune adrenalitis, and it is more common in women. Secondary AI caused by therapeutic glucocorticoid administration is the most prevalent; pituitary tumors and surgeries are other common etiologies.

Risk Factors

Primary Adrenocortical Insufficiency

A personal or family history of autoimmune disease (e.g., type 1 diabetes, Hashimoto disease, vitiligo, pernicious anemia) is a risk factor for autoimmune adrenalitis. Especially in the context of acute AI in the hospital, thrombosis and secondary hemorrhage

must be ruled out and the possibility of heparin-induced thrombocytopenia (HIT) must be elicited if the patient is receiving parenteral anticoagulation. Miliary tuberculosis is the most frequent cause of primary AI in developed countries. Infiltration in the context of malignancy is often due to a known plurimetastatic cancer; other infiltrative diseases are rare.

Secondary Adrenocortical Insufficiency

The most prevailing risk factor for secondary AI is prolonged use of exogenous glucocorticoids. Patients taking more than 5 mg of prednisone or equivalent for longer than 3 weeks are at risk for secondary AI. In some patients with glucocorticoid receptor hypersensitivity, even smaller doses of glucocorticoid other than oral (topical, injected, or inhaled) can also suppress the hypothalamo-pituitary-adrenal axis. Ritonavir (Norvir) may enhance exogenous glucocorticoid exposition and lead to AI upon withdrawal. Chronic opioid use can also suppress central ACTH and induce AI.

Patients with a tumor of the hypothalamic-pituitary region or history of treatment of such tumors with surgery and/or radiation are at significant risk. Patient with traumatic brain injury may experience AI in both the acute and/or recovery phase and can be transient or permanent. Other causes, such as autoimmune lymphocytic hypophysitis, are most frequent peripartum, either in the third trimester or postpartum. Sheehan syndrome is rare and characterized by pituitary apoplexy secondary to shock due to severe blood loss during parturition.

Pathophysiology

Primary AI is characterized by a complete destruction of the adrenal cortex, inducing deficits in all hormones: glucocorticoid, mineralocorticoid, and androgens. With loss of cortisol feedback inhibition, ACTH will be markedly elevated. Secondary AI is the result of isolated low glucocorticoid production due a defect at the pituitary or hypothalamus level resulting in low ACTH. Mineralocorticoid activity is maintained in secondary AI, as it is controlled by the renin-angiotensin-aldosterone system.

Prevention

No clinically practical strategy for preventing primary AI exists. Glucocorticoid-associated secondary AI may be prevented through judicious use of systemic glucocorticoids, with efforts made to limit administration of glucocorticoids to the lowest effective dose for the shortest possible time.

Clinical Manifestations

Primary Adrenocortical Insufficiency

The presentation of primary AI is sometimes dramatic, with a constellation of weakness, fatigue, anorexia, weight loss, nausea, abdominal pain, salt craving, and orthostatic hypotension. Symptoms start as subtle and nonspecific in some patients but may evolve rapidly in adrenal crisis. The skin and buccal mucosa are often hyperpigmented, owing to the effect of excess ACTH on cutaneous melanocortin receptors. Hyponatremia and hyperkalemia (as a result of mineralocorticoid deficiency) are often present.

Secondary Adrenocortical Insufficiency

The presentation of secondary AI is more insidious, with weight loss, fatigue, and malaise as presenting features. This often leads to a delay in diagnosis. Because production of mineralocorticoid is relatively intact in secondary AI, electrolyte abnormalities and hypotension are rarer. Hyperpigmentation is not present, reflecting normal or low ACTH levels. Laboratory abnormalities are less common, but hypoglycemia is occasionally seen, especially with concomitant growth hormone deficiency. Because isolated ACTH deficiency is rare, signs and symptoms of other pituitary hormone abnormalities, such as hyperprolactinemia, central hypogonadism, growth hormone deficiency, or central hypothyroidism, may be present.

Diagnosis

Morning cortisol (within 2 hours of waking up) of 5 µg/dL or less has a relatively high predictive value for AI, and a morning cortisol level greater than 15 µg/dL effectively rules out AI. To confirm the diagnosis of AI, a cortisol stimulation test is performed. Insulin tolerance testing has largely been replaced by stimulation testing with synthetic cosyntropin (ACTH—Cortrosyn, Synacthen). ACTH stimulation testing of cortisol is a reliable method of evaluating the adrenal reserve. In high-dose testing, a cortisol level is checked before and 30 and 60 minutes after 250 µg of IV cosyntropin is administered. A peak cortisol level greater than 18 to 20 µg/dL defines a normal response. Cosyntropin testing should not be used in cases of short-term secondary insufficiency, such as after recent pituitary surgery, because adrenal atrophy must have occurred for the adrenal response to cosyntropin to be blunted. The low-dose (1 µg) test measures cortisol 20 to 30 minutes after cosyntropin administration and may be more sensitive for diagnosis of secondary AI, with cutoff of 16–18 µg/dL. However, the high-dose (250 µg) test remains the standard. One must consider the total serum cortisol as affected by its binding protein, which is elevated by high estrogen levels and could be low in hypoalbuminemia. If the clinical picture is not concordant with the investigation, an endocrinology consult should be sought.

Once diagnosis is confirmed, a low or normal plasma ACTH level indicates secondary AI, although care must be taken with the methodology of the test as some immunoassays for ACTH can give falsely low results if preanalytic precautions are not respected. An elevated ACTH level (more than twofold the upper limit of normal) typically indicates primary AI, and high plasma renin and simultaneously low aldosterone levels will confirm associated mineralocorticoid deficiency. After the diagnosis of primary versus secondary AI has been established, an etiology should be sought (Boxes 1 and 2). Serology for antiadrenal (21-hydroxylase) antibodies or evidence of other autoimmune diseases is useful in primary AI, given the very large fraction of these patients with autoimmune adrenalitis. Enlarged adrenal glands with high-density areas or calcification on computed tomography can suggest granulomatous disease or neoplasm. Acute hematoma or fluid collections around the adrenals during an acute adrenal crisis can indicate adrenal hemorrhage. Secondary AI is most often associated with chronic glucocorticoid therapy but may be caused by a number of other diseases affecting the hypothalamo-pituitary region. If exogenous steroids have been excluded, MRI and testing of the other pituitary axes are appropriate.

Differential Diagnosis

Because the presentation of AI can be subtle (especially in secondary AI), the differential diagnosis is broad and includes a number of illnesses associated with fatigue, weight loss, and malaise, including occult malignancies, renal or hepatic dysfunction, and electrolyte disturbances. In acute AI crisis, differential diagnosis includes other systemic illnesses associated with orthostatic hypotension and electrolyte abnormalities, including dehydration and distributive and septic shock. Fever can be part of an AI crisis, but one must rule out an infectious process as the precipitating cause.

Treatment

Glucocorticoid replacement is recommended with oral hydrocortisone two or three times daily. One-half to two-thirds of the daily dose is given upon waking, and the dosage is roughly 15 to 20 mg per day (or 10–12 mg/m² body surface area per day), typically 10 or 15 mg in the morning and 5 mg in the afternoon. Once-daily, modified-release hydrocortisone is available in Europe and may better mimic the physiological circadian rhythm of cortisol, but it is not yet available in the United States.

Patients should be instructed to increase this dosage according to physiologic stress, as doses should be doubled or tripled for 3 or more days in case of fever or intercurrent systemic illness. Day-to-day emotional stress does not require an increment in dosing. For surgery, parenteral glucocorticoid doses should be

Metastatic cancer

Infiltrative Diseases

Sarcoidosis, tuberculosis, or other granulomatous diseases
Lymphocytic hypophysitis
Idiopathic adrenocorticotrophic hormone deficiency
Adrenal insufficiency
Associated with cirrhosis
Associated with critical illness

If a patient with known AI presents in adrenal crisis, hydrocortisone (Solu-Cortef) 50 to 100 mg IV every 6 to 8 hours is an appropriate initial therapy, with the dose tapered to an appropriate oral dose as the patient's condition improves. Aggressive hydration with a saline solute will help increase the intravascular volume, and high-dose glucocorticoids have some mineralocorticoid activity; thus mineralocorticoids are not required in the treatment of acute adrenal crisis.

In critical illness, treatment of AI should not be delayed if diagnosis cannot be established and the patient is unstable. Baseline cortisol and ACTH levels should preferably be drawn prior to initiation of treatment and should be interpreted as a stress value (i.e., should be $>18 \mu\text{g/dL}$). If in doubt, high-dose stress steroids are administered until testing is complete, and cosyntropin stimulation testing may be delayed until the patient's condition improves because hydrocortisone has to be suspended at least 24 hours before testing. The controversial entity of suboptimal cortisol response during acute stress may be associated with worse outcome, but no consensus exists for its diagnosis and treatment.

Dehydroepiandrosterone (DHEA) use is controversial and not recommended by present guidelines. However, a trial may be warranted in selected cases of women with primary AI and persistent symptoms, including low libido and low energy. DHEA is only available as a dietary supplement.

Monitoring

Patients should be interviewed and examined routinely for indicators of excess glucocorticoid replacement, such as weight gain, striae, facial plethora, osteoporosis, or glucose intolerance, or under replacement if symptoms of AI persist. Cortisol levels and ACTH are not helpful in monitoring glucocorticoid doses. Monitoring of mineralocorticoid status should include volume status, electrolytes, blood pressure, and occasionally serum renin levels. Development of hypertension, edema, or hypokalemia could mandate a dose reduction.

Complications

Adrenal crisis in patients with known AI occurs at a rate of approximately 6 cases per 100 patient-years. Precipitating causes of adrenal crisis are mainly gastrointestinal infection and other infections, with other stressful events (pain, surgery, severe emotional distress,

and pregnancy) occurring less commonly. Iatrogenic Cushing syndrome can develop if the dose of glucocorticoid replacement is supraphysiologic over the long term.

CUSHING'S SYNDROME

Method of

Constantine A. Stratakis, MD, PhD

**CURRENT DIAGNOSIS**

- Cushing's syndrome remains one of the most challenging diagnoses in endocrine medicine.
- Cushing's disease is caused by corticotropin (ACTH)-producing pituitary adenomas (corticotropinomas) and constitutes the most common cause of endogenous Cushing's syndrome, although its prevalence varies across different age groups.
- Growth failure in children, facial plethora and rounded face, central fat deposition, supraclavicular fat accumulation, buffalo hump, purple striae, thin skin, and proximal myopathy are relatively sensitive clinical features of Cushing's syndrome.
- Ectopic ACTH syndrome occasionally has an unusual presentation of rapid onset, severe weakness, and hypokalemia without classic symptoms of Cushing's syndrome.
- A urinary free cortisol test is the most cost-effective and reliable outpatient screening test.
- A 1-mg overnight dexamethasone screening test is less useful and more expensive than the urinary free cortisol test, but it provides a good alternative for patients in whom urinary collection is impossible or unreliable.
- Midnight salivary cortisol levels greater than 3.6 nmol/L ($0.13 \mu\text{g/dL}$) have a sensitivity and specificity of approximately 95% for the diagnosis of Cushing's syndrome.
- Undetectable ACTH levels ($<1 \text{ pmol/L}$ or $<5 \text{ pg/mL}$) indicate a primary autonomous adrenocortical disease.
- Postcontrast spoiled gradient-recalled acquisition (SPGR) magnetic resonance imaging (MRI) is superior to conventional MRI for the localization of corticotropinomas in children and adults.

Iatrogenic/Medication

Chronic steroid therapy, most often oral or parenteral, but could also be inhaled, topical, or injected
Chronic opioid therapy

Pituitary Injury

Post-transsphenoidal or transcranial surgery
Radiation to the sella
Infarction (e.g., Sheehan)
Traumatic brain injury

Tumors of the Sella

Pituitary adenoma
Craniopharyngioma
Meningioma
Rathke cleft cyst
Metastatic cancer

Infiltrative Diseases

Sarcoidosis, tuberculosis, or other granulomatous diseases
Lymphocytic hypophysitis
Idiopathic adrenocorticotrophic hormone deficiency
Adrenal insufficiency
Associated with cirrhosis
Associated with critical illness

If a patient with known AI presents in adrenal crisis, hydrocortisone (Solu-Cortef) 50 to 100 mg IV every 6 to 8 hours is an appropriate initial therapy, with the dose tapered to an appropriate oral dose as the patient's condition improves. Aggressive hydration with a saline solute will help increase the intravascular volume, and high-dose glucocorticoids have some mineralocorticoid activity; thus mineralocorticoids are not required in the treatment of acute adrenal crisis.

In critical illness, treatment of AI should not be delayed if diagnosis cannot be established and the patient is unstable. Baseline cortisol and ACTH levels should preferably be drawn prior to initiation of treatment and should be interpreted as a stress value (i.e., should be $>18 \mu\text{g/dL}$). If in doubt, high-dose stress steroids are administered until testing is complete, and cosyntropin stimulation testing may be delayed until the patient's condition improves because hydrocortisone has to be suspended at least 24 hours before testing. The controversial entity of suboptimal cortisol response during acute stress may be associated with worse outcome, but no consensus exists for its diagnosis and treatment.

Dehydroepiandrosterone (DHEA) use is controversial and not recommended by present guidelines. However, a trial may be warranted in selected cases of women with primary AI and persistent symptoms, including low libido and low energy. DHEA is only available as a dietary supplement.

Monitoring

Patients should be interviewed and examined routinely for indicators of excess glucocorticoid replacement, such as weight gain, striae, facial plethora, osteoporosis, or glucose intolerance, or under replacement if symptoms of AI persist. Cortisol levels and ACTH are not helpful in monitoring glucocorticoid doses. Monitoring of mineralocorticoid status should include volume status, electrolytes, blood pressure, and occasionally serum renin levels. Development of hypertension, edema, or hypokalemia could mandate a dose reduction.

Complications

Adrenal crisis in patients with known AI occurs at a rate of approximately 6 cases per 100 patient-years. Precipitating causes of adrenal crisis are mainly gastrointestinal infection and other infections, with other stressful events (pain, surgery, severe emotional distress,

and pregnancy) occurring less commonly. Iatrogenic Cushing syndrome can develop if the dose of glucocorticoid replacement is supraphysiologic over the long term.

CUSHING'S SYNDROME

Method of

Constantine A. Stratakis, MD, PhD

**CURRENT DIAGNOSIS**

- Cushing's syndrome remains one of the most challenging diagnoses in endocrine medicine.
- Cushing's disease is caused by corticotropin (ACTH)-producing pituitary adenomas (corticotropinomas) and constitutes the most common cause of endogenous Cushing's syndrome, although its prevalence varies across different age groups.
- Growth failure in children, facial plethora and rounded face, central fat deposition, supraclavicular fat accumulation, buffalo hump, purple striae, thin skin, and proximal myopathy are relatively sensitive clinical features of Cushing's syndrome.
- Ectopic ACTH syndrome occasionally has an unusual presentation of rapid onset, severe weakness, and hypokalemia without classic symptoms of Cushing's syndrome.
- A urinary free cortisol test is the most cost-effective and reliable outpatient screening test.
- A 1-mg overnight dexamethasone screening test is less useful and more expensive than the urinary free cortisol test, but it provides a good alternative for patients in whom urinary collection is impossible or unreliable.
- Midnight salivary cortisol levels greater than 3.6 nmol/L ($0.13 \mu\text{g/dL}$) have a sensitivity and specificity of approximately 95% for the diagnosis of Cushing's syndrome.
- Undetectable ACTH levels ($<1 \text{ pmol/L}$ or $<5 \text{ pg/mL}$) indicate a primary autonomous adrenocortical disease.
- Postcontrast spoiled gradient-recalled acquisition (SPGR) magnetic resonance imaging (MRI) is superior to conventional MRI for the localization of corticotropinomas in children and adults.

- Computed tomography (CT) is used to investigate adrenal disease in patients with ACTH-independent Cushing's syndrome. Usually, conventional MRI is less useful owing to motion artifacts.

CURRENT THERAPY

- The initial therapy of choice for patients with Cushing's disease is transsphenoidal surgery of the pituitary gland to remove the responsible adenoma.
- Transsphenoidal surgery has a success rate greater than 80% in most experienced centers. Lower success rates and higher incidence of relapse are recorded in less-experienced centers.
- Laparoscopic adrenalectomy has become the treatment of choice for benign adrenal lesions with a diameter of less than 6 cm.
- In stages I to III adrenocortical carcinoma, complete tumor resection offers the best chance for cure.
- Mitotane (Lysodren), an adrenolytic agent, is used in the treatment of metastatic adrenocortical carcinoma and also as an adjuvant for tumors with a high risk of recurrence.
- Medical treatment with ketoconazole¹, metyrapone¹, aminoglutethimide (Cytadren)², and mitotane¹ may be used to control hypercortisolism in preparation for surgery; medical adrenalectomy may also be used in cases of cyclic Cushing's syndrome.
- Pasireotide (Signifor) and mifepristone (Korlym) may be used for the treatment of Cushing's disease that cannot be cured by surgery and/or irradiation.
- The most effective treatment option for ectopic ACTH syndrome is resection of the tumor. Somatostatin analogues and various chemotherapeutic regimens have been used in the treatment of metastatic tumors.

Definition and Epidemiology

Cushing's syndrome remains one of the most difficult diagnoses in endocrinology. By definition, Cushing's syndrome is a multi-system disorder that develops in response to glucocorticoid excess. Iatrogenic Cushing's syndrome is common, but endogenous Cushing's syndrome is a rare condition, with an estimated incidence of 0.7 to 2.4 per million population per year. The etiology of Cushing's syndrome may be excessive adrenocorticotrophic hormone (ACTH) production from the pituitary gland, ectopic ACTH secretion by nonpituitary tumors, or autonomous cortisol hypersecretion from adrenal hyperplasia or tumors (Table 1). Cushing's disease refers to the subset of Cushing's syndrome cases caused by an ACTH-producing pituitary adenoma. Cushing's disease is the most common cause of spontaneous Cushing's syndrome in almost all ages, including older children and adolescents. Approximately 20% to 30% (with the exception of very young children) of endogenous Cushing's syndrome is caused by primary adrenocortical diseases that are not ACTH-dependent. Cushing's disease and adrenocortical adenomas occur more commonly in women, with a female-to-male ratio of 3–5:1.

Pathophysiology

Cortisol inhibits the biosynthesis and secretion of corticotropin-releasing hormone (CRH) and ACTH in a negative-feedback loop that is tightly controlled. The hallmark of Cushing's syndrome is the absence of suppression of cortisol levels after low-dose dexamethasone (Decadron) administration owing to autonomous ACTH secretion by a tumor or autonomous glucocorticoid production by a primary adrenocortical disease. It is essential to understand that all diagnostic testing in Cushing's syndrome relies on the disturbance

TABLE 1 Etiology of Cushing's Syndrome in Older Children, Adolescents, and Young Adults*

SYNDROME	% OF TOTAL

of this feedback mechanism, as revealed by dexamethasone, CRH (corticotropin ovine trifluate [Acthrel]), and all related testing.

ACTH-producing pituitary adenomas are microadenomas (<1 cm in diameter) in 80% to 90% of cases. Macroadenomas are rare and often invasive, with extension outside of the sella turcica. Chronic ACTH hypersecretion commonly leads to secondary adrenocortical hyperplasia.

Ectopic ACTH secretion is most often associated with small cell lung carcinoma, which accounts for half of the cases in adult patients with Cushing's syndrome. The ectopic ACTH syndrome causes severe hypokalemia and is usually underdiagnosed in patients during advanced stages of neoplasia. Other tumors causing the syndrome are bronchial, thymic, and pancreatic carcinoids; medullary thyroid carcinoma; pheochromocytoma; or other rare neuroendocrine tumors, especially in pediatric patients.

Adrenocortical tumors are more often adenomas that are usually smaller than 5 cm. Adrenocortical carcinomas are rare but very aggressive neoplasms; they most commonly occur as large nonsecreting abdominal masses at diagnosis, and only rarely does Cushing's syndrome develop.

Up to recently, only two types of primary adrenal hyperplasias that are ACTH-independent and cause Cushing's syndrome were known: primary pigmented nodular adrenocortical disease (PPNAD) and ACTH-independent macronodular adrenocortical hyperplasia, also known as massive macronodular adrenocortical disease.

Table 2 lists no fewer than six types of bilateral adrenocortical hyperplasias. They are divided into two groups of disorders, macronodular and micronodular hyperplasias, on the basis of the size of the associated nodules. In macronodular disorders, the greatest diameter of each nodule exceeds 1 cm; in the micronodular group, nodules are less than 1 cm. Although nodules less than 1 cm can occur in macronodular disease (especially the form associated with McCune-Albright syndrome), and single large tumors may be encountered in PPNAD (especially in older patients), the size criterion has biological relevance, because we rarely see a continuum in the same subject: most patients have either macronodular or micronodular hyperplasia. We use two additional basic characteristics in this classification of bilateral adrenocortical hyperplasias: presence of tumor pigment and status (hyperplasia or atrophy) of the surrounding cortex.

Pigment in adrenocortical lesions is rarely melanin; most of the pigmentation in adrenocortical adenomas and bilateral adrenocortical hyperplasias that produce cortisol is lipofuscin. The accumulation of lipofuscin-like material results from the progressive oxidation of unsaturated fatty acids by oxygen-derived free radicals in lysosomes. Lipofuscin pigmentation appears macroscopically as light brown to occasionally dark brown or even black discoloration of the tumor or hyperplastic tissue. Lipofuscin can be

TABLE 2 Bilateral Adrenal Hyperplasias Causing Cushing's Syndrome

LESION	AGE GROUP	HISTOPATHOLOGY	GENETICS	GENE, LOCUS
Macronodular Hyperplasias (Multiple Nodules >1 cm Each)				
Bilateral macroadenomatous hyperplasia	Middle age	Distinct adenomas (usually 2 or 3) with internodular atrophy	MEN1, FAP, MAS, HLRCS; isolated (AD); other	Menin, APC, GNAS, FH, ectopic GPCRs, ARMC5, PRKACA 5
Bilateral macroadenomatous hyperplasia of childhood	Infants, very young children	Distinct adenomas (usually 2 or 3) with internodular atrophy; occasional microadenomas	MAS	GNAS
ACTH-independent macronodular adrenocortical hyperplasia, also known as massive macronodular adrenocortical disease	Middle age	Adenomatous hyperplasia (multiple) with internodular hyperplasia of the zona fasciculata	Isolated, AD	Ectopic GPCRs; WISP2 and Wnt-signaling; 17q22-24, other; ARMC5, PRKACA 5
Micronodular Hyperplasias (Multiple Nodules <1 cm Each)				
Isolated primary pigmented nodular adrenocortical disease	Children; young adults	Microadenomatous hyperplasia with (mostly) internodular atrophy and nodular pigment (lipofuscin)	Isolated, AD	PRKAR1A, PDE11A; PDE8B; 2p16; PRKACA 5 other
Carney complex–associated primary pigmented nodular adrenocortical disease	Children; young and middle aged adults	Microadenomatous hyperplasia with (mostly) internodular atrophy and (mainly nodular) pigment (lipofuscin)	CNC (AD)	PRKAR1A, 2p16; other
Isolated micronodular adrenocortical disease	Mostly children; young adults	Microadenomatous, with hyperplasia of the surrounding zona fasciculata and limited or absent pigment	Isolated, AD; other	PDE11A, PDE8B; other; 2p12-p16, other

Abbreviations: ACTH = adrenocorticotrophic hormone; AD = autosomal dominant; APC = adenomatous polyposis coli gene; cAMP = cyclic adenosine monophosphate; CNC = Carney complex; FAP = familial adenomatous polyposis; FH = fumarate hydratase; GNAS = gene coding for the stimulatory subunit alpha of the G-protein (Gsa); GPCR = G-protein-coupled receptor; HLRCS = hereditary leiomyomatosis and renal cancer syndrome; MAS = McCune–Albright syndrome; MEN1 = multiple endocrine neoplasia type 1; PDE8B = phosphodiesterase 8B gene; PDE11A = phosphodiesterase 11A gene; PRKAR1A = protein kinase, cAMP-dependent, regulatory, type I, alpha gene; WISP2 = Wnt1-inducible signaling pathway protein 1; Wnt = wingless-type MMTV integration site family.

seen with a light microscope, but it is better detected by electron microscopy. Massive macronodular adrenocortical disease is a bilateral disease and may be caused by abnormal hormone receptor expression or activating mutations of $G_{s\alpha}$, which lead to stimulation of steroidogenesis. About 30% to 50% of the cases may be caused by ARMC5 mutations. Another cause of ACTH-independent Cushing's syndrome is primary pigmented nodular adrenocortical disease, usually associated with a syndrome of cardiac myxomas, lentigines, and schwannomas (Carney's complex).

Clinical Manifestations

The clinical presentation of Cushing's syndrome is variable and differs in severity (Table 3). Truncal obesity is the most common clinical sign and is usually the initial manifestation in most patients. Growth failure in children is the most reliable sign of Cushing's syndrome, especially when combined with continuing weight gain. Other symptoms include central fat deposition, supraclavicular fat accumulation, buffalo hump, plethora, rounded face, purple striae, thin skin, proximal muscle weakness, hypertension, impaired glucose metabolism, gonadal dysfunction, and hirsutism (see Table 3). Diabetes mellitus and hypertension also develop. Osteoporosis, mood disorders, emotional lability and cognitive deficits are commonly observed. Proximal myopathy is common, especially in older patients. Ectopic ACTH syndrome caused by small cell lung cancer can have an unusual presentation characterized by rapid onset, severe weakness, and associated hypokalemia without classic symptoms of Cushing's syndrome. In contrast, ACTH-secreting carcinoids manifest with typical clinical manifestations.

Diagnosis

Confirmation of the Diagnosis

The initial evaluation should always include a careful clinical history and physical examination. Reliable symptoms and signs of

TABLE 3 Clinical Manifestations of Cushing's Syndrome

SIGNS AND SYMPTOMS	INCIDENCE (%)

Purple striae	60
Buffalo hump	54
Osteoporosis	50
Headache	10

Cushing's syndrome (see Table 3) should be present in any patient who undergoes evaluation for Cushing's syndrome; patients with no reliable symptoms and signs of Cushing's syndrome should not be investigated, as this often leads to unnecessary, extensive, and expensive testing. It is essential to investigate the use of

exogenous glucocorticoids and other conditions that may be associated with mild hypercortisolism, such as alcoholism, anorexia nervosa, severe depression, and morbid obesity; these are pseudo-Cushing's states and are often difficult to exclude, especially in older or chronically ill patients.

The first task in the workup of any patient is documentation of hypercortisolism. On an outpatient basis, this is typically done through the urinary free cortisol test. This is the most cost-effective and reliable outpatient screening test. We typically recommend collections over two or three consecutive days so that we avoid errors due to over- or undercollection that are not uncommon with single 24-hour studies. The results of the test need to be corrected for body surface area, as long as total creatinine excretion is normal. A 1-mg overnight dexamethasone test is less useful and more expensive, but it provides a good alternative for patients in whom urinary collection is impossible or unreliable. During these screening tests for hypercortisolism, patients should avoid any activation of the hypothalamic-pituitary-adrenal axis by stress, especially physical. The baseline measurements may be repeated as needed, because cyclic hypercortisolism often precedes overt Cushing's syndrome (Figure 1).

A 24-hour urinary free cortisol excretion of greater than 250 nmol per 24 hours (90 $\mu\text{g}/24$ hours measured by radioimmunoassay) is highly specific for the diagnosis of hypercortisolism. However, pseudo-Cushing's states are often associated with abnormal levels of 24-hour urinary free cortisol. Administration of 1 mg dexamethasone (1.5 $\mu\text{g}/\text{kg}$ for children) at 11 PM results in suppression of the hypothalamic-pituitary-adrenal axis in normal persons and a fall in plasma and urinary cortisol levels. At 8 AM, serum cortisol should be less than 50 nmol/L (1.8 $\mu\text{g}/\text{dL}$). Unfortunately, dexamethasone is primarily metabolized by the cytochrome P-450 (CYP) system; several drugs, such as phenobarbital, carbamazepine (Tegretol), and rifampicin (Rifadin), that induce the activity of CYP3A4 can lead to false-positive tests. Oral contraceptives also interfere with serum cortisol levels owing to an increase in corticosteroid-binding globulin and by increasing dexamethasone metabolism. The test can only be interpreted if the serum dexamethasone levels reach the expected range; however, this additional requirement can make the test significantly more cumbersome and expensive.

Once hypercortisolism is suspected by the urinary free cortisol or the overnight dexamethasone test, the patient may undergo testing

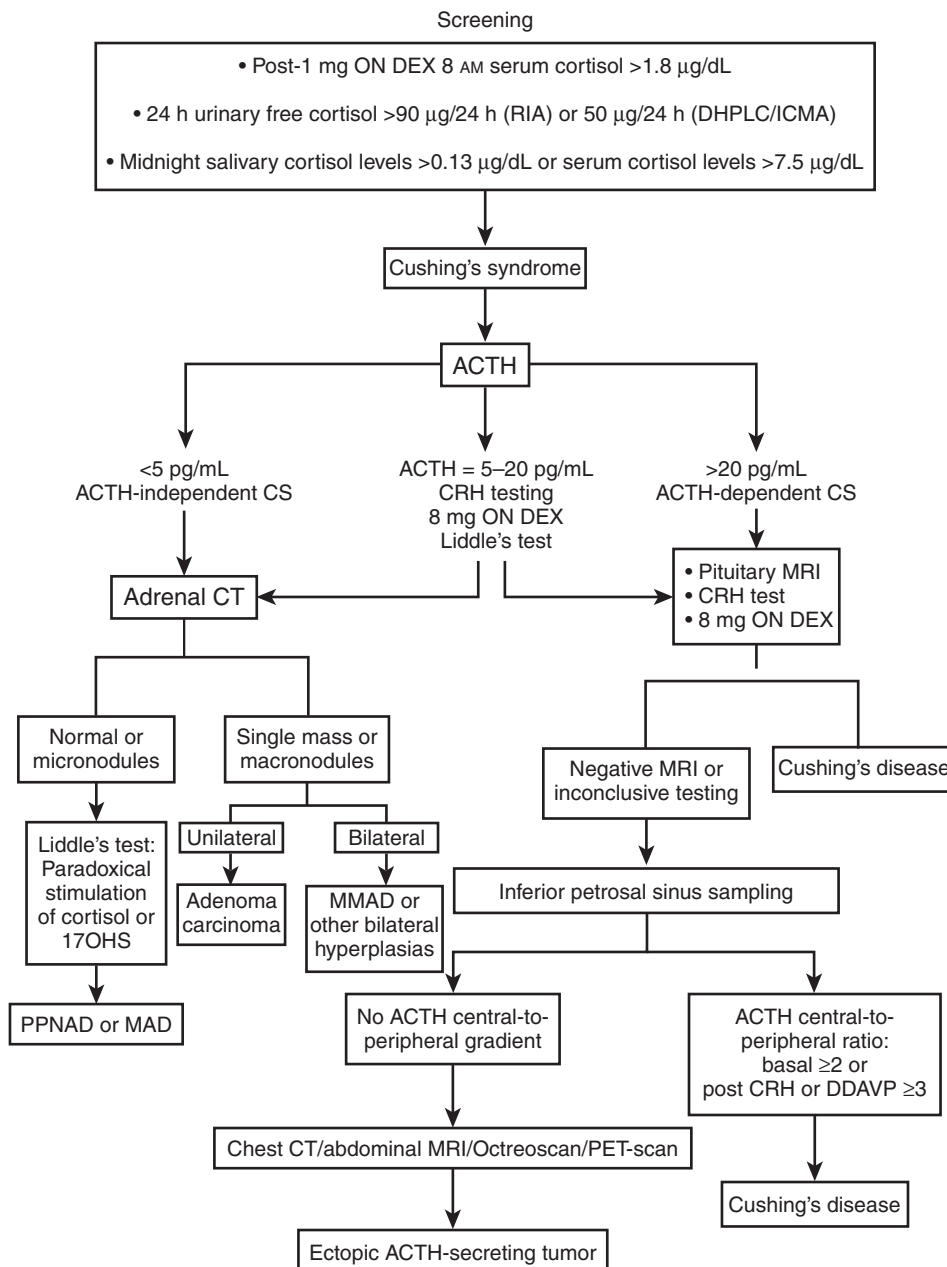

Figure 1 Algorithm for evaluating patients with Cushing's syndrome. *Abbreviations:* ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; CS = Cushing's syndrome; CT = computed tomography; DDAVP = desmopressin; DHPLC = denaturing high-performance liquid chromatography; ICMA = immunochemiluminometric assay; MAD = micronodular disease; MMAD = massive macronodular adrenocortical disease; MRI = magnetic resonance imaging; 17OHS = 17-hydroxysteroids; ON DEX = overnight dexamethasone; PET = positron emission tomography; PPNAD = primary pigmented nodular adrenocortical disease; RIA = radioimmunoassay.

of the cortisol diurnal rhythm. The lack of circadian rhythm of cortisol is the earliest consistent biochemical abnormality of Cushing's syndrome, even in situations of cyclic or other atypical forms of Cushing's syndrome. Serum or salivary cortisol levels at midnight may be used for this test. Normally, the level of serum cortisol begins to rise at 3 to 4 AM and reaches a peak at 7 to 8 AM, falling during the day. A sleeping midnight serum cortisol level lower than 50 nmol/L (1.8 µg/dL) excludes the diagnosis of Cushing's syndrome, whereas a midnight serum cortisol higher than 207 nmol/L (7.5 µg/dL) is highly suggestive of Cushing's syndrome. This test does require inpatient admission. Salivary cortisol levels have an excellent correlation with serum cortisol levels and offer an easy and convenient outpatient way of evaluating circadian rhythm; saliva is also stable at room temperature (for up to 7 days). Midnight salivary cortisol levels greater than 3.6 nmol/L (0.13 µg/dL) have a sensitivity and specificity of approximately 95% for the diagnosis of Cushing's syndrome (see [Figure 1](#)).

After the biochemical confirmation of hypercortisolism, the next step is to investigate the source (see [Figure 1](#)). Baseline ACTH plasma levels greater than 2 to 5 pmol/L (>20–25 pg/mL) are diagnostic of ACTH-dependent Cushing's syndrome. On the other hand, undetectable ACTH levels (<1 pmol/L or 5 pg/mL) indicate a primary autonomous adrenocortical disease. Values in between should be further investigated with dynamic testing.

High-Dose Dexamethasone Testing

Oral dexamethasone is administered as 2 mg every 6 hours for 48 hours or as a single 8 mg (120 µg/kg for children) overnight dose. Urinary and serum cortisol levels are suppressed by more than 50% in most patients with Cushing's disease.

Corticotropin-Releasing Hormone Testing

Synthetic ovine CRH (corticotropin-releasing hormone [Actrel]), an analogue of human CRH is administered intravenously (100 µg), and plasma ACTH and cortisol levels are measured at 15-minute intervals during the next 60 minutes. Patients with Cushing's disease typically have an increase in ACTH or cortisol level of 35% and 22%, respectively. This test has a sensitivity of approximately 85% for the diagnosis of Cushing's disease, but it is often falsely positive in patients with adrenal, ACTH-independent Cushing's syndrome, who do not have a fully suppressed hypothalamic-pituitary-adrenal axis.

Inferior Petrosal Sinus Sampling

None of the noninvasive tests are 100% accurate in distinguishing pituitary (Cushing's disease) from ectopic sources of ACTH. Inferior petrosal sinus sampling (IPSS) is indicated in all cases where an ACTH-dependent source of hypercortisolism is expected but the diagnosis of Cushing's disease versus an ectopic source remains uncertain. Typically, IPSS is done when the ovine CRH and dexamethasone tests are in disagreement or when the pituitary imaging by magnetic resonance imaging (MRI) is negative. An ACTH gradient of central-to-peripheral ACTH levels of 2 or more suggests Cushing's disease. When ovine CRH, human CRH, or desmopressin (DDAVP) testing is performed during IPSS, the diagnostic accuracy of IPSS increases. After ovine CRH stimulation, a central-to-peripheral ratio of ACTH levels of 3 or more suggest the diagnosis of Cushing's disease with specificity and sensitivity greater than 95%. The test is less useful for suggesting the tumor location (right versus left side of the pituitary gland).

Imaging Studies

Pituitary Magnetic Resonance Imaging

Unfortunately, less than 50% of ACTH-producing pituitary adenomas are detectable with MRI, even with the use of contrast enhancement. Typically, we recommend against obtaining an MRI until ACTH dependency is established, because as many as 20% of the patients have an incidental pituitary microadenoma. To avoid false-negative and false-positive imaging, several centers have sought improved methods for MRI detection of ACTH-producing tumors. Our studies demonstrated that postcontrast

spoiled gradient-recalled acquisition (SPGR) MRI in addition to the conventional T1-weighted spin echo was superior to conventional MRI for the diagnostic evaluation of corticotropinomas in both children and adults.

Adrenal Imaging

Computed tomography (CT) and MRI are used to investigate adrenal disease in patients with ACTH-independent Cushing's syndrome. Adrenal tumors larger than 6 cm are highly suspicious for adrenocortical carcinomas. The fat content contributes to the differentiation between benign and malignant adrenal tumors. Measurement of Hounsfield units (HU) in unenhanced CT is of great value in differentiating malignant from benign adrenal lesions. Adrenal lesions with an attenuation value of more than 10 HU in unenhanced CT or an enhancement washout of less than 50% and a delayed attenuation of more than 35 HU (on 10- to 15-min delayed enhanced CT) are suspicious for malignancy. MRI with dynamic gadolinium-enhanced and chemical shift technique is as effective as CT in distinguishing malignant from benign lesions. However, MRI is much less useful for detecting adrenal nodularity owing to motion artifacts. Thus, especially for detecting small unilateral adrenocortical adenomas or bilateral micronodular hyperplasia, we recommend a dedicated (thin-sliced) adrenal CT rather than MRI.

Ectopic Adrenocorticotrophic Hormone Syndrome

High Resolution Chest-CT 7 and abdominal MRI are the recommended imaging procedures in patients with an IPSS that indicates a nonpituitary ACTH-producing source. Additionally, somatostatin receptor scintigraphy is a useful and complementary tool in the evaluation of patients with ectopic ACTH-dependent Cushing's syndrome. Recent studies have demonstrated a higher sensitivity of somatostatin receptor scintigraphy in comparison to CT or MRI for diagnosing occult ectopic tumors. Additional methods include PET-CT and FDG scans.

Treatment

Untreated chronic hypercortisolism is associated with high morbidity and mortality owing to diabetes mellitus, hypertension, cardiovascular disease, thromboembolism, and suppression of the immune system. Cushing's syndrome should be treated effectively; patients should be closely monitored to rapidly detect recurrent disease.

Treatment of Pituitary Corticotropinomas

Transsphenoidal Pituitary Surgery

The initial therapy of choice for patients with Cushing's disease is transsphenoidal surgery. This procedure is associated with low mortality and morbidity, but complications can include cerebrospinal fluid leaks, meningitis, hypopituitarism, and venous thromboembolism. The success rate for transsphenoidal surgery varies between 60% and 80%, but in experienced centers can be as high as 90% to 95%. Relapses are rare when surgery is performed in an experienced tertiary care center; it can be as high as 30% in less-experienced centers. Postoperative morning serum cortisol levels of less than 50 nmol/L (2 µg/dL) are highly predictive of remission and a low recurrence rate of less than 10% at 10 years.

After successful transsphenoidal surgery, glucocorticoid replacement therapy (hydrocortisone at 12–15 mg/m²/day; 20–30 mg daily in adults) is mandatory until the hypothalamic-pituitary-adrenal axis recovers from the chronic exposure to glucocorticoid excess; this usually takes place within a year after surgery. For recurrent disease, the choice of second-line therapy remains controversial. Repeat surgery can be successful when residual tumor is detectable on MRI imaging, but it carries a high risk of hypopituitarism. Irradiation is recommended in most cases where a tumor is not seen on MRI.

Radiotherapy

Radiotherapy has been used to suppress pituitary secretion of ACTH, but its success rate is variable (50% in some series). It can take as long as 5 years for a full effect; hypopituitarism

develops in more than 70% of the patients over a period of 10 to 20 years after the therapy is completed. Stereotactic radiosurgery with gamma knife is associated with a more-rapid effect and a lower risk of hypopituitarism, but it has not been extensively studied.

Medical Treatment to Control Secretion of Adrenocorticotrophic Hormone

Cushing's disease responds to the dopamine agonist cabergoline (Dostinex)¹ with a normalization of cortisol production in as many as 40% of the cases. The peroxisome proliferator-activated receptor γ (PPAR- γ) agonist rosiglitazone (Avandia)¹ was demonstrated to be effective in animal models, but it was unsuccessful in controlling ACTH oversecretion in patients with Cushing's disease. A new agent, SOM-230 (pasireotide [Signifor]), blocks both type 2 and type 5 somatostatin receptors and reduces ACTH secretion in vitro. Mifepristone (Korlym), a glucocorticoid receptor antagonist, recently became available for patients who failed surgical or irradiation therapies (see also below).

Bilateral Adrenalectomy

Bilateral adrenalectomy offers a definitive treatment that provides immediate control of hypercortisolism, but this surgery should be reserved for patients with Cushing's disease who have failed all other treatments. Bilateral adrenalectomy in active Cushing's disease often leads to Nelson's syndrome, a condition characterized by unabated progression of a corticotropinoma (owing to the lack of negative feedback by cortisol), very high ACTH levels, and high morbidity.

Treatment of Adrenal Disease

Adrenocortical Tumors

For adrenocortical tumors, the recommended treatment is surgical. Laparoscopic adrenalectomy has become the treatment of choice for benign adrenal lesions with a diameter of less than 6 cm. In stages I to III adrenocortical carcinoma, complete tumor removal by a well-trained surgeon offers by far the best chance for cure. Surgery often needs to be extensive, with en bloc resection of invaded organs, and regularly includes lymphadenectomy. Surgery for local recurrences or metastatic disease is accepted as a valuable therapeutic option and was associated with improved survival in retrospective studies. The overall 5-year survival in different series ranged between 16% and 38%. Median survival for metastatic disease (stage IV) at the time of diagnosis is still consistently less than 12 months.

Radiotherapy has been considered ineffective for treatment of adrenocortical cancer, but it can be indicated to control localized disease not amenable to surgery.

Mitotane (α,p' -DDD [Lysodren]) is the only adrenal-specific agent available for treating adrenocortical cancer. Mitotane is indicated in metastatic adrenocortical carcinoma and can also be used as an adjuvant for tumors with a high risk of recurrence. Mitotane exerts a specific cytotoxic effect on adrenocortical cells, leading to

focal degeneration of the fascicular and particularly the reticular zone. In most patients, treatment should be initiated with a dose that does not exceed 1.5 g/day; this is then rapidly increased, depending on gastrointestinal symptoms, to 5 to 6 g/day. This high-dose regimen requires measurement of mitotane blood levels 14 days after initiation of therapy. The dose is then adjusted according to the medicine's plasma concentrations (which should be greater than 14 mg/L) and tolerance of the side effects. Because mitotane treatment induces adrenal insufficiency and increases the metabolic clearance of glucocorticoids, glucocorticoid replacement is indicated, often at higher than normal doses owing to increased clearance.

Cytotoxic Chemotherapy

Cytotoxic chemotherapy includes etoposide (VePesid)¹, doxorubicin (Adriamycin)¹, and cisplatin (Platinol)¹, or streptozocin (Zanosar)¹ plus mitotane. Chemotherapy has limited efficacy for advanced adrenocortical cancer and is associated mainly with partial responses.

Bilateral Adrenal Hyperplasias

The treatment of choice for bilateral adrenal hyperplasias associated with ACTH-independent Cushing's syndrome is bilateral adrenalectomy. Patients require lifelong replacement therapy with glucocorticoids and mineralocorticoids, and they should be adequately educated about the risk of acute adrenal insufficiency.

Treatment of Ectopic Corticotropin Syndrome

The choice of treatment for ectopic ACTH syndrome depends on tumor identification, localization, and classification. The most effective treatment option is surgical resection, although this is not always possible in metastatic disease or in the case of occult tumors. Because the ectopic ACTH syndrome is usually severe and occult tumors can become evident at imaging studies only during the follow-up, medical treatment to control hypercortisolism is often necessary. Bilateral adrenalectomy may be an option to be considered when the hypercortisolism cannot be controlled by other treatment options.

Medical Adrenalectomy

Several drugs that inhibit steroid synthesis are often effective for rapidly controlling hypercortisolism in preparation for surgery, after unsuccessful transsphenoidal surgery or removal of an adrenal tumor such as extensive cancer, or while awaiting the full effect of radiotherapy in recurrent Cushing's disease (Table 4).

Most experience with inhibitors of steroidogenesis has been with metyrapone (Metopirone)¹ and ketoconazole (Nizoral)¹, two medications that appear to be more effective and better tolerated than aminoglutethimide (Cytadren)². Metyrapone reduces cortisol and aldosterone production by inhibiting 11 β -hydroxylation in the adrenal cortex. Ketoconazole is a broad-spectrum antifungal drug,

²Not available in the United States.

which inhibits c17-20 desmolase, cholesterol side-chain cleavage, and 11 β -hydroxylation. Ketoconazole is also associated with inhibition of testosterone biosynthesis and gynecomastia.

RU-486, or mifepristone (Korlym), is an antagonist of the progesterone and glucocorticoid receptors. Unexpectedly, the treatment of Cushing's disease with this glucocorticoid antagonist has been associated with increased ACTH secretion and consequent stimulation of cortisol production. RU-486 may be more useful in ectopic ACTH-producing tumors and in adrenal Cushing's syndrome, but its efficacy and potential side effects when administered chronically are currently unknown.

DIABETES INSIPIDUS

Method of
Rami Mortada, MD

CURRENT DIAGNOSIS

- Diabetes insipidus (DI) is a disorder of excess urine production (i.e., “diabetes”) that is dilute and tasteless (i.e., “insipidus”). DI contrasts with the concentrated and sweet urine in diabetes mellitus.
- Patients with DI present with polyuria and polydipsia; urine output is usually more than 40 mL/kg/day or more than 3 L/day.
- There are three subtypes of DI:
 - Central DI: due to relative or absolute lack of vasopressin
 - Nephrogenic DI: due to partial or total resistance to the renal antidiuretic effects of vasopressin
 - Dipsogenic DI (also called primary polydipsia): where polyuria is secondary to excessive, inappropriate fluid intake
- Initial labs should include plasma sodium and urine osmolality. Under normal physiologic conditions, the urine osmolality is less than 300 mOsm/L, but if the patient does not have sufficient fluid intake, the urine osmolality can be higher.
- The diagnosis is confirmed by examining urine output and osmolality. It can be followed by an assessment of renal response to the synthetic arginine vasopressin (AVP) analogue desmopressin (DDAVP).
- In primary polydipsia, urine concentration is normal in response to dehydration.
- In central DI, urine concentration does not increase appropriately with dehydration, but does respond to desmopressin (DDAVP). After dehydration in central DI, urine osmolality remains <300 mOsm/kg, and plasma osmolality is >290 mOsm/kg. Urine osmolality rises to >750 mOsm/kg after desmopressin.

- In nephrogenic DI, urine concentration does not increase appropriately with either dehydration or exogenous desmopressin.

CURRENT THERAPY

- The treatment goal is to control polyuria and ensure electrolyte stability.
- In Central DI:
 - The mild form might not require treatment.
 - Significant polyuria can be treated with desmopressin in divided doses: nasal spray 5 to 100 μ g/day; tablets 100 to 1000 μ g/day; or parenterally 0.1 to 2.0 μ g/day.
 - Overtreatment can cause hyponatremia.
- In Nephrogenic DI:
 - Urine output should not be expected to normalize after DDAVP administration.
 - Correct the culprit cause (hypercalcemia or lithium [Eskalith, Lithobid] cessation).
 - Follow a low-sodium, low-protein diet, as tolerated.
 - Hydrochlorothiazide¹ 25 to 50 mg/day may be taken either alone or in combination with indomethacin (Indocin) 25 to 50 mg twice daily.
 - Symptoms may respond partly to high-dose desmopressin (e.g., 4 mcg IM twice daily).
- Primary polydipsia is treated by limiting an excessive fluid intake.

¹Not FDA approved for this indication.

Physiology of Antidiuretic Hormone

Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is a neurohypophysial hormone. It is a peptide hormone that promotes water retention by increasing the permeability of the kidney's collecting duct and distal convoluted tubule to water. It also increases peripheral vascular resistance, which in turn increases arterial blood pressure. In the clinical setting, the terms AVP, ADH, and vasopressin are used interchangeably.

Vasopressin is considered the main hormone involved in the regulation of water homeostasis and osmolality. The regulation and synthesis of vasopressin is under the influence of two systems: osmotic and pressure/volume status. In the case of osmoregulation, a small increase in plasma osmolality produces a parallel increase in vasopressin secretion; a small decrease in plasma osmolality causes a parallel drop in vasopressin.

Vasopressin is one among other hormones and systems that are involved in the regulation of volume and blood pressure. Other factors influence vasopressin production. For example, glucocorticoids inhibit secretion, whereas nausea and vomiting have a stimulatory effect.

Pathophysiology of Diabetes Insipidus

The kidneys exercise one of their urine-concentrating abilities by promoting water retention. If the concentration of vasopressin is decreased, polyuria occurs and diluted urine is excreted. A decrease in total body water results in an increase in the plasma osmolality. If the physiologic response is intact, thirst is stimulated, which leads to an increase in water consumption and the correction of plasma osmolality. Therefore, unless there is a dysregulation in the thirst mechanisms or water consumption is limited due to a lack of availability (e.g., decreased level of consciousness, immobility, or physical restraints) severe dehydration does not develop.

Clinical Causes

There are three subtypes of diabetes insipidus (DI).

- DI secondary to excess water intake (primary polydipsia)
Primary polydipsia is a disorder characterized by inappropriate excess fluid intake due to a disordered thirst sensation seen

which inhibits c17-20 desmolase, cholesterol side-chain cleavage, and 11 β -hydroxylation. Ketoconazole is also associated with inhibition of testosterone biosynthesis and gynecomastia.

RU-486, or mifepristone (Korlym), is an antagonist of the progesterone and glucocorticoid receptors. Unexpectedly, the treatment of Cushing's disease with this glucocorticoid antagonist has been associated with increased ACTH secretion and consequent stimulation of cortisol production. RU-486 may be more useful in ectopic ACTH-producing tumors and in adrenal Cushing's syndrome, but its efficacy and potential side effects when administered chronically are currently unknown.

Physiology of Antidiuretic Hormone

Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is a neurohypophysial hormone. It is a peptide hormone that promotes water retention by increasing the permeability of the kidney's collecting duct and distal convoluted tubule to water. It also increases peripheral vascular resistance, which in turn increases arterial blood pressure. In the clinical setting, the terms AVP, ADH, and vasopressin are used interchangeably.

Vasopressin is considered the main hormone involved in the regulation of water homeostasis and osmolality. The regulation and synthesis of vasopressin is under the influence of two systems: osmotic and pressure/volume status. In the case of osmoregulation, a small increase in plasma osmolality produces a parallel increase in vasopressin secretion; a small decrease in plasma osmolality causes a parallel drop in vasopressin.

Vasopressin is one among other hormones and systems that are involved in the regulation of volume and blood pressure. Other factors influence vasopressin production. For example, glucocorticoids inhibit secretion, whereas nausea and vomiting have a stimulatory effect.

Pathophysiology of Diabetes Insipidus

The kidneys exercise one of their urine-concentrating abilities by promoting water retention. If the concentration of vasopressin is decreased, polyuria occurs and diluted urine is excreted. A decrease in total body water results in an increase in the plasma osmolality. If the physiologic response is intact, thirst is stimulated, which leads to an increase in water consumption and the correction of plasma osmolality. Therefore, unless there is a dysregulation in the thirst mechanisms or water consumption is limited due to a lack of availability (e.g., decreased level of consciousness, immobility, or physical restraints) severe dehydration does not develop.

Clinical Causes

There are three subtypes of diabetes insipidus (DI).

- DI secondary to excess water intake (primary polydipsia)
Primary polydipsia is a disorder characterized by inappropriate excess fluid intake due to a disordered thirst sensation seen

mostly in patients with psychiatric illnesses. A central defect in thirst regulation plays an important role in the pathogenesis of primary polydipsia. Such patients continue drinking even if the plasma osmolality falls below normal. It is not easy to achieve or maintain a low plasma osmolality because vasopressin secretion will normally be suppressed by the fall in plasma osmolality, resulting in rapid excretion of the excess water. If vasopressin regulation is intact, primary polydipsia should not lead to clinically important disturbances in the plasma sodium concentration unless hyposmolar fluid intake overwhelms the kidneys' ability to excrete excess water. Thus the serum sodium concentration is usually normal or slightly reduced in primary polydipsia. These patients may be asymptomatic or present with complaints of polydipsia and polyuria. In rare circumstances where water intake exceeds the kidneys' ability to excrete the water load of about 500 mL/hour, symptomatic severe hyponatremia might result in severe psychosis. Psychosis from hyponatremia in primary polydipsia is most commonly seen in institutionalized patients or in individuals attempting to dilute their urine to avoid a positive urine drug test.

- DI secondary to a decrease in or absence of vasopressin secretion (central DI)

Central DI may be caused by genetic anomalies of the vasopressin gene (Table 1). Familial neurohypophyseal DI is characterized by the onset of DI with polyuria and polydipsia in childhood or early adulthood. The most common MRI finding in familial neurohypophyseal DI is the progressive disappearance of the posterior pituitary bright spot in children. The normal pituitary bright spot seen on unenhanced T₁-weighted MRI is thought to result from the T₁-shortening effect of the vasopressin stored in the posterior pituitary. The disappearance of the bright spot corresponds to the disappearance of vasopressin stores in the posterior pituitary. Wolfram's syndrome is a rare autosomal recessive syndrome manifested by DI, diabetes mellitus, optic atrophy, and deafness.

Central DI may be caused by mass lesions of the neurohypophysis, such as craniopharyngiomas, and primary germ cell tumors in childhood. DI can be the initial presentation. MRI often shows a thickened pituitary stalk and may show a hypothalamic mass. Metastasis to the pituitary usually is found with widespread metastatic disease and is twice as likely to involve the posterior pituitary than the anterior pituitary. DI can be associated with pituitary infiltration associated with lymphomas and leukemias.

In granulomatous disease that affects the hypothalamic-pituitary axis, there is usually clear evidence of disease elsewhere in the body. MRI shows an absence of the pituitary bright spot and widening of the hypothalamic-pituitary stalk. Lymphocytic infundibuloneurohypophysitis is a new, well-recognized cause of autoimmune DI, characterized by MRI appearance of a thickened hypothalamic-pituitary stalk and large posterior pituitary gland mimicking a pituitary tumor. Pituitary abscess is a rare

cause of pituitary mass and DI. In situations where the cause is not easily diagnosed, an autoimmune process should be suspected. In some patients, the cause is idiopathic.

Central DI may be caused by surgery or trauma to the pituitary region. Vasopressin is normally secreted after any kind of surgical stress, and secretion is more pronounced after surgery to the pituitary region. Only a small percentage of patients undergoing pituitary surgery have permanent DI. A triphasic DI can occur after complete hypothalamic-pituitary stalk transection. The first phase is polyuric and appears within the first 24 hours after surgery. It is thought to be secondary to axonal shock with a resultant inability to release prefabricated vasopressin. The second phase is antidiuretic and starts on about day 6, after stalk injury. It is thought to be secondary to the unregulated release of vasopressin stores. The third phase, also polyuric, starts about day 12, after vasopressin stores have been depleted. It may result in permanent or partial DI or resolve to clinically asymptomatic disease.

The same patterns of DI that occur after pituitary surgery can be seen in patients who experience a closed head trauma. Three-quarters of traumatic induced DI are secondary to motor vehicle accidents. Trauma is usually severe and causes unconsciousness. There is a high association of anterior pituitary deficiency in association with DI induced by head trauma, so the possibility of central hypocortisolism should be considered and treated immediately. DI is reported in 50% to 90% of patients with brain death.

- DI secondary to the lack of renal response to vasopressin (nephrogenic DI)

Genetic anomalies resulting in a lack of renal response to vasopressin are caused by either a mutation in the V₂ receptors or a mutation of the aquaporin 2 water channels gene. The majority of the cases are X-linked recessive disorders in males. Newborns present with polyuria, vomiting, constipation, and failure to thrive. Symptoms usually occur within the first week of life.

Acquired nephrogenic DI can be caused by a kidney disease that distorts the architecture of the kidney and impairs its urine-concentrating ability (e.g., polycystic kidney disease, sickle cell disease). Decreased function of vasopressin or downregulation of aquaporin 2 channels can be caused by hypokalemia, hypercalcemia, and relief of bilateral urinary tract obstruction. Drugs such as lithium (the most common cause of drug-induced nephrogenic DI) and demeclocycline (used clinically to treat a syndrome of inappropriate ADH secretion) may cause nephrogenic DI.

Clinical Manifestations

Patients with central DI typically present with polyuria, nocturia, and polydipsia. The serum sodium concentration in untreated central DI is often in the high normal range, which provides the ongoing stimulation of thirst that replaces urinary water losses. Moderate to severe hypernatremia can develop when thirst is impaired or if there is a lack of access to free water, such as the postoperative period in patients with unrecognized DI or infants with DI. For uncertain pathophysiologic reasons, patients with central DI may develop decreased bone mineral density at the lumbar spine and femoral neck, even if treated with desmopressin.

Nephrogenic DI in its mild form can be asymptomatic. Patients with moderate to severe nephrogenic DI, as with central DI, typically present with polyuria, nocturia, and polydipsia.

Primary polydipsia is the result of an abnormal compulsion to drink water. This disorder is most often seen in middle-aged women and in patients with psychiatric illnesses. The excessive water intake initially drives the excessive urination.

Diagnosis

Polyuria must be distinguished from simple urinary frequency in the absence of excess urine volume. The initial diagnostic approach should be to confirm polyuria, defined as greater than 30 mL/kg or 3 L/day, with a urine osmolality measuring less than 300 mOsm/L. Simple metabolic causes such as hyperglycemia, uremia, and

TABLE 1 Central Diabetes Insipidus (DI) Etiologies

Idiopathic	Unknown etiology
Genetic	Familial neurohypophyseal DI, Wolfram's syndrome (autosomal recessive)
Mass effect	Craniopharyngiomas, primary germ cell tumors, metastatic tumors
Infiltrative diseases	Lymphoma, leukemia, sarcoidosis, amyloidosis
Autoimmune	Lymphocytic infundibuloneurohypophysitis
Trauma	Motor vehicle accident, closed head trauma
Surgical	Surgical intervention at the pituitary region

hypercalcemia should be excluded. A definitive diagnosis of DI requires testing of vasopressin production and action in response to osmolar stress. All forms of DI may be partial or complete. In primary polydipsia, the plasma sodium, blood urea nitrogen (BUN), and uric acid are relatively low. In other forms of DI, the plasma sodium and uric acid are relatively high and the BUN is relatively low.

Central DI usually has an abrupt onset resulting from destruction of more than 80% of vasopressin-secreting hypothalamic neurons. The etiology of polyuria is not always evident after history and laboratory tests are completed. In that case, a water restriction test (e.g., dehydration test or water deprivation test) is completed. The water deprivation test is an indirect assessment of the AVP axis, measuring renal concentrating capacity in response to dehydration. It can be followed by assessment of the renal response to the synthetic AVP analogue desmopressin to determine whether any defect identified in urine-concentrating ability can be corrected with AVP-replacement. Office testing is acceptable unless the patient cannot be watched closely. No food or water is allowed. The patient is watched for signs of dehydration and surreptitious water drinking. Baseline measurements include weight, plasma osmolality, sodium, BUN, glucose, and urine volume and osmolality. Weight, plasma osmolality, and urine osmolality are measured hourly. The test is ended if urine osmolality has not increased to more than 300 mOsm/kg for 3 consecutive hours, plasma osmolality has reached 295 to 300 mOsm/kg, or the patient has lost 3% to 5% of body weight. All initial measurements are repeated at the end of the water restriction test. Then, 5 units of aqueous AVP (Pitressin) is administered or 2 µg of desmopressin is given subcutaneously and the plasma osmolality, sodium, BUN, glucose, and urine volume and osmolality are measured at 30, 60, and 120 minutes.

In primary polydipsia, urine concentration is normal in response to dehydration (Table 2).

In central DI, urine concentration does not increase appropriately with dehydration, but responds to desmopressin. Urine osmolality remains <300 mOsm/kg, accompanied by plasma osmolality >290 mOsm/kg after dehydration, and urine osmolality rising to >750 mOsm/kg after desmopressin administration.

In nephrogenic DI, urine concentration does not increase appropriately with either dehydration or exogenous desmopressin.

In practice, many results are indeterminate. If central DI is suspected, but the water deprivation test data are inconclusive, a reasonable approach is a therapeutic trial of 10 to 20 µg intranasal desmopressin per day with close monitoring of plasma sodium. If the diagnosis is confirmed, pituitary function testing and cranial MRI should follow.

Treatment

The treatment goal is to improve polyuria and polydipsia symptoms while attempting to treat the etiologic factors (Table 3). This is achieved by appropriate correction of dehydration, if present, and replacing vasopressin or augmenting its effect on the target tissue.

Mild forms of central DI may not require pharmacologic treatment. Desmopressin effectively treats polyuria and polydipsia. Desmopressin comes in different forms, and dosages usually need to be divided.

TABLE 3 Treatment Options for Diabetes Insipidus

Central DI	Divide doses of two to three times per day: Desmopressin nasal spray 5–100 µg/day Desmopressin tablets 0.1–1 mg/day Desmopressin injection 0.1–2 µg/day
Nephrogenic DI	Low-salt, low-protein diet HCTZ ¹ 25 mg one to two times per day Indomethacin ¹ 25–50 mg bid Amiloride ¹ 5–10 mg bid
Primary polydipsia	Water restriction to less than 1.5 L/day

¹Not FDA approved for this indication.

Hyponatremia from plasma dilution can be avoided by skipping treatment for a short period on a regular basis (e.g., on Sunday). No second dose of desmopressin should be given unless the patient has urine output after the first dose.

Nephrogenic DI may respond to the removal of the offending agent (e.g., lithium) or correction of the underlying electrolyte disturbance (e.g., hypercalcemia or hypokalemia). Drug-induced nephrogenic DI, however, may persist after discontinuation of the drug.

Patients should be instructed to eat a low-sodium, low-protein diet, resulting in a decrease in urine output secondary to the drop in solute excretion. If symptomatic polyuria persists, hydrochlorothiazide¹ can be started. Hydrochlorothiazide presumably acts by inducing mild hypovolemia that induces an increase in proximal sodium and water reabsorption, thereby diminishing water delivery to the vasopressin-sensitive sites in the collecting tubules and reducing the urine output. Indomethacin (Indocin¹) is an add-on medication if there is not enough response. Given that prostaglandins antagonize the action of vasopressin, indomethacin inhibits renal prostaglandin synthesis and subsequently decreases urine output.

Amiloride (Midamor)¹ might be more effective for lithium-induced nephrogenic DI. This drug closes the sodium channels in the luminal membrane of the collecting tubule cells. These channels constitute the mechanism by which filtered lithium normally enters the collecting tubule cells and interferes with the collecting tubule response to ADH.

The approach to primary polydipsia treatment is reduction in fluid intake. Desmopressin treatment should be avoided due to the risk of hyponatremia.

Monitoring

Primary polydipsia is the most challenging of all types of DI to treat. It requires a multidisciplinary approach that frequently demands medical and psychiatric involvement.

In central DI, patients will require frequent follow-up to adjust desmopressin dosing. Once stable, patients can be seen less

TABLE 2 Values Before and After Water Restriction

	INITIAL PLASMA OSMOLALITY	INITIAL PLASMA SODIUM	POSTTEST URINE/PLASMA OSMOLALITY	POSTTEST URINE/PLASMA OSMOLALITY + ADH
Normal	NL	NL	>1	>1
Central DI	High (high NL)	High (high NL)	<1	>1
Nephrogenic DI	High (high NL)	High (high NL)	<1	<1
Primary polydipsia	Low (low NL)	Low (low NL)	>1	>1

¹Not FDA approved for this indication.

frequently to assess symptom control and to check plasma sodium levels to avoid overtreatment resulting in hyponatremia.

In nephrogenic DI, after the precipitating agent has been withdrawn, follow-up is needed to assess the reversibility of polyuria. If acquired nephrogenic DI becomes irreversible, patients might require prolonged pharmacological treatment. In both central and nephrogenic DI, the patient is advised to wear a medical alert bracelet stating the disease and the potential complications.

DIABETIC KETOACIDOSIS

Method of

Aidar R. Gosmanov, MD, PhD, DMSc; and Barry M. Wall, MD

CURRENT DIAGNOSIS

- Initial evaluation includes physical examination and comprehensive metabolic panel, serum osmolality, serum ketones and β -hydroxybutyrate, complete blood count, urinalysis, urine ketones, and arterial blood gases.
- Search for precipitating cases. Omission of insulin, underlying medical illness, cardiovascular events, gastrointestinal disorders, recent surgery, stress, medications, eating disorders, psychological stress, insulin pump malfunction, and infection are potential causes; white blood cell count greater than 25,000 suggests presence of infection.
- β -Hydroxybutyrate of 3.8 mmol/L or greater in adults indicates presence of diabetic ketoacidosis (DKA) even if serum ketones are negative.
- Patients with severe chronic kidney disease (CKD) require careful evaluation of acid–base status.

CURRENT THERAPY

- Start intravenous fluids early before insulin therapy.
- Potassium level should be more than 3.3 mEq/L before insulin therapy is initiated. Supplement potassium intravenously if needed.
- Initiate continuous insulin infusion at 0.14 U/kg per hour and measure bedside glucose every 1 hour to adjust the insulin infusion rate.
- Avoid hypoglycemia during the insulin infusion by initiating dextrose-containing fluids and/or reducing the insulin infusion rate until DKA is resolved.
- Transition to subcutaneous insulin only when DKA resolution is established.

Epidemiology

There were 168,000 hospital discharges for DKA in 2014 in the United States, compared to 140,000 in 2009 and 80,000 in 1988. In 2005, the direct and indirect annual cost of DKA hospitalization was \$2.4 billion.

Risk Factors

Omission of insulin is the most common precipitant of DKA. Infections, acute medical illnesses involving the cardiovascular system (myocardial infarction, stroke) and gastrointestinal tract (bleeding, pancreatitis), diseases of the endocrine axis (acromegaly, Cushing's syndrome), and stress of recent surgical procedures can contribute to the development of DKA by causing dehydration, increase in insulin counterregulatory hormones, and worsening of peripheral insulin resistance. Medications such as diuretics, β -blockers, corticosteroids, second-generation antipsychotics, and anticonvulsants can affect carbohydrate metabolism and volume status and therefore can precipitate DKA. Other factors that can contribute to DKA include psychological problems, eating disorders, insulin pump malfunction, lower socioeconomic status, and drug abuse. It is now recognized that new-onset type 2 diabetes mellitus can manifest with DKA. These patients are obese, mostly African American or Hispanic, and extremely insulin resistant on presentation. Recently, the use of sodium-glucose cotransporter 2 (SGLT-2) inhibitors has been implicated in the development of DKA in patients with both type 1 and type 2 diabetes.

Pathophysiology

Insulin deficiency, increased insulin counterregulatory hormones (cortisol, glucagon, growth hormone, and catecholamines), and peripheral insulin resistance lead to hyperglycemia, dehydration, ketosis, and electrolyte imbalance, which underlie the pathophysiology of DKA. The hyperglycemia of DKA evolves through accelerated gluconeogenesis, glycogenolysis, and decreased glucose utilization, all due to absolute insulin deficiency. Owing to increased lipolysis and decreased lipogenesis, abundant free fatty acids are converted to ketone bodies: acetoacetate and β -hydroxybutyrate (β -OHB). Hyperglycemia-induced osmotic diuresis, if not accompanied by sufficient oral fluid intake, leads to dehydration, hyperosmolality, electrolyte loss, and subsequent decrease in glomerular filtration.

With decline in a renal function, glycosuria diminishes and hyperglycemia worsens. With impaired insulin action and hyperosmolar hyperglycemia, potassium uptake by skeletal muscle is markedly diminished, which, along with hyperosmolality-mediated efflux of potassium from cells, results in intracellular potassium depletion. Potassium is lost via osmotic diuresis, causing profound total body potassium deficiency. Therefore DKA patients can present with a broad range of serum potassium concentrations. A “normal” plasma potassium concentration still indicates that potassium stores in the body are severely diminished and the institution of insulin therapy and correction of hyperglycemia will result in hypokalemia.

On average, patients with DKA have the following deficit of water and key electrolytes: water 100 mL/kg, sodium 7 to 10 mEq/kg, potassium 3 to 5 mEq/kg, and phosphorus 1 mmol/kg.

Clinical Manifestations

Polyuria, polydipsia, weight loss, vomiting, and abdominal pain usually are present in patients with DKA. Abdominal pain can be closely associated with acidosis and resolves with treatment. Physical examination findings such as hypotension, tachycardia, poor skin turgor, and weakness support the clinical diagnosis of dehydration in DKA. Mental status changes can occur in DKA and likely are related to degree of acidosis and hyperosmolality. A search for symptoms of precipitating causes such as infection, vascular events, or existing drug abuse should be initiated in the emergency department. Patients with hyperglycemic crises can be

frequently to assess symptom control and to check plasma sodium levels to avoid overtreatment resulting in hyponatremia.

In nephrogenic DI, after the precipitating agent has been withdrawn, follow-up is needed to assess the reversibility of polyuria. If acquired nephrogenic DI becomes irreversible, patients might require prolonged pharmacological treatment. In both central and nephrogenic DI, the patient is advised to wear a medical alert bracelet stating the disease and the potential complications.

- Patients with severe chronic kidney disease (CKD) require careful evaluation of acid–base status.

CURRENT THERAPY

- Start intravenous fluids early before insulin therapy.
- Potassium level should be more than 3.3 mEq/L before insulin therapy is initiated. Supplement potassium intravenously if needed.
- Initiate continuous insulin infusion at 0.14 U/kg per hour and measure bedside glucose every 1 hour to adjust the insulin infusion rate.
- Avoid hypoglycemia during the insulin infusion by initiating dextrose-containing fluids and/or reducing the insulin infusion rate until DKA is resolved.
- Transition to subcutaneous insulin only when DKA resolution is established.

Epidemiology

There were 168,000 hospital discharges for DKA in 2014 in the United States, compared to 140,000 in 2009 and 80,000 in 1988. In 2005, the direct and indirect annual cost of DKA hospitalization was \$2.4 billion.

Risk Factors

Omission of insulin is the most common precipitant of DKA. Infections, acute medical illnesses involving the cardiovascular system (myocardial infarction, stroke) and gastrointestinal tract (bleeding, pancreatitis), diseases of the endocrine axis (acromegaly, Cushing's syndrome), and stress of recent surgical procedures can contribute to the development of DKA by causing dehydration, increase in insulin counterregulatory hormones, and worsening of peripheral insulin resistance. Medications such as diuretics, β -blockers, corticosteroids, second-generation antipsychotics, and anticonvulsants can affect carbohydrate metabolism and volume status and therefore can precipitate DKA. Other factors that can contribute to DKA include psychological problems, eating disorders, insulin pump malfunction, lower socioeconomic status, and drug abuse. It is now recognized that new-onset type 2 diabetes mellitus can manifest with DKA. These patients are obese, mostly African American or Hispanic, and extremely insulin resistant on presentation. Recently, the use of sodium-glucose cotransporter 2 (SGLT-2) inhibitors has been implicated in the development of DKA in patients with both type 1 and type 2 diabetes.

Pathophysiology

Insulin deficiency, increased insulin counterregulatory hormones (cortisol, glucagon, growth hormone, and catecholamines), and peripheral insulin resistance lead to hyperglycemia, dehydration, ketosis, and electrolyte imbalance, which underlie the pathophysiology of DKA. The hyperglycemia of DKA evolves through accelerated gluconeogenesis, glycogenolysis, and decreased glucose utilization, all due to absolute insulin deficiency. Owing to increased lipolysis and decreased lipogenesis, abundant free fatty acids are converted to ketone bodies: acetoacetate and β -hydroxybutyrate (β -OHB). Hyperglycemia-induced osmotic diuresis, if not accompanied by sufficient oral fluid intake, leads to dehydration, hyperosmolality, electrolyte loss, and subsequent decrease in glomerular filtration.

With decline in a renal function, glycosuria diminishes and hyperglycemia worsens. With impaired insulin action and hyperosmolar hyperglycemia, potassium uptake by skeletal muscle is markedly diminished, which, along with hyperosmolality-mediated efflux of potassium from cells, results in intracellular potassium depletion. Potassium is lost via osmotic diuresis, causing profound total body potassium deficiency. Therefore DKA patients can present with a broad range of serum potassium concentrations. A “normal” plasma potassium concentration still indicates that potassium stores in the body are severely diminished and the institution of insulin therapy and correction of hyperglycemia will result in hypokalemia.

On average, patients with DKA have the following deficit of water and key electrolytes: water 100 mL/kg, sodium 7 to 10 mEq/kg, potassium 3 to 5 mEq/kg, and phosphorus 1 mmol/kg.

Clinical Manifestations

Polyuria, polydipsia, weight loss, vomiting, and abdominal pain usually are present in patients with DKA. Abdominal pain can be closely associated with acidosis and resolves with treatment. Physical examination findings such as hypotension, tachycardia, poor skin turgor, and weakness support the clinical diagnosis of dehydration in DKA. Mental status changes can occur in DKA and likely are related to degree of acidosis and hyperosmolality. A search for symptoms of precipitating causes such as infection, vascular events, or existing drug abuse should be initiated in the emergency department. Patients with hyperglycemic crises can be

hypothermic because of peripheral vasodilation and decreased utilization of metabolic substrates.

Diagnosis

Diagnostic criteria for DKA include blood glucose higher than 250 mg/dL, arterial pH 7.30 or less, bicarbonate level 18 mEq/L or less, and adjusted for albumin anion gap greater than 10 to 12. Therefore initial laboratory evaluation should include a comprehensive metabolic panel and arterial blood gases. Positive serum and urine ketones can further support the diagnosis of DKA but are not required. In early DKA, acetoacetate concentration is low, but it is a major substrate for ketone measurement by many laboratories; therefore ketone measurement in serum by usual laboratory techniques has a high specificity but low sensitivity for the diagnosis of DKA. Conversely, β -OHB is an early and abundant ketoacid that can first signal development of DKA, but its measurement requires use of specific assay that is different from ketone measurement. β -OHB of 3.8 mmol/L or higher was shown to be highly sensitive and specific for DKA diagnosis.

In patients with chronic kidney disease stage 4 or 5, the diagnosis of DKA is challenging because of presence of chronic metabolic acidosis and possibility of mixed acid–base disorders on presentation with DKA. Anion gap greater than 20 supports the diagnosis of DKA in such patients.

Differential Diagnosis

Hyperglycemic hyperosmolar state is usually not associated with ketosis, but mixed hyperglycemic hyperosmolar state and DKA can occur. Clinical scenarios that may be accompanied by acidosis are described in Table 1. Pregnancy, starvation, and alcoholic ketoacidosis are not characterized by hyperglycemia greater than 250 mg/dL. With hypotension or history of metformin (Glucophage) use, lactic acidosis should be suspected. Ingestion of methanol, isopropyl alcohol, and paraldehyde¹ can also alter anion gap and/or osmolality but are not associated with hyperglycemia.

Treatment

The therapeutic goals of management include optimization of volume status, hyperglycemia and ketoacidosis, electrolyte abnormalities, and potential precipitating factors. DKA management workflow is presented in Figure 1. Efficiency of early DKA therapy can be improved by clustering key diagnostic and therapeutic steps in one protocol that is easy to understand by nursing staff and physicians. Table 2 provides one example of such DKA care bundle. Given the complexity of the condition management, provision of a single care bundle/order set allows fundamentals of DKA treatment to be delivered safely and efficiently while giving the providers guidance on tackling unanticipated issues during the DKA care. Special considerations should be given to patients with con-

gestive heart failure and CKD. These patients tend to retain fluids; therefore caution should be exercised during volume resuscitation in these patient groups.

Bicarbonate therapy is not indicated in mild and moderate forms of DKA because metabolic acidosis should correct with insulin therapy. The use of bicarbonate in severe DKA is controversial owing to lack of prospective randomized studies. It is thought that the administration of bicarbonate actually results in peripheral hypoxemia, worsened hypokalemia, paradoxical central nervous system acidosis, cerebral edema in children and young adults, and an increase in intracellular acidosis. Because severe acidosis is associated with worse clinical outcomes and can lead to impairment in sensorium and deterioration of myocardial contractility, bicarbonate therapy may be indicated if the pH is 6.9 or less. Therefore the infusion of 100 mmol (2 ampoules) of bicarbonate in 400 mL of sterile water mixed with 20 mEq potassium chloride over 2 hours and repeating the infusion until the pH is greater than 7.0 can be recommended pending the results of prospective trials.

A whole-body phosphate deficit in DKA can average 1 mmol/kg. Insulin therapy during DKA will further lower serum phosphate concentration. Prospective randomized studies have failed to show any beneficial effect of phosphate replacement on the clinical outcome in DKA. However, a careful phosphate replacement sometimes is indicated in patients with serum phosphate concentration less than 1.0 mg/dL and in those with cardiac dysfunction, anemia, or respiratory depression who have serum phosphate level between 1.0 and 2.0 mg/dL. Initial replacement strategy may include infusion of potassium phosphate at the rate of 0.1 to 0.2 mmol/kg over 6 hours depending on the degree of phosphate deficit (1 mL potassium phosphate solution for intravenous use contains 3 mmol phosphorous and 4.4 mEq potassium). Overzealous phosphate replacement can result in hypocalcemia; therefore close monitoring of phosphorous and calcium levels is recommended. Patients who have renal insufficiency or hypocalcemia might need less-aggressive phosphate replacement.

When DKA is resolved, and independent of the patient's ability to tolerate oral intake, transition to subcutaneous insulin must be initiated. Patients are given intermediate (NPH) or long-acting insulin (detemir [Levemir], glargine [Lantus]) 2 hours before termination of intravenous insulin to allow sufficient time for injected insulin to start working (Table 3). When the patient can eat, we recommend addition of short- or rapid-acting insulin for prandial glycemic coverage (see Table 3). This is the basal-bolus insulin regimen and provides physiologic replacement of insulin. It is common to see transition from intravenous to subcutaneous insulin using sliding-scale insulin only. This strategy as a sole approach should be discouraged because it cannot provide the necessary insulin requirement in patients recovering from hyperglycemic crisis and beta-cell failure.

If the patient used insulin prior to admission, the same dosage can be restarted in the hospital. Insulin-naïve patients require insulin at a total dose of 0.5 to 0.8 U/kg/day divided as 50% basal

¹Not available in the United States.

*Respiratory alkalosis or metabolic acidosis

[†]Acetest and Ketostix (Bayer, Leverkusen, Germany) measure acetoacetic acid only; thus, misleadingly low values may be obtained because the majority of “ketone bodies” are β -hydroxybutyrate.

Abbreviations: BUN = blood urea nitrogen; DKA = diabetic ketoacidosis.

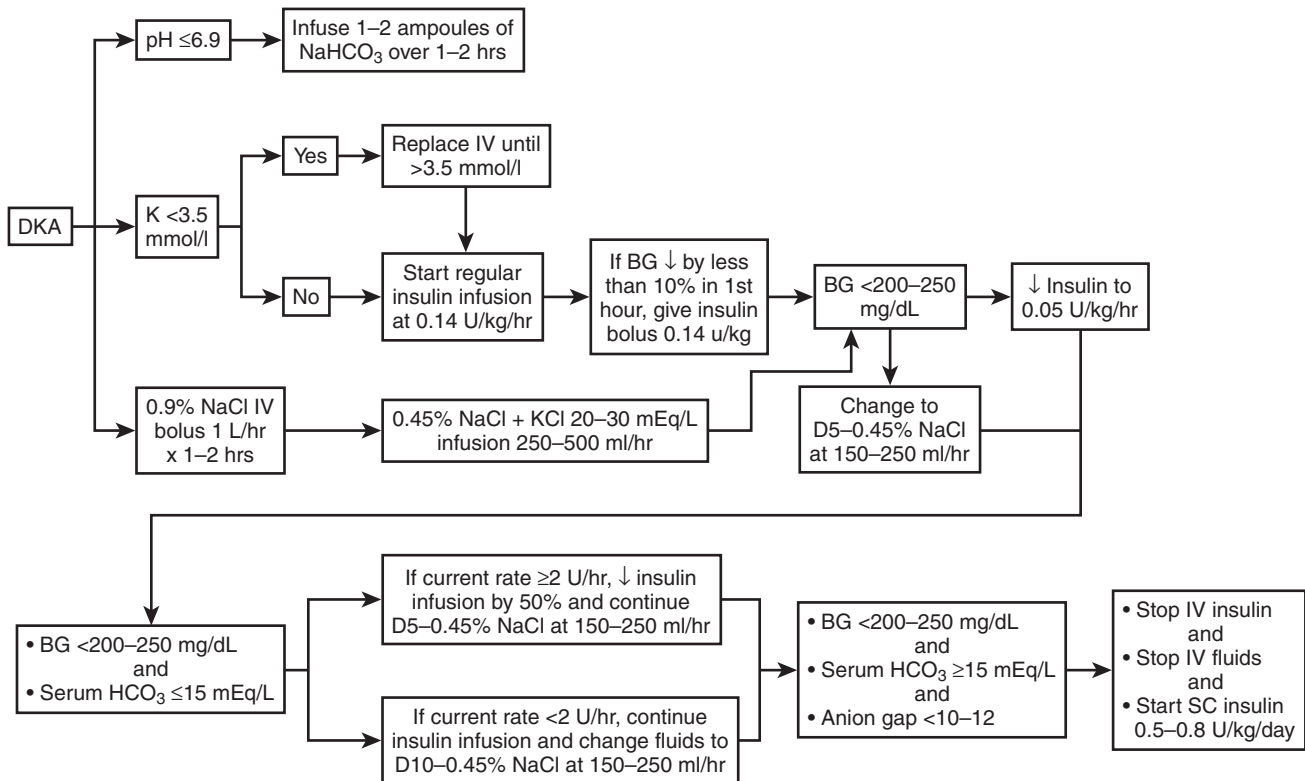

Figure 1 DKA management protocol. *Abbreviation:* BG = blood glucose.

insulin and 50% as prandial insulin before each meal. Initially, after DKA resolution, given the possibility of fluctuating oral intake, use of once-daily long-acting insulin such as glargine or detemir to provide basal insulin coverage is encouraged. Approved by the FDA in 2015, long-acting insulin glargine U300 (Toujeo) and insulin degludec (Tresiba) have not been studied in hospitalized patients treated for DKA and therefore cannot be recommended for subcutaneous administration immediately following DKA resolution. For patients who are not able to adhere to or afford multiple daily insulin injections, conversion of inpatient basal-bolus insulin regimen before discharge to split-mix insulin preparation (Humulin 70/30, Novolin 70/30, Humalog mix 75/25, Novolog mix 70/30) twice a day that contains a mixture of intermediate-acting insulin NPH and short-acting insulin formulations such as regular (Humulin R, Novolin R), aspart (Novolog), or lispro (Humalog) can be considered. Finger-stick glucose measurements before each meal and at night should be taken after discontinuation of intravenous insulin to correct for possible fluctuations in insulin needs while in the hospital.

Monitoring

Serial measurements—every 2 to 4 hours—of metabolic parameters are required to monitor therapy and then confirm resolution of DKA. DKA is considered resolved when plasma glucose is less than 200 to 250 mg/dL, serum bicarbonate concentration is 15 mEq/L or higher, venous blood pH is greater than 7.3, and anion gap 12 or less. In general, resolution of hyperglycemia, normalization of bicarbonate level, and closure of the anion gap is sufficient to stop insulin infusion. Anion gap is calculated by subtracting the sum of Cl^- and HCO_3^- from measured (not corrected) Na^+ concentration and can improve even before the restoration of serum bicarbonate owing to hyperchloremia from normal saline infusion. Venous pH is adequate to assess the degree of acidosis with consideration that it is 0.02 to 0.03 lower than arterial blood. If plasma glucose is less than 200 mg/dL but bicarbonate and pH are not normalized, insulin infusion must be continued

and dextrose-containing intravenous fluids started. The latter approach will continue to suppress ketogenesis and prevent hypoglycemia.

Complications

Hypoglycemia is the most common complication and can be prevented by timely adjustment of insulin dosage and frequent monitoring of blood glucose levels. Hypoglycemia is defined as any blood glucose level below 70 mg/dL. If DKA is not resolved and blood glucose level is below 200 to 250 mg/dL, decrease in insulin infusion rate and/or addition of 5% or 10% dextrose to current intravenous fluids may be implemented (see Figure 1). For patients in whom DKA is resolved, strategies to manage hypoglycemia depend on whether patient is able to eat or not. For patients who are able to drink or eat, ingestion of 15 to 20 grams of carbohydrates—for example, four glucose tablets or 6 oz orange or apple juice or “regular” soft drink—is advised. In patients who are allowed nothing by mouth, are unable to swallow, or have altered level of consciousness, administer 25 mL 50% dextrose IV or give 1 mg glucagon (Glucagon) IM if no IV access present. Blood glucose should be rechecked in 15 minutes; only if the glucose level is less than 80 mg/dL should these steps be repeated.

Non-anion-gap hyperchloremic acidosis occurs from urinary loss of ketoanions, which are needed for bicarbonate regeneration, and preferential reabsorption of chloride in proximal renal tubules secondary to intensive administration of chloride-containing fluids and low plasma bicarbonate. The acidosis usually resolves and should not affect treatment course. Cerebral edema has been reported in young adult patients. This condition is manifested by appearance of headache, lethargy, papillary changes, or seizures. Mortality is up to 70%. Mannitol (Osmitol) infusion and mechanical ventilation should be used to treat this condition. Rhabdomyolysis is another possible complication resulting from hyperosmolality and hypoperfusion. Pulmonary edema can develop from excessive fluid replacement in patients with CKD or congestive heart failure.

Lispro (Humalog)	5–15 min	30–90 min	4–6 h	15 min before meal
NPH (Humulin N, Novolin N)	2–4 h	4–10 h	12–18 h	Twice a day
Detemir (Levemir)	2 h	No peak	12–24 h	Once or twice a day
Glargine (Lantus)	2 h	No peak	20–24 h	Once a day

Prevention

Discharge planning should include diabetes education, selection of an appropriate insulin regimen that the patient can understand and afford, and preparation of set of supplies for the initial insulin administration at home. Many cases of DKA can be prevented by better access to medical care, proper education, and effective communication with a health care provider during an intercurrent illness.

Sick-day management should be reviewed periodically with all patients. It should include specific information on when to contact the health care provider, blood glucose goals and the use of supplemental short- or rapid-acting insulin during illness, insulin use during fever and infection, and initiation of an easily digestible liquid diet containing carbohydrates and salt. Most importantly, the patient should be advised to never discontinue insulin and to seek professional advice early in the course of the illness. The patient or family member must be able to accurately measure and record insulin administered, blood glucose, and blood β -hydroxybutyrate with a point-of-care device when blood glucose is higher than 300 mg/dL. Recent studies demonstrated that b-OHB testing in outpatient setting is more effective than urine acetoacetate testing in preventing DKA, which may reduce costs of care of patients with insulin-dependent diabetes.

Because of the significant cost of repeated admissions for DKA, resources should be directed toward educating primary care providers and school personnel so that they can identify signs and symptoms of uncontrolled diabetes earlier.

DIABETES MELLITUS IN ADULTS

Method of

Anthony L. McCall, MD, PhD; J. Terry Saunders, PhD; Niyaz Gosmanov, MD; and Albina Gosmanova, MD

CURRENT DIAGNOSIS

- Screening for diabetes should be done in high-risk populations, especially:
 - Those with prediabetes, signs of insulin resistance (e.g., acanthosis nigricans), or the metabolic syndrome.
 - High-risk ethnic groups (e.g., Native American, Latino American, African American).
 - History of gestational diabetes or polycystic ovary disease.

- Patients might present with atypical symptoms.
- Most diabetes is type 2 in adults, but type 1 does occur in adults, and delayed diagnosis is common.
- Cardiovascular risk should be aggressively screened for and treated.
- Complications should be documented and tracked.
 - Check fasting lipids or, if inconvenient, get non-fasting lipids focused on cardiovascular risk using a calculator.
 - Check renal function and albuminuria yearly.
 - Have a low threshold for stress testing, with imaging for all patients who have symptoms of ischemia or clinical equivalents.
 - Refer for yearly eye examinations by an eye professional.
 - Check feet for sensation, deformity, and circulation at regular visits.
- All patients should receive an ongoing educational assessment and training in self-management and self-monitoring of blood glucose in both class and individual settings.
- Take a diet history; this is especially important for patients on insulin.
- Get a baseline HbA1c and repeat 2 to 4 times per year (twice yearly, if at glycemic goal).

CURRENT THERAPY

- Diabetes requires nutrition and behavioral self-management counseling, as well as drug therapy.
 - Individualize goals for every patient (for glycemia, lipids, blood pressure): Base individualization on age, quality of life, life expectancy, motivation, complications, diabetes duration, hypoglycemia risk.
 - Involve patient and caregivers in the decision making.
- Repeatedly encourage healthy eating and an active lifestyle.
- Prediabetes diagnosis represents an opportunity for behavioral and drug interventions.
- Metformin (Glucophage) is usually the first drug therapy.
- Don't expect one drug to do the job for very poorly controlled glycemia, especially if HgbA1c is >9% or >2% above the target.
- Dual defects (insulin resistance and secretion) should be addressed in most patients.
- Very insulin-resistant patients might need a dual insulin resistance strategy.
- Therapy goals for both HbA1c and self-monitored blood glucose can be achieved in most patients.
- Cardiovascular risk reduction therapy is a very high priority—statins and blood pressure control are best.
- Consider use of new ACC/AHA Omnibus cardiovascular disease risk calculator for when to start statin therapy.
- When patients have not met goals on two or three oral agents as therapy, basal insulin is often the most appropriate choice, particularly when patients are not near glycemic goals.
- For oral agent therapy, add—don't switch—unless side effects require it.
- When adding basal insulin, initially continue oral agent therapies.
- Threatening patients with insulin therapy is counterproductive.
- Follow the 3F rule: Fix the fasting glucose first, especially in patients with poor glycemic control. As control improves, pay attention to post-meal sugar levels.
- Prompt recognition of the need for meal-time insulin is critical to achieve glycemic goals.
- Usually start with a single-meal insulin dose for the largest meal.
- Balance meal and basal insulin; check post-meal BG.

Epidemiology

The Centers for Disease Control and Prevention (CDC) estimated that in 2015 the prevalence of diabetes in the United States was

Prevention

Discharge planning should include diabetes education, selection of an appropriate insulin regimen that the patient can understand and afford, and preparation of set of supplies for the initial insulin administration at home. Many cases of DKA can be prevented by better access to medical care, proper education, and effective communication with a health care provider during an intercurrent illness.

Sick-day management should be reviewed periodically with all patients. It should include specific information on when to contact the health care provider, blood glucose goals and the use of supplemental short- or rapid-acting insulin during illness, insulin use during fever and infection, and initiation of an easily digestible liquid diet containing carbohydrates and salt. Most importantly, the patient should be advised to never discontinue insulin and to seek professional advice early in the course of the illness. The patient or family member must be able to accurately measure and record insulin administered, blood glucose, and blood β -hydroxybutyrate with a point-of-care device when blood glucose is higher than 300 mg/dL. Recent studies demonstrated that b-OHB testing in outpatient setting is more effective than urine acetoacetate testing in preventing DKA, which may reduce costs of care of patients with insulin-dependent diabetes.

Because of the significant cost of repeated admissions for DKA, resources should be directed toward educating primary care providers and school personnel so that they can identify signs and symptoms of uncontrolled diabetes earlier.

DIABETES MELLITUS IN ADULTS

Method of

Anthony L. McCall, MD, PhD; J. Terry Saunders, PhD; Niyaz Gosmanov, MD; and Albina Gosmanova, MD

CURRENT DIAGNOSIS

- Screening for diabetes should be done in high-risk populations, especially:
 - Those with prediabetes, signs of insulin resistance (e.g., acanthosis nigricans), or the metabolic syndrome.
 - High-risk ethnic groups (e.g., Native American, Latino American, African American).
 - History of gestational diabetes or polycystic ovary disease.

- Patients might present with atypical symptoms.
- Most diabetes is type 2 in adults, but type 1 does occur in adults, and delayed diagnosis is common.
- Cardiovascular risk should be aggressively screened for and treated.
- Complications should be documented and tracked.
 - Check fasting lipids or, if inconvenient, get non-fasting lipids focused on cardiovascular risk using a calculator.
 - Check renal function and albuminuria yearly.
 - Have a low threshold for stress testing, with imaging for all patients who have symptoms of ischemia or clinical equivalents.
 - Refer for yearly eye examinations by an eye professional.
 - Check feet for sensation, deformity, and circulation at regular visits.
- All patients should receive an ongoing educational assessment and training in self-management and self-monitoring of blood glucose in both class and individual settings.
- Take a diet history; this is especially important for patients on insulin.
- Get a baseline HbA1c and repeat 2 to 4 times per year (twice yearly, if at glycemic goal).

CURRENT THERAPY

- Diabetes requires nutrition and behavioral self-management counseling, as well as drug therapy.
 - Individualize goals for every patient (for glycemia, lipids, blood pressure): Base individualization on age, quality of life, life expectancy, motivation, complications, diabetes duration, hypoglycemia risk.
 - Involve patient and caregivers in the decision making.
- Repeatedly encourage healthy eating and an active lifestyle.
- Prediabetes diagnosis represents an opportunity for behavioral and drug interventions.
- Metformin (Glucophage) is usually the first drug therapy.
- Don't expect one drug to do the job for very poorly controlled glycemia, especially if HgbA1c is >9% or >2% above the target.
- Dual defects (insulin resistance and secretion) should be addressed in most patients.
- Very insulin-resistant patients might need a dual insulin resistance strategy.
- Therapy goals for both HbA1c and self-monitored blood glucose can be achieved in most patients.
- Cardiovascular risk reduction therapy is a very high priority—statins and blood pressure control are best.
- Consider use of new ACC/AHA Omnibus cardiovascular disease risk calculator for when to start statin therapy.
- When patients have not met goals on two or three oral agents as therapy, basal insulin is often the most appropriate choice, particularly when patients are not near glycemic goals.
- For oral agent therapy, add—don't switch—unless side effects require it.
- When adding basal insulin, initially continue oral agent therapies.
- Threatening patients with insulin therapy is counterproductive.
- Follow the 3F rule: Fix the fasting glucose first, especially in patients with poor glycemic control. As control improves, pay attention to post-meal sugar levels.
- Prompt recognition of the need for meal-time insulin is critical to achieve glycemic goals.
- Usually start with a single-meal insulin dose for the largest meal.
- Balance meal and basal insulin; check post-meal BG.

Epidemiology

The Centers for Disease Control and Prevention (CDC) estimated that in 2015 the prevalence of diabetes in the United States was

30.3 million affecting 9.4% of the US population. Diabetes is diagnosed in 23.1 million persons and undiagnosed in 7.2 million. Type 2 diabetes mellitus (T2DM) is 90% to 95% of prevalent diabetes, and type 1 diabetes (T1DM) is about 3% to 4%. There are few persons with secondary or monogenic forms of diabetes, such as *maturity-onset diabetes of the young*. About 84 million people above the age of 20 in the United States are thought to have prediabetes.

The focus of this chapter is T2DM because it is the most prevalent form and continues to increase in prevalence in the United States and worldwide. A few comments are made on adult T1DM. This chapter emphasizes both lifestyle and pharmacologic treatments. Although prediabetes may not require drug therapy, it represents an important opportunity to prevent or delay onset of diabetes and initiate critical lifestyle changes.

Diagnosis and Classification of Diabetes and Prediabetes

Diagnosis

Most diabetes is diagnosed by random or fasting glucose (Table 1). Symptoms should be present (e.g., thirst, frequent urination) if random glucose criteria are used, but, surprisingly, many people with diabetes are relatively symptom free. In the elderly, cognitive changes can occur, and atypical symptoms such as prostatism or genital or skin fold yeast infections can suggest the diagnosis. The American Diabetes Association (ADA) screening recommendations suggest screening every 3 years starting at age 45 for the general population, but they suggest earlier and more frequent screening in those at high risk. Elevated HbA1c when 6.5% or higher can be used for screening and diagnosis of diabetes.

Patients from diabetes-prone ethnic groups (e.g., Latin Americans, African Americans, Native Americans, Asian Americans) or with a strong family history, polycystic ovary syndrome, or gestational diabetes should have early and frequent screenings. High-risk persons include those with prediabetes (impaired glucose tolerance, impaired fasting glucose) or who meet the National Cholesterol Education Program criteria for the metabolic syndrome or its individual components (dyslipidemia, hypertension, central obesity, prediabetes). Despite the limitations of the metabolic syndrome as a diagnostic tool, it does not reduce the importance of fully documenting and treating coexisting cardiometabolic risk factors in those with or at risk for T2DM in a targeted manner (see Box 1). Teach patients and clinicians about these risks and encourage the overweight and sedentary to adopt a healthier lifestyle. Effective intervention programs, like the Diabetes Prevention Project, provide strong support for effectiveness of life style modification in prevention of type 2 diabetes.

Classification

The classification of diabetes into its two most prominent types (T1DM and T2DM) seems straightforward in theory, but in practice is increasingly confusing as more Americans become overweight. Although T1DM patients were traditionally described as

BOX 1 Summary of Goals for Treatment

Lifestyle

Medical Nutrition Therapy (individualized)

- Appropriate calories for weight, 5%–10% weight loss for obese patients
- Low saturated and trans fats, substitute with healthy fats
- Moderate, consistent carbohydrates (whole grains, vegetables, fruits with low glycemic effects)
- Foods that can reduce postmeal sugar surges (low glycemic index and load)
- Healthy fats and proteins (decreased saturated and trans fats, increased monosaturated fat; reduced consumption of animal protein)

Activity

- Consistent, regular activity tailored to complications and safety (ECG or stress test may be needed before starting an exercise program)

Glycemia: it is critical that these goals are individualized*

- Best possible without frequent or severe hypoglycemia
- HbA1c <7% generally; 6% or less if possible in selected patients early in disease course; 7%–8% may be appropriate in those with shortened lifespan

Self-Monitored Blood Glucose

- Preprandial 80–130[†]
- Postprandial (1–2 h) < 180 minimal; <140 ideal

Lipids

- All DM patients with overt ASCVD should be on high intensity statins
- DM patients <40 or >75 years old with CVD risk[‡]
- DM patients 40–70 years old with CVD risk consider high intensity statins
- DM patients >40 without CVD risk statins are not recommended
- Blood Pressure[§]
- Systolic <140 mm Hg
- Diastolic <90 mm Hg

*See ADA guidelines for factors.

[†]80 mg/dL is too low for patients with high risk of hypoglycemia. 110 ideally; 20–30 mg/dL higher is acceptable for high-risk for hypoglycemia patients or those with hypoglycemia unawareness.

[‡]CVD risk factors include low-density lipoprotein cholesterol ≤ 100 mg/dL (2.6 mmol/L), high blood pressure, smoking, and overweight and obesity consider medium-intensity to high-intensity statins

[§]More-aggressive BP goals may be appropriate for individual patients if tolerated well and there are no increases in risk of side effects. Relaxed criteria based on age, comorbidities, long duration of diabetes, behavioral, motivational criteria and others.

Abbreviations: ACS = acute coronary syndrome, ASCVD = atherosclerotic cardiovascular disease.

TABLE 1 Diagnosis and Classification of Diabetes and Prediabetes

DIAGNOSIS	GLUCOSE TEST	DIAGNOSTIC LEVEL	COMMENTS
Diabetes	Random	≥ 200 mg/dL	Plus classic symptoms*
Diabetes	Fasting	≥ 126 mg/dL	8-hour fast; need confirmation
Diabetes	Postglucose load (75 g in nonpregnant adults)	≥ 200 mg/dL at 2 h	Need confirmation
Diabetes	HbA1c [†]	6.5%	NGS standardized lab
Prediabetes	IFG Fasting	≥ 100 mg/dL	Decreased insulin secretion
Prediabetes	IGT Postglucose load (75 g)	140–199 mg/dL at 2 h	Increased insulin resistance
Prediabetes	HbA1c	5.7%–6.4%	NGS standardized lab

*Polyuria, polydipsia, unexplained weight loss.

[†]NGS nationally standardized lab method.

Abbreviations: IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

being lean, a significant proportion of the group is overweight and some have characteristics of metabolic syndrome. About 80% to 90% of persons with T2DM are overweight or have metabolic syndrome characteristics, but some are leaner and more active and do not have features of the metabolic syndrome. C-peptide measurements are not very helpful for those who are difficult to classify, but measuring three antibodies—including IA-2 (islet cell antigen 512), anti-GAD₆₅ (glutamic acid decarboxylase), and anti-insulin antibodies in high titers—can clarify a diagnosis of latent autoimmune diabetes. Younger age at onset, lean body habitus, severe loss of glycemic control with or without ketonemia, and weight loss all suggest insulin deficiency but might not be definitive.

Pathophysiology

The primary causes of most adult diabetes are insulin resistance and lack of compensatory insulin secretion. Abnormalities in incretin hormone physiology may also underlie early pathophysiology, although deficiency of glucagon-like peptide-1 (GLP-1) is probably not the simple explanation. Insulin resistance is typically long-standing and begins at a young age because of heredity combined with environmental causes (sedentary lifestyle and calorie overconsumption with resultant overweight). Insulin secretory defects usually start about 10 years before diagnosis, and no therapy is proven so far to prevent progressive loss of insulin secretion, although consistent life style modifications, involving diet and exercise, can help slow down the process and reduce rates of conversion of prediabetes to clinically apparent diabetes. Long-standing insulin resistance is associated with dyslipidemia, central obesity, and hypertension, which suggests a shared etiology of diabetes and metabolic derangements.

Cardiovascular Risk Management

Cardiovascular risk management in diabetes starts at the time of diagnosis and includes lifestyle counseling and education. It is paramount that patients understand the intimate and direct links among diabetes, glycemic control, and cardiovascular disease. Drug interventions are ultimately needed for glycemia, lipid risks, and blood pressure in most patients. Women have higher relative risk and similar overall risk as men and are often undertreated. Specific recommended targets of therapy for diabetes in glycemia, blood pressure, dyslipidemia, and lifestyle are shown in [Box 1](#). Latest guidelines incorporate the use of diabetes drugs with known cardiovascular benefit. For adults with type 2 diabetes and heart disease, the ADA recommends that, after lifestyle management and metformin, health care providers should prescribe medications proven to improve heart health by prevention of major acute cardiac event, related hospitalizations, and death.

Documenting and Monitoring Complications

Patients should have a thorough examination and evaluation for complications at the time of diabetes diagnosis. About half of patients with newly diagnosed T2DM have established chronic complications, indicating delayed recognition of this disorder.

Neuropathy and circulatory signs and symptoms on foot examination should be assessed. Risk of ulcer and amputation can be gauged by 10-g Semmes-Weinstein monofilaments that test for severe neuropathy and attendant risk of ulceration. Retina examinations should be done by skilled eye professionals likely to pick up significant eye disease. High-risk patients (poor glycemic control, established retinopathy, especially if preproliferative or worse) should be referred promptly to an eye specialist. Pregnancy counseling should be given to all women of childbearing age with diabetes. Albumin-to-creatinine ratio in the urine should be assessed and kidney function (serum creatinine, estimated glomerular filtration rate [eGFR], and blood urea nitrogen) should be tracked yearly. Many drugs for diabetes are dosed based on kidney function, so it may be appropriate to track eGFR closely (e.g., every 3-6 months) when it is abnormal.

Home glucose monitoring should be taught to patients so they understand the effects of food, stress, acute intercurrent illness, and exercise on glycemic patterns. Diabetes education in both

individual and group settings should be arranged for all patients, preferably by a diabetes educator. Diabetes is unique in being a self-managed condition where patient knowledge and skills are critical to avoiding complications. Moreover, behavioral management is critical to success in diabetes care.

Treatment

Behavioral Self-Management

Self-management of behavioral factors, including eating, physical activity, and psychological stress, is essential to good diabetes self-care. Ideally, professional support for behavioral self-management should be a coordinated, multidisciplinary effort involving expertise appropriate to a given patient from the areas of nutrition, nursing, physical activity, and behavioral counseling. The provider should develop basic behavior change skills and refer to appropriate multidisciplinary and community-based resources.

Quick, one-shot interventions seldom change long-standing patterns of behavior. Initial sessions should be scheduled close together (1-2 weeks), then further apart as the patient gains momentum and confidence. If multiple one-on-one sessions are impossible, other options such as group meetings, telephone support, or e-mail messaging should be considered.

Behavior change interventions should be highly individualized and specific. General advice about diet and exercise does not address the life experience or problems of a given patient and is often perceived as insensitive or unhelpful. Arriving at individualized objectives for behavior change can be accomplished using a simple three-step process composed of initial assessment, setting behavioral objectives, and follow-up and reassessment. Basic principles of the process of setting behavioral objectives can be summed up by the mnemonic SMART (specific, measurable, achievable, relevant, and time-oriented).

Initial Assessment

Initial assessment includes identifying salient features of social and family history that can affect efforts to change behavior. A nutrition assessment should be performed, including an appraisal of usual food intake, the patient's perception of problem eating behavior, and weight history. A physical activity assessment should also be conducted, focusing on past and current physical activity, preferences, perceived barriers, and general attitudes. Readiness to make changes in behavior should be assessed by asking how important a patient thinks it is to change a given area of behavior and how confident she or he is that she or he can succeed in making changes (on a scale of 1 to 10). Discussion of specific objectives for behavioral change should occur in areas where the patient indicates a definite readiness to begin. Finally, ask patients about current levels and sources of stress. Because depression is common with diabetes, patients should be screened for possible depression.

Behavioral Objectives

Setting behavioral objectives is initiated and facilitated by the provider, but the patient is responsible for selecting his or her own behavioral objectives. Objectives should be *FIRM*: *few* (1-3 at a time is plenty), *individualized* to the patient's specific behavioral challenges, *realistic* (beware of trying to make big strides quickly), and *measurable* (weight, waist circumference, exercise capacity). The patient should be encouraged to keep a daily record of progress on each objective. For those with access, phone and computer-based applications enhance the ease and accuracy of tracking. The primary focus of provider-patient discussions of progress should be on behavioral objectives, not outcomes.

Accurate knowledge of current behavior is key to setting behavioral objectives for nutrition and exercise. Obtaining a 3-day food record (2 work days and 1 non-work day) and a baseline for activity (we generally use a week of daily steps measured with a pedometer) provide a solid baseline for setting objectives.

A modest reduction in caloric consumption of around 250 to 500 kcal/day and moderate physical activity on the order of at least 150 minutes a week are the recommended approaches to weight loss. Reducing calories through decreased food consumption is

☒ **Eat meals and snacks at set times to promote health.****Examples:**

- I will eat breakfast within 1 hour of getting up.
- I will not skip meals.
- Other:.....

☒ **Eat healthy carbohydrates.****Examples:**

- I will avoid regular soft drinks and choose water or diet soft drinks instead.
- I will eat 5–7 servings of fruits and vegetables every day.
- I will choose whole-grain breads and cereals.
- Other:.....

☒ **Decrease serving sizes.****Examples:**

- I will keep a record of the food I eat and drink.
- I will know what counts as a serving size.
- When I am eating out, I will share or split an entrée and eat a salad.
- Other:.....

☒ **Eat less fat and choose healthy fats.****Examples:**

- I will bake, broil, roast, grill, or boil instead of fry food.
- I will have a meatless meal at least once a week.
- I will choose fried or high-fat foods no more than once a week.
- I will drink fat-free or low-fat milk.
- I will use healthy oils (olive oil, canola oil) and buy tub margarine.
- Other:.....

☒ **Make other healthy choices.****Examples:**

- I will drink plenty of fluids (at least 8 glasses of water or low-calorie fluid per day).
- I will limit how much alcohol I drink. (Women should drink no more than 1 alcoholic drink per day. Men should drink no more than 2 alcoholic drinks per day.)
- Other:.....

more effective for weight loss than increasing energy expenditure through physical activity. Box 2 contains a checklist of healthy eating behaviors that can be used to stimulate patients' thinking about areas in which they might like to make changes. Note that an irregular pattern of eating often underlies unhealthy food choices. For example, staying up late encourages late-night snacking, which in turn can suppress interest in eating breakfast. Eating tends to be deferred to the afternoon or evening, perpetuating the cycle.

Physical activity plays an important role in weight maintenance. Higher levels of activity (200 min/week) may be required to prevent long-term weight regain. Box 3 lists ways that patients can become more active. It is worth repeating that the point of these and other suggestions is not to direct patients but to expand their thinking about what might work for them.

Follow-up and Reassessment

Follow-up and reassessment occur during each return visit, after a period of patient efforts to carry out mutually agreed on behavioral objectives. Reassessment focuses on the behavioral records kept by patients as well as on their verbal reports of difficulties and successes. Praise and encouragement are the order of the day. Efforts to initiate behavior change are highly responsive to external positive reinforcement, and the patient will need maximum external reinforcement until new behavior becomes self-sustaining. After review and discussion of patient records, new behavioral objectives or incremental changes in existing objectives are selected by mutual agreement, with the patient taking the lead.

A modest weight loss of 5% to 10% has a positive impact on cardiovascular risk factors and progression of diabetes. Reassure

☒ **Do something that you enjoy.****Examples:**

- I will take the stairs.
- I will park my car farther away and walk.
- I will walk.
- I will swim or do water exercises.
- I will ride a bike.
- I will use an exercise video.
- I will do yoga.
- Other:.....

☒ **How often?****Examples:**

- ☐ Every day
- ☐ 3x/week
- ☐ 5x/week
- ☐

☒ **How long?****Examples:**

- ☐ 10 minutes
- ☐ 15 minutes
- ☐ 20 minutes
- ☐ 30 minutes
- ☐ 60 minutes
- ☐ ___ minutes

☒ **Limit inactivity.****Examples:**

- I will watch no more than 1 hour of television per day.
- I will spend no more than 2 hours per day on the computer.

patients that medical goals for weight loss are achievable and worth the effort.

When discussing changes in eating with patients, distinguish dieting from gradual behavioral changes that result in a lasting pattern of healthy eating. Diets are impermanent and run the risk of large weight losses followed by even larger weight gains. Gradual behavioral changes offer the possibility of permanent lifestyle changes.

Prohibiting or demonizing foods is counterproductive. It leads patients to think of food in moral extremes (e.g., “sugar is bad for my diabetes”) rather than along a continuum of nutritional benefit and blood glucose control with emphasis on moderation. Food prohibition also casts the provider as withholding and overly controlling. These traps can be avoided by exploring very small changes that are not perceived as significant losses with periods of consolidation of the acquired knowledge and experience.

Current nutrition therapy recommendations emphasize a flexible, individualized approach to macronutrient distribution and a carbohydrate-counting meal-planning approach for individuals with type 1 diabetes. Patients should be encouraged to emphasize vegetables, fruits, whole grains, legumes, and dairy products as preferred sources of carbohydrate. Recommendations for achieving consistent, appropriate carbohydrate intake at meals are based on controlling postprandial blood glucose (<180 mg/dL 1–2 hours after beginning a meal). Carbohydrate counting and blood glucose pattern management are complicated and time-consuming to teach. Referral to a dietitian for medical nutrition therapy or nutrition education through an ADA-recognized diabetes patient education program is recommended.

Stress reduction is important in controlling blood glucose and can also play a role by helping patients achieve a mental focus on their behavior-management efforts. We encourage patients to sit calmly for a period of 5 to 10 minutes each day, focusing on slow deep breathing and muscle relaxation. Activities such as yoga or tai chi also reduce stress and support awareness of body and mind. [Box 4](#) contains suggestions for coping behaviors that may be useful to patients in dealing with stress.

Use of weight-loss medications should be considered to either “jump-start” weight loss or for the maintenance of achieved results.

Pharmacologic Therapy

Overview

Optimal glycemia goals must be individualized but may be generally defined as a hemoglobin A1c (HgbA1c) <7% (see [Table 1](#)) as recommended by the ADA. Pre-prandial capillary blood glucose should be 80 to 130 mg/dL and postprandially at the peak (typically about 2 hours after meals) they should be generally less than 180 mg/dL. Individualizing glycemic goals should be based on several factors including duration of diabetes, age, life expectancy, comorbid conditions such as known cardiovascular disease, advanced microvascular complications, hypoglycemia unawareness, and other individual patient considerations. Both HgbA1c and capillary blood glucose concentrations should be individualized to reduce the risk of hypoglycemia. A summary of other goals is provided in [Box 1](#).

Eventually, most patients with T2DM require drug treatment, often using multiple agents (combination therapy). Progressive insulin secretory loss probably is the primary explanation for the need to advance treatment. A resultant general rule with all therapies is *add, don't switch*, but it is important to remember that lifestyle modification should always be part of the therapy if possible. [Table 2](#) lists major types of pharmacotherapeutic interventions with their usual hemoglobin (Hb) A1c lowering, balance of pre-prandial versus postprandial effects, and some comments on their actions and side effects. [Table 3](#) lists classes of drugs, commonly used agents, and typical doses.

In 2016 the ADA and European Association for the Study of Diabetes updated a joint consensus algorithm on controlling hyperglycemia in T2DM. It is now becoming a common practice to initiate behavioral self-management with and sometimes without medication. Metformin is the first medication usually started unless there are contraindications or intolerance. Commonly, ineffective early attempts by physicians to change behavior (e.g., giving general advice) lead to abandonment of this therapy. Referral to an ADA-recognized diabetes education program is a more efficacious alternative. A second oral medication may be initiated if patients cannot achieve glycemic goals. Commonly, we favor insulin secretagogues, especially glimepiride (Amaryl) or extended-release glipizide (Glucotrol XL), for their relatively low risk of hypoglycemia, convenient once-daily dosing, and low expense, or an oral incretin drug. An alternative treatment strategy for heavier, more insulin-resistant patients is use of a thiazolidinedione, pioglitazone, effectively a dual insulin resistance strategy (see Thiazolidinediones).

More reliably effective is the use of basal insulin treatment as a second agent to achieve control, although it is less accepted by many patients. Insulin initiation should be preceded by an open discussion of the patient's attitudes, beliefs, and possible fears regarding insulin. Insulin therapy should never be used as a threat or possible negative consequence for failure to carry out behavioral management. Many patients associate insulin with serious diabetes complications and mortality. A positive attitude about the value of insulin therapy and its natural presence and essential role in the body, along with reassurance that insulin can prolong life and improve its quality, can help reduce initial fears enough to begin. Availability of many non-insulin medications has often moved insulin to later in the sequence, but it can be used at any time.

In-clinic demonstrations of injection technique using saline is also useful in overcoming fear of injections and increasing acceptance. Improvement in blood glucose control with insulin generally makes patients feel better, which further reinforces its perceived value. Use of insulin pens may further increase acceptance of insulin treatment, patient convenience, and dosing accuracy.

It should be noted that an alternative algorithm for glycemic control therapy is proposed by the American College of Endocrinology. A patient-centered approach with emphasis on safely achieving goals and including patient choices and preferences is increasingly emphasized in both ADA and AACE guidelines.

BOX 4 Checklist of Coping Behaviors

Examples:

- Talk about how you feel to people you trust.
- Decide one small way to change your mood or old habit, and do it.
- Write down 10 good things about your life and think about and appreciate them.
- Organize your day with a “To Do” list.
- Learn how to relax through yoga, meditation, biofeedback, tai chi, deep breathing, or visual imagery.
- Take 30 minutes each day to relax through music, yoga, bath, writing, etc.
- Take time to have fun every day by exploring a new interest, watching a funny movie, going shopping, playing with a pet, etc.
- Get in touch with your spiritual side to help you feel better about yourself.
- Keep a stress diary to see what triggers your stress and discover better ways to react.
- Exercise every day to help you focus your energy on a more positive path.
- Keep your sleep cycle as regular as possible.
- Develop a favorite hobby.
- Other:.....

TABLE 2 Overview and Characteristics of Therapy Interventions in T2DM

DRUG TYPE	HbA1c LOWERING (%)	EFFECT ON GLYCEMIA		ACTIONS	SIDE EFFECTS/ COMMENTS
		PREPRANDIAL	POSTPRANDIAL		
SU and non-SU secretagogues	1.5–2.0*	++	+ [†]	Direct and indirect secretagogue	Hypoglycemia, weight gain, rash
Biguanides	1.5–2.0*	+++	0	↓ hepatic glucose release, weight neutral	[‡] Adjust dose for CKD, lactic acidosis (rare)
Thiazolidinediones	0.5–1.5	+++	0	↑ insulin sensitivity in muscle, fat	Edema, CHF, fractures
GLP-1 agonists	0.8–1.5	+	++	Strong GLP-1 effects, ↑ insulin, ↓ glucagon, ↓ stomach emptying	Nausea, vomiting, weight loss [§]
DPP-4 inhibitors	0.6–0.8	+	++	Moderate GLP-1 effects, ↑ insulin, ↓ glucagon	Weight neutral
Colesevelam (bile acid sequestrant)	0.4–0.8	+	+	Mechanisms of action uncertain	Constipation, hypertriglyceridemia
Canagliflozin (SGLT inhibitor), Dapagliflozin, Empagliflozin	0.5–1.0	+	+	↓ renal tubule reabsorption of glucose	Altered kidney function, hypotension, UTI, <i>Candida</i> in groin
Pramlintide (amylin agonist)	0.5–0.7	0–+	++	↓ glucagon, slow stomach emptying	Hypoglycemia, GI upset
Basal insulin	1.5–2.5	+++	0*	↓ hepatic glucose output, ↑ muscle glucose disposal	Hypoglycemia, weight gain
Meal insulin	1.0–2.0	0–+	++	↓ hepatic glucose output, ↑ muscle glucose disposal	Hypoglycemia, weight gain

*Older drugs may be less effective in well-controlled patients.

[†]Rapid-acting secretagogues may have less fasting and more early postprandial effects.

[‡]Metformin dosing: Adjust for CKD stage 3a (45–60 eGFR); watch closely but continue, and in 3b (30–44 eGFR), reduce dose to ½ usual or less and check eGFR every 3 months.

[§]Although risk of pancreatitis exists, unclear if increased. Risk of pancreatic cancer not proven and based on controversial data.

Oral Agents

Secretagogues. These drugs enhance insulin secretion. There are first- and second-generation oral sulfonylureas; the latter are most commonly used. They are inexpensive, are moderately effective, and often can be dosed once daily. First-generation agents such as tolbutamide, chlorpropamide (Diabenese), and tolazamide (Tolinase) are less often used than the second-generation agents glyburide (Diabeta, Glynase), glipizide (Glucotrol), and glimepiride (Amaryl). Glyburide should not generally be used in elderly patients or those with renal disease due to hypoglycemia risk.

The dose-response characteristics of sulfonylureas suggest that one-half the approved maximum dose achieves maximum HbA1c lowering, typically 1 to 1.5 percentage points (the latter with poorer baseline control). If the patient is not at goal with half-maximum doses, it is more effective to add a second agent than to raise the dose. Common side effects include hypoglycemia, weight gain of about 2 kg, and, more rarely, hematologic or skin reactions.

Shorter-acting secretagogues. The glinides (repaglinide [Prandin] and nateglinide [Starlix]), are more expensive and should be considered for patients who are sulfonylurea allergic, erratic in eating, or at high risk for hypoglycemia between meals and at night time.

Biguanides. Metformin is the only available agent in this class. It is useful in both obese and normal-weight patients with T2DM. HbA1c lowering is typically about 1.5 percentage points in monotherapy or in combination therapy. Maximum efficacy is achieved with 2000 mg daily. The sustained-release preparation will last 24 hours if given with the evening meal.

Metformin's hypoglycemic mechanism is primarily by reduction of liver glucose production, probably through effects on adenosine monophosphate-activated protein kinase, a fuel sensor enzyme, and partially through effects on glucagon. It is cleared by

the kidney, and the risk of lactic acidosis, a rare side effect (1:30,000 patient-years) with a 50% mortality rate, may be increased in renal dysfunction. The original FDA guidelines suggesting serum creatinine should be less than 1.4 mg/dL in women and less than 1.5 mg/dL in men have recently been supplanted by a more practical approach to use eGFR, which should be assessed in all patients, for decision making about continuation of the drug. Full doses of metformin appear safe down to eGFR of 45 mL/min, with routine checking of eGFR every 3 to 6 months. Once eGFR falls to the 30 and 44 mL/min range, the metformin dose should be reduced to 1000 mg or less, and eGFR should be checked every 3 months. There may be an increased lactic acidosis risk in patients with congestive heart failure (CHF) or respiratory insufficiency, especially during exacerbations of these conditions with hypoxia and activation of anaerobic glycolysis. Intravascular contrast administration should prompt holding the drug for 24 to 48 hours until renal function is confirmed to be adequate. Gastrointestinal (GI) side effects are common initially and are dose dependent but wane; they can require gradual titration and are often ameliorated by post-prandial administration. Sustained-release preparations have fewer GI side effects. Weight gain is less with this drug than with many others for diabetes, and in fact, the use of metformin might contribute to a loss of 3 to 4 lbs of weight. The United Kingdom Prospective Diabetes Study found that risk of myocardial infarction (MI) and death was reduced among metformin users, making it a first choice for pharmacotherapy in most patients.

Thiazolidinediones. Two thiazolidinediones (TZDs) are used, and they are pioglitazone and rosiglitazone. TZDs increase the sensitivity of muscle tissue and fat to the action of insulin via the peroxisome proliferator-activated receptor gamma mechanism. HbA1c lowering varies, dependent on the degree of insulin resistance (i.e., central adiposity) and levels of endogenous insulin

TABLE 3 Dosing Used for Noninsulin Agents

AGENT	DOSE
Thiazolidinediones	
Pioglitazone (Actos)	15, 30, 45 mg
Rosiglitazone* (Avandia)	2, 4, 8 mg
α-Glucosidase Inhibitors	
Acarbose (Preset)	25, 50, 100 mg ac
Miglitol (Glyset)	25, 50 mg ac
Biguanides	
Metformin IR (Glucophage)	500, 850, 1000 mg [†]
Metformin ER	500, 750, 1000 mg
Glinides	
Nateglinide (Starlix)	60–120 mg ac
Repaglinide (Prandin)	0.5–4 mg ac
Sulfonylureas (Second Generation)	
Glipizide IR (Glucotrol)	2.5–20 mg
Glipizide ER (Glucotrol XL)	2.5–10 mg
Glimepiride (Amaryl)	1–4 mg
Glyburide (Glynase)	1.25–10, 1.5–6 mg
Incretins	
Exenatide (Byetta)	5, 10 μ g
Exenatide QW Bydureon	2.0 mg
Liraglutide (Victoza)	0.6, 1.2, 1.8 mg
Albiglutide [‡] (Tanzeum)	30, 50 mg
Dulaglutide (Trulicity)	0.75, 1.5 mg
Lixisenatide (Adlyxin)	10, 20 μ g
DPP-4	
Sitagliptin (Januvia)	100, 50, 25 mg [§]
Saxagliptin (Onglyza)	5, 2.5 mg
Linagliptin (Tradjenta)	5 mg
Alogliptin (Nesina)	25, 12.5, 6.25 mg
Amylin Agonist	
Pramlintide (Symlin)	15, 30, 45, 60, 90, 120 μ g ^{¶¶}
Bile Acid Sequestrant	
Colesevalam (Welchol)	1875–3750 mg
Dopamine Agonist	
Bromocriptine (Cycloset)	0.8–4.8 mg [¶]
SGLT-2 Inhibitor	
Canagliflozin (Invokana) **	100, 300 mg
Dapagliflozin** (Farxiga)	5, 10 mg
Empagliflozin** (Jardiance)	10, 25 mg

*Restriction on use lifted as CVD risk not clearly increased.

[†]Also available as a liquid preparation 500 mg/5 mL.

[‡]Powder reconstitutes in the pen before use with twist.

[§]Dose adjusted for renal function.

[¶]Take with food within 2 hours of awakening.

**All SGLT2 drugs use lower doses with moderate renal dysfunction and are contraindicated in severe renal dysfunction.

^{¶¶}Pens come in range for type 1 (15–60 μ g) and type 2 (60–120 μ g).

secretion, duration of clinical diabetes, use of secretagogues, or use of insulin.

TZDs can precipitate edema, weight gain caused by redistribution of fat (from central to peripheral location), and occasionally congestive heart failure, even absent a prior heart failure history. It is thus wise to track weight in all patients and limit gains to 5 or 6 pounds. TZDs are contraindicated in patients with heart failure, yet they have been shown to significantly reduce ischemic risk (e.g., stroke or myocardial infarction) in individuals with high insulin resistance, prediabetes, and history of transient ischemic attack

or stroke as was demonstrated in the recently published IRIS Trial with pioglitazones. As a class, TZDs are associated with an increase in fractures in women, which suggests avoiding this medication in patients with high risk for osteoporosis or fragility fractures. The use of pioglitazone is associated with a slightly higher risk of bladder cancer. Sales of rosiglitazone in the United States were restricted by the FDA between 2011 and 2013 due to concerns about an increase in heart attacks and death. These restrictions were lifted in 2013.

Incretins. Incretins are gut hormones that enhance food-induced insulin secretion. Incretin drugs either are receptor agonists (e.g., exenatide) for GLP-1, perhaps the most important incretin, or they enhance endogenous levels for both GLP-1 and gastrointestinal insulinotropic polypeptide (GIP).

Exenatide is available as immediate release (Byetta) given twice daily and in once-weekly slow release (Bydureon). There are two GLP-1 receptor agonists, liraglutide (Victoza) and lixisenatide (Adlyxin), with once-daily dosing. Other agonists, albiglutide (Tanzeum), dulaglutide (Trulicity), and semaglutide (Ozempic), are approved by the FDA; they are given once weekly. Manufacturer of albiglutide has announced plans to discontinue sale of albiglutide by July 2018. These incretin agonists increase meal insulin, decrease meal hyperglucagonemia, decrease rate of stomach emptying, and suppress appetite, which may cause a moderate weight loss. They work rapidly on injection. Substantial GI side effects including nausea, vomiting, and diarrhea are experienced by approximately 25% of patients. Despite this, many patients favor them, probably because the side effects generally wane within weeks and there can be moderate weight loss, especially in significantly overweight patients. Typically, exenatide is given in doses of 5 μ g twice daily at meals, advancing after a month to 10 μ g twice daily. Liraglutide is usually started at 0.6 mg once daily and advanced to 1.2 and then 1.8 mg as needed and tolerated. Patients might report that nausea is more tolerable if they have a little food in their stomach at the time of dosing. Pancreatitis may rarely occur (case reports). Exenatide in a sustained-release once-weekly preparation is embedded into microspheres that permit slow release. To deliver the medication, injections require a somewhat larger needle (23 gauge) that is short and well tolerated, although somewhat more frequent site reactions and immunogenicity occur with this formulation. Adaptation to nausea seems quicker in longer-acting preparations (once daily or weekly) than in immediate-release exenatide.

Because incretin drugs all have a glucose-dependent insulin secretion and glucagon suppression, there is little risk for hypoglycemia used alone or when they are combined with metformin and TZDs; in contrast, hypoglycemia is increased when combined with sulfonylureas or with insulin therapy. HbA1c lowering with exenatide has been 0.9 to 1.1 percentage points, and while albiglutide is similar to exenatide, liraglutide, dulaglutide, or sustained-release exenatide have similar to slightly more efficacy in lowering HbA1c but equal weight effects. Concerns are raised about pancreatitis risk and pancreatic dysplasia, but these remain inconclusive and controversial. Risk of C-cell hyperplasia or medullary thyroid cancer prevents these drugs from use in patients with that disorder.

Dipeptidyl Peptidase-4 Inhibitors. Dipeptidyl peptidase-4 (DPP-4) is the enzyme that normally rapidly degrades the incretins GLP-1 and GIP to inactive proteolytic products. Inhibitors of DPP-4 have been shown to enhance GLP-1 and GIP levels to high physiological levels and thereby reduce HbA1c concentrations, typically about 0.6 to 0.8 percentage points. Four drugs, sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina), are approved in the US and appear to be similarly effective in recommended doses (see Table 3). Sitagliptin (standard dose 100 mg/d) and alogliptin (standard dose 25 mg/d) are excreted by the kidneys and thus should be given in lower doses (50 mg/d for sitagliptin and 12.5 mg/d for alogliptin) for those with moderate renal insufficiency (eGFR 30–50 for sitagliptin and 30–59 for alogliptin) and further reduced (25 mg/day and 6.25 mg/d, respectively) for those with severe renal dysfunction (GFR <30 mL/min). Saxagliptin is reduced from 5 mg/d to

2.5 mg/d in moderate renal insufficiency (eGFR <50), whereas linagliptin does not need dose adjustment with kidney disease. All have similar actions and probably potential side effects, including pancreatitis. These drugs are available in combination pills with metformin and some with SGLT2 inhibitors.

Because DPP-4 inhibitors are oral, they may be preferred to the injectable incretins. The side effects for these drugs are relatively minor, and these drugs cause little nausea, vomiting, or diarrhea. They appear to be weight neutral. Rare but serious allergic reactions such as angioedema and Stevens-Johnson syndrome have been reported in a few patients. Pancreatitis has been observed with this class of drugs in post-marketing analysis and is very rare. Joint pain is a new uncommon side effect.

Amylin Agonists. Insulin is cosecreted with another beta cell hormone called *amylin*. The effects of amylin appear to be to help lower glycemia, reduce excess glucagon levels, curb appetite, and possibly reduce the rate of gastric emptying. A synthetic analogue of amylin, pramlintide (Symlin), is available as an injectable agent for treating both T1DM and T2DM as an adjunct to insulin. It lowers HbA1c about 0.5 to 0.7 percentage point. It also appears to have some weight loss effect, typically around 1 to 2 kg. Its action primarily controls glucose postprandially. Nausea and vomiting can occur in patients with either T2DM or T1DM but are worse in patients with T1DM who require lower doses at first (≤ 15 μ g with meals) and slower titration. Those with T2DM usually start with 60 μ g and can usually advance to 90 to 120 μ g at meals.

Bile Acid Sequestrants. Colesevalam hydrochloride (Welchol), in either single or divided doses of 3.8 g daily, reduces hyperglycemia compared with placebo in patients with T2DM. A1c reductions range from 0.4% to 0.8% when used alone, with metformin, with sulfonylureas, and when used with insulin and other oral agents. Although this drug has already been approved for treatment of hyperlipidemia, it is now also FDA approved for T2DM. It has the potential, however, to increase triglycerides, and thus baseline fasting lipid values should be obtained and tracked, especially in patients with hypertriglyceridemia—use is not recommended when baseline triglycerides exceed 250 mg/dL. There is little justification for its use alone or with thiazolidinediones, but it may be appropriate for some patients with T2DM not at goal on other therapies.

Dopamine Receptor Agonists. Bromocriptine, a dopamine receptor agonist in a rapid-release formulation, is a relatively new addition to antidiabetes medications. Although its mechanism of action is not precisely clear, the drug will reduce premeal and post-meal blood sugars without changing insulin levels, which suggests a benefit to insulin action, perhaps through mediation of central nervous system mechanisms. Its side effects are somewhat similar to those of the bromocriptine used for pituitary disease. Nausea is a common initial side effect. Its efficacy is moderate, with HbA1c reductions of 0.5% or slightly more. Its preliminary data suggest a favorable cardiovascular safety profile associated with its use, which is reassuring. Usual starting doses are 0.8 mg once daily with gradual increase based on tolerance of nausea to bromocriptine in higher doses (up to 4.8 mg daily).

SGLT-2 Inhibitors. Four approved drugs are available: canagliflozin (Invokana), dapagliflozin (Farxiga), empagliflozin (Jardiance), and ertugliflozin (Steglatro). They act as inhibitors of sodium glucose transporters, which lead to urinary glucose reabsorption blockade, shifting the glucose reabsorption threshold to low-normal range, resulting in substantial glucosuria (causing on average 80–120 gm of glucose loss per day). This drug is effective in lowering HbA1c to $\geq 1\%$ with a relatively low risk of hypoglycemia when used alone or with other drugs such as metformin, but they may cause hypoglycemia when combined with insulin or insulin secretagogues such as sulfonylureas. These drugs may have favorable effects on blood pressure, partly from diuretic effects, and may cause postural hypotension if volume is allowed to get depleted. In monotherapy with these drugs, average HbA1c reductions of 0.5% to 0.8% may be seen, although it is dependent on the initial HbA1c level. Added to metformin, the reduction is 0.5% to 0.75%. Additional benefits may include weight loss of 1.2 to 3.3 kg

and a modest reduction in systolic blood pressure of 4 to 9 mm Hg, but postural hypotension symptoms or acute kidney injury may occur. Urinary infections are more common but are treatable. *Candida* vulvovaginitis and balanitis are more common with SGLT-2 inhibitors. The usual starting dose is the lowest dose shown in Table 3 once daily before the first meal. The dose may be advanced if needed for improving glucose control but only if the eGFR is ≥ 60 mL/min/1.73 m² for canagliflozin, whereas for empagliflozin it should not be started if eGFR is <45, but for values >45 no dose adjustment is needed, and for dapagliflozin it should not be started if eGFR is <60, and if >60 no dose adjustment is needed. For canagliflozin if the eGFR is between 45 and 60, the dose of should not be advanced beyond 100 mg, and if the eGFR is persistently <45, the drug should not be used. Frequent monitoring of eGFR is recommended with values <60. These drugs should be used with caution in the event of significant renal dysfunction and should not be used in advanced liver or kidney dysfunction. Rarely, ketoacidosis can occur when used with insulin.

The recent landmark trial, EMPA-REG OUTCOME, demonstrated that empagliflozin reduced the primary major adverse cardiac event end points (cardiovascular [CV] death, nonfatal myocardial infarction, nonfatal stroke) by 14% in patients with T2DM with a high risk for or prior history of cardiovascular disease (CVD). This beneficial effect was driven by a 38% reduction in CV mortality with no significant decrease in nonfatal myocardial infarction or stroke. The drug also caused a 35% reduction in hospitalization for heart failure without affecting hospitalization for unstable angina. Although SGLT-2 inhibitors exert multiple metabolic benefits (e.g., decreases in HbA1c, body weight, and blood pressure and an increase in HDL cholesterol), all of which could reduce CVD risk, it is unlikely that the reduction in CV mortality can be fully explained by these factors. More likely, a combination of positive hemodynamic effects is enhanced by changes in intrarenal blood flow dynamics, contributing to the reduction in CV mortality and heart failure hospitalization. This subject is currently being intensively investigated. Impact of the study results was significant enough that it led to a new ADA recommendation: in patients with established atherosclerotic cardiovascular disease on metformin, empagliflozin is a preferred add-on agent to reduce major adverse cardiovascular events.

Insulin

Barriers to Insulin Use. Insulin deficiency underlies the genesis of both T1DM and T2DM. Progression of therapy to use of insulin, typically with oral agents in T2DM, also seems predicated on progressive loss of insulin secretion. Nonetheless, it is often started too late, and patients often are in very poor control when this is done. Reluctance by patients and physicians alike might underlie this. Physicians should understand that exogenous insulin in T2DM is needed, does not negatively alter life quality, and is more likely to achieve therapeutic targets. Moreover, exogenous insulin does not worsen insulin resistance, does not cause excess cardiovascular disease, and has a low frequency of severe hypoglycemia, especially when used relatively early in the disease. Table 4 lists common insulin preparations and some notes about kinetics and timing.

Starting Insulin: Use of Basal Insulin in Type 2 Diabetes. How should insulin be started? Practitioners should use temporary insulin for patients whose glycemia is initially poorly controlled or when patients temporarily have worse control due to illness or medications, such as glucocorticoids. It is unwise to use insulin as a threat because it creates a sense of personal failure and dread of insulin use. When therapy progresses but there is failure to achieve glycemic goals after one or two oral medications, use of basal insulin is often the best way to achieve euglycemia, especially if patients are much more than 1 percentage point from HbA1c goal (<7%).

The Treat-to-Target Trial offers a good example of how to initiate insulin therapy. In this study, as often in our practice, patients started with a basal insulin either with NPH insulin or insulin glargine (Lantus). A majority of patients (~60%) attained HbA1c $\leq 7\%$ with either type of insulin. However, with glargine, nearly

TABLE 4 Insulin Preparations

INSULIN TYPE	PHARMACOKINETICS			COMMENTS
	ONSET (h)	PEAK (h)	DURATION (h)	
Basal Insulins				
NPH (Humulin N, Novolin N)	0.5	4–10	18	Kinetics are dose dependent Peak effects exert meal action Dose at breakfast, bedtime, supper*
Glargine [†] (Lantus)	2–4	Little peak	24*	Dose can be given at any time of day if consistent
Glargine U-300 (Toujeo) [‡]	3–4	No peak	30+	Dose at any time but consistently
Detemir [†] (Levemir)	2–3	Little peak		Kinetics are dose dependent Dose at breakfast, bedtime, supper*
U-500 regular insulin	1-3 hours	3-6 hours	8-10	Kinetics are dose dependent, even though they are similar to NPH
	Approximately 2 hours	No peak	>40 hours	
Insulin Degludec [†] (Tresiba)	2 hours	No peak	Up to 40	No risk of “stacking”; can be preferred in those who might be skipping doses
Meal Insulins				
Regular (Humulin R, Novolin R)	0.25–0.5	2–3	5–8	Give 30 minutes before meals Do not use at bedtime
Lispro (Humalog)	0.1–0.2	1.5–2.0	4	Dose up to 20 min before mealtime or immediately after
Aspart (Novolog)	0.1–0.2	1.5–2.0	4	Dose up to 20 min before mealtime or immediately after
Glulisine (Apidra)	0.1–0.2	1.5–2.0	4	Dose up to 20 min before mealtime or immediately after
Mixed Preparations				
NPH/regular (Humulin, Novolin)	70/30 dual kinetics based on components			Dosing 1/2 hour before meals Should not be dosed at bedtime
Lispro/NPLispro (Humalog 75/25)	75/25 dual kinetics based on components			Dosing at mealtime; should not be dosed at bedtime
Lispro/NPLispro Humalog 50/50)	50/50 dual kinetics based on components			Dosing at mealtime, should not be dosed at bedtime
Aspart/NPAspart (NovoLog 70/30)	70/30 dual kinetics based on components			Dosing at mealtime; should not be dosed at bedtime

*Bedtime dosing may be preferred for some patients, especially those on low doses.

[†]Should not be mixed with other insulins or used in the same syringe that other insulin has been in.

[‡]Advance dose no faster than every 3–4 days, slightly higher doses may be needed compared with U-100 insulin glargine.

Abbreviation: NPH = neutral protamine Hagedorn.

25% more patients attained this target without documented nocturnal hypoglycemia. Moreover, rates of other categories of symptomatic hypoglycemia were 21% to 48% lower with glargine. Insulin detemir (Levemir) represents another long-acting insulin analog option to be used similarly. Insulin is instituted as 10 U once daily, commonly in the evening near bedtime, followed by weekly increases of between 2 and 8 units depending on proximity to glucose goals, focusing on the fasting glucose.

This strategy is sometimes called the *fix the fasting first* rule. Average doses in that study were around 45 to 50 units for patients whose body mass index was about 31 kg/m². An alternative initial dosing might be 0.2 U/kg body weight, but whatever the starting dose, a forced titration guided by patient self-monitoring with clear communication of target fasting glucose (90–130 mg/dL), size of increment (or decrement in case of hypoglycemia; usually 10%–20% of dose), and frequency of change (every 3–7 days) is necessary to get most patients to overall glycemic (HbA1c) goal. This strategy is referred to as *pattern management*. The intent is to use monitoring to adjust the insulin dose likely to affect the fasting glucose for basal insulin therapy. NPH and detemir usually can be used once daily, typically at bedtime. Patients using glargine may choose any time of the day as long as it is reasonably consistent, usually within the hour of a

24 hour day cycle. In some patients, twice-daily NPH or detemir is used if day time insulin levels are deemed insufficient. The new U-300 insulin glargine (Toujeo) may be helpful in reduction of overnight hypoglycemia, as it has a flatter kinetic profile and longer duration of action.

When and How to Add Meal Insulin. At some point, basal insulin therapy alone may be insufficient for glycemic control for T2DM patients. Usually this is a consideration in patients whose HbA1c values are 9% to 9.5% or where the fasting goal is met but HbA1c or daytime glycemia remains elevated. The need for meal insulin is particularly likely to occur with larger meals, such as supper. Diagnostically, what is important is to have patients check either both before and after large meals or, if they are unwilling to check frequently, simply check about 2 to 3 hours after meals. Self-monitored glucose values that exceed even minimum postprandial glycemic guidelines (<180 mg/dL) indicate the need for meal insulin. A common mistake made in practice is to treat fasting hyperglycemia only with increases in basal insulin, when in some patients the cause is overeating or lack of meal insulin coverage from the previous evening. This can be discerned by observing the pattern of glycemia, with lows often between meals or overnight and highs occurring after meals or at bedtime.

Fixed-Ratio Combined Insulins

A commonly used strategy to use fixed-ratio combination short-acting (either regular or rapid analog) insulin combined with intermediate insulin (NPH or neutral protamine modified rapid analog that mimics NPH timing) is being replaced by basal-bolus regimens. However, for the purposes of compliance, fixed-ratio combination preparations are still used and include 70/30 NPH and regular insulin, 75/25 neutral protamine lispro and lispro insulin (Humalog), and 70/30 neutral protamine aspart and aspart insulin (Novolog). These combination products have the advantage of being able to achieve glycemic improvement conveniently (i.e., simple twice-daily injection regimen) in T2DM patients whose conditions otherwise are poorly controlled (HbA_{1c} of 9.5% or more). These preparations also offer the advantage of greater dosing accuracy, especially when used with insulin pens. Important to the success of these formulations is consistent eating and carbohydrate intake with meals. Unfortunately, when such consistency is not attainable, patterns of glycemia can be erratic, and hypoglycemia can be significantly increased. Patients who skip meals are poor candidates for combination product therapy and should either switch to individual dosing of an insulin mixture or, even safer, use a basal-bolus insulin regimen.

Fixed-Ratio Combinations of Long-acting Insulin With GLP-1 agonists

In 2016, the FDA approved two new fixed-ratio combinations of insulin and a GLP-1 agonist: LixiLan (glargine/lixisenatide) and IDegLira (degludec/liraglutide). These products can be considered as an option before starting basal-bolus insulin therapy. Both preparations are indicated after failure of one shot (either insulin or GLP-1 agonist) in combination with oral hypoglycemic agents to achieve the target. Slow up-titration of the combination has significantly improved tolerability, offset insulin therapy-associated weight gain, and resulted in a substantially higher portion of T2DM patients achieving glycemic goals with no additional risk of hypoglycemia.

Adults With T1DM

A significant minority of patients with a diagnosis of T2DM actually have a late onset of T1DM and typical autoimmunity (IA-2 antibodies, GAD-65 antibodies, and insulin antibodies), also known as LADA (latent autoimmune diabetes of adults). The diagnosis should certainly be suspected in patients for whom combination oral agent therapy rapidly fails. Nonobese body habitus, marked weight loss, extremely elevated glucose values, or a family or personal history of autoimmune disease (e.g., Hashimoto's or Graves' thyroid problems) should lead to diagnostic evaluation for such signs of autoimmunity.

Patients with T1DM need combined mealtime and basal insulin therapy. Although it is tempting to do so in a convenient fashion with combined preparations, such as those with analogue fixed ratios, it is usually far preferable to use a better basal insulin, such as glargine or detemir combined with a rapid-acting analogue (separately injected) before meals. Sometimes an insulin pump is the best way for patients who have frequent hypoglycemia or marked variability to achieve good glycemic control safely. Patients with T1DM should preferably be seen by an endocrine specialist or other practitioner with extensive experience in T1DM management. Ready access to diabetes educators is an important key to success with both T1DM and T2DM.

Adults With T2DM

Many patients with T2DM eventually need mealtime insulin. For those on basal insulin alone, incretin mimetics¹ can be successfully used for mealtime control, because they effectively lower prandial hyperglycemia. If exenatide is used, then additional injections will be required at the two major meals of the day. If using an

incretin-enhancer drug such as sitagliptin, injections are not required. This approach is useful with incretin agonists exenatide or liraglutide in patients who need to lose weight, who gain considerable weight with meal insulin, or who experience poor control despite attempts to regulate meal glycemia with short-acting insulins. Recent studies suggest possible benefit of combining long-acting basal insulins with incretin receptor agonists.

¹Not FDA approved for this indication.

GOUT AND HYPERURICEMIA

Method of

Saima Chohan, MD

CURRENT DIAGNOSIS

- Gout is the most common inflammatory arthritis in men and is increasing in prevalence.
- A definitive diagnosis of gout requires demonstration of monosodium urate crystals in synovial fluid or tophi.
- Gouty arthritis often begins in the lower extremity joints.
- Septic arthritis, rheumatoid arthritis, and calcium pyrophosphate disease (pseudogout) can mimic gout and should be ruled out.

CURRENT THERAPY

- The goals of successful gout treatment include terminating the acute attack, preventing intermittent attacks, and undertaking long-term therapy to avoid chronic arthritis.
- Indications for chronic treatment of gout include frequent attacks, recurrent arthritis, and kidney disease.
- A serum urate level of <6.0 mg/dL is the goal when using urate-lowering therapy.
- Nonpharmacologic treatment includes lifestyle modification and dietary changes.
- The mainstay of urate-lowering therapies remains xanthine oxidase inhibition.

Epidemiology

Gout, or monosodium urate crystal deposition disease, is the most common inflammatory arthritis of men and is an increasingly common problem among postmenopausal women. It is a chronic disorder, affecting more than 5 million people in the United States and increasing in both prevalence and incidence, especially in persons older than 65 years. Gout is often accompanied by serious comorbid disorders (hypertension, cardiovascular disease, chronic kidney disease, and all of the component features of the metabolic syndrome) and is managed in primary care practice in about 90% of affected persons. Therefore identifying risk factors, optimizing diagnosis, and choosing the appropriate treatment for gout are important skills for a wide array of caregivers.

Pathophysiology and Risk Factors

Uric acid is the end product of purine metabolism in humans. Hyperuricemia, a serum urate concentration exceeding urate solubility (6.8 mg/dL), is an invariable accompaniment of gout, although serum uric acid levels might not be elevated during an acute attack. Hyperuricemia predisposes affected persons to urate crystal formation and deposition, which lead to the inflammatory responses underlying the symptoms of gout. Thus treatment of gout is aimed at reducing and maintaining serum urate concentration at subsaturating levels, usually set at less than 6.0 mg/dL.

Hyperuricemia

Risk factors for hyperuricemia include obesity, hypertension, hyperlipidemia, insulin resistance, renal insufficiency, and use of diuretics. Diets rich in certain foods are also associated with increased risk for gout. Many studies with large patient cohorts have demonstrated a relationship between hyperuricemia and hypertension, cardiovascular and peripheral vascular disease, chronic kidney disease, and diabetes mellitus. The association of hyperuricemia and metabolic syndrome has also been shown in children and adolescents. Interventional trials of asymptomatic

patients with hyperuricemia and high cardiovascular risk must be performed before such treatment can be advocated.

Diagnosis

Acute gout is characterized by an abrupt onset of joint pain, erythema, and swelling, usually of one joint, but less commonly of more than one. The arthritis most often occurs first in a lower extremity joint, especially the first metatarsophalangeal (MTP) joint at the base of the great toe. The predilection for this site is thought to be secondary to cooler acral temperature or repeated trauma and pressure on this joint.

The gold standard for diagnosis of gout is the demonstration of monosodium urate crystals by polarized light microscopy, either in joint fluid aspirated during an acute attack or between attacks, or from material aspirated from suspected tophi. To aspirate the first MTP joint, the joint is first identified by palpating the space at the base of the metacarpal on the dorsal aspect while flexing and extending the toe. The needle is then inserted perpendicularly into the joint space to avoid the extensor hallucis tendon. Synovial fluid from affected joints should immediately be examined under polarized microscopy to confirm the diagnosis of needle-shaped crystals with negative birefringence. If polarized microscopy is unavailable, then fluid should be promptly sent in a sterile tube for crystal confirmation to an appropriate laboratory.

Unfortunately, the equipment and analytical expertise necessary to make this diagnosis are not widely available to primary care physicians. As a result, the diagnosis of acute gout is commonly made on clinical grounds, using the 2015 American College of Rheumatology and the European League Against Rheumatism classification criteria. These diagnostic guidelines use a point system and emphasize the presence of signs of inflammation (redness, tenderness, and loss of joint function), abrupt onset, monoarticular involvement, occurrence in the first MTP joint, presence of tophi, and radiographic findings.

The initial symptoms and signs of gout often occur after many years of asymptomatic hyperuricemia. In untreated or inadequately treated patients, the course of the disease often involves acute attacks at increasing frequency, with shortening of asymptomatic periods (called intercritical gout) and, ultimately, development of chronic joint disease (gouty arthropathy) and tophi (masses of urate crystals in a chronic inflammatory matrix) in bone, joints, skin, and even solid organs (Figure 1).

Indications for Treatment

Early in gout, patients might have attacks that are separated by years and manageable over the course of a few days with anti-inflammatory medications and adjuncts such as joint rest and application of ice. Over time, the attacks usually become more frequent, prolonged, and disabling, eventually requiring long-term urate-lowering treatment aimed at preventing urate crystal deposition and eventually abolishing acute flares and resolving tophi. Indications for urate-lowering (antihyperuricemic) therapy are listed in Box 1.

Treatment

Acute Gout

Gouty arthritis occurs suddenly, and attacks are often very painful and disabling. Patients describe acute onset of exquisite pain, swelling, erythema, and inability to bear weight on the afflicted joint. Occasionally, patients have constitutional symptoms including fever and chills, with an elevation of sedimentation rate and white blood cell count. To terminate an attack, nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine (Colcrys), or corticosteroids can be offered. If given at full antiinflammatory dosage, NSAIDs have a rapid onset and are quite efficacious in relieving pain and shortening the duration of an attack. The utility of this class of drugs may be limited by renal insufficiency, cardiovascular risk factors, and gastrointestinal bleeding. Although indomethacin (Indocin), sulindac (Clinoril), and naproxen (Naprosyn) are all FDA approved for treating acute attacks of gout, nearly every drug in this class and the selective cyclooxygenase (COX) 2 inhibitors

Figure 1 Intradermal urate deposit (tophus). (Reprinted with permission from Mandell BF: Gout and crystal deposition disease. In Weisman MH, Weinblatt ME, Louie JS, Van Vollenhoven R (eds): Targeted Treatment of the Rheumatic Diseases. Philadelphia, Saunders, 2010, 293–302).

BOX 1 Indications for Urate-Lowering Therapy

- Frequent and disabling gouty attacks, often defined as two or three flares annually, although this is not evidence based; the decision to treat is based on both number of flares and the consequent disability resulting from flares
- Chronic gouty disease: clinically or radiographically evident joint erosions
- Tophaceous deposits: subcutaneous or intraosseous
- Gout with renal insufficiency
- Recurrent kidney stones
- Urate nephropathy
- Urinary uric acid excretion exceeding 1100 mg/d (6.5 mmol), when determined in men younger than 25 years or in premenopausal women

also have considerable efficacy. High-dose salicylate therapy lowers serum uric acid by interfering in renal urate transport; low-dose aspirin¹ has the opposite effect, but it is often continued in gout patients because of its overriding importance in managing coronary artery disease.

Oral colchicine has been used to treat gout for many years as an unproven drug with no FDA dosage recommendations or prescribing information. In July 2009, however, the FDA approved Colcrys, a single-ingredient colchicine product, for the first day of treatment of acute gout attacks at a low-dose regimen of 1.2 mg followed by 0.6 mg in 1 hour (total 1.8 mg). With this regimen, colchicine can be used to abort an attack if taken immediately after the development of the first symptom of gout flare. Higher colchicine doses (0.6 mg every hour, until symptoms improve or

until gastrointestinal symptoms of diarrhea, nausea, or vomiting develop, for a total of 4.8 mg over 6 hours)³ have traditionally been recommended. A randomized, placebo-controlled trial comparing the low-dose and high-dose regimens showed both approaches had equivalent efficacy in pain relief at 24 hours (compared with placebo). However, adverse gastrointestinal events were significantly less common with the low-dose regimen. In subjects warranting additional flare treatment, continued use of colchicine 0.6 mg twice daily (reducing to once daily as the flare subsides) is appropriate in persons with normal renal and hepatic function. Oral colchicine is now available in generic and two branded versions (Colcrys, Mitigare).

Gastrointestinal symptoms are generally the first clinical signs of colchicine toxicity in patients with normal renal and hepatic function. More serious toxicities do occur and include neuromyopathy, aplastic anemia, and worsening renal and hepatic function. Care should be used in patients with renal or hepatic impairment, and because of potentially serious drug-drug interactions, colchicine should be avoided in patients receiving cyclosporine (Neoral), clarithromycin (Biaxin), verapamil (Calan), and amlodipine (Norvasc). Intravenous colchicine is not available in Europe. The FDA has stopped the marketing of unapproved injectable colchicine products in the United States and discourages the compounding of IV colchicine because of reports of preparation errors causing deaths.

Corticosteroids provide a safe alternative for patients with contraindications to NSAIDs or colchicine. For isolated monoarticular attacks, especially of medium or large joints, aspiration of joint fluid and intraarticular injection with triamcinolone acetate (Kenalog) 20 to 40 mg can quickly terminate an attack. For polyarticular attacks or attacks in smaller joints, systemic corticosteroids (oral or intramuscular) may be used. Oral prednisone starting at 20 mg twice daily with a taper over 10 to 14 days is very effective. Patients can have rebound attacks if oral steroids are terminated too quickly, and thus methylprednisolone (Medrol) dose packs should be avoided. If intramuscular injection is used, a single dose of triamcinolone 40 mg may be used.

There is interest in agents blocking the action of interleukin 1 (IL-1), a cytokine thought to play a major role in initiating and sustaining acute gouty inflammation. Anakinra (Kineret)¹ and canakinumab (Ilaris)¹ are potent injectable IL-1 inhibitors, and studies are ongoing to assess the utility of these agents to mitigate acute attacks. In 2013 canakinumab became the first biologic agent approved for acute gout in Europe. It was approved by the European Medicines Agency for symptomatic treatment of adult patients with frequent gouty arthritis attacks in whom NSAIDs and colchicine are contraindicated, are not tolerated, or do not provide an adequate response and in whom repeated courses of corticosteroids are not appropriate. Rilonacept (Arcalyst)¹, which is also in this class, was declined approval for gout by the FDA in 2012 because of concerns about long-term safety.

Intercritical Gout

After an attack subsides, management is directed at preventing recurrent attacks. During acute attacks of gout, normal serum urate concentration is reported in up to 40% of affected patients, and thus it is not an accurate reflection of the true urate pool. Confirmation of hyperuricemia is best achieved either before the resolution of an attack or 2 to 4 weeks after it, to achieve an accurate serum urate concentration. There is a generalizable correlation between the serum urate level and risk for recurrent attack.

Prophylaxis of future attacks during early urate-lowering therapy can consist of colchicine at doses of 0.6 mg once or twice a day (based on renal function) or NSAIDs. If chronic NSAIDs are used, acid-reducing medications such as proton pump inhibitors or histamine-2 blockers may be used for patients at risk for gastrointestinal bleeding.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Long-Term Urate-Lowering (Antihyperuricemic)

Therapy

The aim of urate-lowering therapy is to reduce and maintain serum urate at concentrations below those at which extracellular fluids are saturated with monosodium urate. In general, an ultimate serum urate concentration of less than 6.0 mg/dL is advised. Urate lowering can be achieved either by increasing urinary excretion or by decreasing production of urate.

Nonpharmacologic urate-lowering treatment begins with lifestyle changes. Diet and weight loss must be addressed. Obesity and weight gain are risk factors for gout, and weight loss has been shown to decrease the risk of gout. A purine-restricted diet has often been recommended to patients but is often unpalatable and impractical. Reduction in alcohol intake, namely beer and liquor, can effectively reduce urate levels. Similarly, reduced intake of red meat and shellfish also lowers the risk of recurrent gouty attacks. Studies have shown an increased frequency of attacks in patients who consume fruit juices and soft drinks containing high-fructose corn syrup, an ingredient not found in diet drinks.

Once the decision is made to institute serum urate-lowering therapy, the duration of treatment is indefinite and must be long-term to be effective. The majority of patients with gout and tophaceous disease will continue to have attacks if therapy is discontinued, and thus education is a key part of the treatment plan. Patients should be instructed that, with initiation of any urate-lowering therapy, they will be at increased risk for a flareup and thus must continue regular use of prophylactic agents as outlined above. At least 80% to 95% of cases of hyperuricemia and gout are attributable to impaired urate excretion, which is reflected in diminished urate clearance or fractional excretion of uric acid but not usually in low daily urine uric acid excretion. In practice, 24-hour urine collections are rarely performed. Patients are preferentially treated with xanthine oxidase inhibitors because of the easier dosing schedule and because many patients have contraindications to uricosurics such as renal insufficiency and kidney stones.

Uricosurics

Relative to medications aimed at urate synthesis, uricosurics are relegated to second-line treatment of patients with elevated urate burden or tophaceous disease. The most commonly used uricosuric agent in the United States is probenecid. This is a very effective drug that concentrates and promotes urinary excretion of urate. Its utility is limited in patients with renal insufficiency, and probenecid is not recommended as first-line therapy in patients with nephrolithiasis or uric acid overexcretion. The maintenance dose of probenecid required to achieve and maintain serum urate concentration at less than 6.0 mg/dL is 0.5 to 3 g/day³, administered in 2 or 3 daily doses. Once goal serum urate concentration is achieved with a uricosuric agent, the risk of uric acid calculi is diminished, because urinary uric acid excretion becomes normal.

Lesinurad (Zurampic) is another uricosuric agent; it is an inhibitor of renal transport proteins and was FDA approved in 2016. It is used at a dose of 200 mg/day in combination with a xanthine oxidase inhibitor, including allopurinol (Zyloprim) or febuxostat (Uloric). In 2017, the FDA approved Duzallo, a combination product of lesinurad 200 mg and allopurinol 300 mg, one tablet in the morning for hyperuricemia. Duzallo is also available in lesinurad 200 mg and allopurinol 200 mg tablet for patients with renal impairment. This drug has a boxed warning regarding the risk of acute renal failure.

Other drugs found to have uricosuric effects include fenofibrate (Tricor)¹, a fibric acid derivative used to treat hyperlipidemia, and the antihypertensives losartan (Cozaar)¹ and amlodipine (Norvasc)¹. These agents have mild uricosuric properties and may be useful adjuncts to urate-lowering therapy. Skim milk ingestion has been shown to lower serum urate levels through uricosuric effects. Lower urate levels have also been seen in patients who consume coffee, but the mechanism of action is unknown.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Xanthine Oxidase Inhibitors

Allopurinol (Zyloprim) and febuxostat (Uloric) are the only FDA-approved xanthine oxidase inhibitors for the treatment of gout. Allopurinol, introduced in 1966, is approved in doses of 100 to 800 mg/day. More than 90% of patients with gout treated with urate-lowering medication in the United States are given allopurinol, but dosages of more than 300 mg/day are infrequently employed, and often patients do not achieve serum urate concentrations of 6.0 mg/dL or less. Appropriate use of allopurinol is limited for several reasons. There are genuine concerns about allopurinol drug interactions, gastrointestinal intolerance, rashes (ranging from mild to life-threatening), and the rare but sometimes fatal hypersensitivity syndrome. Allopurinol should be avoided with the immunosuppressives azathioprine (Imuran) and 6-mercaptopurine (Purinethol) because it can increase the risk of bone marrow toxicity, because these medications are partially metabolized by xanthine oxidase. Allopurinol should not be taken with ampicillin owing to increased risk of rash.

Effective dosing of allopurinol is often not achieved because of compliance with published but recently disputed recommendations for allopurinol dose reduction in states of renal impairment. Allopurinol should be initiated at 100 mg daily in patients with creatinine clearance of 40 mL/min or greater, and it should be titrated in 100-mg increments every 2 to 4 weeks, with the endpoint of dosing determined by achievement of serum urate concentration of 6.0 mg/dL or less.

The FDA approved febuxostat (Uloric) in 2009. Unlike allopurinol, this is a nonpurine analogue and selective xanthine oxidase inhibitor that is not incorporated into purine nucleotides and does not appear to affect pyrimidine metabolism. Febuxostat is primarily metabolized by oxidation and glucuronidation in the liver, with little renal excretion of drug; this contrasts with the renal elimination of oxypurinol, the main allopurinol metabolite. The recommended starting dose of febuxostat is 40 mg daily, with an increase to 80 mg daily if serum urate concentrations do not reach goal urate levels in 2 weeks in patients with normal renal function. In Europe, higher dosages (80–120 mg daily)³ have received approval, and studies have affirmed the efficacy and safety of dosing in this range. In the FOCUS trial, a 5-year study of efficacy and safety, febuxostat was shown to have durable maintenance of serum urate concentration at 6.0 mg/dL or less, nearly complete elimination of gouty flares, and resolution of baseline tophi in subjects. An advantage of febuxostat over allopurinol is that it can safely be taken by patients with creatinine clearance greater than 30 mL/min.

Pegloticase

Pegloticase (pegylated porcine recombinant uricase, Krystexxa) was granted FDA approval in 2010 for treatment of refractory gout. Humans lack the enzyme uricase, which converts uric acid to allantoin, a more soluble purine degradation product. Replacement of this missing enzyme allows direct conversion of urate to allantoin, with eventual depletion of increased body urate pools and control of disease, including resolution of tophi. Recombinant uricase therapy profoundly lowers serum urate concentration, as was demonstrated in two large trials. Pegloticase is approved at a dosage of 8 mg intravenously every 2 weeks.

Potential New Therapies

A number of other novel agents with new therapeutic targets for the treatment of acute and chronic gout are under investigation.

³Exceeds dosage recommended by the manufacturer.

HYPERALDOSTERONISM

Method of

Jongoh Kim, MD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperaldosteronism may be suspected in patients with severe, resistant, or early-onset hypertension and hypertensive patients with family history, hypokalemia, adrenal mass, and obstructive sleep apnea. Evaluation begins with measurement of morning plasma aldosterone concentration (PAC in ng/dL) and plasma renin activity (PRA in ng/mL/hr) in a sodium- and potassium-repleted state and off of significantly interfering medications (spironolactone [Aldactone], eplerenone [Inspra], amiloride [Midamor], triamterene [Dyrenium], potassium-wasting diuretics, and licorice-derived products⁷) for at least 4 weeks.
- Elevated PRA and PAC suggest secondary hyperaldosteronism; suppressed PRA and PAC suggest conditions mimicking hyperaldosteronism; suppressed PRA but elevated PAC suggests primary hyperaldosteronism (screening positive if PAC/PRA ratio >20–40 and PAC >5–10 ng/dL).
- Positive screening of primary hyperaldosteronism should be confirmed with one of the following tests: IV saline suppression, oral salt loading, fludrocortisone (Florinef)¹ suppression, or captopril (Capoten)¹ challenge test (may skip if spontaneous hypokalemia, renin below the detection limit, and PAC >20 ng/dL).
- Once primary hyperaldosteronism is biochemically confirmed, computed tomography (CT) of the adrenal glands is recommended to exclude adrenocortical carcinoma and help subtype primary hyperaldosteronism.
- If surgical treatment is considered, adrenal vein sampling is indicated to differentiate unilateral vs. bilateral lesions (may skip if the patient is <35 years with spontaneous hypokalemia, PAC >30 ng/dL, and unilateral adenoma). A cortisol-corrected aldosterone ratio from the high to the low side >4:1 with cosyntropin (Cortrosyn) stimulation confirms unilateral aldosterone excess.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

CURRENT THERAPY

- Laparoscopic adrenalectomy is recommended for unilateral disease. Otherwise, medical treatment with a mineralocorticoid receptor antagonist (MRA; spironolactone [Aldactone] as the primary agent and eplerenone [Inspra]¹ as an alternative) is recommended.

- Spironolactone: 12.5 to 25 mg/day titrated to a maximum dose of 400 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased serum creatinine, hyperkalemia, gynecomastia, and menstrual irregularities.
- Eplerenone: 25 mg once or twice daily titrated to a maximum dose of 100 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased creatinine, hyperkalemia, hypertriglyceridemia, increased liver enzymes, headache, and fatigue.
- Amiloride (Midamor)¹ or triamterene (Dyrenium)¹ (epithelial sodium channel antagonists) can be used in those who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Other antihypertensive agents are also added if necessary to control hypertension.

¹Not FDA approved for this indication.

Introduction

Hyperaldosteronism is a state of excessive aldosterone secretion. Primary hyperaldosteronism occurs due to autonomous hypersecretion of aldosterone, whereas secondary hyperaldosteronism occurs due to activation of the renin angiotensin aldosterone system (RAAS). Primary hyperaldosteronism is the most common cause of secondary hypertension, and recent reports suggest that 5% to 20% of hypertensive patients have primary hyperaldosteronism (as opposed to less than 1%, as previously reported). Secondary hyperaldosteronism includes two different categories; one is compensatory activation of the RAAS due to decreased effective circulating volume, as in congestive heart failure and liver cirrhosis; the other is overactivity of the RAAS accompanied by hypertension, as in renovascular hypertension. There are also several conditions that mimic aldosterone excess through various mechanisms that present with hypertension and other metabolic perturbations. Except for the compensatory activation of the RAAS, these conditions cause secondary hypertension with or without other metabolic consequences, such as hypokalemia and metabolic alkalosis, which bring them to medical attention. This chapter covers the current approaches to hyperaldosteronism for patients suspected of having hypertension secondary to excess aldosterone production.

Pathophysiology

Aldosterone is a steroid hormone produced by the zona glomerulosa in the adrenal gland and contributes to volume and potassium homeostasis via its action primarily on the principal cells in the collecting tubule of the kidney. The main stimuli of aldosterone secretion are angiotensin II and hyperkalemia, which increase synthesis and activity of aldosterone synthase mediated by calcium signaling. Angiotensin II releases calcium from the endoplasmic reticulum, whereas both angiotensin II and hyperkalemia depolarize membrane potential and open voltage gated calcium channels. Therefore changes in genes regulating ionic homeostasis and membrane potential can affect aldosterone secretion. Aldosterone and angiotensin II are part of the RAAS; plasma renin from the juxtaglomerular apparatus converts angiotensinogen to angiotensin I, and angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II. Subsequently, angiotensin II stimulates secretion of aldosterone. Renin secretion is controlled by renal artery pressure, sodium delivery to the distal nephron, and sympathetic activation (via β_1). Increased effective arterial circulating volume from the action of aldosterone decreases renin secretion by negative feedback (Figure 1). Other minor factors involved in aldosterone secretion are adrenocorticotrophic hormone and hyponatremia (which increase aldosterone secretion) and atrial natriuretic peptide (which decreases aldosterone secretion).

Aldosterone binds to the nuclear mineralocorticoid receptors. Activation of the mineralocorticoid receptors up-regulates the basolateral Na^+K^+ pumps and the epithelial sodium channels (ENaC), leading to increased reabsorption of Na^+ and Cl^- and secretion of K^+ and H^+ . The mineralocorticoid receptors can also

HYPERALDOSTERONISM

Method of

Jongoh Kim, MD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperaldosteronism may be suspected in patients with severe, resistant, or early-onset hypertension and hypertensive patients with family history, hypokalemia, adrenal mass, and obstructive sleep apnea. Evaluation begins with measurement of morning plasma aldosterone concentration (PAC in ng/dL) and plasma renin activity (PRA in ng/mL/hr) in a sodium- and potassium-repleted state and off of significantly interfering medications (spironolactone [Aldactone], eplerenone [Inspra], amiloride [Midamor], triamterene [Dyrenium], potassium-wasting diuretics, and licorice-derived products⁷) for at least 4 weeks.
- Elevated PRA and PAC suggest secondary hyperaldosteronism; suppressed PRA and PAC suggest conditions mimicking hyperaldosteronism; suppressed PRA but elevated PAC suggests primary hyperaldosteronism (screening positive if PAC/PRA ratio >20–40 and PAC >5–10 ng/dL).
- Positive screening of primary hyperaldosteronism should be confirmed with one of the following tests: IV saline suppression, oral salt loading, fludrocortisone (Florinef)¹ suppression, or captopril (Capoten)¹ challenge test (may skip if spontaneous hypokalemia, renin below the detection limit, and PAC >20 ng/dL).
- Once primary hyperaldosteronism is biochemically confirmed, computed tomography (CT) of the adrenal glands is recommended to exclude adrenocortical carcinoma and help subtype primary hyperaldosteronism.
- If surgical treatment is considered, adrenal vein sampling is indicated to differentiate unilateral vs. bilateral lesions (may skip if the patient is <35 years with spontaneous hypokalemia, PAC >30 ng/dL, and unilateral adenoma). A cortisol-corrected aldosterone ratio from the high to the low side >4:1 with cosyntropin (Cortrosyn) stimulation confirms unilateral aldosterone excess.

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

CURRENT THERAPY

- Laparoscopic adrenalectomy is recommended for unilateral disease. Otherwise, medical treatment with a mineralocorticoid receptor antagonist (MRA; spironolactone [Aldactone] as the primary agent and eplerenone [Inspra]¹ as an alternative) is recommended.

- Spironolactone: 12.5 to 25 mg/day titrated to a maximum dose of 400 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased serum creatinine, hyperkalemia, gynecomastia, and menstrual irregularities.
- Eplerenone: 25 mg once or twice daily titrated to a maximum dose of 100 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased creatinine, hyperkalemia, hypertriglyceridemia, increased liver enzymes, headache, and fatigue.
- Amiloride (Midamor)¹ or triamterene (Dyrenium)¹ (epithelial sodium channel antagonists) can be used in those who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Other antihypertensive agents are also added if necessary to control hypertension.

¹Not FDA approved for this indication.

Introduction

Hyperaldosteronism is a state of excessive aldosterone secretion. Primary hyperaldosteronism occurs due to autonomous hypersecretion of aldosterone, whereas secondary hyperaldosteronism occurs due to activation of the renin angiotensin aldosterone system (RAAS). Primary hyperaldosteronism is the most common cause of secondary hypertension, and recent reports suggest that 5% to 20% of hypertensive patients have primary hyperaldosteronism (as opposed to less than 1%, as previously reported). Secondary hyperaldosteronism includes two different categories; one is compensatory activation of the RAAS due to decreased effective circulating volume, as in congestive heart failure and liver cirrhosis; the other is overactivity of the RAAS accompanied by hypertension, as in renovascular hypertension. There are also several conditions that mimic aldosterone excess through various mechanisms that present with hypertension and other metabolic perturbations. Except for the compensatory activation of the RAAS, these conditions cause secondary hypertension with or without other metabolic consequences, such as hypokalemia and metabolic alkalosis, which bring them to medical attention. This chapter covers the current approaches to hyperaldosteronism for patients suspected of having hypertension secondary to excess aldosterone production.

Pathophysiology

Aldosterone is a steroid hormone produced by the zona glomerulosa in the adrenal gland and contributes to volume and potassium homeostasis via its action primarily on the principal cells in the collecting tubule of the kidney. The main stimuli of aldosterone secretion are angiotensin II and hyperkalemia, which increase synthesis and activity of aldosterone synthase mediated by calcium signaling. Angiotensin II releases calcium from the endoplasmic reticulum, whereas both angiotensin II and hyperkalemia depolarize membrane potential and open voltage gated calcium channels. Therefore changes in genes regulating ionic homeostasis and membrane potential can affect aldosterone secretion. Aldosterone and angiotensin II are part of the RAAS; plasma renin from the juxtaglomerular apparatus converts angiotensinogen to angiotensin I, and angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II. Subsequently, angiotensin II stimulates secretion of aldosterone. Renin secretion is controlled by renal artery pressure, sodium delivery to the distal nephron, and sympathetic activation (via β_1). Increased effective arterial circulating volume from the action of aldosterone decreases renin secretion by negative feedback (Figure 1). Other minor factors involved in aldosterone secretion are adrenocorticotrophic hormone and hyponatremia (which increase aldosterone secretion) and atrial natriuretic peptide (which decreases aldosterone secretion).

Aldosterone binds to the nuclear mineralocorticoid receptors. Activation of the mineralocorticoid receptors up-regulates the basolateral Na^+K^+ pumps and the epithelial sodium channels (ENaC), leading to increased reabsorption of Na^+ and Cl^- and secretion of K^+ and H^+ . The mineralocorticoid receptors can also

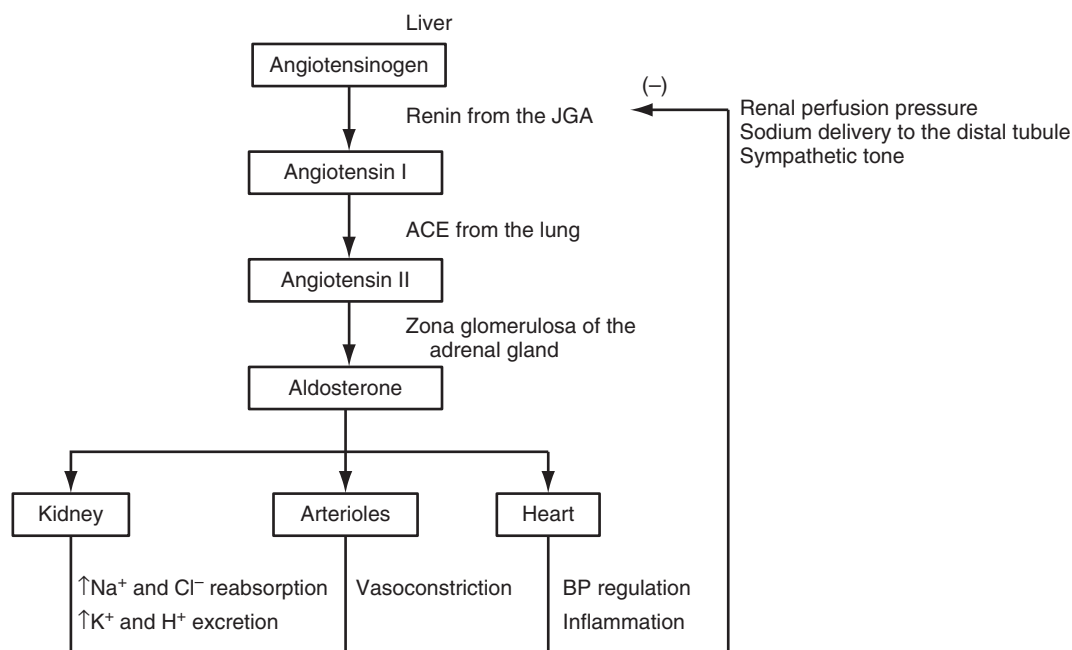

Figure 1 The renin-angiotensin-aldosterone system (RAAS). *Abbreviations:* ACE = angiotensin-converting enzyme; BP = blood pressure; JGA = juxtaglomerular apparatus.

be activated by other hormones with mineralocorticoid activity. Cortisol is able to bind to the mineralocorticoid receptors with similar affinity as aldosterone but normally is converted to inactive cortisone by 11 β hydroxysteroid dehydrogenase 2 (11 β HSD2). Mutations/inhibition of 11 β HSD2 or very high cortisol levels above the capacity of 11 β HSD2, as in Cushing's syndrome (particularly ectopic Cushing's syndrome), and glucocorticoid resistance can cause activation of the mineralocorticoid receptors. Aldosterone precursors such as deoxycorticosterone have a weak mineralocorticoid effect but can cause features of hyperaldosteronism when they are present at very high levels as in some forms of congenital adrenal hyperplasias (11 β hydroxylase deficiency or 17 α hydroxylase deficiency) or deoxycorticosteroid-secreting tumors. Additionally, activating mutations of the ENaCs also cause increased sodium absorption and hypertension mimicking hyperaldosteronism (Liddle's syndrome).

Clinical Manifestations

Primary hyperaldosteronism usually presents with normokalemic hypertension. Hypokalemia is present only in 9% to 37% of cases and may indicate more severe cases. Patients with primary hyperaldosteronism usually do not develop severe volume overload or edema because of aldosterone escape possibly related to atrial natriuretic peptide, pressure natriuresis, or decreased sodium absorption at other nephron segments. Metabolic alkalosis, mild hypernatremia (due to reset osmostat from volume expansion), and hypomagnesemia may be observed. Glomerular filtration rate and urinary albumin excretion can be elevated independent of systemic hypertension. Cardiovascular morbidity and mortality are higher in primary hyperaldosteronism than in essential hypertension. Secondary hyperaldosteronism (when it is not from hypovolemia) and other conditions mimicking hyperaldosteronism can present with similar features as primary hyperaldosteronism plus specific manifestations for each disease entity. Depending on the mechanism of disease, more severe volume overload and pulmonary edema may be found (e.g., renovascular hypertension) because aldosterone escape may not work.

Evaluation

Screening

Hyperaldosteronism may be suspected based on severe or resistant hypertension, early-onset hypertension without known risk

BOX 1

Groups Indicated for Case Detection With Relatively High Prevalence of Primary Hyperaldosteronism

- Sustained blood pressure >150/100 mm Hg on three different occasions
- Drug-resistant hypertension (>140/90 mm Hg despite 3 medications including a diuretic)
- Hypertension and hypokalemia (spontaneous or diuretic-induced)
- Hypertension and family history of early-onset hypertension or cerebrovascular accident at a young age (<40 years)
- Hypertension with adrenal incidentaloma
- Hypertensive first-degree relatives of primary hyperaldosteronism patients
- Hypertension with obstructive sleep apnea

factors, and hypertension with other features such as family history of hyperaldosteronism, early-onset hypertension, cerebrovascular accident at a young age, hypokalemia, adrenal mass, and obstructive sleep apnea. Currently, there is no evidence-guided screening strategy. Some experts believe that routine screening for primary hyperaldosteronism is warranted in newly diagnosed hypertension considering its high prevalence, whereas others recommend that targeted screening is more appropriate, such as the Endocrine Society guidelines for primary hyperaldosteronism in 2016 (Box 1).

When a decision is made to screen for excessive mineralocorticoid effect, one should first examine the plasma renin and aldosterone levels; that is, plasma renin activity (PRA, ng/mL/hr) and plasma aldosterone concentration (PAC, ng/dL). It is important to note that several factors can affect PRA and PAC, such as age, medications, time of day, diet (salt intake), posture, method of blood collection, level of potassium, and level of creatinine (Table 1). Diuretics (both potassium sparing and wasting) and mineralocorticoid antagonists can have a significant effect on PRA and PAC. Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers (ACEI/ARB) and dihydropyridine calcium channel blockers can affect PRA and PAC modestly. Ideally, all medications and other factors that may affect PRA and PAC should be removed;

*Premenopausal women have higher aldosterone level during the luteal phase and lower renin level throughout the cycle than men. False positive ARR during the luteal phase was reported when direct renin concentration was used.

unfortunately, it is not always practical and safe to do this because of the possibility of uncontrolled hypertension. If necessary, antihypertensive agents that affect PRA and PAC only minimally such as slow-release verapamil (Calan SR), hydralazine (Apresoline), prazosin (Minipress), doxazosin (Cardura), or terazosin (Hytrin) can be used. The Endocrine Society 2016 guidelines recommend certain caveats that optimize the chance for obtaining more easily interpretable PRA and PAC results (Box 2).

Patterns of PRA and PAC help differentiate among primary hyperaldosteronism, secondary hyperaldosteronism, and conditions mimicking hyperaldosteronism. Differential diagnoses according to different patterns of PRA and PAC are listed in Box 3. If both PRA and PAC are high, further investigation for causes of secondary hyperaldosteronism should follow. If both PRA and PAC are suppressed, further investigation for conditions that mimic hyperaldosteronism is indicated. Suppressed PRA and elevated PAC suggest primary hyperaldosteronism, and aldosterone renin ratio (ARR) should be calculated; ARR above 20–40 is considered screening positive for primary hyperaldosteronism. PAC >15 ng/dL was recommended by some investigators to avoid false-positive ARR from very low renin level, but many cases with

PAC <15 ng/dL, more commonly in bilateral adrenal hyperplasia than in aldosterone producing adenoma, were reported. PAC should at least be above the level considered positive for confirmatory tests (5–10 ng/dL). Confirmatory tests should follow to avoid false positives. Diagnostic flow and subsequent management of hyperaldosteronism are summarized in Figure 2. Of note, there is no consensus on cutoff values for PRA, PAC, or ARR. In addition, PRA and PAC are often obtained in a less-than-optimal condition. Therefore it is important to understand how PRA and PAC can be affected by various factors. For example, if ARR is positive while on medications that decrease PAC or increase PRA (thus decreasing ARR), ARR off this medication will be clearly positive. Screening tests should be repeated if results are inconclusive.

Confirmatory Tests of Primary Hyperaldosteronism

The positive screening test should be followed by confirmatory tests to avoid false positives. The confirmatory tests are designed to physiologically suppress aldosterone levels that would normally occur in the absence of primary hyperaldosteronism. However, some experts believe that some aldosterone-producing lesions are

BOX 2 Approach to Measure PRA and PAC

- Correct hypokalemia to 4 mmol/L.
- Liberalize sodium intake.
- Withdraw the following agents that markedly affect PRA and PAC for at least 4 weeks: spironolactone (Aldactone), eplerenone (Inspra), amiloride (Midamor), triamterene (Dyrenium), potassium-wasting diuretic, and products from licorice.⁷
- If not diagnostic and hypertension can be controlled with relatively non-interfering medications, withdraw the following agents for at least 2 weeks: β -blockers, central α_2 agonists (clonidine [Catapres], methyldopa [Aldomet]), NSAIDs, ACEIs/ARBs, renin inhibitors, and dihydropyridine calcium channel antagonists.
- If necessary, start other antihypertensive agents that have fewer effects on ARR: slow-release verapamil (Calan-SR), hydralazine (Apresoline) (with verapamil to prevent reflex tachycardia), prazosin (Minipress), doxazosin (Cardura), and terazosin (Hytrin).
- Obtain blood for PRA and PAC mid-morning after the patient has been up for at least 2 hours and seated for 5–15 minutes.
- Establish use of estrogen products and menstrual cycles. Premenopausal females have higher ARR than men, especially during the luteal phase. False-positive ARR was reported during the luteal phase and from the use of estrogen products when direct renin concentration was used.

⁷Available as dietary supplement.**BOX 3** Differential Diagnoses According to PRA and PAC**Causes of Primary Hyperaldosteronism: \downarrow PRA and \uparrow PAC (>5 – 10 ng/dL); ARR >20 – 40**

- Most Common
 - Aldosterone-producing adenoma
 - Bilateral adrenal hyperplasia or idiopathic hyperaldosteronism
- Less Common
 - Unilateral hyperplasia or primary adrenal hyperplasia
 - Familial hyperaldosteronism type 1 or glucocorticoid remediable aldosteronism
 - Familial hyperaldosteronism type 2
 - Aldosterone-producing adrenocortical carcinoma
 - Ectopic aldosterone-secreting tumor (ovary, kidney)
 - Multiple endocrine neoplasia type 1

Causes of Secondary Hyperaldosteronism: \uparrow PRA and \uparrow PAC; ARR ≈ 10

- Renovascular hypertension
- Diuretic use
- Renin-secreting tumor
- Malignant hypertension
- Coarctation of the aorta

Causes of Conditions Which Mimic Mineralocorticoid Excess: \downarrow PRA and \downarrow PAC

- Congenital adrenal hyperplasia
- Exogenous mineralocorticoid
- Deoxycorticosterone producing tumor
- Cushing's syndrome
- 11β HSD2 deficiency
- Altered aldosterone metabolism
- Liddle's syndrome
- Glucocorticoid resistance

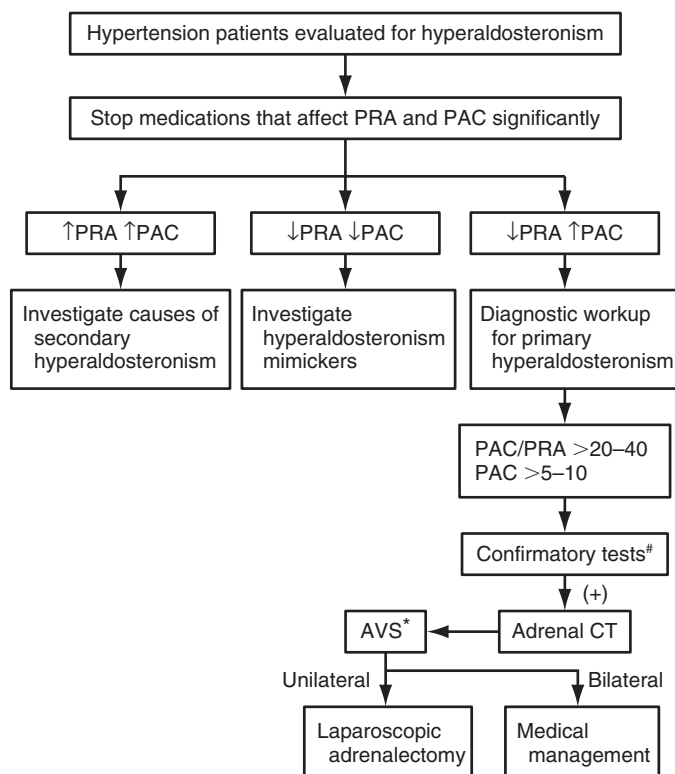

Figure 2 Evaluation of hyperaldosteronism. *Abbreviations:* AVS = adrenal vein sampling; CT = computed tomography; PAC = plasma aldosterone concentration in ng/dL; PRA = plasma renin activity in ng/ml/hr. *If surgical treatment is pursued. May skip if <35 years old, spontaneous hypokalemia, PAC >30 ng/dL, and unilateral adenoma. #May skip if spontaneous hypokalemia, renin level below the detection limit, and PAC >20 ng/dL.

not completely independent of the RAAS, and confirmatory suppression tests can give false-negative results. Other experts think that confirmatory tests are not necessary for those with obvious clinical/biochemical features. Those with spontaneous hypokalemia, renin level below the detection level plus PAC >20 ng/dL may not need further confirmatory tests. Furthermore, there is no gold-standard confirmatory test. Therefore factors such as cost, accessibility, feasibility, patient compliance, local expertise, and accuracy of assay should be taken into consideration in selecting confirmatory tests. The Endocrine Society guidelines in 2016 state that any of the following four confirmatory tests can be used: oral salt loading test, saline suppression test, fludrocortisone (Florinef)¹ suppression test, and captopril (Capoten)¹ challenge test (Table 2).

Subtype Classification of Primary Hyperaldosteronism

Once primary hyperaldosteronism is biochemically confirmed, subtype classification follows to guide treatment. Unilateral lesions such as aldosterone-producing adenomas (APAs) can be treated surgically, whereas bilateral lesions such as bilateral adrenal hyperplasias (BAHs) are treated medically. Aldosterone-producing carcinoma is rare but should be ruled out. In this regard, CT of the adrenal glands should be done first to rule out aldosterone-producing carcinoma and obtain anatomic information. However, imaging studies are usually not reliable enough to lateralize lesions. If surgical treatment is considered, adrenal vein sampling should be performed. Young patients (<20 years of age) and those with family history of primary hyperaldosteronism or strokes at young age <40 years should have genetic testing for glucocorticoid remediable aldosteronism (GRA) or familial hyperaldosteronism type 1 (FH-1), which is caused by the hybrid gene of 11β hydroxylase and aldosterone synthase (increased aldosterone synthesis by

¹Not FDA approved for this indication.

TABLE 2 Protocols and Interpretation of Recommended Confirmatory Tests

	PROTOCOL	INTERPRETATION	REMARKS
Oral sodium loading test	<ol style="list-style-type: none"> 1. Place the patient on a high-sodium diet (> 200 mmol/day) for 3 days. 2. Replace potassium to compensate for the kaliuresis induced by the high-sodium diet. 3. Collect a 24-hour urine on the third day for determination of aldosterone, sodium, and creatinine; adequate if the urine sodium > 200 mmol/24 hr 	Confirmed if the 24-hour urine aldosterone is > 12 mcg (33.3 nmol) to 14 mcg (38.8 nmol). Ruled out if the 24-hour urine aldosterone is < 10 mcg (27.7 nmol). The test is equivocal if the value falls in between.	Do not perform this test in patients with severe uncontrolled hypertension, renal failure, cardiac failure/arrhythmias, or severe hypokalemia.
IV saline infusion test*	<ol style="list-style-type: none"> 1. Place the patient supine 1 hour before drawing blood for morning baseline fasting levels of renin, aldosterone, cortisol, and potassium. 2. Infuse 2 L of 0.9% NaCl over 4 hours, keeping the patient supine. Monitor blood pressure and heart rate. 3. After 4 hours, draw blood for measurement of renin, aldosterone, cortisol, and potassium. 	Confirmed if the PAC is > 10 ng/dL (277 pmol/L). Ruled out if the PAC is < 5 ng/dL (139 pmol/L). If the PAC falls between these values, the test is equivocal.	Do not perform this test in patients with severe uncontrolled hypertension, renal failure, cardiac failure/arrhythmias, or severe hypokalemia.
Fludrocortisone ¹ suppression test	<ol style="list-style-type: none"> 1. Give 0.1 mg fludrocortisone every 6 hours for 4 days, with the potassium level checked every 6 hours to make sure that it is greater than 4 mmol/L. 2. Encourage a liberal sodium diet to keep urinary sodium excretion greater than 3 mmol/kg/day. 3. On day 4, draw blood for an upright 7 AM plasma cortisol level and 10 AM plasma aldosterone, renin, and cortisol levels. 	Confirmed if the 10 AM PAC is > 6 ng/dL, as long as PRA is < 1 ng/ml/hr and the plasma cortisol at 10 AM is less than at 7 AM (to exclude the ACTH effect).	The test may require hospitalization. Risks include severe hypokalemia, QT changes, worsening of left ventricular function, hypertension, and frequent phlebotomy
Captopril ¹ challenge test	<ol style="list-style-type: none"> 1. Give 25–50 mg captopril after the patient has been sitting or standing for 1 hour. The patient remains seated throughout the test. 2. Draw blood for measurement of plasma renin, aldosterone, and cortisol at time 0, at 1 hour, and at 2 hours. 	Normally, captopril suppresses PAC by more than 30% from baseline. Confirmed if there is no suppression of PAC and PRA remains suppressed. The false-negative rate for this test is high because suppression occurs in more than 30% of cases. A slight decrease in aldosterone can suggest bilateral adrenal hyperplasia.	

Abbreviations: ACTH = adrenocorticotropic hormone; PAC = plasma aldosterone concentration; PRA = plasma renin activity.

¹Not FDA approved for this indication.

*The patient may be seated for 30 min before and during the infusion to improve sensitivity and PAC > 6 ng/dL (170 pmol/L) confirms primary hyperaldosteronism.

adrenocorticotropic hormone). In very young patients, *KCNJ5* germline mutations, causing familial hyperaldosteronism type III, should be tested. Familial hyperaldosteronism type II is clinically indistinguishable from non-familial hyperaldosteronism and its molecular basis has not been identified.

Imaging

CT/MRI scans of the adrenal glands provide one of five conclusions: normal adrenal glands, unilateral macroadenomas (> 1 cm), minimal unilateral adrenal limb thickening, unilateral microadenomas (≤ 1 cm), and bilateral macroadenomas and/or microadenomas. APAs are typically smaller than 2 cm, and BAHs exhibit either normal or nodular changes. Aldosterone-producing adrenal carcinomas are almost always larger than 4 cm in diameter and have imaging characteristics suspicious for malignancy. However, there are limitations; small APAs may be missed, hyperplasia may be misread as adenomas, and nonfunctional tumors are radiologically indistinguishable from APAs. Although several studies suggested imaging criteria for different subtypes, no study has conclusively established specific criteria that differentiate among different subtypes of primary hyperaldosteronism. In fact, CT accurately lateralizes in only about 50% to 70% of cases. Therefore adrenal vein sampling is required to differentiate unilateral from bilateral lesions if surgical resection is being pursued. Younger patients $< \text{age } 35$ with marked hyperaldosteronism with

BOX 4 Adrenal Vein Sampling

- After both adrenal veins have been cannulated, draw baseline samples for PRA, PAC, ACTH, and cortisol from the peripheral such as cubital or iliac, right adrenal vein, and left adrenal vein.
- Inject 250 mcg of cosyntropin (Cortrosyn) after cannulation, or infuse 50 mcg cosyntropin per hour beginning 30 minutes before adrenal vein cannulation. This reduces stress-related fluctuations in aldosterone and cortisol values and augments the biochemical gradients (this step is controversial).
- Draw blood for aldosterone and cortisol levels at 5, 15, and 30 minutes from the peripheral site and from each adrenal vein.

spontaneous hypokalemia and PAC > 30 ng/dL and solitary unilateral adenoma may not need adrenal vein sampling because non-functioning tumors are uncommon in this young age group.

Adrenal Vein Sampling

Aldosterone levels are measured from adrenal venous blood samples (Box 4) obtained through adrenal vein cannulation to distinguish between unilateral and bilateral lesions. Unilateral lesions are associated with a marked increase in PAC on the side of the

tumor (and suppressed PAC on the other side), whereas bilateral lesions have little difference between the two sides. Adrenal vein sampling (AVS) should be performed only by experienced physicians in part because recognition and successful cannulation of the right adrenal vein especially can be challenging. Complications of AVS include adrenal hemorrhage, adrenal infarction, adrenal vein perforation, and adrenal vein thrombosis, which occur only rarely (<2.5%) in the hands of a physician skilled in the procedure.

The use of cosyntropin (Cortrosyn) stimulation to minimize stress-induced fluctuation in aldosterone level is controversial, and some believe that it has no effect on AVS accuracy. If cosyntropin is not used, then AVS should be done in the morning after overnight recumbency to avoid postural aldosterone changes and reflect circadian aldosterone secretion.

In reality, different centers use different techniques, protocols, and interpretation criteria. The Endocrine Society guidelines in 2016 provide interpretation criteria with and without cosyntropin use. The first step for interpretation is to determine whether the procedure was done correctly. The adrenal vein-to-IVC cortisol ratio should be greater than 5:1 with cosyntropin given and greater than 3:1 without cosyntropin. If the ratio is significantly lower than these values, improper cannulation is implied. Next, divide the PAC values for the right and left adrenal veins by their respective cortisol values to correct the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; this is termed the *cortisol-corrected aldosterone* (A/C). If cosyntropin is used, an A/C ratio of the high to the low side of greater than 4:1 indicates unilateral aldosterone hypersecretion, whereas an A/C ratio of less than 3:1 suggests bilateral aldosterone hypersecretion. These cutoffs were reported to have sensitivity of 95% and specificity of 100% for unilateral lesions. If the A/C ratio is between 3:1 and 4:1, the results of AVS should be interpreted in the context of CT, clinical findings, and other tests. Without cosyntropin, an A/C ratio of the high to the low side of greater than 2 or an A/C ratio of the high side to the periphery greater than 2.5 plus an A/C ratio of the low side to the periphery of less than 1 (suppressed contralateral aldosterone secretion) is consistent with unilateral aldosterone excess.

Ancillary Tests

Clinical findings and other ancillary tests may help differentiate unilateral APAs from BAHs. BAHs will respond with increase in plasma aldosterone to postural stimulation, whereas APAs will not. Plasma 18-hydroxycorticosterone level tends to be higher in APAs as compared with BAHs. Iodocholesterol scintigraphy may be able to show functional correlation of anatomical abnormalities (but is not available at most centers). APA-specific tracers such as (11)C metomidate for positron emission tomography may be useful. Interpretation criteria of these tests are listed in Table 3. Patients with APAs tend to be younger (<40 years), predominantly female, very hypertensive with marked hypokalemia (<3 mmol/L), and tend to have a very high PAC (>25 mg/dL) as compared with those with BAHs.

Treatment

Treatment of secondary hyperaldosteronism and conditions mimicking hyperaldosteronism depends on their etiology. Treatment of primary hyperaldosteronism is discussed here. The goals of treatment of primary hyperaldosteronism are (1) normalization of the serum potassium in hypokalemic patients, (2) normalization of the blood pressure, and (3) reversal of the effects of hyperaldosteronism on the cardiovascular system. When a small group of patients were followed after treatment with adrenalectomy or mineralocorticoid receptor antagonists (MRAs), left ventricular mass was reduced (faster with adrenalectomy than MRAs), glomerular filtration rate and urinary albumin secretion decreased and became similar to that in essential hypertension, and excessive cardiovascular risk compared to essential hypertension disappeared. Cardiovascular complications were rather related to age, duration of hypertension, and smoking. Therefore timely diagnosis and treatment is essential. For unilateral lesions, surgical resection of the

TABLE 3 Interpretation of Dynamic Testing

TEST	FINDINGS
Screening Test	
PAC/PRA ratio	Positive if >20–40 with PAC >5–10 ng/dL
Confirmatory Tests	
Oral sodium loading test	Positive if 24-hr urine aldosterone excretion is >12–14 mcg
Saline infusion test	Positive if PAC after infusion is >10 ng/dL
Fludrocortisone ¹ suppression test	Positive if upright PAC is >6 ng/dL on day 4 at 10 am
Captopril ¹ challenge test	Positive if PAC does not decrease by 30% and PRA remains suppressed
AVS	
With cosyntropin stimulation	A/C ratio (the high to the low side) >4:1 → unilateral aldosterone excess A/C ratio 3:1 to 4:1 → unclear A/C ratio <3:1 → bilateral aldosterone excess
Without cosyntropin stimulation	A/C ratio from the high to the low side >2:1 → unilateral aldosterone excess A/C ratio from the high side to the periphery >2.5 and A/C ratio from the contralateral side to the periphery <1 → unilateral aldosterone excess
If Equivocal AVS	
Postural stimulation test	PAC falls or fails to rise by 30%: consistent with APAs PAC increases by at least 33%: consistent with BAHs
Recumbent 18-hydroxycorticosterone	>100 ng/dL is consistent with APAs
NP-59 iodocholesterol scintigraphy	Unilateral early uptake (<5 d): consistent with unilateral aldosterone excess Bilateral early uptake (<5 d): consistent with bilateral aldosterone excess Negative scan does not rule out either etiology
(11)C-Metomidate positron emission tomography	Preliminary data showed (11)C-metomidate uptake in APA

¹Not FDA approved for this indication.

Abbreviations: A/C ratio = cortisol-corrected aldosterone ratio; APA = aldosterone-producing adenomas; AVS = adrenal vein sampling; BAH = bilateral adrenal hyperplasia; PAC = plasma aldosterone concentration; PRA = plasma renin activity.

affected adrenal gland is recommended mainly to obviate the need for prolonged medical treatment and side effects. For bilateral lesions, medical treatment is recommended because surgical risk outweighs benefits. Blood pressure control per se does not reduce risk of cardiovascular complications unless renin activity is restored to normal (>1 ng/ml/hr), which can be accomplished by salt restriction or increasing the dose of the MRA. MRAs are a key component of medical treatment and used as a preoperative measure or maintenance treatment (GRA should be treated with the lowest dose of glucocorticoid that can normalize blood pressure and potassium levels rather than MRAs). A low-sodium diet (sodium <100 mEq/day = 2.3 g/day or salt 6 g/day) is also important, because left ventricular hypertrophy is associated with urine sodium excretion in primary hyperaldosteronism but not in

essential hypertension. Other lifestyle changes include aerobic exercise, smoking cessation, and weight loss.

Unilateral Hypersecretion

Adrenalectomy, usually laparoscopic, is recommended. After adrenalectomy, blood pressure improves in all patients (maximal improvement in 1–6 months, sometime continues to fall up to 1 year), but 30% to 60% of patients have persistent hypertension. Blood pressure and potassium level should be controlled before surgery. MRAs such as spironolactone (Aldactone) and eplerenone (Inspra)¹ can be used to control blood pressure in patients awaiting adrenalectomy and also to prevent postoperative hypoaldosteronism. Postoperatively, normal saline is given to maintain volume status, MRAs and potassium supplements are discontinued, and antihypertensive medications may be reduced. To confirm biochemical cure, PAC and PRA should be checked shortly after the operation. Risk factors for persistent hypertension after adrenalectomy include older age, duration of hypertension (>5 years), use of two or more antihypertensive agents preoperatively, blood pressure higher than 165/100 mm Hg, low ARR preoperatively, low urine aldosterone, poor response to spironolactone preoperatively, family history of more than one first-degree relative with hypertension, and elevated serum creatinine level.

Bilateral Hypersecretion

MRAs and/or ENaC antagonists combined with other antihypertensives are used. One study showed that spironolactone had stronger antihypertensive effect than eplerenone, but there is insufficient evidence to choose one medication over another. Subtotal adrenalectomy has been tried, but only a minority of patients have responded with significant blood pressure improvement. Unilateral adrenalectomy, however, may help selected patients by debulking aldosterone-producing tissues.

Spironolactone is the most widely used MRA. It is very effective in decreasing blood pressure. The medication is initiated at 12.5 to 25 mg/day and can be titrated to 400 mg/day, with most patients requiring at least 200 mg/day. Potassium should be maintained at normal levels without use of potassium supplements. Use of spironolactone can be limited by side effects; antiandrogenic effects can cause gynecomastia in men and progesterone effect can cause menstrual irregularities in women. There are drug interactions to consider; spironolactone increases the half-life of digoxin (Lanoxin) and salicylates, and other NSAIDs may decrease the effectiveness of spironolactone. Serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks, in particular for those with renal insufficiency or diabetes. Spironolactone is not recommended if creatinine clearance is less than 30 mL/minute.

Eplerenone¹ is a competitive and selective antagonist of the aldosterone receptors. It has a lower binding affinity to androgen and progesterone receptors than spironolactone. This leads to fewer side effects. Eplerenone is 25% to 50% less potent in antagonizing the aldosterone receptors than spironolactone. Eplerenone has a short half-life and should be taken twice daily. Dosing is started at 25 mg twice daily, with a maximum dose of 100 mg/day. Again, serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks in particular for those with renal insufficiency or diabetes. Other adverse effects include hypertriglyceridemia, increased liver enzymes, headache, and fatigue. Eplerenone is contraindicated if serum potassium is greater than 5.5 mEq/L at initiation, if creatinine clearance is less than 30 mL/minute, or if there is concomitant use of strong CYP3A4 inhibitors such as ketoconazole (Nizoral) and itraconazole (Sporanox).

ENaC antagonists, amiloride (Midamor)¹ and triamterene (Dyrenium)¹, can be used in patients who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Amiloride is prescribed at 10 to 20 mg/day in divided doses. Side effects include

dizziness, fatigue, and impotence. Triamterene is dosed at 100 to 300 mg/day in divided doses, and its side effects are mainly dizziness and nausea. Addition of thiazide diuretics can help control blood pressure by relieving volume overload. If blood pressure remains uncontrolled, other antihypertensive agents such as ACEIs/ARBs or calcium channel blockers may be used.

HYPERLIPIDEMIA

Method of

Jongoh Kim, MD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperlipidemia is diagnosed based on the fasting lipid profile in the context of global cardiovascular risk. The exception is when the triglyceride level is greater than 500 mg/dL because of substantial risk of pancreatitis.
- Secondary causes of hyperlipidemia, such as hypothyroidism, alcoholism, uncontrolled diabetes mellitus, kidney disorders,

¹Not FDA approved for this indication.

essential hypertension. Other lifestyle changes include aerobic exercise, smoking cessation, and weight loss.

Unilateral Hypersecretion

Adrenalectomy, usually laparoscopic, is recommended. After adrenalectomy, blood pressure improves in all patients (maximal improvement in 1–6 months, sometime continues to fall up to 1 year), but 30% to 60% of patients have persistent hypertension. Blood pressure and potassium level should be controlled before surgery. MRAs such as spironolactone (Aldactone) and eplerenone (Inspra)¹ can be used to control blood pressure in patients awaiting adrenalectomy and also to prevent postoperative hypoaldosteronism. Postoperatively, normal saline is given to maintain volume status, MRAs and potassium supplements are discontinued, and antihypertensive medications may be reduced. To confirm biochemical cure, PAC and PRA should be checked shortly after the operation. Risk factors for persistent hypertension after adrenalectomy include older age, duration of hypertension (>5 years), use of two or more antihypertensive agents preoperatively, blood pressure higher than 165/100 mm Hg, low ARR preoperatively, low urine aldosterone, poor response to spironolactone preoperatively, family history of more than one first-degree relative with hypertension, and elevated serum creatinine level.

Bilateral Hypersecretion

MRAs and/or ENaC antagonists combined with other antihypertensives are used. One study showed that spironolactone had stronger antihypertensive effect than eplerenone, but there is insufficient evidence to choose one medication over another. Subtotal adrenalectomy has been tried, but only a minority of patients have responded with significant blood pressure improvement. Unilateral adrenalectomy, however, may help selected patients by debulking aldosterone-producing tissues.

Spironolactone is the most widely used MRA. It is very effective in decreasing blood pressure. The medication is initiated at 12.5 to 25 mg/day and can be titrated to 400 mg/day, with most patients requiring at least 200 mg/day. Potassium should be maintained at normal levels without use of potassium supplements. Use of spironolactone can be limited by side effects; antiandrogenic effects can cause gynecomastia in men and progesterone effect can cause menstrual irregularities in women. There are drug interactions to consider; spironolactone increases the half-life of digoxin (Lanoxin) and salicylates, and other NSAIDs may decrease the effectiveness of spironolactone. Serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks, in particular for those with renal insufficiency or diabetes. Spironolactone is not recommended if creatinine clearance is less than 30 mL/minute.

Eplerenone¹ is a competitive and selective antagonist of the aldosterone receptors. It has a lower binding affinity to androgen and progesterone receptors than spironolactone. This leads to fewer side effects. Eplerenone is 25% to 50% less potent in antagonizing the aldosterone receptors than spironolactone. Eplerenone has a short half-life and should be taken twice daily. Dosing is started at 25 mg twice daily, with a maximum dose of 100 mg/day. Again, serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks in particular for those with renal insufficiency or diabetes. Other adverse effects include hypertriglyceridemia, increased liver enzymes, headache, and fatigue. Eplerenone is contraindicated if serum potassium is greater than 5.5 mEq/L at initiation, if creatinine clearance is less than 30 mL/minute, or if there is concomitant use of strong CYP3A4 inhibitors such as ketoconazole (Nizoral) and itraconazole (Sporanox).

ENaC antagonists, amiloride (Midamor)¹ and triamterene (Dyrenium)¹, can be used in patients who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Amiloride is prescribed at 10 to 20 mg/day in divided doses. Side effects include

dizziness, fatigue, and impotence. Triamterene is dosed at 100 to 300 mg/day in divided doses, and its side effects are mainly dizziness and nausea. Addition of thiazide diuretics can help control blood pressure by relieving volume overload. If blood pressure remains uncontrolled, other antihypertensive agents such as ACEIs/ARBs or calcium channel blockers may be used.

HYPERLIPIDEMIA

Method of

Jongoh Kim, MD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperlipidemia is diagnosed based on the fasting lipid profile in the context of global cardiovascular risk. The exception is when the triglyceride level is greater than 500 mg/dL because of substantial risk of pancreatitis.
- Secondary causes of hyperlipidemia, such as hypothyroidism, alcoholism, uncontrolled diabetes mellitus, kidney disorders,

¹Not FDA approved for this indication.

pregnancy, and medications, should be thoroughly investigated and treated if found.

- Possibility of familial hyperlipidemia based on family history and physical findings should be considered because cardiovascular risk can be underestimated and treatment can be challenging.

CURRENT THERAPY

- Therapy should be guided by goals of treatment based on estimated cardiovascular risk unless triglyceride level >500 mg/L, in which case lowering triglycerides to prevent pancreatitis is a priority.
- Low-density lipoprotein (LDL) cholesterol is a primary goal followed by non-high-density lipoprotein (HDL) cholesterol as a secondary goal.
- Therapeutic lifestyle changes should be initiated in everyone with LDL cholesterol above their target. Therapeutic lifestyle changes are also recommended for those with very high, high, or moderately high cardiovascular risk.
- Pharmacologic agents should be added if therapeutic lifestyle changes are not successful. Pharmacologic agents can be considered from the beginning for those with very high, high, or moderately high cardiovascular risk.
- Statin therapy is preferred if tolerated, and the intensity of therapy should be strong enough to lower LDL cholesterol at least by 30% to 40%.
- Statins are the treatment of choice for their proven effects on cardiovascular outcomes. Other agents can be added based on response to statins and other targets such as high triglycerides or low-HDL cholesterol.
- All other cardiovascular risk factors should be treated aggressively at the same time.

Hyperlipidemia is a condition of elevated serum lipids and lipoproteins. Hyperlipidemia is associated with an increased risk of cardiovascular disease and, if the triglyceride level is greater than 500 mg/dL, pancreatitis. Unless the triglyceride level is greater than 500 mg/dL, the primary goal of management of hyperlipidemia is to decrease the risk of cardiovascular disease. In this regard, appropriate treatment of hyperlipidemia is essential in patients with established cardiovascular disease (secondary prevention), whereas detection and treatment of hyperlipidemia are guided by the risk of cardiovascular disease in asymptomatic patients (primary prevention).

The prevalence of hyperlipidemia varies with the definition of hyperlipidemia and the population studied. The percentage of U.S. adults with a total cholesterol level of 240 mg/dL or higher declined from 19% to 14% in men and from 21% to 15% in women from 1988 to 2008. This may be in part due to increased use of lipid-lowering medications, from 3.4% to 15.5%. However, major risk factors for cardiovascular disease actually have become more common: the prevalence of obesity ($\text{BMI} \geq 30 \text{ kg/m}^2$) increased from 19.9% to 31.6% in men and from 25.2% to 34.1% in women, and the prevalence of diabetes increased from 5.5% to 11.1% in men and from 4.6% to 6.3% in women over this period. Therefore optimal treatment of hyperlipidemia to reduce cardiovascular risk is of paramount importance.

Various societies and professional organizations have published clinical guidelines for hyperlipidemia. The approach used in this chapter is mostly based on *The Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III)* published in 2002 and updated in 2004 by National Heart Blood Lung Institute (NHLBI) and 2013 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk

in Adults: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. The 2013 ACC/AHA guideline represents a substantial departure from previous guidelines in that it emphasizes the use of statins of appropriate strength according to the estimated cardiovascular risk without specific low-density lipoprotein (LDL) cholesterol targets. In 2016, updated new guidelines were proposed by the European Society of Cardiology and European Atherosclerosis Society (ESC/EAS) [Guidelines for the Management of Dyslipidaemias (2016)], and the ACC [2016 ACC Expert Consensus Decision Pathway on the Role of Non-Statins Therapies for LDL-Cholesterol Lowering in the Management of Atherosclerotic Cardiovascular Disease Risk], which will be integrated in the sections on Evaluation and Treatment.

Pathophysiology

Lipids have two main points of entry into the circulation: the gut (exogenous pathway) and the liver (endogenous pathway). The exogenous and endogenous pathways are interconnected by intermediate pathways (reverse cholesterol transport pathway and others). These pathways are outlined in Figure 1.

Exogenous Pathway

Lipids in food are emulsified by bile acids and then hydrolyzed into fatty acids and cholesterol by pancreatic lipases in the intestinal lumen. Inside the intestinal cells, fatty acids and cholesterol are reesterified and then packaged with apolipoprotein (Apo) B48 into chylomicrons. Chylomicrons are secreted into the intestinal lymph and delivered to the systemic circulation. At peripheral tissues, triglycerides are hydrolyzed by lipoprotein lipase with Apo CII acting as a cofactor. Released free fatty acids are then taken up for further metabolism or storage. Chylomicron remnants are taken up by the liver via the chylomicron remnant receptors.

Endogenous Pathway

The endogenous pathway begins in the liver with the synthesis of triglyceride-rich very-low-density lipoproteins (VLDLs). Microsomal triglyceride transfer protein facilitates the transfer of lipids onto Apo B100 and stabilizes the protein for secretion as VLDLs. VLDLs, as chylomicrons, undergo lipolysis by lipoprotein lipase, releasing free fatty acids, generating smaller particles called intermediate-density lipoproteins (IDLs, also known as VLDL remnants). IDLs are either removed by the liver or further processed into cholesterol-rich LDLs. LDLs are taken up into the liver or other cells via LDL receptors, a process regulated by cellular cholesterol requirement. Macrophages can also take up LDLs via the scavenger receptors and become foam cells. Foam cells play a key role in the development of atherosclerosis.

Reverse Cholesterol Transport

High-density lipoproteins (HDLs) are the major lipoproteins involved in the transport of cholesterol from peripheral tissues back to the liver. HDLs are synthesized by both the hepatocytes and the enterocytes in the form of small discoidal particles containing Apo AI and phospholipids. HDLs acquire additional lipids and apolipoproteins from triglyceride-depleted chylomicrons and

Figure 1 Overview of exogenous and endogenous pathways of lipid metabolism. Abbreviations: CM = chylomicrons; HDL = high-density lipoproteins; IDL = intermediate-density lipoproteins; LDL = low-density lipoproteins; VLDL = very-low-density lipoproteins.

VLDL remnants. HDLs remove free cholesterol from tissues with the help of Apo AI and esterify it with lecithin cholesterol acyltransferase. Cholesteryl esters are then transferred to Apo B 100-containing lipoproteins (VLDLs, IDLs, and LDLs) by cholesteryl ester transfer protein (CETP). HDLs can also be taken up directly by the liver class B type I scavenger receptors (SR-BI).

Plasma Lipids and Atherosclerosis

Multiple studies have shown that total cholesterol and LDL cholesterol levels contribute to cardiovascular disease risk and that lowering of total cholesterol and LDL cholesterol levels reduces the risk. Non-HDL cholesterol (i.e., total cholesterol – HDL cholesterol = VLDL + IDL + LDL cholesterol) reflects total atherogenic lipoprotein burden and may be a better risk indicator than LDL cholesterol, especially in people with combined hyperlipidemia, diabetes, metabolic syndrome, and chronic kidney disease. Elevated triglycerides, in particular nonfasting levels, also may be an independent cardiovascular risk factor. Even mildly elevated triglycerides (>150 mg/dL) can indicate metabolic syndrome, which is a strong risk factor for cardiovascular disease. Elevated triglycerides are often associated with low-HDL cholesterol and high levels of small, dense LDL particles (hyperlipidemia triad). HDL particles are considered protective against the formation of atherosclerotic plaque through reverse cholesterol transport and also possibly antiinflammatory and antioxidative activities. HDL cholesterol levels have been shown to be inversely associated with cardiovascular risk. However, the benefits of using drugs to lower triglycerides only and/or raising HDL cholesterol in reducing cardiovascular risk have not been proved. Table 1 shows the ATP III classification of lipid profile.

Evaluation

Global Cardiovascular Risk Assessment

The first step in assessing risk is to stratify global cardiovascular risk scores. Global risk scores estimate 10-year cardiovascular risk, which combines the effects of well-known risk factors, using one of

TABLE 1 The NCEP ATP III Classification of LDL, Total, and HDL Cholesterol and Triglycerides (mg/dL)

LDL Cholesterol (mg/dL)	
<100	Optimal
100–129	Near optimal/above optimal
130–159	Borderline high
160–189	High
≥190	Very high
Total Cholesterol (mg/dL)	
<200	Desirable
200–239	Borderline high
≥240	High
HDL Cholesterol (mg/dL)	
<40	Low
≥60	High
Triglycerides (mg/dL)	
<150	Normal
150–199	Borderline high
200–499	High
≥500	Very high

Abbreviations: ATP III = National Cholesterol Education Program Adult Treatment Panel III guidelines; HDL = high-density lipoprotein; LDL = low-density lipoprotein.

several risk-calculation tools. Individual tools have been developed based on large epidemiology studies examining a limited number of available risk factors. Traditional risk factors such as age, sex, cigarette smoking, cholesterol, diabetes, and blood pressure are able to predict 80% to 90% of the cardiovascular events in people 40 years or older. However, these tools may not accurately estimate cardiovascular risk in individuals with different demographics or unaccounted risk factors. The Framingham risk score, one of the most commonly used tools, provides several different risk assessment tools for different outcome measures (<http://framinghamriskscore.com>). The hard coronary heart disease (CHD) tool, used in the ATP III, incorporates age, sex, total cholesterol, HDL cholesterol, smoking, systolic blood pressure, and antihypertensive medications, and it predicts coronary death or myocardial infarction (<http://hp2010.nhlbi.nih.net/atpiiii/calculator.asp?usertype=prof>). The SCORE, used in the ESC/EAS guidelines for the management of dyslipidemias, incorporates similar risk factors and predicts fatal cardiovascular events (www.heartscore.org). The Reynolds risk score incorporates high-sensitivity CRP and parental premature myocardial infarction, in addition to the risk factors mentioned above, and predicts major cardiovascular events (www.reynoldsriskscore.org).

In the 2004 ATP III update, risk assessment begins with identifying the following cardiovascular risk factors: cigarette smoking, hypertension (BP ≥ 140/90 mm Hg) or use of antihypertensive agents, HDL cholesterol less than 40 mg/dL (≥ 60 mg/dL is a negative risk factor), age >45 years in men and >55 years in women, family history of premature CHD (male first-degree relatives <55 years, female first-degree relatives <65 years). The presence of zero or only one risk factor is considered as low risk (almost always, the risk for hard CHD over 10 years is <10%). If two or more risk factors are present without CHD or CHD equivalents, the Framingham risk score for the hard CHD over 10 years needs to be calculated. A risk of less than 10% is considered as moderate risk. If the risk is between 10% and 20%, it is considered as moderately high risk. If the risk is higher than 20%, it is considered as a CHD risk equivalent. Diabetes and clinical forms of atherosclerotic disease (abdominal aortic aneurysm, carotid artery disease—transient ischemic attack, stroke of carotid origin, greater than 50% obstruction of carotid artery, and peripheral vascular disease) are also considered as CHD equivalents. CHD and CHD equivalents belong to the high-risk group. Recently, chronic kidney disease with glomerular filtration rate less than 60 mL/minute/1.73 m² is also recognized as a CHD equivalent by some societies. The very-high-risk group was introduced in the ATP III update and more recent guidelines. The ATP III update defined the very-high-risk group as established cardiovascular disease plus multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially continued smoking), multiple risk factors of the metabolic syndrome, and acute coronary syndrome. The therapeutic approach is determined by this risk stratification. Established cardiovascular disease itself and diabetes with other cardiovascular risk factor(s) are also considered as very high risk by some authorities (see the Treatment section and Tables 2 and 3).

The 2013 ACC/AHA guideline focuses on identifying four subgroups of patients for whom the benefits of statin therapy outweigh the risk (Table 4). The new Pooled Cohort Equation is used to estimate a 10-year risk of atherosclerotic cardiovascular disease (nonfatal myocardial infarction, CHD death, and nonfatal and fatal stroke) for those aged 40 to 79 years, incorporating age, sex, race, HDL and total cholesterol, diabetes, hypertension, and smoking status (<http://tools.cardiosource.org/ASCVD-Risk-Estimator>). Statin therapy is recommended regardless of the baseline LDL cholesterol level in these four subgroups (see Table 4). The new guideline provides no recommendations for individuals requiring maintenance hemodialysis or with class II to IV ischemic systolic heart failure.

Measurement of Lipid Profiles

Lipid profiles should be measured as a part of global risk assessment, and the frequency of checkup is determined by age, sex,

TABLE 2 LDL Cholesterol Goals (mg/dL) and Levels for Initiating Lifestyle and Pharmacologic Interventions (The ATP III Update)

	RISK CATEGORY	GOAL (mg/dL)	LDL CHOLESTEROL LEVEL AT WHICH TO INITIATE TLC (mg/dL)	LDL CHOLESTEROL LEVEL AT WHICH TO INITIATE DRUG THERAPY (mg/dL)
High	CHD or CHD risk equivalents or 10-year risk of heart attack > 20%	<100 (<70 if very high risk*)	>100	>100 (<100 optional)
Moderately high	2 or more risk factors and 10-year risk 10%–20%	<130 (<100 optional)	>130	>130 (100–129 optional)
Moderate	2 or more risk factors and 10-year risk <10%	<130	>130	>160
Low	0–1 risk factor	<160	>160	>190

*Very high risk: acute coronary syndrome or established cardiovascular disease plus multiple major risk factors (especially diabetes), severe and poorly controlled risk factors (especially continued smoking), or multiple risk factors of the metabolic syndrome.

Abbreviations: ATP III = National Cholesterol Education Program Adult Treatment Panel III guidelines; CHD = coronary heart disease; LDL = low-density lipoprotein; TLC = therapeutic lifestyle changes.

TABLE 3 LDL Cholesterol and Apo B Goals in the ESC/EAS Guideline*

	GOAL	
	LDL Cholesterol (mg/dL)	Apo B (mg/dL)
Very high risk: established cardiovascular disease, diabetes plus major cardiovascular risk factor(s), severe CKD (GFR <30 mL/min/1.73 m ²), or 10 year fatal CVD risk ≥ 10%	70 or >50% reduction if baseline 70–135	80
High risk: markedly uncontrolled risk factor(s), diabetes, moderate CKD (GFR 30–59 mL/min/1.73 m ²), or 10 year fatal CVD risk 5–10%	100 or >50% reduction if baseline 100–200	100

*10-year risk calculation using SCORE.

TABLE 4 The Four Target Groups and Two Exceptions for Statin Therapy in the 2013 ACC/AHA Guideline

CHARACTERISTICS	TREATMENT
Clinical atherosclerotic cardiovascular disease*	<75 years: high-intensity statin; >75 years or not candidate for high-intensity statin: moderate-intensity statin
LDL cholesterol >190 mg/dL	High-intensity statin
40–75 years with diabetes, LDL cholesterol 70–189 mg/dL	Moderate-intensity statin (may use high-intensity statin if 10-year risk ≥ 7.5%)
40–75 years without diabetes, LDL cholesterol 70–189 mg/dL, 10-year atherosclerotic cardiovascular risk † ≥ 7.5%	Moderate- to high-intensity statin
Maintenance hemodialysis	No recommendation
Ischemic systolic heart failure, NYHA class II–IV	No recommendation

*Coronary heart disease, stroke, and peripheral arterial disease of presumed atherosclerotic origin.

†10-year risk of nonfatal myocardial infarction, coronary heart disease death, and nonfatal and fatal stroke using the Pooled Cohort Equation (<http://tools.cardiosource.org/ASCVD-Risk-Estimator>).

and risk factors for cardiovascular disease. A fasting lipid profile (fasting for 9–12 hours) is recommended to ensure the most precise lipid assessment, specifically triglycerides (subsequently LDL cholesterol if calculated using the Friedewald equation). Nonfasting lipid profile provides an accurate measurement of other lipids, including total cholesterol, HDL cholesterol, Apo B, and Apo AI. Recent studies showed that differences in triglyceride levels according to fasting time were small. Therefore lipid values from nonfasting samples should not be ignored.

LDL cholesterol is either calculated using the Friedewald equation (LDL cholesterol = total cholesterol – HDL cholesterol – triglycerides/5) or directly measured. The Friedewald equation should be used with appropriate caution: fasting state samples should be used, it becomes less accurate if triglycerides >200 mg/dL, not valid if triglycerides >400 mg/dL and LDL cholesterol can be underestimated at levels <70 mg/dL.

Apolipoproteins, including Apo B and Apo AI, may also be measured. The Apo B level (Apo B100) reflects the number of atherogenic lipoprotein particles and appears to be a better measure of cardiovascular disease than the LDL cholesterol level or the LDL particle size. Apo B level and Apo B/Apo AI ratio are as good as traditional lipid profiles and are especially useful in certain situations such as combined hyperlipidemia, metabolic syndrome, diabetes, and chronic kidney disease.

Other medical conditions may also affect lipid profiles. Secondary causes include hypothyroidism, nephrotic syndrome, dysgammaglobulinemia, use of progestin (especially those with androgenic activity), cholestasis, use of protease inhibitors, chronic kidney

disease, uncontrolled diabetes, obesity, excessive alcohol intake, use of thiazide or β -blockers, use of corticosteroids, use of oral estrogen (not transdermal), and pregnancy. These conditions should be detected and treated, if appropriate, to improve control of hyperlipidemia.

Family history of premature cardiovascular disease and hyperlipidemia and physical findings such as xanthomas, xanthelasmas, and premature arcus cornealis may suggest familial hyperlipidemia. Familial hyperlipidemia can be associated with significantly high risk of cardiovascular disease, which could be underestimated by the global risk scores.

Treatment

Overview

Treatment is primarily aimed at lowering LDL cholesterol level, which has been shown to decrease the risk of cardiovascular disease in numerous studies unless the triglyceride level is higher than 500 mg/dL, in which case triglycerides should be lowered immediately to prevent pancreatitis. Every reduction of LDL cholesterol by 40 mg/dL is associated with about 20% reduction in cardiovascular risk. The absolute risk reduction by lowering LDL cholesterol is proportional to the global cardiovascular risk. Therefore the

targeted goal of LDL cholesterol is determined by the global cardiovascular risk.

The treatment goals and approaches according to the ATP III are summarized in Table 2. The optional goal of LDL cholesterol less than 70 mg/dL was added in the 2004 update for the very-high-risk group. Established cardiovascular disease itself, diabetes with other cardiovascular risk factor(s), and advanced chronic kidney disease are also considered as very high risk by some authorities. The 2013 ACC/AHA guideline focuses on identification of risk groups and treatment without LDL cholesterol targets, whereas the 2016 ESC/EAS guideline maintains as a goal the LDL cholesterol target presented in Table 3. As a first line, therapeutic lifestyle changes should be initiated when LDL cholesterol is above the target range. People with very high, high, or moderately high risk should also start making therapeutic lifestyle changes regardless of their LDL cholesterol level. Medications may be added at the same time as therapeutic lifestyle changes for those with very high, high, or moderately high risk. If medications are indicated, statin is preferred because of proven efficacy that has been consistently shown in multiple clinical trials. The intensity of treatment should be strong enough to reduce LDL cholesterol level by at least 30% to 40%. Once the LDL cholesterol goal is achieved, then non-HDL cholesterol level should be controlled. The treatment goal for the non-HDL cholesterol is 30 mg/dL above the LDL cholesterol goal. Specific treatment of low-HDL cholesterol is controversial. CETP inhibitors, which specifically increase HDL cholesterol by blocking transfer of cholesterol to Apo B-containing lipoproteins, were not effective in reducing cardiovascular risk. The effect of increasing HDL cholesterol with niacin¹ in people taking statins has not been encouraging. Generally, response to treatment can be evaluated in 6 weeks. Once under control, lipid profiles can be monitored every 4 to 6 months.

The ACC/AHA Task Force on Practice Guidelines issued a new guideline in 2013. The new approach recommends treating at-risk patients with statins of appropriate strength (reflecting the design of most published clinical trials), rather than titrating combinations of lipid-lowering medications to a preset target based on baseline cholesterol levels. Strength of the statin (high intensity: LDL cholesterol reduction >50%, moderate intensity: LDL cholesterol reduction 30%–50%) is determined by the global risk. The Pooled Cohort Equation, a new algorithm for risk calculation, is used to estimate the global risk in those with LDL cholesterol 70 to 189 mg/dL but without clinical atherosclerotic or diabetes (see Table 4). This new approach initially faced considerable skepticism because of the absence of LDL cholesterol targets, neglect of non-statin therapy, and questionable validity of the new algorithm for risk calculation (the Pooled Cohort Equation).

Part of the controversy over the new ACC/AHA guideline pertains to the risk-calculation tools, which have limitations: most of the risk calculators do not consider family history of premature cardiovascular events, which can lead to a serious underestimation of the risk in some patients (the Reynolds Risk Score includes family history of premature myocardial infarction); some of the risk calculators do not predict risk of stroke, which is another major cardiovascular event (the hard CHD tool in the ATP III predicts only fatal and nonfatal myocardial infarction whereas the new Pooled Cohort Equation predicts both nonfatal/fatal myocardial infarction and stroke); these risk calculators are not always validated beyond the original cohorts from which they were developed. The new risk prediction algorithm (the Pooled Cohort Equation) was also criticized for overestimating cardiovascular risk when applied to different cohorts. The panel that developed the algorithm countered that the criticism was largely based on data obtained from cohorts that include volunteers who tend to be healthier than the general population. On the other hand, validity of the algorithm has not been established by prospective clinical trials.

The 2013 ACC/AHA guideline focuses on the proven effects of statins on cardiovascular disease. It is predicted that patients eligible for statin therapy may double according to the new guideline and patients who are at high risk for cardiovascular disease will benefit from wider use of statins. Efficacy of adding fibrates, bile acid sequestrants or niacin to achieve previously recommended target is limited (discussed below), but management of those who are not tolerant or contraindicated to moderate-high-intensity statins is not well addressed. However, subsequent studies support further reduction of LDL cholesterol below 70 mg/dL by ezetimibe (Zetia) or PCSK 9 inhibitors in very-high-risk group with established cardiovascular disease and risk factor(s). The high efficacy of the newly developed PCSK9 inhibitors may significantly change the landscape of effective cholesterol management in such individuals.

Therapeutic Lifestyle Changes

All patients with hyperlipidemia should be counseled on lifestyle modifications. Dietary modification to limit intake of lipids is an essential component, given that the main source of lipids is exogenous dietary fat. Saturated fatty acids and trans-unsaturated fatty acids increase LDL cholesterol while dietary fibers decrease LDL cholesterol. Carbohydrates do not affect LDL cholesterol but increase triglycerides and decrease HDL cholesterol, particularly if they have a high glycemic index. Intake of fructose, a component of sucrose, increases triglycerides and decreases HDL cholesterol. Body weight reduction and physical activity have a small effect on LDL cholesterol but reduce triglycerides and increase HDL cholesterol significantly. Alcohol intake has an adverse effect on triglycerides.

Individual patients will need different approaches based on their cardiovascular risk and lipid profiles. Generally, total dietary fat is recommended to constitute 25%–35% of the total calorie intake mainly as mono- or poly-unsaturated fat, limiting saturated fat <7% and trans fat <1% of the total calorie intake. Therapeutic lifestyle changes include diets with emphasis on vegetables, fruits, whole grains, low-fat dairy products, poultry, fish, legumes, non-tropical vegetable oils, and nuts as well as limited intake of sweets, sugar-sweetened beverages, and red meats; further reduction of saturated fat (<5–6% of the total caloric intake) and trans fat; weight reduction; and increased regular physical activity. The amount of cholesterol intake is not well correlated with LDL cholesterol level and there is no recommended limit for intake. Management of other risk factors such as smoking cessation and controlling blood pressure in hypertensive patients and blood glucose in diabetics is also very important.

Pharmacologic Agents

The currently available lipid-lowering agents can be classified based on their mechanism of action into statins (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors), fibrates, niacin, bile acid sequestrants, cholesterol absorption inhibitors such as ezetimibe (Zetia), and PCSK9 (Proprotein convertase subtilisin/kexin type 9) inhibitors. These classes of agents differ with regard to degree and type of lipid lowering, and agents within the same group may differ in efficacy and side effects. Conventional dosing regimens and common adverse effects are summarized in Table 5. Expected changes in lipid profiles are shown in Table 6. The choice of drug depends on the specific lipid abnormalities and concurrent medical conditions. In general, statins are the most effective drugs to lower cardiovascular risk and are the treatment of choice when medications are indicated based on the global cardiovascular risk. If the primary goal is to lower triglycerides, fibrates or niacin may be more effective. If the treatment goal is not achieved by statins or statins are not tolerated, another agent should be used.

Statins

Statins are usually the first drug of choice in patients with high cholesterol levels to reduce cardiovascular risk. Statins are the only class of lipid-lowering agents that has been shown in multiple randomized clinical trials to improve cardiovascular outcomes in primary and secondary prevention. Furthermore, risk reduction was

¹Not FDA approved for this indication.

TABLE 5 Major Drugs for Management of Hyperlipidemia

AGENT	STARTING DAILY DOSAGE	DOSAGE RANGE	MECHANISM	SIDE EFFECTS
Statins				
Lovastatin (Mevacor)	20 mg	10–80 mg	Decreased cholesterol synthesis, increased hepatic LDL receptors, decreased VLDL release	Myalgias, arthralgias, high liver enzymes, dyspepsia
Pravastatin (Pravachol)	40 mg	10–80 mg		
Simvastatin (Zocor)	20–40 mg	5–80 mg		
Fluvastatin (Lescol)	40 mg	20–80 mg		
Atorvastatin (Lipitor)	10–20 mg	10–80 mg		
Rosuvastatin Crestor)	10 mg	5–40 mg		
Pitavastatin (Livalo)	2 mg	2–4 mg		
Fibrates				
Fenofibrate (Tricor)	48–145 mg	48–145 mg	Increased LPL activity, decreased VLDL synthesis	Dyspepsia, myalgia, gallstones, high liver enzymes
Gemfibrozil (Lopid)	1200 mg	1200 mg		
Fenofibric acid (Trilipix)	45–135 mg	45–135 mg		
Niacin				
Immediate release	250 mg	250–3000 mg	Decreased VLDL synthesis	Flushing, high glucose, uric acid, high liver enzymes
Extended release (Niaspan)	500 mg	500–2000 mg		
Bile Acid Sequestrants				
Cholestyramine (Questran)	8–16 g	4–24 g	Increased bile acid excretion, increased LDL receptors	Bloating, constipation, elevated triglycerides
Colestipol (Colestid)	2 g	2–16 g		
Colesevelam (Welchol)	3.75 g	3.75–4.375 g		
Cholesterol Absorption Inhibitors				
Ezetimibe (Zetia)	10 mg	10 mg	Deceased intestinal cholesterol absorption	High liver enzymes
Combination Therapies (single pill)				
Ezetimibe/Simvastatin (Vytorin)	10/20 mg	10/10–10/80 mg		
PCSK9 Inhibiting Monoclonal Antibodies (subcutaneous)				
Alirocumab (Praluent)	75 mg every 2 weeks	75–150 mg every 2 weeks	Increased hepatic LDL receptors	Injection site reactions, nasopharyngitis, upper respiratory tract infection, influenza, back pain
Evolocumab (Repatha)		140 mg every two weeks or 420 mg monthly		

*See the text for the FDA warning.

Adapted from lipoprotein management in patients with cardiometabolic risk, consensus statement from the American College of Cardiology Foundation and the American Diabetes Association (ACC/ADA) (2008), and American Association of Clinical Endocrinologists' (AACE) guidelines for management of dyslipidemia and prevention of atherosclerosis (2012).

apparent in a wide range of patients including men, women, smokers, those with diabetes, and those with hypertension as well as in older populations. Also, statins lead to the highest degree of LDL cholesterol reduction among all of the lipid-lowering agents. The approximate equipotent dosages of various statins and their

cholesterol-lowering effects are listed in [Table 7](#). The 2013 ACC/AHA guideline recommends moderate- or high-intensity statins (see [Table 7](#)) based on the global risk (see [Table 4](#)). Statins inhibit HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis. By blocking cholesterol biosynthesis, statins upregulate

[‡]High-intensity statins (reduction of LDL cholesterol > 50%).

the LDL receptor on the hepatocytes and increase clearance of IDL and LDL. In addition to their direct effects on lipid metabolism, statins have been reported to have pleiotropic effects (e.g., reduced formation of reactive oxygen species, inhibition of platelet reactivity, and decreased vasoconstriction).

Statins are usually well tolerated. Potential common side effects include nonspecific gastrointestinal symptoms such as dyspepsia, headaches, fatigue, and myopathy. Hepatitis occurs in less than 1%. There is a small increase in risk of developing diabetes. It is recommended that the physician monitor for development of myopathy clinically and hepatotoxicity with liver function tests (baseline and within 3 months and then periodically). Myopathy is one of the most common causes for cessation of statins. Myalgias can occur in about 10% to 20% of patients, which is much more often than reported in the clinical trials. The risk of rhabdomyolysis, however, is very low (0.1–0.2 per 1000 person-years). Risk for myopathy is increased in patients with advanced age, female sex, small body habitus, hypothyroidism, alcoholism, medical conditions (particularly liver or kidney disease), major surgery, excessive physical activity, history of myopathy, family history of myopathy, high-dose statins, and interacting medications or food such as grapefruit juice (> 1 L/day). Simvastatin (Zocor), lovastatin (Mevacor), and atorvastatin (Lipitor) are primarily metabolized through CYP3A4, which is inhibited by protease inhibitors, cyclosporine (Neoral, Sandimmune), amiodarone (Cordarone, Pacerone), nondihydropyridine calcium channel blockers, fibrates, and other agents. Pravastatin (Pravachol) is metabolized by the kidney, not by the P450 system. Fluvastatin (Lescol) and rosuvastatin (Crestor) are primarily metabolized through CYP2C9. Simvastatin and lovastatin should be avoided in patients receiving protease inhibitors. Statin dosage should be reduced in patients taking cyclosporine. Because of significant risk of myopathy related to simvastatin, the FDA recommends that 80 mg/day should not be used unless the patient has been taking 80 mg safely for longer than 12 months. The FDA further recommends that the dose be limited to 20 mg if the patient is also taking amiodarone, amlodipine (Norvasc), or ranolazine (Ranexa), and to 10 mg/day if taking diltiazem (Cardizem), dronedarone (Multaq), or verapamil (Calan). Addition of fibrates increases the risk of myopathy; in patients on a statin, fenofibrate (Tricor) is preferred over gemfibrozil (Lopid), which has a much higher risk of rhabdomyolysis. Symptoms of statin myopathy are heaviness, stiffness, cramping associated with weakness during exertion, and tendon-associated pain. Location of symptoms can be at the thighs, at the calves, or generalized. Symptoms can be very nonspecific, and differentiating statin-related myopathy from other causes is not easy. Therefore baseline symptoms, physical examination, and assessment of creatinine kinase level before the initiation of statins can be very helpful. Further decisions regarding stopping or switching medications can be made based on the severity of symptoms, level of creatinine kinase elevation, and presence of rhabdomyolysis. In patients who develop

myopathy while on simvastatin or atorvastatin, if the decision is to continue treatment with a statin, one option is to cautiously switch them to pravastatin, fluvastatin, or rosuvastatin, which are less prone to cause myopathy. Furthermore, rosuvastatin has a long duration of action and can be taken once every other day or weekly¹ if necessary. Theoretically, coenzyme Q10⁷ may help statin-induced myopathy, but there is insufficient data to support its use. For patients who cannot tolerate statins, other agents should be used.

Fibrates

The effect of fibrates on cardiovascular outcomes is not as favorable as with statins or niacin. However, fibrates can be useful in subsets of patients with high triglycerides and low-HDL cholesterol. Recently, the ACCORD lipid trial showed that addition of fenofibrate to simvastatin in type 2 diabetic patients with cardiovascular risk factors did not improve cardiovascular outcomes, though there was a trend for better outcomes in a subgroup with triglycerides greater than 204 mg/dL and HDL cholesterol less than 34 mg/dL. Fibrates have multiple favorable metabolic effects including activation of peroxisome proliferator-activated receptor- α (contributing to the regulation of both lipid and carbohydrate metabolism), stimulation of lipoprotein lipase (increasing triglyceride hydrolysis), and downregulation of Apo CIII (improving lipoprotein remnant clearance as Apo CIII inhibits lipoprotein lipase). An enhanced VLDL-to-LDL conversion may lead to mild LDL cholesterol elevation in some patients. This effect may decrease over weeks as the LDL receptors are upregulated. Fibrates are generally well tolerated. The most common side effect is dyspepsia. Other side effects include myopathy and hepatic enzyme elevation, particularly when fibrates are added to statins. The FDA has concluded that the totality of evidence no longer supports the conclusion that a drug-induced reduction in triglyceride levels and/or increase in HDL-triglyceride levels in statin-treated patients results in a reduction in the risk of cardiovascular events. It has recently withdrawn the approval for indication for coadministration of fenofibric acid delayed release capsules (Trilipix) with statins. Fibrates increase the risk of gallstones, and patients on warfarin (Coumadin) may need dose adjustment. Monitoring of liver enzymes is recommended, at baseline and within 3 months and then periodically. Creatinine level can be increased through unclear mechanisms.

Niacin

Niacin or nicotinic acid effectively decreases the hepatic production of VLDL and thus LDL cholesterol levels, and raises HDL cholesterol levels by reducing cholesterol transfer from HDL to Apo B-containing lipoproteins and HDL clearance by the liver. Niacin

¹Not FDA approved for this indication.

⁷Available as a dietary supplement.

is the most potent agent available to increase HDL cholesterol. Several trials showed the effect of niacin in preventing cardiovascular disease. But the benefit of adding niacin to statins has not been proved. Niacin did not improve cardiovascular risk when added to simvastatin in patients with high risk for cardiovascular disease in the AIM HIGH study and the HPS2-Thrive study. There were excess adverse events and trends toward signs of harm among the niacin groups. The FDA has recently withdrawn the approval for the coadministration of niacin extended-release tablets (Niaspan) with statins. The most common side effect of niacin is flushing. This can be avoided or minimized by initiating therapy with a low dose of niacin, taking an aspirin 1 hour before niacin, avoiding hot foods or beverages at the time the niacin is taken, or switching to extended-release forms (Niaspan). Hepatotoxicity can occur at any time. Immediate-release forms are less likely to cause hepatotoxicity than sustained-release forms (Slo-Niacin). Extended-release forms can minimally elevate transaminases but significant hepatotoxicity is rare. They can, however, also cause dose-dependent reversible thrombocytopenia, which can be insidious and severe. When switching to different forms, it is recommended that one should start with low doses and titrate up to achieve desired response. Liver function tests should be monitored regularly, at baseline and every 3 months for the first year and then periodically. Other side effects include pruritus, increased uric acid levels, and hyperglycemia.

Bile Acid Sequestrants

Bile acid sequestrants have been in clinical use for many decades. These agents promote fecal excretion of bile acids. The liver responds with increased integration of cholesterol into bile acid synthesis to maintain a stable bile acid pool. The consequent decrease in cholesterol in the liver leads to upregulation of the LDL receptor and enhanced LDL clearance from the plasma. HMG-CoA synthase activity can increase, so combination therapy with statins would be synergistic, especially in patients with a sub-optimal response. Available agents are cholestyramine (Questran), colestipol (Colestid), and colesevelam (Welchol). Most side effects involve the gastrointestinal tract, with constipation and bloating being the most common. These agents may interfere with the absorption of warfarin, phenobarbital, levothyroxine (Synthroid), and digoxin (Lanoxin), among other medications. Patients on multiple medications should be advised to take bile acid sequestrants 1 hour before or 4 hours after taking the other medications. These agents can also cause elevation of triglyceride level. As they are not systemically absorbed, the bile acid sequestrants may be the preferred agents when systemic absorption is to be avoided, such as during pregnancy or lactation.

Cholesterol Absorption Inhibitors

Ezetimibe is the first in a new class of pharmaceutical agents that inhibit the sterol transporters in the intestine. Ezetimibe is a good add-on agent in people taking a statin if the LDL cholesterol goal is not achieved or high doses of statin cannot be tolerated. Ezetimibe was shown to modestly decrease cardiovascular events when added to simvastatin in high risk patients in the IMPROVE-IT study. For this reason, ezetimibe is preferred when statin is intolerated or insufficient. Elevated liver enzymes have been reported but the risk of hepatotoxicity seems to be not different from that of placebo.

PCSK9 Inhibitors

The PCSK9 (proprotein convertase subtilisin/kexin type 9) protein appears to control the number of LDL receptors. When it binds to the LDL receptor, the latter is destroyed with the LDL particle. Interference with PCSK9's LDL receptor-binding capacity or silencing the gene for PCSK9 allows the LDL receptor to recycle to the cell surface to remove more circulating plasma LDL. Over a decade ago, individuals with gain-of-function mutations of the PCSK9 gene were found to underlie a rare form of autosomal dominant hypercholesterolemia. Subsequently, individuals with loss-of-function mutations were found to have very low LDL cholesterol levels and were protected from CHD. These discoveries led

to the development of monoclonal antibodies directed against PCSK9 as a novel cholesterol lowering agent.

Two humanized monoclonal antibodies against PCSK9, alirocunab (Praluent) and evolocumab (Repatha), were approved by the FDA in 2015. Both are given by injection. Alirocunab is indicated for (1) heterozygous familial hypercholesterolemia or clinical atherosclerotic cardiovascular disease as an adjunct to maximally tolerated statin and is given at 75–150 mg every 2 weeks. Evolocumab is indicated for (1) heterozygous familial hypercholesterolemia or clinical atherosclerotic cardiovascular disease as an adjunct to maximally tolerated statin that is given at 140 mg every 2 weeks or 420 mg monthly, or (2) homozygous familial hypercholesterolemia as an adjunct to other LDL lowering therapies and given at 420 mg monthly. Alirocunab and evolocumab reduce LDL cholesterol by up to ~60% as a single agent or an adjunct therapy. Post hoc analyses showed that addition of PCSK9 inhibitors for 12–18 months decreased cardiovascular events by ~50%. In a 2.2-year study, evolocumab treatment was found to be associated with a significant reduction in cardiovascular events in a high-risk population.

PCSK9 inhibitors enable reduction of LDL cholesterol to levels previously not achievable, e.g., as low as <25 mg/dL. Among possible adverse effects, neurocognitive adverse events were uncommon, occurring in ~0.9% in evolocumab-treated patients compared to 0.3% of placebo-treated controls, though the slight excess occurrence was not related to LDL cholesterol level. Compared to placebo, myalgia was slightly more common in alirocunab but not different in evolocumab groups, whereas CK elevations were not different between placebo and treatment groups. LDL cholesterol lower than 25mg/dL was not associated with neurological, neurocognitive, musculoskeletal adverse reactions or diabetes, but more cataracts were observed in the alirocunab-treated group. Common side effects include injection site reactions, nasopharyngitis, upper respiratory tract infection, influenza, and back pain. The risk–benefit ratio will become better defined as long-term and larger clinical trials are being completed. A serious drawback in the use of PCSK9 inhibitors is the very poor cost efficiency. Use of PCSK9 inhibitors at the current price may actually lead to significantly increased health care expenditure.

HYPERPARATHYROIDISM AND HYPOPARATHYROIDISM

Method of

Claudio Marcocci, MD

CURRENT DIAGNOSIS

Primary Hyperparathyroidism

- Third most common endocrine disorder and most common cause of hypercalcemia in the general population.
- Diagnosis based on confirmed hypercalcemia (total calcium [albumin corrected] or ionized calcium) associated with elevated or inappropriately normal serum parathyroid hormone level.
- Hypercalcemia on routine blood testing or in postmenopausal women investigated for osteoporosis is typically the first clue to the diagnosis.
- Mainly occurs as a solitary disease (90%) but may be part of hereditary syndromes.
- Genetic causes should be searched for in young patients.

Secondary Hyperparathyroidism

- Secondary hyperparathyroidism defines any condition in which the increased PTH secretion occurs as a normal physiologic response, often mediated by a decrease of serum calcium.

- Vitamin D deficiency, as a result of inadequate nutritional intake/sun exposure, malabsorption, liver diseases, or chronic renal failure, is the most common cause.
- At variance with primary hyperparathyroidism, secondary hyperparathyroidism is characterized by low or, more often, low-normal serum calcium and decreased urinary calcium excretion.

Hypoparathyroidism

- Rare disorder.
- Inadvertent removal or damage to the parathyroid gland during thyroid surgery and, much less frequently, autoimmune destruction are the most common causes.
- Diagnosis based on low serum calcium along with undetectable or inappropriately low serum parathyroid hormone level.

CURRENT THERAPY

Primary Hyperparathyroidism

- Parathyroidectomy is the only definitive therapy.
- Surgery should be considered in all cases and recommended in symptomatic patients and in those who, albeit asymptomatic, meet the surgical criteria.
- Surveillance without surgery can be considered in asymptomatic patients who do not meet the surgical criteria.
- Patients followed without surgery should be replete with vitamin D and calcium intake should not be restricted.
- Medical treatment can be considered in selected cases: antiresorptive therapy to increase bone mineral density and cinacalcet (Sensipar) to lower serum calcium.

Hypoparathyroidism

- Severe hypocalcemia is a medical emergency and treatment with intravenous calcium should be promptly instituted and maintained for 24 to 48 hours; oral therapy with calcium and active vitamin D metabolites should be started as soon as practical.
- The goal of chronic treatment is to maintain serum calcium in the low-normal range, avoiding hypocalcemic symptoms and long-term complications.
- Chronic conventional therapy is based on adequate calcium intake (calcium supplement needed in most cases) and active vitamin D metabolites.
- Recombinant full-length parathyroid hormone 1-84 (Natpara) has been approved by the U.S. Food and Drug Administration for patients not controlled with conventional therapy.
- An individualized approach is necessary to optimize patient care. Lifelong monitoring is needed to decrease the risk of complications.

Primary Hyperparathyroidism

Epidemiology

Primary hyperparathyroidism (PHPT) is currently the third most common endocrine disorder and the most frequent cause of hypercalcemia in the general population.

The disease was considered rare until the early 1970s, when its incidence in the United States rose dramatically following the introduction of serum calcium in the multichannel autoanalyzer. The incidence varies according to geographic areas and assessment measures; recent data in the United States indicate an incidence of 79.6 per 100,000 person-years in women and 35.6 per 100,000 person-years in men of all races, with the highest rate among blacks. The incidence peaks in the sixth decade of life. The prevalence ranges between 1 and 7 cases per 1000 adults. Most cases occur in women (with a female-to-male ratio of 3:1), but there is no sex difference before the age of 45 years. PHPT is rare in children and adolescents.

Primary Hyperparathyroidism

Epidemiology

Primary hyperparathyroidism (PHPT) is currently the third most common endocrine disorder and the most frequent cause of hypercalcemia in the general population.

The disease was considered rare until the early 1970s, when its incidence in the United States rose dramatically following the introduction of serum calcium in the multichannel autoanalyzer. The incidence varies according to geographic areas and assessment measures; recent data in the United States indicate an incidence of 79.6 per 100,000 person-years in women and 35.6 per 100,000 person-years in men of all races, with the highest rate among blacks. The incidence peaks in the sixth decade of life. The prevalence ranges between 1 and 7 cases per 1000 adults. Most cases occur in women (with a female-to-male ratio of 3:1), but there is no sex difference before the age of 45 years. PHPT is rare in children and adolescents.

Pathogenesis

PHPT mainly occurs as a solitary disease (90%) but may be part of hereditary syndromes (e.g., multiple endocrine neoplasia [MEN] types 1, 2A, and 4; hyperparathyroidism–jaw tumor syndrome [HPT-JT], and familial isolated hyperparathyroidism [FIPH]) (Table 1). A single, benign adenoma is found in 80% to 85% of cases, multigland involvement in 15% to 20%, and parathyroid carcinoma in less than 1%. Multigland involvement is more common in hereditary cases, particularly MEN1. In the absence of local infiltration or metastases, the diagnosis of parathyroid carcinoma may be difficult at histology. Genetic studies (*CD73* gene mutations) and immunohistochemical studies (loss of parafibromin [the protein encoded by the *CD73* gene] expression) may help in equivocal cases. Predisposing factors are external neck irradiation in childhood and long-term lithium therapy.

PHPT is characterized by excessive parathyroid hormone (PTH) secretion from one or more parathyroid glands, due to the loss of the homeostatic control of PTH synthesis and secretion. Extracellular ionized calcium (Ca^{2+}_o) is the main regulator of PTH secretion. Ca^{2+}_o interacts with the Ca^{2+} -sensing receptor (CaSR) present on the surface of parathyroid cells; there is an inverse sigmoidal relationship between Ca^{2+}_o concentration and PTH release. In adenomas hypercalcemia is due to the loss of normal sensitivity of the parathyroid cell to the inhibitory action of Ca^{2+}_o , whereas in parathyroid hyperplasia the increased number of parathyroid cells, which have a normal sensitivity to the inhibitory action of Ca^{2+}_o , causes hypercalcemia. Serum phosphate, 1,25-dihydroxyvitamin D ($1,25(\text{OH})_2\text{D}$), and fibroblast growth factor 23 (FGF23) are also involved in the control of PTH secretion.

Although major progress has been made in the last two decades, the molecular basis of PHPT is still unclear in the majority of cases. The clonality of most parathyroid tumors suggests a defect in the pathways that control parathyroid cell proliferation or the expression of PTH. The genes involved are listed in Table 1. Germline mutations are often found in hereditary forms. On the other hand, somatic mutations may occur in sporadic cases, even

though germline mutations have also been described in apparently sporadic cases.

Clinical Presentation

In recent years the clinical presentation of PHPT in Western countries has changed from a symptomatic disease, characterized by hypercalcemia and renal (nephrolithiasis and nephrocalcinosis) and skeletal (osteitis fibrosa cystica, fragility fractures) manifestations, to one with subtle and nonspecific clinical manifestations (asymptomatic PHPT). Nephrolithiasis remains the most common classic clinical manifestation (15%–20%), and silent stones are frequently detected at ultrasound. Bone mineral density (BMD) is reduced particularly at sites rich in cortical bone (one-third distal radius). Studies using peripheral high-resolution quantitative computed tomography (CT) has shown involvement of both cortical and trabecular sites, the latter confirmed by the trabecular bone score (TBS) at the lumbar spine. An increased rate of vertebral and nonvertebral fractures has also been documented. Nonclassical manifestations, including subtle cardiovascular abnormalities and psychological and cognitive symptoms, have also been reported.

A new variant of PHPT (normocalcemic PHPT) has recently been identified, namely patients with increased serum PTH levels in the absence of hypercalcemia (also by measurement of ionized calcium) or other causes of secondary hyperparathyroidism. This condition, called normocalcemic PHPT, has been typically recognized in persons evaluated for low BMD, in whom PTH was measured even in the absence of hypercalcemia. In some cases this new phenotype may represent an early phase of classical hypercalcemic PHPT, when PTH elevation precedes the occurrence of hypercalcemia.

Evaluation and Diagnosis

The finding of hypercalcemia on routine blood testing or in postmenopausal women investigated for osteoporosis is typically the first clue to the diagnosis of PHPT. Hypercalcemia should be confirmed in repeated testing, preferably evaluating albumin-corrected total calcium (measured total calcium in mg/dL + $[0.8 \times (4.0 - \text{serum albumin in g/dL})]$) or ionized calcium. The next diagnostic step is the measurement of serum PTH. An elevated (or unexpectedly normal) serum PTH in the face of hypercalcemia is virtually diagnostic of PHPT. Serum phosphate is normal or in the low-normal range in mild PHPT and low in severe cases. A low or undetectable PTH level in a hypercalcemic patient rules out the diagnosis of PHPT. The most common cause of PTH-independent hypercalcemia is malignancy, where hypercalcemia is due to the secretion by the tumor of PTH-related peptide, a molecule that shares with PTH the amino-terminal active part but does not cross-react in the PTH assay, or osteolytic lytic bone metastases. Urinary calcium should also be measured. If hypercalciuria is greater than 400 mg per day, a more extended evaluation of the stone risk profile should be performed. Urinary calcium measurement is also useful to exclude familial hypocalciuric hypercalcemia (FHH), which is suggested by the finding of the calcium-to-creatinine clearance ratio of less than 0.01.

A hereditary form of PHPT, accounting for 5% to 10% of cases, should be sought in patients younger than 30 years at diagnosis, with a family history of hypercalcemia and/or neuroendocrine tumors (see Table 1). In this setting serum calcium should be measured in first-degree relatives and genetic tests performed. Parathyroid cancer should be suspected in individuals, especially males, with marked hypercalcemia, a palpable neck mass, and serum PTH concentration 3 to 10 times the upper normal value.

Renal ultrasound should be performed in all patients, even in those with no history of nephrolithiasis, since recent studies have shown that silent kidney stones are common in patients with asymptomatic PHPT. Routine BMD testing by dual-energy x-ray absorptiometry (DXA) at the lumbar spine, hip, and distal forearm is also an essential component of the evaluation. BMD is typically low at the one-third distal radius, a site of enriched cortical bone, but a few patients may show predominant cancellous bone involvement, as documented by vertebral osteopenia or osteoporosis. The involvement of the trabecular compartment is also confirmed by

TABLE 1 Hereditary Forms of PHPT and Related Involved Gene

Abbreviations: *AP2S1* = Adaptor-related protein complex 2 sigma 1 subunit *CASR* = calcium-sensing receptor; *CDC73* = cell division cycle 73; *CDKN1B* = cyclin-dependent kinase inhibitor 1B; *GNA11* = G protein subunit alpha 11; *MEN1* = multiple endocrine neoplasia type 1; PHPT = primary hyperparathyroidism; *RET* = rearranged during transfection.

the TBS at the lumbar spine. Vertebral imaging by x-ray or DXA (vertebral fracture assessment, VFA) should also be routinely performed to detect silent vertebral deformities since vertebral fracture risk is increased in asymptomatic patients.

Neck imaging (ultrasound and sestamibi scanning) has no value in the diagnosis of PHPT, but it is a useful tool for localizing the abnormal parathyroid gland in patients selected for parathyroidectomy (PTx). Sestamibi has the advantage of localizing the ectopic parathyroid gland outside the neck. The 4D computerized tomography protocol has emerged as a useful tool.

Treatment

The aim of treatment is to remove all hyperfunctioning parathyroid tissue, resolve biochemical abnormalities, improve BMD, and decrease the risk of nephrolithiasis and fractures.

Surgical Treatment

Parathyroid surgery represents the only definitive cure of PHPT. Successful PTx normalizes serum calcium and PTH, improves BMD, and decreases the risk of nephrolithiasis and fragility fractures. Patients selected for surgery should be referred to an experienced parathyroid surgeon. A focused, minimally invasive approach, guided by imaging studies associated with intraoperative monitoring of serum PTH, is the preferred surgical procedure in sporadic PHPT. In experienced hands the rate of surgical cure reaches 95% to 98% with a negligible rate of surgical complications. In hereditary cases the surgical approach (bilateral neck exploration by classical cervicotomy) may differ, since multigland involvement is common. An *en bloc* resection of the parathyroid lesion together with the ipsilateral thyroid lobe with clear gross margins and the adjacent structures is recommended when parathyroid carcinoma is suspected. Particular attention should be paid to avoid seeding of neoplastic parathyroid cells. Surgery should be considered for any patient with a confirmed diagnosis of PHPT and recommended in those with symptomatic disease.

Patients with mild hypercalcemia (serum calcium < 12 mg/dL [3 mmol/L]) can proceed directly to surgery. When serum calcium is higher, preoperative treatment with saline infusion eventually followed by loop diuretics, intravenous bisphosphonates, denosumab (Prolia, Xgeva)¹, or cinacalcet (Sensipar) may be considered to reduce serum calcium levels and decrease the risk of complications, particularly cardiac arrhythmias, which are associated with more severe hypercalcemia.

Surgery is also a reasonable option for patients with asymptomatic PHPT. International guidelines provide guidance to select patients who should be referred for surgery or followed without surgery. The most recent revised (2013) guidelines for surgery or monitoring are reported in Table 2. These guidelines are largely consistent with the previous ones and recommend PTx for all patients with symptomatic PHPT and asymptomatic patients who meet one or more of the indicated criteria. The new indications for surgery in asymptomatic patients include (1) the presence of silent vertebral fractures detected by x-ray, CT, magnetic resonance imaging (MRI), or vertebral fracture assessment (VFA) by DXA; and (2) a 24-hour urinary calcium excretion greater than 400 mg/dL, increased stone risk (evaluated by urinary stone risk profile), and subclinical kidney stone or nephrocalcinosis detected by x-ray, ultrasound, and CT. According to the guidelines, about 60% of patients with asymptomatic PHPT meet the criteria for surgery. As mentioned before, patients with mild PHPT may have subtle cardiovascular abnormalities and complain of psychological and cognitive symptoms. It is unclear whether and to what extent these abnormalities are reversible after successful PTx; for the time being they are not considered indications for surgery. Nonetheless, surgery could be considered in a middle-aged patient in whom asymptomatic PHPT is associated with increased cardiovascular risk (metabolic syndrome, hypertension, ischemic heart disease) if the surgical risk is low.

¹Not FDA approved for this indication.

TABLE 2 Guidelines for Surgery for Patients With Asymptomatic PHPT and Monitoring for Those Followed Without Surgery

PARAMETER	GUIDELINES FOR SURGERY	GUIDELINES FOR MONITORING
Serum calcium	> 1 mg/dL (0.25 mmol/L) above the upper normal limit	Annually
Skeletal	<ul style="list-style-type: none"> BMD by DXA: T-score < -2.5 at lumbar spine, femoral neck, total hip, or distal one-third radius Vertebral fractures by x-ray, CT, MRI, or VFA 	<ul style="list-style-type: none"> BMD by DXA every 1–2 years at lumbar spine, total hip, or distal one-third radius Spine x-ray of VFA when clinically indicated (e.g., back pain or height loss)
Renal	<ul style="list-style-type: none"> Creatinine clearance < 60 mL/min Daily urinary calcium excretion > 400 mg and increased stone risk by the urinary biochemical stone risk profile Nephrolithiasis or nephrocalcinosis by x-ray, ultrasound, or CT 	<ul style="list-style-type: none"> Serum creatinine annually If renal stone suspected: <ul style="list-style-type: none"> 24-h urinary biochemical stone risk profile Renal imaging by x-ray, ultrasound, or CT
Age	< 50 years	-

Abbreviations: BMD = bone mineral density; CT = computed tomography; DXA = dual x-ray absorptiometry; MRI = magnetic resonance imaging; PHPT = primary hyperparathyroidism; VFA = vertebral fracture assessment.

Modified from Bilezikian et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: Summary statement from the fourth international workshop. *J Clin Endocrinol Metab* 99:3561, 2014.

Randomized clinical trials have also shown that patients with sporadic asymptomatic PHPT who do not meet the surgical criteria may benefit from surgery, not only because it normalizes serum calcium and PTH, but also because it improves BMD and quality of life (QoL). On the other hand, surgery could be postponed in hereditary cases with mild hypercalcemia, because multigland disease, occasionally with asynchronous involvement of the various parathyroid glands, is not uncommon and carries an increased risk of surgical complications and recurrence/persistence of PHPT.

Therefore individual counseling addressing the benefits and risks of PTx is mandatory, and the preference of the patients should be taken into account. It is well known that parathyroid surgery, when performed by skilled neck surgeons, is safe, cost-effective, and associated with low perioperative morbidity. On the other hand, it is important to recognize that PTx, particularly if performed by inexperienced surgeons, may be associated with complications that could be invalidating and not acceptable for a patient with mild disease and a good QoL. In this regard, the choice of surgery may be reconsidered in a patient with asymptomatic PHPT in whom parathyroid surgery was initially advised or selected by the patient when preoperative imaging studies are negative. Indeed, in this setting the patient may feel uncomfortable undergoing a blind neck exploration, a surgical procedure more extensive than the minimally invasive approach and carrying the greatest risk of complications.

Nonsurgical Management

As mentioned before, many patients with PHPT do not meet the criteria for surgery. These patients, as well as those who decline surgery or have contraindications to surgery, need to be monitored.

Monitoring. Randomized clinical studies have shown stability over a short period of observation (up to 2 years) in patients with asymptomatic PHPT followed without surgery and benefits in those who underwent PTx even if they did not meet the criteria

for surgery. The extension up to 5 years of one of these randomized studies has shown a more frequent occurrence of a vertebral fracture in patients belonging to the observation group than in those cured by PTx. Long-term observational studies indicate that the disease remains stable in the majority for up to 8 to 9 years, but more than one-third of patients show a progression of the disease.

Calcium intake should not be restricted, and an intake appropriate for age and sex as in the general population (preferably with food) should be recommended (Table 3). Vitamin D–depleted patients should be supplemented with daily doses of 800 to 1000 IU of vitamin D; weekly or monthly doses calculated on this daily dose can also be used. A serum level of 25(OH)D greater than 20 ng/mL should be reached, and the attainment of a higher target (> 30 ng/mL) is suggested by some guidelines.

General principles for monitoring are reported in Table 2. Serum calcium and creatinine (estimated glomerular filtration rate [eGFR]) should be measured annually and BMD at the lumbar spine, total hip, and distal forearm measured every 1 to 2 years. Vertebral morphometry (by x-ray or VFA) should be performed when clinically indicated (back pain, height loss). Finally, 24-hour urinary collection for biochemical stone risk profile and renal imaging (x-ray, ultrasound, or CT) should be performed if there is a suspicion of renal stones.

Parathyroid surgery should be recommended in patients who are followed without surgery in the following instances: (1) serum calcium concentration greater than 1 mg/dL above the upper normal limit; (2) creatinine clearance less than 60 mL/min; (3) detection of nephrocalcinosis or kidney stones; (4) BMD T-score at any site less than −2.5 or the finding of a significant (greater than the least

significant change as defined by the International Society for Clinical Densitometry) decrease of BMD, even if the T-score is not less than −2.5; and (5) clinical fractures or morphometric vertebral fractures, even if asymptomatic.

Medical Treatment. No medical treatment is currently available to cure PHPT. Therefore when PTx is indicated and there are no contraindications for surgery, medical treatment should not be considered a valuable alternative option. Medical treatment may be considered for patients who have contraindications to surgery or are unwilling to undergo PTx, as well as for those who have failed surgery. Treatment should be guided by the aim of therapy.

Calcimimetics. If the aim of treatment is to reduce serum calcium, the calcimimetic cinacalcet (Sensipar) can be effective. The serum calcium typically declines over a few weeks and may normalize in most patients with moderate hypercalcemia. In addition, cinacalcet increases serum phosphate and only slightly reduces PTH concentration, but has no effect on BMD. The beneficial effects are sustained over time as long as the drug is used. Adverse events are dose related: modest and transient when low doses of cinacalcet are used (up to 30 mg twice daily), but rather frequent, particularly gastrointestinal, symptoms, occasionally severe enough to require treatment withdrawal, when higher doses are employed. The use of cinacalcet has been approved by the US Food and Drug administration (FDA) for the treatment of severe hypercalcemia in patients with PHPT who are unable to undergo PTx, and by the European Medical Agency (EMA) for the reduction of hypercalcemia in patients with PHPT, for whom PTx would be indicated on the basis of serum calcium levels (as defined by relevant guidelines), but in whom surgery is not clinically appropriate or contraindicated. As clearly stated, the EMA indications leave more room for the use of cinacalcet.

Cinacalcet should not be used as an initial treatment or in patients who do not meet the approved criteria for its prescription. The long-term safety of cinacalcet has not been established. Moreover, the rather high cost is another important limit for its long-term use.

Bisphosphonates. If the aim is to increase BMD, antiresorptive therapy can be considered. Alendronate (Fosamax) is the bisphosphonate that has been more extensively used and shown to be effective in reducing bone turnover markers and increasing BMD. Over a short period of time, its effectiveness in increasing BMD is comparable to that observed after successful PTx. No effect has been shown on serum calcium and PTH levels.

Combined Therapy With Cinacalcet and Bisphosphonates. As mentioned before, cinacalcet is effective in the control of hypercalcemia but has no effect on BMD. Conversely, bisphosphonates increase BMD, with no effect on serum calcium. Limited data indicate that combination therapy is associated with both the calcium-lowering effect of cinacalcet and the skeletal advantage of bisphosphonates. Therefore if a patient has a low BMD and serum calcium concentration appropriate for the use of cinacalcet, combined therapy could be of benefit.

Pregnancy and Lactation

PHPT may be diagnosed during pregnancy by the finding of hypercalcemia on routine blood testing. There are some distinctive features that should be considered in the evaluation and management: (1) pregnancy is associated with hemodilution and occasionally hypoalbuminemia, and therefore it would be preferable to measure ionized calcium; (2) the hereditary form should be sought because of the young age of pregnant women; and (3) women with mild elevation of calcium should be managed conservatively, mostly by hydration—in the case of worsening of hypercalcemia PTx in the second trimester and cinacalcet¹ may be considered.

Secondary Hyperparathyroidism

Secondary hyperparathyroidism (SHPT) defines any condition in which the increased PTH secretion occurs as a normal physiologic

TABLE 3 Classification of Hypoparathyroidism*

Congenital

- Isolated
 - Defective PTH biosynthesis (*PTH*) ^
 - Abnormal development of parathyroid glands (*GCMB*, *GCM2*, *GATA3*)
 - Autosomal dominant hypocalcemia
 - Type 1 (*CASR*)
 - Type 2 (*GNA11*)
- Associated with additional features or organ defects
 - Autoimmune
 - Isolated
 - Polyglandular syndrome type 1 (*AIRE*)
 - Di George syndrome (*TBX1*)
 - Sanjad-Sakati/Kenny-Caffey type 2 (*TBCE*)
 - Kenny-Caffey type 2 (*FAM111A*)
 - Mitochondrial DNA mutations
- Defective action of PTH
 - Pseudohypoparathyroidism
 - Type 1a (*GNAS*)
 - Type 1b (*STX16*, *GNAS*; in sporadic form paternal UPD)
 - Type 1c (*GNAS*)
 - Type 2 (not yet identified)

Acquired

- Destruction or removal of the parathyroid glands
 - Postoperative (neck surgery)
 - Radiation induced
 - Infiltration of the parathyroid glands (metastatic, granulomatous)
 - Deposition of heavy metals (iron, copper)
- Reversible impairment or PTH secretion or action
 - Severe magnesium deficiency
 - Hypermagnesemia (e.g., due to tocolytic therapy)
- CaSR-stimulating antibodies

*Mutated genes are indicated in parentheses.

Abbreviations: *AIRE* = autoimmune regulatory; *CASR* = calcium-sensing receptor; *FAM111A* = family with sequence similarity 111 member A; *GATA3* = GATA-binding protein 3; *GCM2* = glial cell missing homolog 2; *GCMB* = glial cell missing gene; *GNA11* = G protein subunit alpha 11; *GNAS* = GNAS complex locus; *PTH* = parathyroid hormone; *STX16* = syntaxin 16; *TBCE* = tubulin folding cofactor E; *TBX1* = T-Box1; UPD = uniparental disomy.

¹Not FDA approved for this indication.

response, often mediated by a decrease of serum calcium. Vitamin D deficiency, as a result of inadequate nutritional intake/sun exposure, malabsorption, liver diseases, or chronic renal failure, is the most common cause. Other, less common causes include vitamin D resistance (Fanconi syndrome, vitamin D receptor defects), PTH resistance (pseudohypoparathyroidism, hypomagnesemia), drugs (calcium chelators, inhibitors of bone resorption, and drugs that interfere with vitamin D metabolism [phenytoin and ketoconazole]), acute pancreatitis, and osteoblastic metastases (prostate and breast cancer).

SHPT should always be considered and ruled out before making the diagnosis of normocalcemic PHPT. At variance with PHPT, SHPT is characterized by low or, more often, low-normal serum calcium and decreased urinary calcium excretion. An elevation of serum phosphate levels can be a clue to pseudohypoparathyroidism.

A prolonged stimulation of PTH synthesis and secretion, as may occur in end-stage renal failure and severe gastrointestinal diseases, may lead to the emergence of an autonomous clone of parathyroid cells into a single gland, leading to hypercalcemia (tertiary hyperparathyroidism).

Hypoparathyroidism

Hypoparathyroidism (HypoPT) is the clinical spectrum caused by insufficient production of PTH by the parathyroid glands. The major distinguishing feature is hypocalcemia, resulting from inadequate mobilization of calcium from bone and reabsorption of calcium at the distal tubule, and decreased activity of renal 1α -hydroxylase and therefore generation of calcitriol; as a consequence, the intestinal calcium absorption will be reduced.

Epidemiology

HypoPT is a rare condition designated in both the United States and Europe as an orphan disease. The estimated prevalence is 37 and 24 per 100,000 inhabitants in the United States and Europe, respectively.

Pathogenesis

HypoPT can be congenital or acquired (Table 3).

Congenital HypoPT is usually hereditary and may be isolated or combined with organ defects. The autoimmune is the most common form and may be either isolated or part of the autoimmune polyglandular syndrome type 1 (APS1). The other forms are much more rare.

Acquired HypoPT is much more common than the congenital counterpart. Bilateral neck surgery for thyroid or parathyroid disorders is the most common cause. Postoperative HypoPT can be transient (caused by reversible parathyroid ischemia and resolving within a few weeks) or chronic/permanent (caused by irreversible parathyroid damage such as ischemia, electric scalpel damage, or, rarely, inadvertent removal of parathyroid glands). Its rate largely depends on the experience of the surgeon and the extent of the neck surgery.

Clinical Presentation

The clinical manifestations of HypoPT are largely related to the level of serum calcium and the speed of its fall and may range from asymptomatic cases, when hypocalcemia is mild (corrected calcium ≥ 7.0 mg/dL [1.75 mmol/L]), to a severe, life-threatening condition that requires hospital admission and intensive treatment. In mild cases signs related to neuromuscular irritability, namely the Chvostek sign (twitching and/or contracture of the facial muscles produced by tapping on the facial nerve just anterior to the ear and just below the zygomatic bone) and Trousseau sign (carpal spasm evoked by inflating a sphygmomanometer cuff above systolic blood pressure for several minutes), may be present at physical examination. Moderate to severe hypocalcemia (corrected calcium < 7.0 mg/dL [1.75 mmol/L]) is usually symptomatic, even though there is no strict relationship between the severity of symptoms and the degree of hypocalcemia. In patients with postoperative HypoPT, symptoms usually appear on the first postoperative

day, but in some cases hypocalcemia may become clinically manifest even after 3 to 4 days. Classical manifestations include paresthesias, carpopedal spasm, tetany, seizures, positive Chvostek and Trousseau signs, and prolongation of the QT interval on electrocardiography. Papilledema and subcapsular cataract can be present. Pseudohypoparathyroidism is a group of genetic disorders caused by end-organ resistance to the action of PTH. Patients with the type 1a variant have a typical phenotype (Albright hereditary osteodystrophy), characterized by short stature, shortened fourth and fifth metacarpals, rounded face, and mild intellectual deficiency. Other endocrine glands, including the thyroid and the gonads, may be dysfunctional. This clinical and endocrine phenotype is also typical of patients with type 1c. Patients with type 1b have PTH resistance and in some cases partial resistance to thyroid-stimulating hormone (TSH) and mild brachydactyly. Patients with the type 2 variant have PTH resistance in the absence of the aforementioned clinical phenotype.

Evaluation and Diagnosis

The finding of low albumin-corrected serum calcium, high serum phosphate, and inappropriately low or undetectable serum PTH confirms the diagnosis of HypoPT. A recent neck surgery strongly suggests the postoperative form. A family history of hypocalcemia suggests a genetic cause. Coexistence of other autoimmune endocrinopathies (i.e., adrenal insufficiency) or candidiasis prompts consideration of APS1. Immunodeficiency and the presence of other congenital organ defects point to DiGeorge syndrome. Genetic testing may be warranted to confirm the diagnosis of this and other genetic forms. Magnesium should also be measured because magnesium deficiency impairs the secretion of PTH and its action in target tissues. Urinary calcium is usually low because of the low filtered calcium. The 24-hour calcium-to-creatinine clearance ratio is increased in patients with the activating mutation of *CaSR*. A biochemical profile of low serum calcium and high phosphate levels, together with high serum PTH, in the absence of vitamin D deficiency, reflects the PTH-resistant state, and suggests a case of pseudohypoparathyroidism.

Treatment

The goal is to control symptoms of hypocalcemia and improve QoL while avoiding side effects and complications. The target serum calcium concentration is in the lower part of the normal range. Treatment relies on the administration of calcium (oral [dietary or supplements] or intravenous), active vitamin D metabolites, magnesium, and, where available, recombinant human PTH₁₋₈₄ (Natpara). Thiazide diuretics may help reduce hypercalciuria; a low-phosphate diet and phosphate binders may help control hypophosphatemia and lower the calcium-phosphate product.

Acute Hypoparathyroidism

Acute hypocalcemia typically follows neck surgery and may be favored by a low vitamin D status and magnesium deficiency that, when present, should be corrected before surgery. In patients with high risk (total thyroidectomy, repeated thyroid surgery), perioperative administration of calcitriol (Rocaltrol) decreases the incidence of postoperative hypocalcemia and shortens the hospital stay.

Mild Hypocalcemia. In mild hypocalcemia (corrected calcium ≥ 7.0 mg/dL [1.75 mmol/L]), oral calcium supplements (usually calcium carbonate, 1–3 grams daily in divided doses) alone or combined with active vitamin D metabolites should be administered. Calcitriol is typically initiated at an initial dose of 0.5 to 1.0 μ g twice daily; equivalent doses of 1α -calcifediol² (1.0–2.0 μ g) may also be used (see later [Chronic Hypoparathyroidism, Conventional Therapy] for more details on calcium and active vitamin D therapy) (Table 4). Serum calcium is checked weekly until optimal levels are reached.

²Not available in the United States.

TABLE 4 Calcium Preparation and Vitamin D Metabolites in the Management of Hypocalcemia

Calcium			
AGENT	FORMULATION AND DOSE	COMMENTS	
Calcium gluconate	One ampule of 10% calcium gluconate contains 93 mg; preferably diluted in 5% dextrose	Tissue necrosis may be caused by elemental calcium; preferably diluted in 5% dextrose extravasation in the adjacent subcutaneous space	
Calcium salts			
Calcium carbonate	40% elemental calcium by weight: 1 g calcium carbonate contains 400 mg elemental calcium	Best absorbed with meals in an acidic environment; constipation is a common side effect	
Calcium citrate	21% elemental calcium by weight, 1 g calcium citrate contains 210 mg elemental calcium	Well absorbed independent of meal and acid environment; in patients with atrophic gastritis or taking proton pump inhibitors	
Vitamin D Metabolites			
MEDICATION	TYPICAL DAILY DOSE	TIME TO ONSET OF ACTION	TIME TO OFFSET OF ACTION
Calcitriol [1,25(OH) ₂ D] ₃ (Rocaltrol)	0.25–2.0 µg once or twice	1–2 days	2–3 days
Alfacalcidol* [1α(OH)D]*	0.5–4 µg once	1–2 days	5–7 days
Dihydrotachysterol [†] *	0.3–1.0 mg once	4–7 days	7–21 days
Vitamin D ₂ (ergocalciferol) (Drisdol) or vitamin D ₃ (cholecalciferol) [‡]	25,000–200,000 IU	10–14 days	14–75 days

*Not available in the United States.

[†]This compound is rapidly activated in the liver to $25(\text{OH})$ dihydrotachysterol.

[‡]These compounds could be used in a setting where active vitamin D metabolites are not available and/or are too expensive.

Modified from Shoback D: Clinical practice. Hypoparathyroidism. *N Engl J Med* 2008;359:391–403, 2008.

Moderate to Severe Hypocalcemia. Patients with moderate to severe hypocalcemia (corrected calcium <7.0 mg/dL [1.75 mmol/L]) are usually admitted to the hospital and treated with IV calcium until an oral regimen can be started. One to two ampules of 10% calcium gluconate diluted in 50 to 100 mL of 5% dextrose should be infused over a period of 10 to 20 minutes with electrocardiographic and clinical monitoring. The calcium infusion will raise the serum calcium concentration for no more than 2 to 4 hours; thus this initial treatment should be followed by a continuous infusion (50–100 mL/h) of a solution containing 1 mg/mL of elemental calcium (11 ampules of 10% calcium gluconate added to 5% dextrose in a final volume of 1 liter). The rate should be adjusted according to corrected serum calcium level, which should be measured initially every 1 to 2 hours and subsequently every 4 to 6 hours, and maintained at the lower limit of the normal range, while the patient is asymptomatic. This calcium infusion protocol maintained for 8 to 10 hours will raise serum calcium by approximately 2 mg/dL. Oral administration of active vitamin D metabolites and calcium should be started as soon as practical. Calcitriol is typically initiated at a dose of 0.5 to 1.0 μg twice daily; oral calcium (1–3 g daily in divided doses) is also added.

If hypocalcemia is due to magnesium deficiency, the previous protocol should be applied while magnesium is being replaced by administering IV magnesium sulfate (initial dose 2 g as a 10% solution over 10–20 minutes, followed by 1 g/h in 100 mL) until a normal serum level of magnesium is reached. The only administration of magnesium will be unable to correct hypocalcemia because hypomagnesemia inhibits the secretion of PTH, and consequently the renal activation of 25OH D and induces a peripheral resistance to the action of PTH.

The rate of calcium infusion should be increased if symptoms of hypocalcemia recur. The IV infusion should be slowly tapered and discontinued when an effective regimen of oral calcium and active vitamin D is reached (up to 24–48 hours or longer) and stable desired serum calcium levels are obtained.

Chronic Hypoparathyroidism

The goal of therapy is to maintain serum calcium in the low-normal range, avoid hypocalcemic symptoms and long-term complications, and improve QoL. An individualized approach is necessary to optimize patient care. Guidelines for the management of chronic

HypoPT have only recently been developed by the European Society of Endocrinology, the American Association of Clinical Endocrinologists, the American College of Endocrinology, and a panel of international experts.

Conventional Therapy. An adequate calcium intake from dietary sources (mainly dairy products) should be recommended, but calcium supplements (1–3 g daily in divided doses) are needed in almost all adult patients. Calcium carbonate is generally preferred because fewer pills per day are needed. Calcium carbonate requires an acidic gastric environment to be absorbed and should be taken with meals. Its bioavailability decreases in patients with atrophic gastritis or taking proton pump inhibitors. In these circumstances, calcium citrate, which is well absorbed independent of meal and acid environments, should be preferred. Calcium citrate might also be a preferred option for patients who complain of gastrointestinal side effects using calcium carbonate or who prefer to take calcium supplements outside mealtimes. Calcium carbonate and calcium citrate interfere with levothyroxine absorption; therefore thyroidectomized patients should be advised to take levothyroxine well apart from calcium supplements.

Prior to the availability of synthetic active vitamin D metabolites, supraphysiologic doses (25,000–200,000 IU daily) of either cholecalciferol (vitamin D₃) or ergocalciferol (vitamin D₂) were used. Nowadays, active 1α -hydroxylated vitamin D metabolites are preferred because patients with HypoPT have impaired renal activation of 25 -hydroxyvitamin D. Calcitriol (Rocaltrol) and alfacalcidol (One-Alpha)² have a similar time of onset, but the latter has a longer time of offset (5–7 vs. 2–3 days). Calcitriol is more potent (about 50%) than alfacalcidol when compared in terms of the calcemic effect. The daily dose of calcitriol in adults ranges between 0.25 and 2.0 μg , equal to 0.5 to 4 μg of alfacalcidol. Weight-based dosing (0.01–0.04 μg per kg per day), eventually associated with calcium supplements (20–40 mg per kg per day) should be used in infants and young children. Adult doses should be used in older children. Another active vitamin D analog, dihydrotachysterol, is also available in some countries. Where active vitamin D metabolites are not available or too expensive, large doses of parent vitamin D can still be used, but attention should be paid to the risk of vitamin D toxicity.

²Not available in the United States.

A low vitamin D status is not uncommon in patients with HypoPT, and vitamin D-deficient patients treated with active vitamin D metabolites should be supplemented with vitamin D₂ or D₃, because active vitamin D metabolites do not correct hypovitaminosis D.

Active vitamin D metabolites stimulate intestinal absorption of phosphate, which may cause hyperphosphatemia and an increased calcium-phosphate product, with the risk of soft tissue calcification. In this setting the intake of phosphate-rich foods should be reduced and the daily dose of calcium supplements increased, since calcium binds phosphate.

Hypercalciuria (≥ 250 mg [6.25 mmol] in women or ≥ 300 mg [7.5 mmol] in men or > 4 mg [0.1 mmol]/kg body weight in both sexes) is a common feature in patients with chronic HypoPT, because of the lack of PTH-dependent renal tubular reabsorption of calcium. In such instances a low-sodium diet should be advised either alone or combined with the administration of a thiazide diuretic that decreases renal calcium excretion. The combination of thiazide with amiloride¹ may further lower urinary calcium excretion and decrease the risk of hypokalemia. Thiazide diuretics are not advised in autosomal dominant hypocalcemia, a condition caused by mutations of the CaSR. Magnesium deficiency, when present, should also be corrected.

Lifelong monitoring is needed in patients with chronic HypoPTH. No study has evaluated how to best monitor these patients. The target serum calcium concentration is within the low-normal range, with no symptoms of hypocalcemia. In some patients a higher serum calcium level is needed to be symptom-free. A baseline renal imaging should be obtained. The recently published guidelines of the European Society of Endocrinology suggest measuring ionized or albumin-corrected total calcium, magnesium, and creatinine (eGFR) and 24-hour urinary calcium excretion every 3 to 6 months and performing renal imaging when patients have symptoms of nephrolithiasis or increasing serum levels of creatinine. Biochemical monitoring should be performed weekly or every other week when changing the daily dose of calcium or active vitamin D metabolites or introducing a new drug. It is important to note that serum calcium may fluctuate once the therapeutic regimen has been stabilized. Several comorbidities (e.g., gastrointestinal disease, diarrhea, immobilization) and drugs (loop and thiazide diuretics, systemic glucocorticoids, proton pump inhibitors, antiresorptive drugs, cardiac glycosides, and chemotherapeutics) may interfere with calcium homeostasis, and therefore patients should be periodically asked about their occurrence or use.

Conventional therapy only partially restores calcium homeostasis, and patients with chronic HypoPT have a reduced QoL and an increased risk of comorbidities, which include nephrocalcinosis, nephrolithiasis, impaired renal function, neuropsychiatric diseases, muscle stiffness and pain, infections, and seizures. An increased rate of intracerebral calcifications and cataracts has been documented in nonsurgical HypoPT. Bone mineral content is increased in patients with chronic HypoPT, but cancellous bone microarchitecture is abnormal.

Parathyroid Hormone. Until recently, HypoPT was the only major hormonal insufficiency state not treated with the missing hormone. The development of the recombinant human N-terminal 1-34 fragment (rhPTH₁₋₃₄) and the full-length 1-84 (rhPTH₁₋₈₄) molecule has stimulated several studies on its use as replacement therapy, which led to the approval by the Food and Drug Administration of rhPTH₁₋₈₄ (Natpara) for the management of chronic HypoPT.

The official recommendation is to consider rhPTH₁₋₈₄ therapy “only in patients who cannot be well-controlled on calcium and active forms of vitamin D and for whom the potential benefits are considered to outweigh the potential risk.” Treatment should be started with subcutaneous administration in the thigh of 50 µg once daily, while reducing by 50% the daily dose of active

vitamin D if serum calcium is greater than 7.5 mg/dL (1.875 mmol/L). Serum calcium should be monitored every 3 to 7 days and the daily dose of rhPTH₁₋₈₄ titrated every 4 weeks, aiming to reduce the daily calcium supplements to 500 mg and discontinue active vitamin D therapy while maintaining the serum calcium in the low-normal range. Afterward, serum calcium should be monitored every 3 to 6 months. Hypercalcemia has been reported in some cases, but a careful adjustment of the daily dose may decrease this risk. A “black box” in the official recommendation highlights the potential risk of osteosarcoma (studies in rats have shown that both rhPTH₁₋₃₄ and rhPTH₁₋₈₄ can cause osteosarcoma). However, there is no evidence that individuals treated with either PTH molecules are at increased risk for osteosarcoma. The safety and efficacy of rhPTH₁₋₈₄ in pediatric patients have not been established.

The FDA and the European Medical Agency approval for using rhPTH₁₋₈₄ in patients with HypoPT leaves room for decision making in individual cases. The guidelines recently elaborated by a panel of international experts suggest considering the use of rhPTH₁₋₈₄ therapy, where available, in any patient with chronic HypoPT of any etiology, except in patients with autosomal dominant hypocalcemia.

Pregnancy and Lactation

There are limited data to inform treatment strategies in chronic HypoPT in pregnancy and lactation. The guidelines of the European Society of Endocrinology suggest the use of active vitamin D metabolites and oral calcium as in nonpregnant women. Frequent monitoring (every 2–3 weeks) of serum calcium, possibly ionized calcium, is recommended. No studies have addressed the use of rhPTH₁₋₈₄ therapy in pregnant women. The FDA suggests that it should be used “only if the potential benefit justifies the potential risk to the fetus.”

HYPERPROLACTINEMIA

Method of

Ming Li, MD, PhD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperprolactinemia is diagnosed by biochemical tests based on two-site immunoassay, which can be confounded by extreme hyperprolactinemia (hook effect) and biologically inactive macroprolactinemia.
- Hyperprolactinemia can be caused by physiological, pharmacological, or pathological conditions; careful clinical, laboratory, and radiology evaluations are required to identify its underlying cause.
- The most common causes of hyperprolactinemia include medications, prolactinoma, and other pituitary and hypothalamic/pituitary stalk diseases.
- Clinical features of hyperprolactinemia include galactorrhea, menstrual abnormalities (in women), impotence (in men), infertility, and osteoporosis.
- Patients with prolactinoma may also have local compression symptoms including headache, visual disturbance, and hypopituitarism.
- Pituitary magnetic resonance imaging (MRI) is the imaging method of choice for diagnosing prolactinoma and other sellar/parasellar lesions.

CURRENT THERAPY

- For secondary hyperprolactinemia, treatment should be directed at correcting underlying causes.
- Treatment goals for prolactinoma are relief of symptoms and the long-term effects of hyperprolactinemia, and of tumor mass effects.
- The dopamine agonists cabergoline (Dostinex) and bromocriptine (Parlodel) are effective in normalizing the prolactin level and shrinking the tumor in patients with prolactinoma.
- Surgery and radiotherapy of prolactinoma are reserved for patients resistant to or intolerant of medical therapy.
- Temozolomide (Temodar)¹ monotherapy is the first-line chemotherapy for aggressive or malignant prolactinomas after failing standard treatments.

¹Not FDA approved for this indication.

Biochemistry and Physiology of Prolactin

Prolactin is a polypeptide hormone produced by pituitary lactotroph cells. It is also produced locally in a variety of extrapituitary tissues such as mammary glands, decidua, gonads, brain, liver, fat, pancreas, and the immune system, along with its receptors. Prolactin is highly pleiotropic in terms of its functions. Many of its actions collectively support puerperal lactation. Prolactin displays considerable sequence homology to growth hormone (GH) and placental lactogen. The prolactin and GH receptors both belong to the class I cytokine/hematopoietic receptor superfamily. Prolactin is responsible for maturation of the mammary glands during pregnancy, but it

plays only a minor role for pubertal mammary development, which requires GH instead. It appears not to be an essential hormone for non-childbearing individuals. Rare patients deficient for either prolactin or its receptor are largely healthy despite difficulty with fertility and lactation.

Prolactin circulates mainly as a 23-kDa 199-aa polypeptide. Several of its cleavage products exist in blood, which may have functions unrelated to lactation; for example, one 16-kDa cleavage product of prolactin displays antiangiogenic and prothrombotic properties, and has been implicated in the development of pre-eclampsia and peripartum cardiomyopathy. Several forms of prolactin aggregate, known as macroprolactins, also exist in circulation at lower levels. They are formed either by covalent bonding of prolactin monomers or by their nucleating around autoimmune IgG. These macroprolactins are not biologically active *in vivo* and have a prolonged half-life. At times they can build up in the circulation to a level high enough to cause diagnostic difficulties.

Among the major pituitary hormones, prolactin is unique for its predominantly negative mode of regulation by the hypothalamus. It does not have a known hypothalamus-derived releasing hormone. Instead, lactotrophs are under tonic inhibition by dopamine secreted from hypothalamic neurons. Increase in prolactin output is mostly mediated by withdrawing dopaminergic control in response to environmental cues, such as physical activity, stress, and nipple stimuli (Figure 1). Under experimental and pathological conditions, several factors, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide (VIP), oxytocin, and vasopressin, have been shown to increase prolactin secretion, but these peptides appear to play only minor and insignificant roles for the physiological regulation of prolactin.

Estrogen is the main driver of prolactin secretion during pregnancy. Stimulated by persistently elevated estrogen, lactotrophs grow in number and size. By term the pituitary gland can reach 2 to 3 times its normal size, and prolactin levels increase some 20-fold. Along with placental hormones such as estrogen, progesterone, and placental lactogen, prolactin drives the maturation of the mammary glands. Lactation starts after parturition, when estrogen withdraws from the circulation. Frequent infant suckling maintains physiological hyperprolactinemia, which is important for sustained milk production. In addition, hyperprolactinemia during this critical period provides a natural though unreliable way of contraception. This is achieved by suppression of the hypothalamus–pituitary–gonad axis. Hyperprolactinemic hypogonadism and parathyroid hormone related peptide (PTHrP) secreted from mammary epithelial cells help mobilize skeletal calcium store in support of milk production. Through its receptors in liver, intestine, fat, and pancreas prolactin also adjusts maternal nutrient metabolism for optimal milk output. In the brain, prolactin modifies parental behavior toward closer infant attendance (see Figure 1).

Pathophysiology of Hyperprolactinemia

Physiological hyperprolactinemia as occurs during pregnancy and nursing is essential for child raising through the actions of prolactin in target organs discussed above. Similar changes in these organs under the influence of persistent pathological hyperprolactinemia in the absence of pregnancy and lactation, however, are inappropriate and could lead to a variety of undesired long-term consequences.

Mammary Glands

One common symptom of persistent hyperprolactinemia is galactorrhea, that is, milk production not associated with childbirth or breast-feeding. As puerperal lactation normally ends within 6 months after delivery or weaning, any milk production beyond this point is also considered galactorrhea. Since maturation of mammary glands is completed during pregnancy, galactorrhea typically happens in women between 20 to 35 years of age with previous childbirths. It also occurs in nulligravid women, postmenopausal women, and men, although less frequently.

Prolactin is a known mitogen for mammary epithelial cells, and concern has been raised regarding its potential role in the

HYPERPROLACTINEMIA

Method of

Ming Li, MD, PhD; and Lawrence Chan, MD

CURRENT DIAGNOSIS

- Hyperprolactinemia is diagnosed by biochemical tests based on two-site immunoassay, which can be confounded by extreme hyperprolactinemia (hook effect) and biologically inactive macroprolactinemia.
- Hyperprolactinemia can be caused by physiological, pharmacological, or pathological conditions; careful clinical, laboratory, and radiology evaluations are required to identify its underlying cause.
- The most common causes of hyperprolactinemia include medications, prolactinoma, and other pituitary and hypothalamic/pituitary stalk diseases.
- Clinical features of hyperprolactinemia include galactorrhea, menstrual abnormalities (in women), impotence (in men), infertility, and osteoporosis.
- Patients with prolactinoma may also have local compression symptoms including headache, visual disturbance, and hypopituitarism.
- Pituitary magnetic resonance imaging (MRI) is the imaging method of choice for diagnosing prolactinoma and other sellar/parasellar lesions.

CURRENT THERAPY

- For secondary hyperprolactinemia, treatment should be directed at correcting underlying causes.
- Treatment goals for prolactinoma are relief of symptoms and the long-term effects of hyperprolactinemia, and of tumor mass effects.
- The dopamine agonists cabergoline (Dostinex) and bromocriptine (Parlodel) are effective in normalizing the prolactin level and shrinking the tumor in patients with prolactinoma.
- Surgery and radiotherapy of prolactinoma are reserved for patients resistant to or intolerant of medical therapy.
- Temozolomide (Temodar)¹ monotherapy is the first-line chemotherapy for aggressive or malignant prolactinomas after failing standard treatments.

¹Not FDA approved for this indication.

Biochemistry and Physiology of Prolactin

Prolactin is a polypeptide hormone produced by pituitary lactotroph cells. It is also produced locally in a variety of extrapituitary tissues such as mammary glands, decidua, gonads, brain, liver, fat, pancreas, and the immune system, along with its receptors. Prolactin is highly pleiotropic in terms of its functions. Many of its actions collectively support puerperal lactation. Prolactin displays considerable sequence homology to growth hormone (GH) and placental lactogen. The prolactin and GH receptors both belong to the class I cytokine/hematopoietic receptor superfamily. Prolactin is responsible for maturation of the mammary glands during pregnancy, but it

plays only a minor role for pubertal mammary development, which requires GH instead. It appears not to be an essential hormone for non-childbearing individuals. Rare patients deficient for either prolactin or its receptor are largely healthy despite difficulty with fertility and lactation.

Prolactin circulates mainly as a 23-kDa 199-aa polypeptide. Several of its cleavage products exist in blood, which may have functions unrelated to lactation; for example, one 16-kDa cleavage product of prolactin displays antiangiogenic and prothrombotic properties, and has been implicated in the development of pre-eclampsia and peripartum cardiomyopathy. Several forms of prolactin aggregate, known as macroprolactins, also exist in circulation at lower levels. They are formed either by covalent bonding of prolactin monomers or by their nucleating around autoimmune IgG. These macroprolactins are not biologically active *in vivo* and have a prolonged half-life. At times they can build up in the circulation to a level high enough to cause diagnostic difficulties.

Among the major pituitary hormones, prolactin is unique for its predominantly negative mode of regulation by the hypothalamus. It does not have a known hypothalamus-derived releasing hormone. Instead, lactotrophs are under tonic inhibition by dopamine secreted from hypothalamic neurons. Increase in prolactin output is mostly mediated by withdrawing dopaminergic control in response to environmental cues, such as physical activity, stress, and nipple stimuli (Figure 1). Under experimental and pathological conditions, several factors, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide (VIP), oxytocin, and vasopressin, have been shown to increase prolactin secretion, but these peptides appear to play only minor and insignificant roles for the physiological regulation of prolactin.

Estrogen is the main driver of prolactin secretion during pregnancy. Stimulated by persistently elevated estrogen, lactotrophs grow in number and size. By term the pituitary gland can reach 2 to 3 times its normal size, and prolactin levels increase some 20-fold. Along with placental hormones such as estrogen, progesterone, and placental lactogen, prolactin drives the maturation of the mammary glands. Lactation starts after parturition, when estrogen withdraws from the circulation. Frequent infant suckling maintains physiological hyperprolactinemia, which is important for sustained milk production. In addition, hyperprolactinemia during this critical period provides a natural though unreliable way of contraception. This is achieved by suppression of the hypothalamus–pituitary–gonad axis. Hyperprolactinemic hypogonadism and parathyroid hormone related peptide (PTHrP) secreted from mammary epithelial cells help mobilize skeletal calcium store in support of milk production. Through its receptors in liver, intestine, fat, and pancreas prolactin also adjusts maternal nutrient metabolism for optimal milk output. In the brain, prolactin modifies parental behavior toward closer infant attendance (see Figure 1).

Pathophysiology of Hyperprolactinemia

Physiological hyperprolactinemia as occurs during pregnancy and nursing is essential for child raising through the actions of prolactin in target organs discussed above. Similar changes in these organs under the influence of persistent pathological hyperprolactinemia in the absence of pregnancy and lactation, however, are inappropriate and could lead to a variety of undesired long-term consequences.

Mammary Glands

One common symptom of persistent hyperprolactinemia is galactorrhea, that is, milk production not associated with childbirth or breast-feeding. As puerperal lactation normally ends within 6 months after delivery or weaning, any milk production beyond this point is also considered galactorrhea. Since maturation of mammary glands is completed during pregnancy, galactorrhea typically happens in women between 20 to 35 years of age with previous childbirths. It also occurs in nulligravid women, postmenopausal women, and men, although less frequently.

Prolactin is a known mitogen for mammary epithelial cells, and concern has been raised regarding its potential role in the

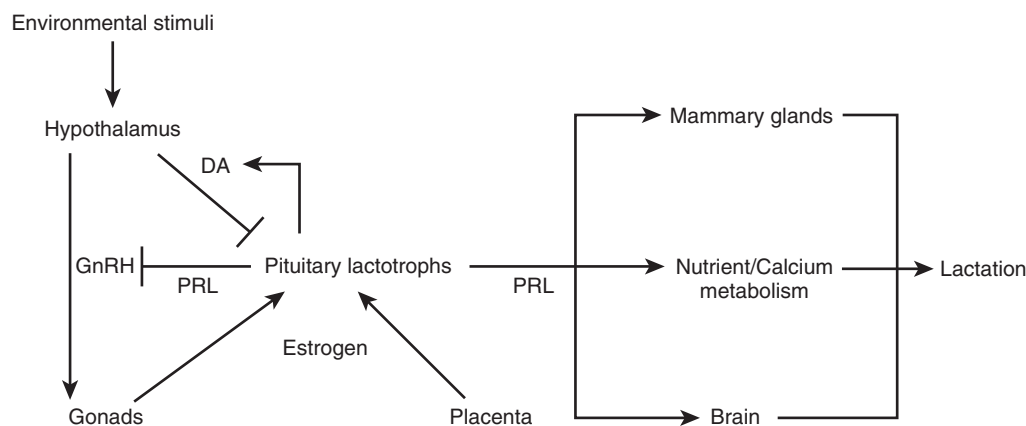

Figure 1 Physiology of prolactin and its regulation. At baseline, prolactin production and secretion are under tonic inhibition by dopamine released from hypothalamic neurons. The hypothalamus controls prolactin production by altering output of dopamine after integrating environmental stimuli and changes in hormonal homeostasis. Prolactin increases hypothalamic dopamine output, providing a negative feedback regulatory loop. Estrogen stimulates prolactin synthesis and secretion during pregnancy. Prolactin supports puerperal lactation via its action on the mammary glands, nutrient/calcium metabolism, and brain. Unlike most other anterior pituitary hormones, feedback regulation of prolactin secretion does not occur via factors produced by a peripheral endocrine target organ. Prolactin also suppresses hypothalamic-pituitary-gonadal axis by inhibiting GnRH release. *Abbreviations:* DA = dopamine; GnRH = gonadotropin releasing hormone; PRL = prolactin.

pathogenesis of breast cancer. In a large prospective study by the Women's Health Initiative (WHI), there was evidence of a significant increase in breast cancer incidence in postmenopausal women with high normal prolactin levels, which is within the highest quartile of the normal range compared with those in the lowest quartile. On the other hand, increased breast cancer risk has not been observed in patients with overt hyperprolactinemia. In fact, early parity and lactation history are strong protective factors against breast cancer. Further research is required to resolve these seemingly discrepant observations.

Female Reproductive System

Persistent hyperprolactinemia significantly diminishes the pulsatile release of gonadotropin-releasing hormone (GnRH). As GnRH neurons do not themselves express prolactin receptors, prolactin exerts its effects on their afferent neurons instead by suppression of secretion of kisspeptin, a potent secretagogue for GnRH. Prolactin receptors are also found in the gonads, and prolactin has been reported to inhibit folliculogenesis and estrogen production in the ovary directly. However, this likely has only a limited contribution to infertility and hypogonadism associated with hyperprolactinemia, for the hypothalamus-pituitary-gonad axis can be reactivated by administration of GnRH or kisspeptin, with return of ovulation and fertility in subjects with hyperprolactinemia.

Male Reproductive System

As in women, hyperprolactinemia causes secondary hypogonadism and infertility in men by suppression of GnRH pulses and a decrease in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels. Patients often have low or low normal testosterone levels, as well as abnormal sperm counts and morphology in semen analysis. Patients usually seek medical attention for diminished libido and impotence. The central nervous system (CNS) actions of prolactin are likely partly responsible for these symptoms, as restoration of testosterone level alone is often inadequate for symptom relief, which occurs only when prolactin levels also return to normal.

Adrenal Glands

Prolactin stimulates the synthesis of androgen in the zona reticularis of the adrenal cortex. Mild elevations in serum levels of adrenal androgens, for example dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEA-S), are seen in approximately 50% of women with hyperprolactinemia. Symptoms of clinical hyperandrogenism such as hirsutism and acne are rare in these patients. When present, they are almost always associated with a concurrent increase in testosterone level. Elevation of

adrenal androgens in hyperprolactinemia may contribute to the suppression of GnRH release in the hypothalamus and secondary hypogonadism.

Skeletal System

Premenopausal women with hyperprolactinemia have lower bone density and approximately a 4.5 times higher risk for osteoporotic fractures. Hypogonadism associated with hyperprolactinemia is the main cause of bone loss, whereas restoration of sex hormones with either hormonal replacement or correction of hyperprolactinemia improves bone density. Bone density is preserved in women with hyperprolactinemia who continue to have regular menses. Nonetheless, not all studies showed a clear correlation between the degree of bone loss and duration of amenorrhea or levels of sex hormones suggesting involvement of additional processes. For example, the levels of parathyroid hormone-related protein (PTHrP) were found to be significantly higher in patients with hyperprolactinemia, and correlated well with bone density measurements. Correction of hyperprolactinemia by dopamine agonists was shown to normalize PTHrP levels.

Etiology of Hyperprolactinemia

Any conditions that affect production or clearance of prolactin can lead to hyperprolactinemia (Table 1). Physiological hyperprolactinemia is transient and adaptive, whereas persistent hyperprolactinemia from pharmacological and pathological causes is often symptomatic with undesired long-term consequences. Pituitary adenomas over producing prolactin (prolactinomas) are the most important cause of pathological hyperprolactinemia. In addition to the elevated prolactin levels, prolactinomas also produce pathological local mass effects. Secondary hyperprolactinemia is most commonly related to disruption of dopaminergic control of lactotrophs, secondary to the use of dopamine antagonists or hypothalamic and pituitary stalk lesions.

Epidemiology and Natural History of Prolactinoma

Prolactinoma is the most common type of pituitary adenoma, contributing to approximately 40–50% of pituitary tumor cases. Prolactinomas are categorized according to size into microprolactinomas (under 1 cm) and macroprolactinomas (larger than 1 cm). Clinically these two conditions behave very differently and can be considered as separate entities. In general, macroprolactinomas tend to grow progressively and are often locally invasive; they are also generally more resistant to treatment and have a higher risk of recurrence. On the other hand, microprolactinomas rarely progress in size (~7% of cases) and have a good chance (~15% of cases) of going into remission on their own.

Adapted from Bronstein, 2016; Melmed et al., 2017.

The prevalence of prolactinoma has been estimated to be 500 cases per million and incidence about 27 cases per million per year based on survey of asymptomatic populations. In autopsy series, however, lactotroph neoplasms staining positive for prolactin are much more common, being found in approximately 5% of the subjects. They are predominantly microadenomas. Only a small fraction of these small lactotroph neoplasms develop overt hyperprolactinemia by escaping tonic dopaminergic suppression from the hypothalamus, presumably via down-regulation of dopamine D₂ receptor-mediated signaling pathway and/or bypassing the portal system for blood supply. Microprolactinomas

predominantly affect women of childbearing age, with a female-to-male ratio of approximately 20:1. Macroprolactinoma, on the other hand, shows no sex predilection. Neoplastic transformation of lactotroph involves accumulation of genetic and epigenetic events. The best-understood candidate genes involved include the pituitary tumor transforming gene (PTTG) and the heparin-binding secretory transforming gene (HST). PTTG expression is positively regulated by estrogen.

Most prolactinomas occur sporadically. The vast majority of prolactinomas are benign, although they can be locally invasive. Malignant prolactinomas, as defined by the presence of extrapituitary metastases, are extremely rare. Familial cases, such as those associated with multiple endocrine neoplasia I (MEN-I) and familial isolated pituitary adenoma (FIPA), typically occur at a younger age and are more often macroprolactinomas that are locally invasive.

Clinical Manifestations

Clinical manifestations of prolactinomas fall under two categories: systemic effects of hyperprolactinemia, and local compression symptoms.

Symptoms of Hyperprolactinemia

Persistent hyperprolactinemia inappropriately recapitulates symptoms associated with normal pregnancy and nursing. In extreme cases, hyperprolactinemia has been associated with delusions of pregnancy in susceptible individuals, for example some women on psychotropic medications.

Menstrual abnormalities and infertility are the most common symptoms associated with hyperprolactinemia in women of childbearing age. These symptoms may be masked by use of oral contraceptive pills, which often delays diagnosis. The mildest cases include women presenting with infertility caused by shortened luteal phase despite preserved regular menses. As the degree of hypogonadism worsens, patients experience menstrual irregularities ranging from anovulatory cycles to oligomenorrhea and amenorrhea. Patients with amenorrhea may also experience psychological stresses and other menopausal symptoms like vaginal dryness and dyspareunia. Of note, high prolactin levels may sometimes mask vasomotor symptoms of menopausal and perimenopausal women with prolactinoma, who may develop hot flashes once they are successfully treated with dopamine agonists.

Galactorrhea occurs in up to 80% of cases of hyperprolactinemia. This will need to be differentiated from nipple discharges of other causes, especially those from breast neoplasms. Further evaluation with breast imaging and cytology is indicated when the discharge is unilateral, bloody, or associated with a breast mass. Galactorrhea is by definition milk-like in appearance, and when in doubt, Sudan Black B staining showing fat globules is confirmatory. Although considered a classic sign and symptom for hyperprolactinemia, galactorrhea per se is a poor predictor for hyperprolactinemia in the absence of additional symptoms, for it can be seen in about 10% of healthy women of childbearing age. If amenorrhea is present at the same time, the patient should be assumed to harbor a prolactinoma unless proven otherwise. The degree of galactorrhea is quite variable, from barely expressible to bothersome bra stain and copious free flow, and does not necessarily reflect the severity of hyperprolactinemia. In fact, the majority of patients with galactorrhea and normal menses have normal prolactin levels. On the other hand, in some patients with extremely high levels of prolactin, galactorrhea could be masked by severe hypogonadism.

Men with hyperprolactinemia mainly present with impotence and diminished libido, which is not always corrected with testosterone replacement. As noted in the section on pathophysiology, these symptoms are not all caused by hypogonadism but may involve the central effects of prolactin. Other symptoms and signs of hypogonadism, such as loss of body hair and muscle bulk, are less common. Infertility could also occur with decrease in sperm count and morphology, although hyperprolactinemia is only present in approximately 5% of male patients seeking treatment for infertility.

For both male and female patients, persistent hypogonadism from hyperprolactinemia leads to osteoporosis and increased risk of fracture. This could be effectively treated with either sex hormone replacement or dopamine agonists.

Mass Effects of Prolactinomas

Headache is the most common neurological symptom caused by pituitary tumors. It can occur even with microadenomas presumably caused by dural stretch. More severe headache results from larger tumors, especially those with extrasellar invasion, and occasionally from apoplexy.

Visual disturbance typically only happens with macroadenomas with suprasellar extension impinging on the optic chiasm leading to loss of visual acuity and visual field defects. The typical pattern of visual field defect is bitemporal hemianopsia, which usually starts from the upper field and progresses downward as the tumor impinges upward from below. Ophthalmoparesis typically happens in the setting of apoplexy and only rarely results from parasellar invasion of the cavernous sinus and impingement of cranial nerves III, IV, or VI.

By compressing the rest of the pituitary gland, including the stalk, prolactinoma can cause deficiencies of other anterior pituitary hormones including GH, thyroid-stimulating hormone (TSH), and adrenocorticotrophic hormone (ACTH), in addition to hypogonadism from the hyperprolactinemia. The degree of the risk is proportional to tumor size.

CSF rhinorrhea occurs when a macroprolactinoma invades inferiorly into the sphenoid sinus. Other rare compressive symptoms from giant prolactinomas include epilepsy (temporal lobe involvement), exophthalmos, and hydrocephalus. Life- and vision-threatening emergencies could arise from apoplexy and CNS infection.

Laboratory Evaluation

Prolactin Assay and Pitfalls

Hyperprolactinemia is diagnosed by individual measurements of serum prolactin levels. Patients should be well rested, as physical activity stimulates prolactin secretion, but fasting is not needed. Dynamic tests such as TRH stimulation do not appear to add to diagnostic value and are not recommended. The level of prolactin may provide valuable diagnostic clues. Secondary hyperprolactinemia rarely exceeds 150 ng/mL. On the other hand, a prolactin level of greater than 100 ng/mL is highly suggestive, and severe hyperprolactinemia of greater than 500 ng/mL is virtually diagnostic for prolactinoma. On rare occasions, secondary hyperprolactinemia can produce prolactin levels in the prolactinoma range. For example, risperidone (Risperdal)-induced hyperprolactinemia could be as high as 250 to 500 ng/mL, and patients with end-stage renal disease who are on antipsychotics or antiemetics can have prolactin levels greater than 1000 ng/mL. The size of the prolactinoma shows a rough correlation with the serum prolactin level. Patients with microprolactinomas usually have prolactin levels in the range of 50 to 300 ng/mL, whereas those with macroprolactinomas have levels of 200 to 5000 ng/mL.

Most clinical laboratories measure prolactin using a two-site immunoassay. A capture antibody first affixes prolactin in the sample to a solid matrix. Subsequently a second signal antibody is attached to the now immobilized prolactin. The signal antibody is engineered to carry either a radioisotope or a chemiluminescent enzyme to provide a readout. The assay is accurate within its designed linear range, which is typically under 10,000 ng/mL. Beyond this level both capture and signal antibodies could be saturated preventing the signal antibody to attach. As a result, signal outputs will be falsely diminished. This phenomenon, known as the hook effect, produces a falsely low reading that could lead to the misdiagnosis of a macroprolactinoma as a nonfunctioning pituitary tumor. This artifact can be circumvented by repeating the assay with a 100-fold diluted sample. Many laboratories also opt for an additional washout step to eliminate excess prolactin before adding the signal antibody, preempting the artifact.

Macroprolactinemia is another potential diagnostic pitfall masquerading as true hyperprolactinemia. Macroprolactins are

biologically inactive prolactin aggregates that could accumulate in blood to a high level. Macroprolactinemia does not cause any morbidities but could contribute to analytical difficulties as the antibodies used in prolactin assays cross-react with macroprolactins. Most laboratories rely on polyethylene glycol (PEG) precipitation to determine the proportion of macroprolactins and the true concentration of monomeric prolactin. Up to 25% of monomeric prolactin can be also precipitated by PEG, potentially masking true hyperprolactinemia. Therefore patients with macroprolactinemia may still need to be further evaluated if clinical suspicion is high for true hyperprolactinemia.

Other Supporting Laboratory Tests

After confirming hyperprolactinemia, a simple chemistry panel may reveal or suggest the underlying cause such as chronic kidney disease and cirrhosis. A pregnancy test (beta human chorionic gonadotropin [β hCG] level) is essential for women of childbearing age, and hypothyroidism needs to be ruled out with a TSH assay. Both pregnancy and hypothyroidism may have presenting symptoms of sellar mass and hyperprolactinemia and therefore be mistaken for prolactinoma.

For established prolactinoma cases it is important to also assess other pituitary axes. Up to 20% of GH-secreting tumors cosecrete prolactin, and IGF-1 level is an essential screening test for these cases. If hypogonadism is suspected, levels of LH, FSH, and sex hormones (testosterone or estrogen) should be obtained. Screening for central hypothyroidism and secondary adrenal insufficiency should be done with TSH, free thyroxine (T₄), and morning cortisol levels, respectively, for patients with pituitary tumors larger than 6 mm.

Neuroimaging

Pituitary imaging should be considered for all patients with unexplained significant hyperprolactinemia, especially if there are signs or symptoms of local compression. MRI with and without gadolinium contrast with dedicated pituitary protocol is the test of choice. Compared with other modalities MRI provides superior soft tissue contrast revealing the tumor's inner structure and its relationship to surrounding tissues, including cavernous sinus, pituitary stalk, and optic chiasm. Computed tomography (CT) scan still has a role for patients with metal implants or other contraindications for MRI, and is especially useful for revealing bony erosions and tissue calcification; its use is limited by suboptimal soft tissue contrast and exposure to ionizing radiation.

Visual Field Testing

A formal visual field test with a perimeter is recommended when suprasellar extension of a pituitary adenoma brings it close to the optic chiasm. Improvement or worsening in visual field often precedes imaging evidence of tumor shrinkage or expansion during treatment. Therefore visual field testing is an excellent monitoring tool for patients under treatment for macroadenoma and visual impairment.

Diagnosis

Prolactin testing is usually prompted by suggestive signs and symptoms of hyperprolactinemia such as menstrual abnormalities, infertility, and galactorrhea. A careful history, including medication use, physical examination, and routine laboratory evaluation (see preceding sections), is invaluable for uncovering secondary causes. Pituitary imaging should be performed when no other underlying causes are found especially if the levels of prolactin are higher than 100 ng/mL. A diagnostic algorithm shown in [Figure 2](#) provides a framework for a structured and cost-effective workup of hyperprolactinemia.

Differential Diagnosis

An exhaustive list of etiologies has been provided in [Table 1](#). A few entities deserve additional comments.

Drug-induced hyperprolactinemia is common and at times may produce serum prolactin levels matching those in patients with

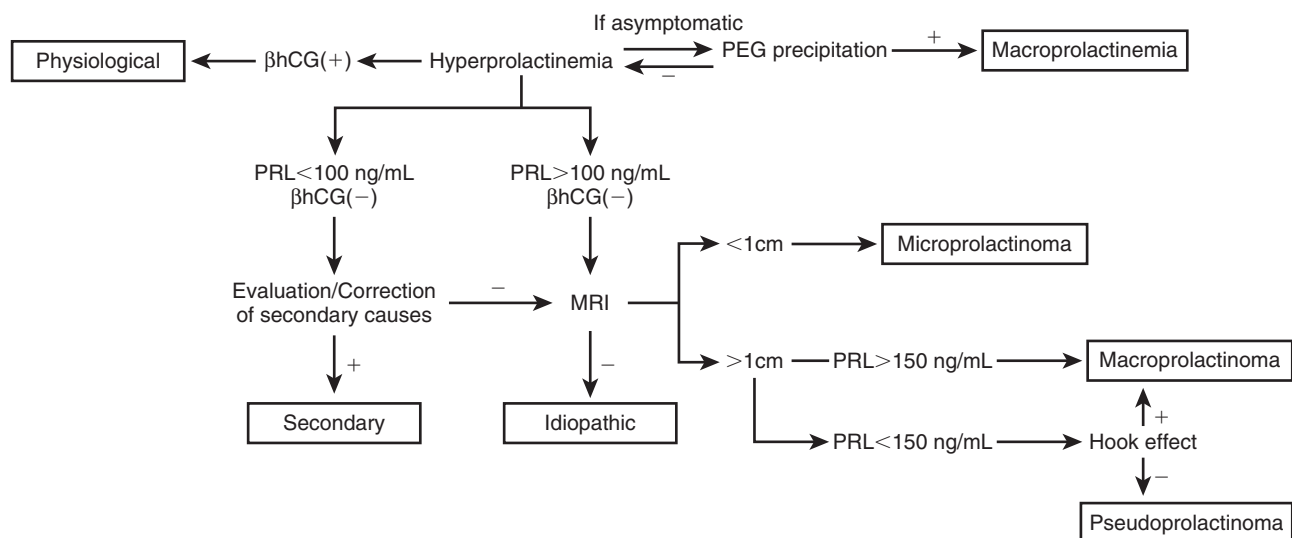

Figure 2 Diagnostic algorithm for hyperprolactinemia. If hyperprolactinemia occurs in the absence of relevant clinical symptoms and signs, one should rule out macroprolactinemia by PEG precipitation. When hyperprolactinemia is confirmed, pregnancy should be ruled out with a β hCG test. In the absence of pregnancy, if the PRL level is higher than 100 ng/dl, the pretest probability for a prolactinoma is high enough to justify a pituitary MRI scan, even if potential secondary causes exist. Regardless of prolactin levels, secondary causes should be carefully evaluated with medication history, physical examination, and laboratory tests such as thyroid function tests and chemistry panel, and appropriately treated. If hyperprolactinemia remains unexplained or persists despite correction of other contributing factors, a pituitary MRI is in order. Patients with negative sellar findings have idiopathic hyperprolactinemia. Patients with sellar mass may have either prolactinoma or pseudoprolactinoma. The latter is suggested by a discordant prolactin level less than 150 ng/mL for a large sellar, or a parasellar mass greater than 1 cm, after hook effect has been ruled out. *Abbreviations:* β hCG = β human chorionic gonadotropin; MRI = magnetic resonance imaging; PEG = polyethylene glycol; PRL = prolactin.

prolactinoma (see prior section on laboratory evaluation). A more typical range of prolactin level is 25 to 100 ng/mL for drug-induced hyperprolactinemia. It is not always possible to correlate in time the initiation of the culprit drug with the onset of symptoms, or rise of prolactin levels. The way to confirm medication-related hyperprolactinemia is to discontinue the putative offending agent(s) for three days before repeating a prolactin assay. Some medications may require a longer period of abstinence, and in such cases the level of prolactin can be retested later if the second value is reduced but still elevated. Before discontinuing psychotropic medications, one should consult with the prescribing psychiatrist to prevent worsening of the patient's mental symptoms.

Pseudoprolactinoma refers to a nonfunctioning sellar or suprasellar mass associated with hyperprolactinemia caused by stalk disruption. The prolactin level is seldom above 150 ng/mL. However, before making such a diagnosis, one must exclude hook effect with a 100-fold diluted sample. Prolactin levels are typically normalized within several days after initiation of dopamine agonists, as lactotrophs are still sensitive to dopamine, but local compressive symptoms do not improve. In contrast, patients with true macroprolactinoma experience more gradual decrease in prolactin levels after they are put on dopamine agonists, but they could expect improvement in compressive symptoms within 12 hours to days, and imaging evidence of tumor shrinkage in weeks.

Polycystic ovary syndrome (PCOS) and hyperprolactinemia are among the most common causes of menstrual irregularities and infertility, and affect women of similar ages. PCOS has also been associated with hyperprolactinemia. However, multiple studies have shown that the prevalence of hyperprolactinemia in women with PCOS is not significantly higher than that of matched populations. Although mild elevations of DHEA-S or DHEA are common in patients with hyperprolactinemia, hirsutism is rare, and when present is always associated with an increase in testosterone level, likely reflecting possible coexisting PCOS. Therefore the presence of hyperprolactinemia in patients with PCOS or hirsutism warrants additional evaluation.

Management of Secondary Hyperprolactinemia

Treatment of secondary hyperprolactinemia should focus on correcting the underlying conditions, for example treating

hypothyroidism, and resection of nonfunctioning pituitary tumors. For drug-induced hyperprolactinemia, the responsible medications should be removed or replaced with alternatives. Newer antipsychotics such as aripiprazole (Abilify) may be used in place of older agents such as risperidone (Risperdal) because they have better metabolic/hormonal profiles. For irreversible conditions such as end-stage renal disease, hyperprolactinemia can be effectively controlled with dopamine agonists. Ectopic prolactin secretion, which occurs in paraneoplastic syndrome, is a rare exception where dopamine agonists are ineffective, because extrapituitary production of prolactin is driven by alternative promoters, which do not respond to dopamine. Asymptomatic patients with modest hyperprolactinemia may not need treatment, however, and sex hormone replacement may be adequate for correcting hypogonadism if fertility is not desired.

Management of Prolactinoma

The goals for managing prolactinomas are twofold: treating symptomatic hyperprolactinemia, and relief of tumor mass effects. Treatment thus needs to be tailored to the patient's unique clinical picture and the desired outcome. Mass effects are not a concern for microprolactinomas, whereas for patients with giant prolactinomas (defined as >4 cm or >2 cm of suprasellar extension) and extreme hyperprolactinemia, normalization of prolactin levels is less likely, and treatment should focus on reversal or minimization of mass effects. The following are appropriate options in specific settings.

Observation

Active surveillance is appropriate for patients with microprolactinoma who are asymptomatic or not troubled by galactorrhea, especially if fertility is not a concern. As long as regular menses are preserved, they seem to be spared from any long-term consequences from hyperprolactinemia. Bone mineral density appears to be preserved in these patients. It is noteworthy that a significant fraction of patients may have tumor resolution during surveillance without treatment. Tumor expansion is a rare event, and serial measurements of serum prolactin level are effective for monitoring interval tumor growth. Pituitary imaging is indicated when there is significant increase in prolactin level or emergence of local compression symptoms.

Hormonal Replacement

For patients with microprolactinoma bothered only by symptoms related to hypogonadism including menstrual abnormalities, sexual dysfunction, and osteoporosis, but who no longer desire fertility, hormonal replacement is a valid alternative to dopamine agonists, especially when the latter are not tolerated or are contraindicated. This can be achieved with oral contraceptive pills in premenopausal women, or testosterone in men. This approach compares favorably to dopamine agonists in terms of cost and side effects. Patients may experience slight increases in prolactin level, but tumor progression has not been associated with use of oral contraceptive pills for up to 2 years. It would be prudent to use lower doses of estradiol ($\leq 30 \mu\text{g/day}$) and closely monitor patients for prolactin level and tumor growth.

Dopamine Agonists

Medical treatment with dopamine agonists has replaced surgery as the first-line treatment for prolactinomas, with excellent efficacy in achieving treatment goals and minimal risk. The therapeutic effects of dopamine agonists are mediated by dopamine D2 receptors in tumor cells, which inhibit prolactin synthesis and secretion, slow cell proliferation, and reduce tumor vascularity. Normalization of prolactin levels and reduction of tumor size can be expected in the majority of patients. A small fraction of prolactinomas is resistant to dopamine agonists, as defined by failure in normalizing prolactin level, reduction in tumor size by 50%, or restoration of gonadal function with standard doses. In general, microprolactinomas are more sensitive to dopamine agonists than macroprolactinomas are, and men are more likely to be drug resistant than are women. Rapid responders experience significant improvement of visual symptoms within 24–72 hours; some of them may develop complications resulting from the rapid receding of macroprolactinomas (uncorking), e.g., pituitary apoplexy, optic chiasm herniation, and/or CSF leak. For most patients, however, progressive reduction of tumor size occurs over the course of months to years, though some patients may never experience tumor shrinkage despite normalization of prolactin levels at the highest tolerated doses.

Patients with microprolactinoma may discontinue treatment upon menopause because their treatment goal has been fulfilled. Patients with macroprolactinoma, on the other hand, may require life-long treatment to prevent tumor regrowth. A meta-analysis showed that a small fraction of patients may enter long-term remission after discontinuing dopamine agonists (21% for microprolactinomas and 16% for macroprolactinomas). The odds are significantly improved if patients have been treated for at least 2 years and tumor size reduced by $\geq 50\%$. The 2011 Endocrine Society practice guidelines suggest that tapering or discontinuing dopamine agonists may be attempted in patients who have been treated for at least 2 years and experienced complete biochemical and radiographic resolution. The risk for recurrence after drug discontinuation is related to the size of adenoma at the time of the diagnosis. For tumors larger than 2 cm, especially giant prolactinomas, tapering the dopamine agonists to a lower maintenance dose for life-long treatment after achieving maximal tumor reduction would be a better strategy for these patients. Tapering or withdrawal of dopamine agonists should be followed by close surveillance of prolactin levels and pituitary MRI when prolactin level increases, especially during the first year.

Three dopamine agonists are currently used for treating hyperprolactinemia, including bromocriptine (Parlodel), cabergoline (Dostinex), and quinagolide (available only in Europe). Bromocriptine was the first dopamine agonist available, and it has the best established safety record. It is still the only dopamine agonist approved by the Food and Drug Administration (FDA) to be used in pregnancy, when indicated. Cabergoline is a more specific agonist of the D2 dopamine receptor, and is superior in many respects to bromocriptine, for example, because of dosing convenience, tolerability, and treatment efficacy. Many patients not controlled with bromocriptine may achieve normal prolactin levels after switching to cabergoline, which has become the drug of choice for cases not involving pregnancy. The safety data for cabergoline are not as extensive as those for bromocriptine. Common side effects for this class of drugs include nausea, orthostatic hypotension, fatigue, mental fogging, and, less frequently, nasal stuffiness, Raynaud phenomenon, constipation, depression, and psychosis. Nausea is more common in patients taking bromocriptine; for these patients the intravaginal route¹ can be tried. Patients receiving higher doses of cabergoline are at risk of developing cardiac valvulopathy. This has so far been a concern for patients with Parkinson's disease, who may require much higher doses. However, the life-long exposure to high cumulative doses in patients with resistant prolactinoma is considerable, and regular echocardiogram surveillance is recommended for patients taking doses higher than 2 mg/week. Dosing regimens for bromocriptine and cabergoline are listed in Table 2. In general, patients should be started on the lowest doses and titrated upward monthly based on the serum prolactin level until treatment goals are reached.

Surgery

With the availability of the second-generation dopamine agonists, surgery is mostly reserved for the following situations: (1) patients intolerant of, or resistant to, dopamine agonists; (2) women with macroprolactinoma who are planning for conception, to forestall tumor expansion during pregnancy; (3) pituitary apoplexy threatening neurological and visual functions if not managed urgently. Transsphenoidal tumor resection is the standard surgical approach. Perioperative mortality and morbidity are low in the hands of experienced pituitary surgeons in high-volume centers. Major surgical complications include visual loss, CNS infection, stroke, and oculomotor palsy. Craniotomy is occasionally needed for masses with extrasellar extensions that may be inaccessible by the transsphenoidal route, with higher risk for complications. Postoperatively patients need to be monitored for signs of diabetes insipidus and secondary adrenal insufficiency, which may be transient or permanent.

Radiotherapy

Radiotherapy is inadequate as a primary treatment for prolactinoma, as its efficacy is poor and latency long. It is also associated with long-term complications including permanent hypopituitarism, cerebrovascular accidents, and secondary intracranial malignancies. Currently it is reserved mostly for patients with aggressive

¹Not FDA approved for this indication.

TABLE 2 Use of Dopamine Agonists in Hyperprolactinemia

	ROUTE	DOSING FREQUENCY	STARTING DOSE	USUAL DOSE RANGE
Bromocriptine	PO intravaginal ¹	Twice a day	1.25 mg after dinner or before bed for 1 week, then twice a day	2.5–10 mg/day
Cabergoline	PO	Once to twice a week	0.25 mg twice a week or 0.5 mg once a week	0.5–2 mg/week

¹Not FDA approved for this indication.

and malignant prolactinomas failing medical/surgical treatment. Stereotactic radiosurgery is preferred over conventional fractionated radiotherapy for more convenient dosing, better efficacy, and lower rate of complications. However, radiosurgery should not be attempted for tumors in close proximity to the visual apparatus (less than 5 mm of clearance), as it is associated with an unacceptably high rate of vision loss.

Management of Prolactinoma During Pregnancy

Mild hyperprolactinemia is part of normal pregnancy, and there are concerns for the safe use of dopamine agonists in pregnant women. There is convincing evidence that as long as bromocriptine is withdrawn within a week after confirmation of pregnancy, obstetric outcome is not altered. Less robust data to date suggest that continuing bromocriptine treatment till term is also safe. Despite its longer half-life, as long as cabergoline is discontinued in early pregnancy, it also has not been found to be associated with adverse outcomes. Until there is incontrovertible evidence for the absolute safety of these dopamine agonists, however, it is prudent to discontinue these drugs as soon as pregnancy is confirmed. Given its shorter half-life and established safety record, bromocriptine is the preferred agent for fertility induction in women with hyperprolactinemia, although cabergoline would also be acceptable if bromocriptine is not tolerated. The major indication to treat prolactinomas medically during pregnancy is the concern for tumor expansion. Such risk is negligible for microprolactinomas. For patients with macroprolactinoma, however, symptomatic tumor expansion during pregnancy can occur in up to about 30% of cases. This risk can be significantly reduced if the patient has been treated with a dopamine agonist for at least a year with evidence of tumor shrinkage, or has undergone pituitary surgery or radiotherapy prior to pregnancy. Until these conditions are met, women of childbearing age with macroprolactinomas should be advised to take nonhormonal contraceptive measures. For patients who fail to achieve tumor shrinkage with dopamine agonists or cannot tolerate them, prophylactic surgery prior to pregnancy may be considered, after careful discussion with the patient on surgical risks and the possibility of permanent hypopituitarism, which further impairs fertility. The Endocrine Society practice guidelines recommend against measurement of serum prolactin levels during pregnancy. Instead the patient should be followed clinically for any signs or symptoms of tumor expansion. MRI without gadolinium and visual field testing should be done when clinical suspicion arises. If tumor expansion is confirmed, the patient should be reinitiated on bromocriptine. Debulking surgery is reserved for patients failing or not tolerating medical treatment. Lactation usually does not cause tumor progression, and patients are encouraged to breastfeed their infants with close surveillance. They should not take either bromocriptine or cabergoline, however, as both are secreted in the milk.

Management of Resistant and Malignant Prolactinoma

Several other treatment options are available for patients who fail the highest tolerated doses of dopamine agonists, surgery, and radiation. A small fraction of these patients have malignant prolactinoma, which is defined by extrapituitary metastasis; histopathologically, malignant prolactinomas can appear very similar to aggressive prolactinomas. An alkylating agent, temozolomide (Temodar)¹, has been successfully used in the treatment of aggressive pituitary adenoma and pituitary carcinoma. Monotherapy with temozolomide has been established as the first-line chemotherapy for these conditions, following documented tumor growth despite standard therapies. Selective estrogen receptor modulators (SERMs), including raloxifene (Evista)¹ and tamoxifen (Nolvadex)¹, have been found to be useful adjuncts that can reduce prolactin level and inhibit tumor growth.

¹Not FDA approved for this indication.

HYPERTHYROIDISM

Method of

William J. Hueston, MD

CURRENT DIAGNOSIS

- Hyperthyroidism or thyrotoxicosis is most often caused by Graves' disease, toxic nodular goiter (Plummer's disease), or acute thyroiditis.
- Common symptoms in hyperthyroidism are tachycardia, elevated systolic blood pressure, tremor, and anxiety. Patients with Graves' disease also might exhibit exophthalmos. In contrast, elderly patients can present with apathetic hyperthyroidism, which can be confused with hypothyroidism.
- Hyperthyroidism should be suspected in all patients who present with atrial fibrillation, palpitations, panic disorder, or unexplained tremors.
- Thyroid storm is an acute, life-threatening condition usually occurring in patients with undiagnosed or untreated hyperthyroidism placed under physiologic stress.
- An elevated free T₄, usually with a low thyroid-stimulating hormone is the hallmark of hyperthyroidism, and anti-thyroid-stimulating hormone antibodies can help identify Graves' disease.

and malignant prolactinomas failing medical/surgical treatment. Stereotactic radiosurgery is preferred over conventional fractionated radiotherapy for more convenient dosing, better efficacy, and lower rate of complications. However, radiosurgery should not be attempted for tumors in close proximity to the visual apparatus (less than 5 mm of clearance), as it is associated with an unacceptably high rate of vision loss.

Management of Prolactinoma During Pregnancy

Mild hyperprolactinemia is part of normal pregnancy, and there are concerns for the safe use of dopamine agonists in pregnant women. There is convincing evidence that as long as bromocriptine is withdrawn within a week after confirmation of pregnancy, obstetric outcome is not altered. Less robust data to date suggest that continuing bromocriptine treatment till term is also safe. Despite its longer half-life, as long as cabergoline is discontinued in early pregnancy, it also has not been found to be associated with adverse outcomes. Until there is incontrovertible evidence for the absolute safety of these dopamine agonists, however, it is prudent to discontinue these drugs as soon as pregnancy is confirmed. Given its shorter half-life and established safety record, bromocriptine is the preferred agent for fertility induction in women with hyperprolactinemia, although cabergoline would also be acceptable if bromocriptine is not tolerated. The major indication to treat prolactinomas medically during pregnancy is the concern for tumor expansion. Such risk is negligible for microprolactinomas. HYPERTHYROIDISM

Method of

William J. Hueston, MD

CURRENT DIAGNOSIS

- Hyperthyroidism or thyrotoxicosis is most often caused by Graves' disease, toxic nodular goiter (Plummer's disease), or acute thyroiditis.
- Common symptoms in hyperthyroidism are tachycardia, elevated systolic blood pressure, tremor, and anxiety. Patients with Graves' disease also might exhibit exophthalmos. In contrast, elderly patients can present with apathetic hyperthyroidism, which can be confused with hypothyroidism.
- Hyperthyroidism should be suspected in all patients who present with atrial fibrillation, palpitations, panic disorder, or unexplained tremors.
- Thyroid storm is an acute, life-threatening condition usually occurring in patients with undiagnosed or untreated hyperthyroidism placed under physiologic stress.
- An elevated free T₄, usually with a low thyroid-stimulating hormone is the hallmark of hyperthyroidism, and anti-thyroid-stimulating hormone antibodies can help identify Graves' disease.

- Ultimately, a thyroid scan and uptake are usually necessary to differentiate the cause of hyperthyroidism.
- Subclinical hyperthyroidism is an uncommon finding of uncertain long-term clinical significance but treatment for patients over 65 with cardiac disease or osteoporosis should be considered.

CURRENT THERAPY

- In patients with Graves' disease or autonomous thyroid nodules (toxic nodular goiter), short-term treatment includes thyroid suppression medications (such as methimazole [Tapazole]) and β -blockers (such as propranolol [Inderal]¹). Long-term management with radioiodine thyroid gland ablation is often pursued once symptoms are controlled.
- Patients with acute thyroiditis might need transient β -blockade but can often be managed expectantly until symptoms abate and thyroid hormone levels normalize. A small number of patients (~10%) have persistent hypothyroidism after an episode of illness.
- Thyroid storm is a medical emergency that requires close monitoring along with an antithyroid drug, β -blockers, corticosteroids, and iodine-potassium solution (Lugol's solution).

¹Not FDA approved for this indication.

Epidemiology

Hyperthyroidism is relatively uncommon and usually caused by three conditions: Graves' disease, toxic nodular goiter, or acute thyroiditis. Graves' disease is the most common cause of hyperthyroidism in the United States and usually affects younger patients from the teens to the 40s. Like other autoimmune diseases, women are at higher risk (seven to eight times) than men. Toxic nodular goiter accounts for 15% to 30% of hyperthyroid diagnoses. It usually occurs after age 50 years, is more common in women, and follows several decades of multinodular thyroid disease. A less-common cause is administration of amiodarone. Amiodarone is about one third iodine and can cause hyperthyroidism either through iodine-induced thyroid damage or from increased thyroxine synthesis owing to excessive iodine.

Subclinical hyperthyroidism, defined as an abnormally low TSH but normal free thyroxine (T_4) and triiodothyronine (T_3) affects 1% to 2% of the population. This condition is most common with mild forms of hyperthyroidism but also can be observed transiently in thyroiditis. Subclinical hyperthyroidism is more common in individuals over age 70 and those with iodine-deficient diets.

Risk Factors

There are no known environmental or reversible risk factors for any of the causes of hyperthyroidism. Graves' disease is associated with a specific human leukocyte antigen (HLA) region on chromosome 6 (*CTLA 4*).

Pathophysiology

The most common causes of hyperthyroidism are shown in [Box 1](#).

Graves' disease is an autoimmune disorder caused by antibodies against thyroid-stimulating hormone (TSH) receptors on the thyroid gland. Graves' disease is associated with many other autoimmune diseases, including pernicious anemia, vitiligo, type 1 diabetes mellitus, autoimmune adrenal disease, Sjögren's syndrome, rheumatoid arthritis, and lupus. As with these other disorders, the etiology is unknown.

Toxic nodular goiter, also known as Plummer's disease, results from the development of autonomous thyroid adenoma. Patients who develop a toxic nodular goiter usually have a long history of many other nodules that spontaneously burn out over time,

BOX 1 Conditions Causing Hyperthyroidism

Graves' disease

Autonomous thyroid nodule (toxic nodular goiter)

Acute thyroiditis

- Hashimoto's thyroiditis
- Subacute granulomatous thyroiditis (de Quervain's thyroiditis)
- Subacute lymphocytic thyroiditis (silent or painless thyroiditis)
- Suppurative thyroiditis (bacterial infection of thyroid)

Excessive exogenous thyroid use

- Over-replacement after thyroid ablation or for hypothyroidism

- Thyroxine (Synthroid) abuse for weight loss

Iodine overconsumption

Amiodarone administration

but then develop a single large nodule (usually 2.5 cm or greater) that continues to produce thyroid hormone in such large quantities that patients become hyperthyroid. No clear cause is known for the development of the nodules.

Acute thyroiditis can also produce hyperthyroidism. Several different conditions can cause thyroiditis (see [Box 1](#)). The inflammation resulting in thyroiditis is thought to be related to subacute viral infections or autoimmune reactions; suppurative thyroiditis is a rare bacterial thyroid infection, usually caused by *Staphylococcus aureus*. During the acute period of thyroid inflammation, damage to the gland leads to the release of stored thyroxine from thyroid lakes, producing hyperthyroidism. However, after the initial release of thyroid hormone from the stored lakes, damage to the gland inhibits production of new thyroxine. After the initial surge in thyroid hormone levels, thyroxine levels drop, often to levels that can result in transient hypothyroidism. Most patients return to the euthyroid state after the thyroid gland heals, but about 10% of patients with acute thyroiditis remain chronically hypothyroid.

Other, less common causes of hyperthyroidism include excessive exogenous administration of thyroid medications. This is most commonly the result of over-replacement of thyroxine (Levothy, Synthroid) in patients with hypothyroidism, but it may be intentional for weight loss. Because thyroxine and triiodothyronine (T_3) are highly protein bound, over-replacement is most common if patients experience hypoproteinemia, such as in nephrotic syndrome, cirrhosis, or malnutrition.

Excessive iodine consumption, referred to as the Jod-Basedow effect, can also lead to thyrotoxicosis. The source of the iodine may include iatrogenic sources such as iodine-containing medications or radiologic contrast agents.

Several other medications, such as amiodarone (Cordarone), lithium, and interferon α (Intron A) also can cause thyrotoxicosis by causing drug-induced thyroiditis.

Prevention

There are no known strategies to prevent hyperthyroidism. For patients with hypothyroidism, annual monitoring of TSH levels is recommended to ensure that patients receive the appropriate replacement dose and not over-replacement.

Clinical Manifestations

Patients with hyperthyroidism complain of a variety of symptoms that can include anxiety, tachycardia, wide-pulse pressure hypertension, palpitations, fine tremor, weight loss, heat intolerance, and, particularly in the elderly, confusion or delirium. Patients with Graves' disease also have ophthalmopathy characterized by lid retraction and exophthalmoses that can lead to optic nerve damage. In contrast, older patients can have few of the classic signs of hyperthyroidism and instead might complain of fatigue or weakness (apathetic hyperthyroidism), unexplained delirium, weight loss, heart failure, or isolated atrial fibrillation.

Some patients have a rapid escalation of symptom severity (thyroid storm) that is life-threatening if not identified and treated promptly. These patients usually have underlying thyrotoxicosis from Graves' disease complicated by a secondary physiological stressor such as infection, surgery, or trauma. This is a medical emergency and needs immediate attention, including hospitalization with close observation.

On physical examination, patients with hyperthyroidism due to Graves' disease or thyroiditis might have a diffusely enlarged and mildly tender thyroid gland. In suppurative thyroiditis, the thyroid gland is red, hot, and very tender and accompanied by a fever and other systemic signs of severe infection. Patients with toxic nodular goiter can have palpable nodules in their thyroid gland and often have a single palpable nodule.

Diagnosis

Hyperthyroidism is diagnosed by finding an elevation in the free thyroxine (T_4) level accompanied by a low TSH level. Patients with Graves' disease often have positive anti-thyroid receptor antibody titers. Only anti-thyroglobulin receptor antibody testing is helpful because it can help differentiate Graves' disease from other causes. No other anti-thyroid tests are clinically indicated. Once the thyroid level abnormalities are found, a definitive diagnosis of the cause for the hyperthyroidism is needed to select the appropriate treatment strategy.

Other conditions can produce a depressed TSH but normal free T_4 levels. These include T_3 toxicosis and subclinical hyperthyroidism. T_3 toxicosis refers to situations where triiodothyronine (T_3) is produced in excess rather than thyroxine (T_4); this can occur in any of the conditions that can cause hyperthyroidism, as well as in surreptitious triiodothyronine (Cytomel) ingestion.

Thyroid scanning and radiolabel uptake are usually necessary to differentiate the causes of hyperthyroidism. Thyroid scanning and uptake rely on the thyroid gland to concentrate radioactive molecules, such as iodine-131 (^{131}I) or technetium. Because of the risk of thyroid storm with iodine administration, patients should be treated with antithyroid drugs for 2 to 8 weeks before a scan and the drugs should be stopped at least 4 days before the test. Patients with Graves' disease show increases in uptake and diffuse distribution of the tracer throughout the thyroid gland. Patients with toxic nodular goiter also have increased uptake, but the isotope is concentrated in a one or a few focal areas, with the remainder of the thyroid gland suppressed. In contrast, patients with thyroiditis have decreased uptake of the radiolabel and a washed-out or mottled distribution on scanning.

Differential Diagnosis

Symptoms of hyperthyroidism also occur in patients with panic disorder and other anxiety conditions. These patients can have sinus tachycardia, tremor, and nervousness that mimic hyperthyroidism.

Treatment

Treatment depends on the cause of the hyperthyroidism (Table 1). In Graves' disease, immediate goals of treatment include reducing thyroid hormone production and blocking the peripheral effects of the excessive thyroid hormone. About 30% to 60% of patients, mostly adolescents, enter remission spontaneously, and the remission may be permanent. Remission rates are highest for those with a small goiter, no ophthalmopathy, thyroglobulin levels less than 50 $\mu\text{g/mL}$, and thyroxine levels less than 20 $\mu\text{g/dL}$. Signs of remission include a decreased ratio of T_3 to T_4 , lower thyroid-stimulating thyroglobulin levels, and decreased radioactive iodine uptake on rescanning. When remissions do occur, it is usually within a year of starting antithyroid medications.

For those who do not undergo spontaneous remission, which includes most adults, consideration should be given to thyroid gland ablation to permanently treat this condition. Although the dosage can be calculated to attempt to leave patients euthyroid, permanent hypothyroidism occurs in about half of all patients treated with radioactive iodine ablation.

TABLE 1 Treatment Strategies for Hyperthyroidism

TREATMENT	DRUG	DOSAGE
Graves' Disease and Toxic Nodular Goiter		
Thyroid hormone suppression	Methimazole	Initial: 30–40 mg/d Maintenance: 5–15 mg/d
	Propylthiouracil	Initial: 300–400 mg/d Maintenance: 100–300 mg/d
β -Blockade	Propranolol ¹ Metoprolol (Lopressor) ¹	10 mg qid 50–100 mg bid
Thyroid gland removal	Radioactive iodine ablation Thyroidectomy	
Acute Thyroiditis		
β -Blockade transiently May need thyroid replacement long term		
Thyroid Storm		
Thyroid hormone suppression	Propylthiouracil	300–400 mg/d
β -Blockade	Propranolol ¹	1 mg/min IV to max 10 mg ³
Iodine	Lugol's solution	1–2 gtt mixed in water tid
Cardiac and fluid monitoring	Dexamethasone (Decadron) ¹	2 mg q6h

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

The initial approach to toxic nodular goiter is similar to that for symptom control, but thyroid ablation should be recommended routinely because remissions are very rare.

Thyroid gland production of hormone can be reduced rapidly with either methimazole (Tapazole) or propylthiouracil. For treatment of Graves' disease, methimazole is the preferred treatment and has the advantage of less frequent dosing, which improves compliance. Propylthiouracil is an alternative that is recommended for women in the first trimester of pregnancy and patients who cannot tolerate methimazole. However, the FDA issued a black box warning about the use of propylthiouracil in 2010 because of liver toxicity; physicians should be aware of this and use propylthiouracil only when methimazole is not suitable. With both drugs, clinicians need to be aware of drug-associated agranulocytosis, which can result in life-threatening bacterial infections. In patients on either of these medications who develop a sore throat, fever, or other signs of infection, a white blood cell count should be done immediately to ensure that they are not neutropenic. Additionally, antithyroid drugs are associated with drug-induced lupus syndromes and other forms of vasculitis.

In addition to reducing production of thyroid hormone, initial therapy for patients with Graves' disease and toxic nodular goiter should include a β -blocker to reduce the tachycardia, tremor, hypertension, and anxiety. A β -blocker that crosses the blood-brain barrier, such as propranolol (Inderal)¹ or metoprolol (Lopressor)¹, is the best choice in this situation because these also reduce the central nervous system effects such as anxiety, as well as the vascular problems caused by thyroid hormones.

¹Not FDA approved for this indication.

Thyroid storm requires immediate attention and should be managed in the hospital setting, especially in older patients where tachycardia and hypertension can lead to cardiac instability. Prompt administration of β -blockers and propylthiouracil along with cardiac monitoring for dysrhythmias and appropriate fluid management are essential for managing this life-threatening condition. Once antithyroid drugs have been administered, iodine-potassium solution (Lugol's solution) at a dose of 1 or 2 drops three times a day should be administered, which will further reduce thyroid hormone production and reduce peripheral conversion of T_4 to T_3 . Finally, corticosteroids also have been shown to rapidly reduce thyroid hormone levels in thyroid storm.

For long-term management, thyroid ablation with radioactive iodine (sodium iodide, ^{131}I) can restore patients to a permanent euthyroid state. However, radioactive iodine thyroid ablation often results in destruction of more thyroid than optimal, causing hypothyroidism. Radioactive iodine thyroid ablation is contraindicated in pregnancy. For patients in whom radioactive iodine is either contraindicated or not acceptable, thyroidectomy is an option. Thyroidectomy almost always results in permanent hypothyroidism, as well as having other risks inherent in surgery including hypoparathyroidism and recurrent laryngeal nerve damage.

In patients with hyperthyroidism associated with acute thyroiditis, symptoms often resolve by the time the evaluation is complete. In the interim, symptoms can be managed with β -blockers. β -Blocker therapy can be discontinued fairly rapidly (2 to 3 weeks) after the initial onset of symptoms.

Indications for the treatment of subclinical hyperthyroidism are less clear. Based on recommendations of the American Thyroid Association, patients with a persistently low TSH who are over age 65 or who have underlying cardiac disease or osteoporosis should be considered for treatment. The treatment strategy should be directed at the presumed cause of the condition and may include antithyroid medication for suspected Graves' Disease or thyroid ablation for toxic nodular goiter or a solitary autonomous nodule.

Monitoring

In patients on antithyroid drugs, thyroid hormone levels should be monitored frequently until they reach a stable euthyroid state. Any change in the patient's underlying health, especially changes that could alter protein levels, should prompt reevaluation. In addition, patients who have thyroid ablation need follow-up testing of TSH and free T_4 levels to ensure that sufficient thyroid tissue has been destroyed to reverse their hyperthyroidism but not make them hypothyroid. This should be done 6 to 8 weeks following ablation therapy.

Complications

Complications of hyperthyroidism include acute and chronic conditions. Acutely, the most concerning complications are cardiac dysrhythmias, especially atrial fibrillation. Chronically, excessive thyroxine is associated with cardiomyopathy and osteoporosis. In patients with ophthalmopathy, untreated Graves' disease can lead to progressive vision loss and blindness.

Hyperthyroidism in pregnancy, even when adequately treated, has been shown to be an independent risk factor for cesarean section but not for any additional pregnancy complications. Some patients with existing hyperthyroidism may experience transient increases in free T_4 levels during pregnancy that can be associated with hyperemesis gravidarum. Assessing free T_4 levels in pregnant patients who have hyperthyroidism and develop hyperemesis may be useful.

HYPOKALEMIA AND HYPERKALEMIA

Method of
Jie Tang, MD

CURRENT DIAGNOSIS

- The "initial approach" to the evaluation of dyskalemia is to determine if it is secondary to transcellular shifts (in vitro or in vivo) of potassium (K), or a result of a true change in total body K.
- A thorough history and physical will provide useful information regarding the causes of hypokalemia and hyperkalemia, especially in cases of low or high intake of K, and transcellular shifts.
- Key steps in the diagnostic approach to hypokalemia include assessments of urinary K excretion and acid-base status.
- Key steps in the diagnostic approach to hyperkalemia include assessments of renal function and aldosterone activity.

CURRENT THERAPY

- For both hypokalemia and hyperkalemia, it is critical to assess the underlying transcellular K shift, given the risk of rebound hyperkalemia after K repletion or hypokalemia after K restriction and removal.
- In cases of severe dyskalemia, close cardiac monitoring is needed.
- The aggressiveness of therapy for dyskalemia is directly related to the rapidity with which the condition has developed, the absolute level of serum K, and the clinical evidence of toxicity.
- In severe or symptomatic cases of hypokalemia, both intravenous and oral K repletion are often needed.
- In severe or symptomatic cases of hyperkalemia, supported by ECG abnormalities, both immediate temporizing measures and definitive therapy for K removal are necessary.

Epidemiology

Hypokalemia is defined as a serum K level of 3.5 mmol/L or lower. It is a common electrolyte disorder encountered in clinical practice. According to one study, serum K < 3.6 mmol/L was found in up to 20% of hospitalized patients. The majority of these patients had serum K concentrations between 3.0 and 3.5 mmol/L, but as many as 25% had values < 3.0 mmol/L. Even mild or moderate hypokalemia increases the risks of morbidity and mortality in patients with cardiovascular disease.

Hyperkalemia is defined as a serum K of 5.5 mmol/L or higher. The prevalence among hospitalized patients not yet on dialysis was reported to be about 3.3%, and among them, up to 10% had significant hyperkalemia (≥ 6.0 mmol/L). Hyperkalemia also carries a significantly increased risk of mortality.

Risk Factors

People most at risk for hypokalemia are those who are malnourished, with poor oral intake; those who use certain medications,

Thyroid storm requires immediate attention and should be managed in the hospital setting, especially in older patients where tachycardia and hypertension can lead to cardiac instability. - In severe or symptomatic cases of hypokalemia, both intravenous and oral K repletion are often needed.
- In severe or symptomatic cases of hyperkalemia, supported by ECG abnormalities, both immediate temporizing measures and definitive therapy for K removal are necessary.

Epidemiology

Hypokalemia is defined as a serum K level of 3.5 mmol/L or lower. It is a common electrolyte disorder encountered in clinical practice. According to one study, serum K < 3.6 mmol/L was found in up to 20% of hospitalized patients. The majority of these patients had serum K concentrations between 3.0 and 3.5 mmol/L, but as many as 25% had values < 3.0 mmol/L. Even mild or moderate hypokalemia increases the risks of morbidity and mortality in patients with cardiovascular disease.

Hyperkalemia is defined as a serum K of 5.5 mmol/L or higher. The prevalence among hospitalized patients not yet on dialysis was reported to be about 3.3%, and among them, up to 10% had significant hyperkalemia (≥ 6.0 mmol/L). Hyperkalemia also carries a significantly increased risk of mortality.

Risk Factors

People most at risk for hypokalemia are those who are malnourished, with poor oral intake; those who use certain medications,

such as diuretics; and those who have uncontrolled vomiting or diarrhea. People most at risk for hyperkalemia are those with reduced kidney function, those who have a history of diabetes mellitus, or those who take certain medications, such as angiotensin-converting enzyme inhibitors.

Pathophysiology

K is the most abundant cation in the human body. It regulates intracellular enzyme function and helps determine neuromuscular and cardiovascular tissue excitability. The total body store is approximately 55 mmol/kg of body weight. Over 98% of total body K is located in the intracellular fluid (primarily in muscle), and less than 2% in the extracellular fluid. A typical western diet provides 40 to 120 mmol of K per day. Tight control of the serum K is primarily accomplished by the kidney, where ~95% of body K is excreted. Under normal circumstances, K losses in stool and sweat are small. In addition, the interplay of several hormonal systems (insulin, catecholamine), serum tonicity, and the internal acid-base environment contribute to the exchange of K between the extracellular fluid and intracellular fluid, which helps keep the serum K concentration tightly controlled.

Hypokalemia occurs when there is a significant intracellular K shift or a reduced total body K store from poor intake, or excessive renal or extrarenal loss, whereas hyperkalemia develops when there is a significant extracellular shift, high body K load, or ineffective K elimination (aldosterone resistance/deficiency or reduced renal function).

Prevention

For patients at risk for hypokalemia, adequate dietary K intake is essential. Additional K supplements may be needed for patients taking high doses of diuretics (especially thiazide diuretics) or experiencing prolonged vomiting or diarrhea. For patients with hyperkalemia and severe kidney dysfunction, dietary K restriction is critical in maintaining body K balance. Sometimes, the empirical use of K exchange resin is needed to prevent hyperkalemia. Lastly, medications that contribute to hypokalemia or hyperkalemia should be avoided if possible.

Clinical Manifestations

Mild hypokalemia (serum K 3.0–3.5 mmol/L) is usually well tolerated. Moderate hypokalemia (serum K 2.5–3.0 mmol/L) may cause nonspecific symptoms, such as fatigue, weakness, muscle cramps, and constipation. When the serum K drops to < 2.5 mmol/L, muscle necrosis and flaccid paralysis with eventual respiratory failure may occur. K depletion also causes supraventricular and ventricular arrhythmias, especially in patients on digitalis therapy. Although severe hypokalemia is more likely to cause complications, even minimal decreases in serum or total body K can be arrhythmogenic in patients with underlying heart disease or who are receiving digitalis therapy. Lastly, increases in systolic and diastolic blood pressures can occur in patients with hypokalemia while they are on a liberal salt diet. Overall, the likelihood of symptoms tends to correlate with the rapidity of the decrease in serum K.

As with hypokalemia, patients with hyperkalemia may present with nonspecific complaints such as fatigue and malaise. But the predominant manifestations in more severe hyperkalemia are neuromuscular and cardiac. Neuromuscular symptoms range from muscle weakness to paralysis. Cardiac arrhythmias, including asystole, ventricular tachycardia or fibrillation, and pulseless electrical activity, can also occur in severe hyperkalemia.

Diagnosis

Figures 1 and 2 illustrate the diagnostic approaches to hypokalemia and hyperkalemia. It is important to assess for pseudodyskalemia (in vitro shift of K) and dyskalemia from in vivo

transcellular shift of K, because neither is associated with disturbances in total body K balance. Although cellular shift of K and changes in total body K occur as isolated problems, they frequently coexist. In hypokalemia, the assessment of renal K excretion is a key step in the initial diagnostic evaluation, followed by the assessment of acid-base status. In hyperkalemia, medical history and laboratory testing can help identify altered K distribution, reduced urinary K excretion or an excessive K load from exogenous intake or transcellular leakage. Under normal circumstances, high K intake alone is not sufficient to lead to significant hyperkalemia unless there are other risk factors present such as reduced aldosterone action, or significant loss of kidney function.

Measurement of the trans-tubular potassium gradient (TTKG) has been widely used as a diagnostic tool in both conditions. However, recent evidence suggests that the assumption inherent in the calculation of the TTKG lacks validity. Therefore I no longer use TTKG in the clinical assessment of patients with dyskalemia.

Differential Diagnosis

Figures 1 and 2 outline a diagnostic approach, including differential diagnosis, for hyperkalemia and hypokalemia.

Therapy

The treatment of hypokalemia depends on the underlying cause, the degree of K depletion, and the risk of K depletion to the patient. In general, hypokalemia secondary to cell shift is managed by treating underlying conditions. For example, hypokalemia in the setting of catecholamine increases, as in chest pain syndromes, is managed with appropriate treatments for the pain. However, when cell-shift hypokalemia is associated with life-threatening conditions such as paresis, paralysis, or hypokalemia in the setting of myocardial infarction, the administration of K is indicated. With K depletion, replacement therapy depends on the estimated degree of decreases in total body K. For example, decreases in total body K accompanied by a fall in serum K from 3.5 to 3.0 mmol/L are associated with a K deficit of 150 to 200 mmol. Decreases in serum K from 3 to 2 mmol/L are associated with 200- to 400-mmol additional decreases in total body K. K can be administered intravenously, but in limited quantities (10 mEq/h into a peripheral vein; 15–20 mEq/h into a central vein). Larger K requirements can only be accomplished by oral therapy or with dialysis.

The treatment of hyperkalemia depends on the presence or absence of ECG and neuromuscular abnormalities. In the absence of symptoms or ECG abnormalities, hyperkalemia is treated conservatively—for example, by decreasing dietary K or withdrawing offending drugs. In the presence of ECG abnormalities or symptoms, the goal of therapy is to stabilize cell membranes. First-line therapy includes calcium gluconate, 10 to 30 mL IV as a 10% solution (onset of action 1 or 2 min). Although the mechanism remains undefined, calcium “stabilizes” the cardiac membranes. Other therapies include 8.4% IV sodium bicarbonate,¹ 50 to 150 mEq (onset 15–30 min), and rapid-acting insulin¹ 5 to 10 units intravenously (onset 5–10 min). Insulin increases the activity of the Na-K-ATPase pump in skeletal muscle and drives K into cells. Glucose 50%, 25 g intravenously, is given simultaneously with insulin to prevent hypoglycemia. Albuterol inhalation solution 0.5%,¹ 20 mg in 4 mL normal saline by nebulizer (onset 15–30 min), also activates the Na-K-ATPase and drives K into cells. K driven intracellularly generally begins to move extracellularly again after approximately 6 hours, increasing the serum K

¹Not FDA approved for this indication.

concentration. Therefore therapy to remove K from the body should be started simultaneously. Reductions in total body K may be achieved through a K exchange resin. The primary K resin used is sodium polystyrene sulfonate (Kayexalate). One gram of this medication binds approximately 1 mEq of K and releases 1 to 2 mEq of sodium back into the circulation. This medication may be given orally (onset 2 hours) or by enema with sorbitol to induce diarrhea (onset 30–60 minutes). If renal function is

adequate, volume expansion with simultaneous diuresis can be attempted. Finally, hemodialysis is very effective in removing excess K.

Monitoring

Treatment for severe or symptomatic dyskalemia requires close cardiac monitoring and frequent laboratory testing to prevent overcorrection. If insulin and glucose are used in patients with

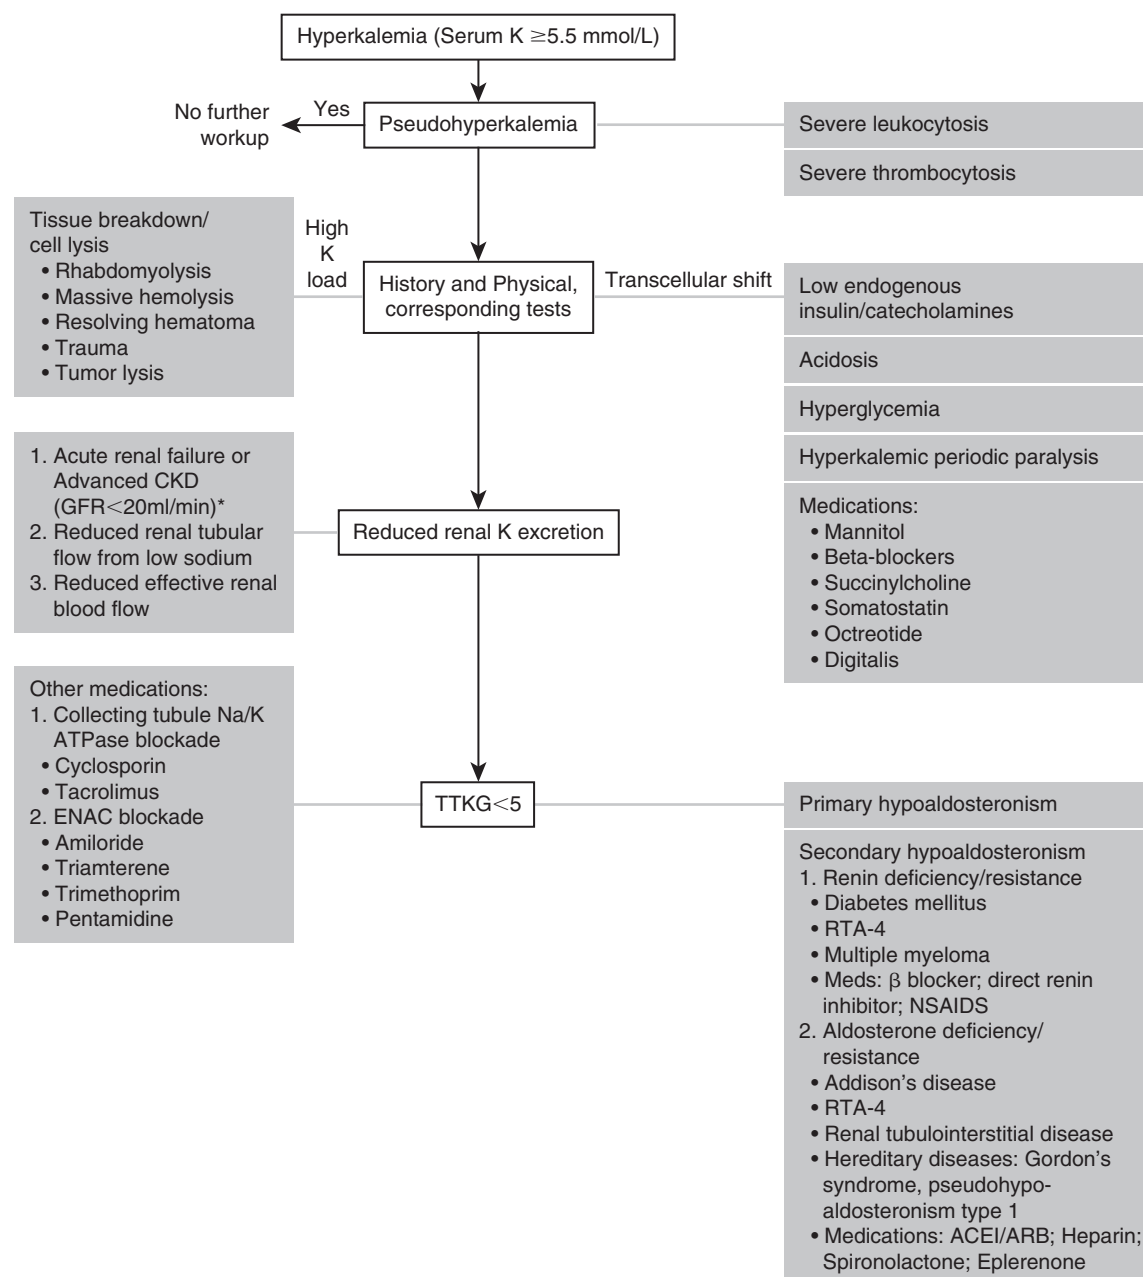

Figure 2 The diagnostic approach to hyperkalemia. *Hyperkalemia may occur with higher GFR if K load is excessive. *Abbreviations:* ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; ENAC = epithelial sodium channel; GFR = glomerular filtration rate; NSAIDS = non-steroidal anti-inflammatory drugs; RTA = renal tubular acidosis.

hyperkalemia, blood sugars should be monitored for approximately 6 hours to identify and treat hypoglycemia from the insulin.

Complications

Complications from dyskalemia include cardiac arrhythmias, neuromuscular events, and, rarely, death. There are potential treatment-related complications if pseudodyskalemia or dyskalemia from in vivo transcellular shift are not recognized.

HYPONATREMIA

Method of

Beejal Shah, MD; and Susan L. Samson, MD, PhD

CURRENT DIAGNOSIS

- Perform a thorough history and physical examination with focus on the accurate assessment of volume status, neurologic symptoms and signs, current medications, and concurrent illnesses.
- Classify the hyponatremia as hypovolemic, euvolemic, or hypervolemic.

- Determine whether the hyponatremia is acute or chronic, based on the history and the clinical manifestations.
- Order the key laboratory tests, including a basic metabolic panel (serum sodium, glucose, blood urea nitrogen, and creatinine), plasma osmolality, urine osmolality, and urine sodium.

CURRENT THERAPY

- Severe and symptomatic hyponatremia should be treated with hypertonic saline (3%) at 1 to 2 mL/kg per hour. Neurologic status and serum sodium should be monitored every 2 to 4 hours. The objective is to raise sodium by 2 mEq/L per hour (or to >125 mEq/L) until deleterious neurologic symptoms improve. After this, the rate of infusion should be titrated to increase the serum sodium by 0.5 to 1.0 mEq/L per hour, with a maximum increase of 10 to 12 mEq/L over 24 hours and no more than 18 mEq/L over 48 hours, to avoid precipitating osmotic demyelination.
- As a general rule, the treatment of hyponatremia should be adjusted so that the serum sodium increases by 0.5 to 1.0 mEq/L per hour with a maximum increase of 10 to 12 mEq/L over 24 hours and no more than 18 mEq/L over 48 hours. Acute hyponatremia (<48 hours) may be treated more rapidly than chronic hyponatremia if dictated by neurologic findings. Treat SIADH with fluid restriction, medications, or observation; rule out adrenal insufficiency and hypothyroidism.
- Most cases of euvolemic hyponatremia are caused by the syndrome of inappropriate antidiuretic hormone (SIADH), which usually can be managed with fluid restriction, salt tablets, and demeclocycline (Declomycin)¹ in refractory cases.
- Discontinue thiazide diuretics in all cases of hypoosmolar hyponatremia.
- Hypovolemic and hypervolemic hyponatremia require therapy to correct the underlying cause (e.g., heart failure) and restore status to euvoolemia.
- Vasopressin receptor antagonists (vaptans) are approved for short term management of euvolemic and hypovolemic hyponatremia. The same parameters apply for rate of sodium correction and monitoring as in conventional therapy.

¹Not FDA approved for this indication.

Homeostasis maintains the concentration of sodium in the serum between 138 and 142 mEq/L (normal, 135–145 mEq/L) despite variations in water intake. Hyponatremia is defined as a serum sodium concentration of less than 135 mEq/L. It is one of the most common electrolyte abnormalities found in the inpatient setting, occurring in up to 2.5% of patients, and it is a significant marker for mortality, associated with a 60-fold higher risk of death. It is not clear whether hyponatremia itself is the cause of a more adverse prognosis or whether it echoes the degree of stress caused by illness. In the outpatient setting, chronic hyponatremia is most prevalent among the elderly and nursing home residents. The approach to management of hyponatremia is highly dependent on the underlying process. Establishing the correct etiology is critical, because inappropriate treatment can worsen hyponatremia. Therapy must be administered judiciously because of the risk of severe neurologic sequelae, including central nervous system demyelination. However, with a systematic approach to the differential diagnosis of hyponatremia, the correct diagnosis can be made and therapy initiated.

Clinical Presentation

Acute hyponatremia is defined as hyponatremia of less than 48 hours in duration. Mild symptoms include headache, nausea, vomiting, confusion, and weakness, which usually occur with a sodium level

of less than 129 mEq/L. More severe neurologic manifestations—seizure and coma—are seen usually below a threshold of 120 mEq/L, although there currently is no evidence-based critical sodium level above which neurologic sequelae do not occur. The neurologic manifestations of acute or recurrent symptomatic hyponatremia can be delayed, so continued monitoring is important.

In contrast, patients with chronic hyponatremia more often are asymptomatic or have blunted symptoms. In elderly patients with mild chronic hyponatremia, subtle neurocognitive manifestations can occur, with decreased balance, lowered reaction speed, memory loss, and directed gait. Mild hypoosmolar hyponatremia is not independently associated with increased morbidity and mortality. Even so, the underlying etiology needs to be determined because of the potential for other factors (e.g., new medications, dehydration, occult illness) to contribute to the development of more severe hyponatremia with its potential for neurologic injury.

Regulation of Water Balance

Approximately two thirds of total body water is contained in the intracellular fluid (ICF) and one third as extracellular fluid (ECF). Plasma osmolality is tightly regulated between 280 and 290 mOsm/kg and reflects the osmolality of the ECF. A change in plasma osmolality results in a shift of total body water between the ECF and the ICF to maintain their osmolar equivalence. Because sodium is the major osmole in the ECF, hyponatremia most often is a manifestation of decreased osmolality, so-called hypoosmolar or hypotonic hyponatremia.

Renal Handling of Water

The major osmoregulatory hormone is arginine vasopressin, also called antidiuretic hormone, which is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported along axons to the posterior pituitary, where it is processed and stored in vesicles. Vasopressin secretion is regulated by osmotic and nonosmotic stimuli. Secretion occurs with a 1% to 2% rise in osmolality (>288 mOsm/kg), as detected by receptors in the anterolateral walls of the hypothalamus adjacent to the third ventricle. Vasopressin secretion is inhibited when the plasma osmolality is lower than 280 mOsm/kg. The major nonosmotic stimulus is a decrease in effective circulating volume, which is detected by baroreceptors in the aortic arch and carotid sinuses. Although this mechanism requires a large drop (10%–15%) in blood pressure, the secretory response is more robust than for increases in osmolality. As such, acutely lowered blood pressure can override the inhibitory signal of low osmolality because of the need to maintain perfusion. Other physiologic nonosmotic stimuli include catecholamines and angiotensin II, but there is a long list of hormones and pharmacologic agents that induce or repress vasopressin secretion (Table 1).

The renal site of action of vasopressin is the V_2 receptors on the basolateral membrane of collecting duct cells in the distal nephron. The hormone-receptor interaction initiates intracellular signaling via cyclic adenosine monophosphate-dependent pathways, resulting in translocation of cytoplasmic aquaporon-2 channels to the surface of the collecting duct luminal membrane. These channels allow movement of water back into the cell for later reabsorption into the circulation. This results in a net concentration of urine and decreased plasma osmolality.

Renal Handling of Sodium

In addition to renal water handling, sodium reabsorption and excretion are important for maintenance of water homeostasis. The renin-angiotensin-aldosterone system is activated by reduced arterial perfusion pressure sensed by the juxtaglomerular apparatus of the afferent renal arteriole. Reduced arteriole effective volume (low or perceived) is sensed by the juxtaglomerular apparatus, which secretes renin, activating the renin-angiotensin system. This cascade of events ultimately stimulates aldosterone secretion, which acts at the distal nephron to cause reabsorption of filtered sodium via Na^+ , K^+ -adenosine triphosphatase (ATPase)-dependent sodium channels.

TABLE 1 Molecules That Regulate Vasopressin Secretion

STIMULATE VASOPRESSIN RELEASE	INHIBIT VASOPRESSIN RELEASE

High-dose morphine	Butorphanol (Stadol)

Central Nervous System Response to Hyponatremia/Hypoosmolality

Osmolar equivalence between the ECF and ICF is closely maintained by shifts in water between the two compartments. The major symptoms and signs of hyponatremia are neurologic in nature and are a clinical manifestation of swelling of the cells in the central nervous system, which results in cerebral edema. The most devastating consequence is herniation due to anatomic limitations on brain volume within the confines of the skull. Premenopausal women are at the highest risk for brain injury from hyponatremia.

A major compensatory mechanism in the central nervous system is the extrusion from the cells of intracellular solutes, which prevents further water influx. In the first few hours, inorganic ions (potassium, sodium, chloride) move out of the cell. After a few days of persistent hypoosmolality, the cells further compensate by extruding organic osmoles (glutamate, taurine, inositol). The clinician must be aware of this protective adaptation, because it necessitates a slower time course of correction during treatment. A rapid rise in plasma osmolality from aggressive treatment causes water to rapidly shift out of the cells, resulting in demyelination of neurons. In the past, this was termed pontine demyelination, but it has also been reported for extrapontine neurons and is now referred to as osmotic demyelination. The sequelae are permanent and devastating. There is clinical progression from lethargy to a change in affect, to mutism and dysarthria, and finally to spastic quadriplegia and pseudobulbar palsy.

Classification and Differential Diagnosis of Hyponatremia

Initial evaluation of hyponatremia requires a systematic and sequential approach. First, a thorough history and physical examination are required. It is important to identify any history of brain

injury, stroke, mental illness, or chronic illness and the patient's current medication usage. On examination, special attention should be paid to mental status and neurologic abnormalities; manifestations of cardiac, hepatic, or renal disease; and signs of adrenal insufficiency or hypothyroidism. From the assessment of volume status, the hyponatremia should be classified as hypervolemic, euvolemic, or hypovolemic; each of these conditions leads in a different direction for diagnosis and treatment of the underlying cause (Figures 1 and 2). Finally, it should be determined whether the hyponatremia is acute (<48 hours) or chronic, because this can determine the time course of treatment.

For the laboratory work-up, essential basic tests are the serum sodium and potassium levels, renal function tests with blood urea nitrogen (BUN) and creatinine, and liver function tests. It is likely that these tests have already been performed, motivating the assessment of hyponatremia. After this, the plasma osmolality (P_{Osm}), urine osmolality (U_{Osm}), and urine sodium concentration are key diagnostic tests. P_{Osm} is directly measured in the laboratory and also can be calculated. Calculated osmolality is the sum of the concentrations of the known major osmoles—sodium and glucose—in the ECF and the BUN:

$$P_{Osm} = (2 \times Na) + (\text{glucose}) + (\text{BUN})$$

The calculation is done in SI units. For sodium, mEq/L is the same as the SI unit, mmol/L; if glucose and BUN values were reported in mg/dL, they must be divided by 18 and 2.8, respectively, to convert to SI units (mmol/L). The directly measured osmolality should be within 10 to 12 mOsm/kg of the calculated value; an increased osmolar gap compared with the calculated value points toward the presence of additional osmoles in the plasma that are causing hypertonicity.

Because hyponatremia usually is a reflection of plasma osmolality, most patients also have a low P_{Osm} , and the clinician often can proceed to the differential diagnosis of hypoosmolar (or hypotonic) hyponatremia after excluding pseudohyponatremia (which usually has normal osmolality) and hyperosmolar hyponatremia. Pseudohyponatremia can occur if the plasma lipid or protein content is greatly increased in the plasma (usually to >6%–8% of volume), as in extreme hypertriglyceridemia and paraprotein disorders. These extra components decrease the aqueous portion of the plasma volume and thereby interfere with the laboratory measurement of sodium by dilutional, indirect methods such as flame

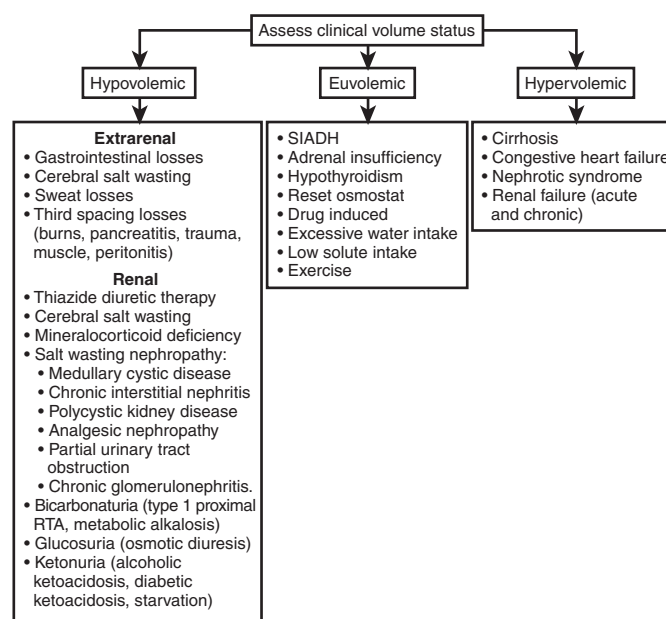

Figure 1 The differential diagnosis of hypoosmolar hyponatremia. Abbreviations: RTA = renal tubular acidosis; SIADH = syndrome of inappropriate antidiuretic hormone.

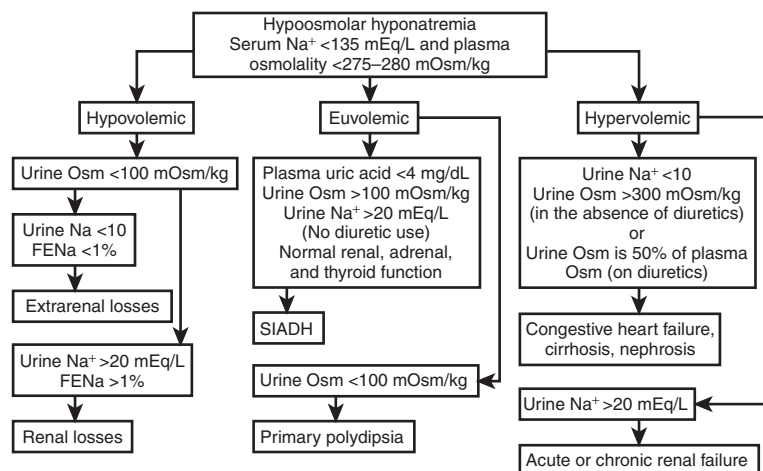

Figure 2 Laboratory findings in hyposmolar hyponatremia. Abbreviations: FENa = fractional excretion of sodium; Osm = osmoles; SIADH = syndrome of inappropriate antidiuretic hormone.

photometry. Most laboratories now use direct measurement of sodium to avoid this problem.

Hyperosmolar hyponatremia can occur if there are additional osmoles present that cause water movement from the ICF into the ECF, resulting in ECF expansion and dilutional hyponatremia. Overall, the total body water and total body sodium are unchanged in this situation. An important clinical example occurs with hyperglycemia, and the reported sodium value should be corrected for high glucose by the clinician by adding 1.6 mEq/L to the measured Na for every 100 mg/dL rise in glucose above 200 mg/dL. Because glucose is included in the calculation of osmolality, there will be no significant osmolar gap.

Other osmotically active solutes encountered clinically are mannitol, which is used to manage increased intracranial pressure, and glycine, which is used for irrigation in urologic procedures. Mannitol and glycine are retained in the ECF and are not part of the calculated osmolality, so their presence results in an osmolar gap. High levels of alcohol or ethylene glycol also increase the osmolality, but these substances are so quickly metabolized that an osmolar gap may not be apparent by the time testing is performed.

Once pseudohyponatremia and hypertonicity have been ruled out, the diagnosis is narrowed to hyposmolar hyponatremia. The combined physical examination and laboratory results allow classification of the patient as having hypervolemic hyponatremia with excess total body sodium, hypovolemic hyponatremia with a deficit of total body sodium, or euvolemic hyponatremia with near-normal total body sodium.

Hypovolemic Hyponatremia

The causes of hypovolemic hyponatremia can be classified as extrarenal or renal (see Figure 1). Signs of volume contraction are apparent on examination, including poor skin turgor, skin tenting (forehead), decreased or undetectable jugular venous pressure, dry mucous membranes, and orthostatic changes in blood pressure and pulse rate. If the volume status is not completely clear from the examination, laboratory values can be helpful (see Figure 2), but they need to be interpreted in the context of renal function tests. If the urine osmolality is less than maximally concentrated (<500 mOsm/kg), an infusion of 0.5 to 1 L of isotonic saline over 24 to 48 hours may help with differentiation. With hypovolemia, the sodium will begin to correct and the patient should improve clinically. Conversely, if the patient is actually euvolemic, such as with syndrome of inappropriate antidiuretic hormone (SIADH), discussed later, the serum sodium level will remain constant or decrease due to retention of free water with a concomitant increase in urinary sodium.

Extrarenal causes of hyponatremia include gastrointestinal losses and third-space losses such as in severe burns and

pancreatitis. In the volume-depleted state, with intact renal function, the urine sodium is low (<10 mEq/L), reflecting a normal response by the kidney to maximally reabsorb sodium in response to volume depletion.

The renal causes of hypovolemic hyponatremia involve the inappropriate loss of sodium into the urine, and this is reflected by a urine sodium concentration of greater than 20 mEq/L.

Thiazide diuretics cause renal sodium loss, so the urine sodium is high. However, they also impair the kidney's diluting capacity, decreasing free water excretion and concentrating the urine. Only certain patients may be susceptible to hyponatremia while on thiazides. These patients may have an abnormally sensitive thirst response to the mild hypovolemia induced by the diuretics, causing increased water intake. Elderly women are the most susceptible, and hyponatremia can occur within days after initiation of thiazide therapy. Additional laboratory results reveal hypokalemia and a metabolic alkalosis. It is appropriate to stop the diuretic and restore potassium levels and volume status. Patients often have a recurrence of hyponatremia if rechallenged with thiazides. Loop diuretics, such as furosemide, are a less frequent cause of hyponatremia, which occurs only after long-term therapy.

In the absence of diuretic use, a urine sodium concentration greater than 20 mEq/L with hypovolemia is evidence for underlying renal pathology. Patients with salt-wasting nephropathy, from a number of causes (see Figure 1), usually have significant renal failure, with a creatinine value in the range of 3 to 4 mg/dL. Because of the large net sodium loss, this condition is treated with salt tablets. Renal tubular acidosis causes bicarbonaturia, which requires a compensatory excretion of urinary cations, mainly Na^+ and K^+ , to maintain electroneutrality. Similarly, excretion of ketones into the urine also demands additional electrolyte losses in spite of ECF volume depletion, leading to a loss of sodium.

Cerebral salt wasting (CSW), although it could be considered an extrarenal cause, also involves the renal loss of sodium (>20 mEq/L). The biochemical presentation is very similar to that of SIADH, but the diagnosis of CSW is restricted to cases involving extreme central nervous system pathology. CSW is most commonly associated with subarachnoid hemorrhage but also has been reported with stroke, brain trauma, infection, metastases and after neurosurgery. Onset of CSW is usually within the first 10 days after the neurologic event.

CSW may be a protective mechanism against increased intracranial pressure. The proposed pathophysiologic mechanism of CSW is controversial, but one hypothesis is that the initiating event is a primary natriuresis, with renal loss of sodium, caused by the secretion of natriuretic peptides. Clinical studies have found both increased brain natriuretic peptide and increased atrial natriuretic peptide in neurosurgical patients with hyponatremia. Both hormones are vasodilators that increase the glomerular filtration rate

while suppressing the renin-angiotensin system. This increases renal sodium losses, as well as water excretion, resulting in volume depletion. Vasopressin levels rise in response to low volume, so that it becomes biochemically difficult to differentiate CSW from SIADH, with a urine sodium level greater than 20 mEq/L, low uric acid, and high urine osmolality. It is helpful if CSW patients have signs of volume depletion in combination with the laboratory results. Also, the hyponatremia of CSW responds to normal saline, whereas SIADH worsens with normal saline. CSW is relatively rare in most case series, and it is important to rule out other causes for natriuresis.

Hypervolemic Hyponatremia

There are a variety of causes of hypervolemic hyponatremia (see Figure 1), all of which are a result of decreased effective circulating volume. To correct this imbalance, the ECF expands, leading to fluid retention and hyponatremia. In spite of the increased total body water and low serum sodium on testing, all of these patients have some degree of total body sodium excess. In many cases, volume overload is clinically evident from the presence of subcutaneous edema, ascites, elevated jugular venous pressure, or pulmonary edema.

In congestive heart failure (CHF), patients can develop hyponatremia with only 2 to 3 L of fluid intake per day despite normal renal function. The decreased filling pressures and cardiac output of CHF are perceived as volume depletion, detected by the baroreceptors. This stimulates vasopressin secretion, overriding the signal of low osmolality detected by the hypothalamic osmoreceptors. This lack of inhibition of vasopressin secretion is believed to be the most important contributing factor to the development of hyponatremia. In addition, decreased right atrial pressures result in inhibition of secretion of atrial natriuretic peptide, contributing to the water and sodium gain. With the low perfusion pressure, there is a decrease in the glomerular filtration rate, which is sensed by the juxtaglomerular apparatus, causing neurohumoral activation of the renin-angiotensin system and sympathetic nervous system. This leads to increased circulating levels of catecholamines, angiotensin II, and aldosterone, further stimulating tubular sodium and water reabsorption. In the absence of diuretics, the urine sodium level is very low (<10 mEq/L) in patients with CHF because

of activation of the renin-angiotensin-aldosterone system and maximal tubular reabsorption of sodium. Also, there is less than maximally dilute urine (usually >300 mOsm/kg) in the absence of diuretic therapy. An elevated brain natriuretic peptide concentration helps to confirm the hypervolemia.

A similar mechanism is at work in cirrhotic patients, in whom the incidence of hyponatremia is even higher and is a strong predictor of poor outcome. In cirrhosis, low albumin results in third-spacing and decreased effective circulating volume. In addition, portal hypertension leads to splanchnic vasodilation, which also decreases the effective circulating volume. This serves to activate vasopressin secretion and the renin-angiotensin-aldosterone system.

Hyponatremia is less common in acute and chronic renal failure, but it can occur with a significant decrease in glomerular filtration rate accompanied by severe hypoalbuminemia. Interpretation of the laboratory results may be confounded by a high urine sodium concentration (>20 mEq/L) that reflects the concomitant presence of tubular dysfunction. Hyponatremia can develop in stage IV or V renal failure when fluid intake is in excess of 3 L/day.

Euvolemic Hyponatremia

Euvolemic hyponatremia is caused by impaired excretion of free water by the kidney. The differential diagnosis is more limited (see Figure 1) and the majority of cases are due to SIADH (Table 2). However, this often is a diagnosis of exclusion, and hypothyroidism and adrenal insufficiency must be ruled out clinically or biochemically in patients with euvolemic hyponatremia.

Hypothyroidism leads to reduced glomerular filtration rate and decreased flow to the distal nephron, causing maximal reabsorption of water to maintain arterial volume. Hypothyroidism has to be severe to cause hyponatremia and usually is obvious on examination. However, in the elderly population, apathetic hypothyroidism may be difficult to diagnose. Hypothyroidism can be confirmed by the presence of a high level of thyroid-stimulating hormone and a low level of free T₄ (thyroxine). Treatment involves thyroid hormone replacement and supportive care.

In primary adrenal insufficiency (Addison's disease), the concomitant aldosterone deficiency results in hyponatremia combined with hyperkalemia, prerenal azotemia, a urine sodium

TABLE 2 Causes of SIADH

CNS DISORDERS	PULMONARY DISORDERS	MEDICATIONS/DRUGS	OTHER
Mass lesions	Viral/bacterial pneumonia	Vasopressin analogues	Pain
Tumors	Positive-pressure ventilation	(Desmopressin [DDAVP])	Nausea

concentration greater than 20 mEq/L, and a urine potassium level lower than 20 mEq/L. In secondary or central adrenal insufficiency, the adrenal zona glomerulosa remains intact for the secretion of aldosterone. However, glucocorticoid deficiency still causes impaired water excretion, which can lead to dilutional hyponatremia. Vasopressin release may be stimulated by the nausea, vomiting, and orthostatic hypotension that occurs with adrenal insufficiency. Finally, corticosteroids normally inhibit vasopressin release, so their deficiency leads to enhanced vasopressin release, causing retention of free water that further contributes to the hyponatremia. The appropriate diagnostic test is a 250- μ g ACTH (cosyntropin, Cortrosyn) stimulation test, although an extremely low 8 AM cortisol level (<3 μ g/dL) can be diagnostic. Treatment consists of glucocorticoid replacement.

Syndrome of Inappropriate Antidiuretic Hormone

SIADH is the most common cause of euvolemic hypoosmolar hyponatremia. Edema, ascites, and orthostasis are absent, and thyroid, adrenal, and renal functions are normal. Recent diuretic use should be ruled out. The primary event is the release of vasopressin, which results in water retention. The increased intravascular volume stimulates a natriuresis, which actually is appropriate, but the resulting loss of sodium compounds the hyponatremia. There is an extensive list of causes of SIADH, usually involving pulmonary or central nervous system pathology (see Table 2). A number of medications also are known to stimulate vasopressin release or to potentiate its antidiuretic properties at the level of the kidney (see Tables 1 and 2).

The diagnosis of SIADH is suggested by a low P_{Osm} (<280 mOsm/kg) with a high U_{Osm} (>100 mOsm/kg), confirming water retention and an inappropriately concentrated urine. A spot urine sodium level will be greater than 20 mEq/L, and usually greater than 30 mEq/L. Other helpful laboratory findings include low plasma uric acid (<4 mg/dL), which has a positive predictive value of 73% to 100% for SIADH in this setting. In complicated cases confounded by use of diuretics, the fractional excretion of uric acid has a positive predictive value of 100% for SIADH when the calculated excretion is greater than 12%.

Reset osmostat can be considered a form of SIADH, but the hyponatremia is usually chronic, mild, and asymptomatic. Vasopressin release continues to be regulated, but at a lower threshold of plasma osmolality. The thirst threshold may be altered as well. Interventions to raise the sodium usually have short-lived effects, and the sodium resets at its previous value over time. Therefore, treatment is not recommended if the sodium level is stable and the patient is asymptomatic. A physiologic example of reset osmostat is seen in pregnancy, when the normal sodium range is lowered by 5 mEq/L.

Other Causes of Euvolemic Hypoosmolar

Hyponatremia

Primary or psychogenic polydipsia should be considered in patients presenting with hyponatremia and a history of psychiatric illness and treatment. Almost 6% to 7% of psychiatric inpatients are at risk for hyponatremia from increased water intake. The polydipsia may be related to a lowered osmolar threshold for thirst, below the threshold of suppression of vasopressin secretion. This can be further complicated by the side effect of dry mouth caused by many psychiatric medications, which compounds the increased thirst and water intake. Because the kidney is capable of excreting up to 15 to 20 L/day of dilute urine, the fact that hyponatremia develops in these patients may point toward an additional and inappropriate increase in vasopressin release or sensitivity. These patients are clinically euvolemic because of renal excretion of the excess water and have otherwise normal laboratory results except for a dilute urine (<100 mOsm/kg), which is caused by vasopressin suppression and helps differentiate primary polydipsia from SIADH. However, some patients have mildly concentrated urine (>100 mOsm/kg), in which case the psychiatric history helps with the diagnosis.

Exercise-induced hyponatremia (e.g., from marathon running) is a form of euvolemic hypoosmolar hyponatremia primarily caused by retention of water relative to fluid lost via sweating or renal excretion. Vasopressin levels are inappropriately increased during exercise-induced hyponatremia. Most importantly, it is an acute hyponatremia, developing in less than 24 hours, and should be treated accordingly.

Vasopressin levels also may be inappropriately high, secondary to pain or the use of NSAIDs, which remove prostaglandin inhibition of vasopressin release. Low solute intake combined with high fluid intake also can cause hyponatremia, as with beer potomania or a low-protein “tea and toast” diet in elderly patients. In both cases, the lack of solute in the urine does not allow retention of water in the filtrate, so the excess water is not excreted.

Hyponatremia also is common after pituitary surgery (transphenoidal or by craniotomy) and may be a result of damage to the hypothalamic-pituitary tract that causes release of preformed vasopressin from damaged neurons. Often, hyponatremia occurs as the second phase of the classic triphasic response: transient diabetes insipidus, transient SIADH, followed by permanent diabetes insipidus. Hyponatremia can be delayed up to 1 week postoperatively, and sodium should be monitored during the second week as well. Contributions by central adrenal insufficiency and hypothyroidism also are considerations after pituitary surgery, although with these conditions there will be obvious clinical manifestations in addition to the hyponatremia.

Management

The major considerations for choosing the type and time course of treatment for hyponatremia are the duration of hyponatremia (acute or chronic) and the presence of neurologic signs and symptoms, especially severe manifestations such as altered mental status or seizure (see Table 2). Treatment options for hyponatremia include fluid restriction, saline infusion (hypertonic or isotonic), vasopressin receptor antagonists and demeclocycline (Declomycin).¹ Also, treatment of the underlying abnormality, such as CHF or salt wasting, and correction of volume status are important for hypovolemic or hypervolemic patients. Autocorrection may occur after initiation of therapy, especially in cases of hypovolemia, adrenal insufficiency, or thiazide use. Once treatment is started, the contribution of the nonosmotic stimulation of vasopressin secretion is removed, and the patient is able to raise the sodium level by 2 mEq/L per hour over 12 hours.

Acute Severe Symptomatic Hyponatremia

Acute severe hyponatremia is defined as a rapid fall in sodium in less than 48 hours to less than 120 mEq/L. Under these circumstances, most patients develop neurologic symptoms because of the rapid fluid shifts between the ECF and the ICF in the brain. If left untreated, it can result in irreversible neurologic damage and death. Because of the acute drop in sodium, initial rapid correction is acceptable and should not lead to osmotic demyelination. Treatment is aimed at raising the sodium enough to resolve the neurologic signs and symptoms. The goal is to raise the serum sodium by 1 to 2 mEq/L per hour or to greater than 125 mEq/L until symptoms resolve. Hypovolemic patients will respond to infusion of isotonic saline (normal saline 0.9%), especially if the urine sodium concentration is less than 30 mEq/L. If the neurologic findings are severe, hypertonic saline (3%) may be infused at rate of 1 to 2 mL/kg per hour, or even up to 4 to 6 mL/kg per hour if the imbalance is life-threatening. A loop diuretic can be combined with the saline to enhance solute-free water excretion. In exercise-induced hyponatremia, hypertonic (3%) saline is the preferred treatment to prevent cerebral edema due to water shifting into the brain along the osmotic gradient. A hypertonic (3%) saline 100 mL bolus can be given to promptly to decrease the osmotic gradient, which is promoting water entry into cells. Thereafter, in the inpatient setting, hypertonic (3%) saline infusion should be continued to

¹Not FDA approved for this indication.

Parameters for acute or chronic hyponatremia:

Do not increase serum Na by more than 9 mEq in 24 hours and 18 mEq in 48 hours

Symptomatic hyponatremia with severe neurologic symptoms (acute <48 hrs or chronic >48 hrs)

1. Correct serum Na at a rate of 1–2 mEq/L per hour (for 2 to 4 hours) until symptoms have resolved
2. Correct Na at a rate of less than 9 mEq/24 h

Acute hyponatremia symptoms

1. Correct at rate of 0.5 to 1 mEq/L per hour to a maximum of 9 mEq/24 h

Chronic hyponatremia with mild symptoms or asymptomatic

1. Correct at a rate of 0.5 mEq/L per hour with fluid restriction
2. Treat underlying etiology

Calculation of the rate of infusion of saline to correct hyponatremia

1. Change in serum sodium per liter infusate
$$(\Delta\text{Na/L}) = \frac{\text{Infusate [sodium]} - \text{Serum [sodium]}}{\text{TBW} + 1}$$
2. Amount of infusate (in L) required in 24 hours
$$L = \frac{\text{desired change in sodium } (\Delta\text{Na}) \text{ over 24 hrs}}{\Delta\text{Na/L (from 1)}}$$
3. Rate of infusate to raise serum Na by desired amount
$$\text{ml/hr} = \frac{L \text{ (from 2)} \times 1000 \text{ mL/L}}{24 \text{ hr}}$$
4. (Simplified) Hypertonic saline infused at 1–2 mL/kg per hour

Monitoring:

1. Monitor frequently for clinical improvement or worsening of symptoms
2. If on hypertonic saline or severely symptomatic check sodium q2–4 hrs.
3. If undergoing treatment but asymptomatic, check sodium q6–12 h.

Infusate	Infusate [Na] (mmol/L)
5% sodium chloride in water	855
3% sodium chloride in water	513
Isotonic saline (0.9%)	154
Ringer's lactate solution	130
0.45% sodium chloride in water	77
0.2% sodium chloride in water	34
5% dextrose in water	0

Total Body Water (TBW) is equal to 60% of body weight in young adult men and 50% in young adult women. Older patients have less TBW. In elderly males, TBW is equal to 50% of body weight and in elderly females it is 45%.

Figure 3 Treatment of hyponatremia. *Abbreviation:* TBW = total body water.

promote correction of hyponatremia. Sodium levels should be monitored every 2 to 4 hours in patients undergoing hypertonic infusion. Once symptoms resolve, the rate of correction should be reduced to 0.5 to 1 mEq/hr, and the total rise in sodium should not exceed 18 mEq in 48 hours. No benefit has been observed for faster rates of correction of hyponatremia, whether acute or chronic. Useful formulas to determine the rate of infusion for fluids are provided in Figure 3. The formulas can only estimate the rate of correction, and sodium should be measured frequently.

Chronic Hyponatremia

Chronic hyponatremia is defined as a gradual fall in sodium over more than 48 hours. By this time, the brain has begun to compensate for hypoosmolality by extrusion of solutes. However, the patient is at risk of osmotic demyelination if hyponatremia is treated too aggressively. If the duration of hyponatremia is unknown, the recommendation is to assume that it is chronic. However, as with acute hyponatremia, severe neurologic symptoms and signs need to be treated with hypertonic saline until they resolve, after which the rate of correction can be slowed to 0.5 to 1 mEq/L per hour. Most cases of osmotic demyelination occur with correction rates of greater than 12 mEq/L in 24 hours, but there are cases reported with increases of 9 or 10 mEq/day. Asymptomatic hyponatremia can be treated with an infusion of isotonic saline calculated to raise the sodium by 0.5 to 1 mEq/hour. If the patient has a dilute urine (<200 mOsm/kg), water restriction may be sufficient.

Syndrome of Inappropriate Antidiuretic Hormone

The mainstays of treatment of SIADH are fluid restriction and treatment of the underlying cause. Mild SIADH usually can be controlled with fluid restriction alone.

In most cases of SIADH, the degree of fluid restriction required can be calculated. It is dependent on three factors: the daily osmolar load, the minimum U_{Osm} , and the patient's maximum urine volume. A typical diet has a daily osmolar load of 10 mOsm/kg of body weight. For a 70-kg person, this would be 700 mOsm/day. With SIADH, the urine osmolality is held constant for that particular patient, as revealed by a spot U_{Osm} . If the U_{Osm} is 500 mOsm/kg and the solute load is 700 mOsm, the fluid load has to be less than 700/500 or 1.4 L/day just to maintain the serum sodium level. Fluid intake above this amount will cause the sodium to decrease.

When needed, salt tablets (sodium chloride tablet 1-3 g taken once to three times daily) can help to make up for renal loss of sodium in SIADH. With symptoms and severe hyponatremia, short-term use of hypertonic saline may also be instituted to restore sodium to the ECF compartment. Loop diuretics (e.g., furosemide [Lasix]) can increase free water clearance when given with solute (e.g., hypertonic saline or salt tablets). In refractory cases, demeclocycline (300–600 mg PO twice daily)¹ can be used. Demeclocycline (Declomycin) antagonizes the actions of vasopressin by inhibiting formation of cyclic adenosine monophosphate in the collecting duct. Long-term use is limited by the side effect of photosensitivity and by nephrotoxicity in patients with underlying liver disease. Vasopressin receptor antagonists also are important adjunct treatments (see later discussion). A less commonly used treatment is urea (powder or capsules),^{1,6} which causes an osmotic diuresis and increased free water excretion. Preclinical data support that urea may decrease osmotic demyelination.

Cerebral Salt Wasting

Management of CSW involves treatment of the underlying neurologic problem, as well as volume replacement. CSW often is difficult to differentiate biochemically from SIADH, but the rise in vasopressin in CSW is secondary to volume depletion. As a result, CSW responds to volume replacement with isotonic saline, suppressing release of vasopressin, whereas SIADH worsens with this therapy. The recommended correction rate is 0.7 to 1.0 mEq/L per hour, with a maximum of 9 mEq per 24 hours. Salt tablets may also be given to replete total body sodium. Fludrocortisone (Florinef 0.05 to 0.1 mg every 12 hours), an aldosterone receptor agonist, is a third-line treatment to encourage volume expansion and sodium retention, but the potassium concentration and blood pressure should be monitored. Fluid restriction is inappropriate for CSW and should be avoided, especially in patients with subarachnoid hemorrhage, because volume depletion can exacerbate cerebral vasospasm and cause infarction. The duration of CSW is usually 3 to 5 weeks.

¹Not FDA approved for this indication.

⁶May be compounded by pharmacists.

Vasopressin Receptor Antagonists

Vasopressin receptor antagonists, or vaptans, are a treatment option for clinically significant euvolemic hyponatremia defined as a serum Na <125 mEq/L or if hyponatremia is symptomatic and resistant to correction with standard therapy. Vaptans also can be used for asymptomatic hypervolemic hyponatremia, but the benefit must clearly outweigh the risk, and the patient should be refractory to standard therapy. There are currently two FDA-approved vaptans, conivaptan (Vaprisol) and tolvaptan (Samsca). Conivaptan is a dual V_{1a}/V₂ arginine vasopressin receptor antagonist and tolvaptan is a selective V₂ arginine vasopressor receptor antagonist with about 29 times the affinity to the V₂ receptor compared to conivaptan. The primary action of both medications is to block the binding of vasopressin to its receptors in the distal nephron which leads to a decrease in translocation of the aquaporin-2 channels to the apical membrane of the collecting duct in the renal tubule. As a result, vaptans cause an increase in excretion of solute-free water resulting in a rise in serum sodium.

Conivaptan is an IV formulation approved for inpatient hospital use for euvolemic and hypervolemic hyponatremia. It is contraindicated for hypovolemic hyponatremia, euvolemic or hypervolemic hyponatremia with moderate to severe central nervous system (CNS) symptoms, and hypervolemic hyponatremia due to cirrhosis. Conivaptan should be used very cautiously in patients with hypervolemic hyponatremia due to heart failure because safety data are limited and efficacy has not been clearly established. Conivaptan is not recommended in those with severe renal impairment CrCl < 30 mL/min. Conivaptan is given intravenously with a bolus of 20 mg over 30 minutes in 100 mL of 5% dextrose in water (D5W) followed by a continuous infusion of 20 mg conivaptan diluted in 250 mL of D5W over 24 hours. After the initial day of treatment, conivaptan can be continued for an additional 1 to 3 days. Sodium is monitored every 2 to 4 hours and the dose may be titrated to 40 mg per 24 hours to obtain an increase in sodium of 0.5 to 1.0 mEq/L per hour. In clinical trials, the average rise in serum Na after 4 days of therapy is about 6 mEq/L. During conivaptan treatment, fluid restriction can be liberal or is not required. Close monitoring of the rate of sodium rise, neurologic status, and hemodynamic stability are required and treatment should be discontinued or resumed at a reduced dose if clinically indicated. The most common side effects of conivaptan are infusion site reactions and to a lesser degree headache, hypotension, nausea, constipation, and postural hypotension.

Tolvaptan is an oral V₂ receptor antagonist that carries the same indications for use as conivaptan. Tolvaptan should be initiated only in the hospital setting for careful monitoring of potassium and the rate of Na rise, and then can be used in the outpatient setting. The starting dose is 15 mg once daily and can be titrated to 60 mg daily after the initial 24 hours. Patients should not be on fluid restriction for the first 24 hours of tolvaptan therapy and be advised to drink based on thirst. Tolvaptan carries a risk of serious liver injury. The FDA recommends that tolvaptan should not be used for durations longer than 30 days or in any patient with underlying liver disease. Monitoring parameters are equivalent to conivaptan the drug should be stopped promptly in patients with abnormal liver tests or symptoms of hepatotoxicity. In clinical studies, the average rise in serum Na after 4 days of therapy is 4.2 mEq/L and 5.5 mEq/L after 30 days of therapy. The vaptans are a substrate and potent inhibitor of cytochrome P-450 3A4 isoenzyme (CYP3A4). Prior to initiation of therapy drug-drug interactions should be reviewed with the pharmacists and vaptans are contraindicated with other CYP3A4 inhibitors.

Summary

Hyponatremia is a common electrolyte abnormality and is usually caused by decreased plasma osmolality. Accurate assessment of volume status is a key to determining the underlying cause and choosing the correct treatment approach. The biggest risk of hyponatremia and its treatment is the possibility of severe neurologic sequelae, including fatal cerebral edema and osmotic demyelination. Therefore more aggressive initial treatment is needed in

patients with neurologic manifestations (hypertonic saline), but a more conservative approach (e.g., fluid restriction) is needed for less symptomatic patients. Vasopressin antagonists are additional tools for the treatment of euvolemic or hypervolemic hyponatremia refractory to more conservative measures.

HYPOPITUITARISM

Method of

Vanessa Ho, MD

CURRENT DIAGNOSIS

- Symptoms can be vague. Having heightened awareness is key to making an early diagnosis with resultant proper treatment.
- The diagnosis of hypopituitarism is based on a combination of brain imaging studies and demonstration of insufficiency of one or more pituitary hormones.
- Always confirm the diagnosis before initiating treatment.

CURRENT THERAPY

- Primary treatment of hypopituitarism is cortisol replacement.
- Treatment for hypopituitarism can be an emergency in severe cases because cortisol is responsible for supporting peripheral vascular function.
- Use higher doses of cortisol in cases of stress such as illnesses or high-risk surgeries to aid in proper recovery.

Epidemiology

In one study published in 2001 comprising a population of 146,000 in northwestern Spain, the prevalence of hypopituitarism is as high as 45.5 cases per 100,000 individuals. The incidence is estimated to be 4.2 per 100,000 per year. About 50% of patients had 3 to 5 pituitary hormonal deficiencies, with luteinizing hormone/ follicle-stimulating hormone (LH/FSH) being the most prevalent. Patients with tumor-induced hypopituitarism showed a tendency to suffer growth hormone (GH) deficiency more frequently than those resulting from nontumor causes.

Risk Factors

The most common cause of hypopituitarism is pituitary tumors (61%), followed by nonpituitary tumors (9%) (Table 1). Thirty percent of cases are caused by nontumors. Nontumor causes include inflammatory diseases such as lymphocytic hypophysitis,

Vasopressin Receptor Antagonists

Vasopressin receptor antagonists, or vaptans, are a treatment option for clinically significant euvolemic hyponatremia defined as a serum Na <125 mEq/L or if hyponatremia is symptomatic and resistant to correction with standard therapy. Vaptans also can be used for asymptomatic hypervolemic hyponatremia, but the benefit must clearly outweigh the risk, and the patient should be refractory to standard therapy. There are currently two FDA-approved vaptans, conivaptan (Vaprisol) and tolvaptan (Samsca). Conivaptan is a dual V_{1a}/V₂ arginine vasopressin receptor antagonist and tolvaptan is a selective V₂ arginine vasopressor receptor antagonist with about 29 times the affinity to the V₂ receptor compared to conivaptan. The primary action of both medications is to block the binding of vasopressin to its receptors in the distal nephron which leads to a decrease in translocation of the aquaporin-2 channels to the apical membrane of the collecting duct in the renal tubule. As a result, vaptans cause an increase in excretion of solute-free water resulting in a rise in serum sodium.

Conivaptan is an IV formulation approved for inpatient hospital use for euvolemic and hypervolemic hyponatremia. It is contraindicated for hypovolemic hyponatremia, euvolemic or hypervolemic hyponatremia with moderate to severe central nervous system (CNS) symptoms, and hypervolemic hyponatremia due to cirrhosis. Conivaptan should be used very cautiously in patients with hypervolemic hyponatremia due to heart failure because safety data are limited and efficacy has not been clearly established. Conivaptan is not recommended in those with severe renal impairment CrCl < 30 mL/min. Conivaptan is given intravenously with a bolus of 20 mg over 30 minutes in 100 mL of 5% dextrose in water (D5W) followed by a continuous infusion of 20 mg conivaptan diluted in 250 mL of D5W over 24 hours. After the initial day of treatment, conivaptan can be continued for an additional 1 to 3 days. Sodium is monitored every 2 to 4 hours and the dose may be titrated to 40 mg per 24 hours to obtain an increase in sodium of 0.5 to 1.0 mEq/L per hour. In clinical trials, the average rise in serum Na after 4 days of therapy is about 6 mEq/L. During conivaptan treatment, fluid restriction can be liberal or is not required. Close monitoring of the rate of sodium rise, neurologic status, and hemodynamic stability are required and treatment should be discontinued or resumed at a reduced dose if clinically indicated. The most common side effects of conivaptan are infusion site reactions and to a lesser degree headache, hypotension, nausea, constipation, and postural hypotension.

Tolvaptan is an oral V₂ receptor antagonist that carries the same indications for use as conivaptan. Tolvaptan should be initiated only in the hospital setting for careful monitoring of potassium and the rate of Na rise, and then can be used in the outpatient setting. The starting dose is 15 mg once daily and can be titrated to 60 mg daily after the initial 24 hours. Patients should not be on fluid restriction for the first 24 hours of tolvaptan therapy and be advised to drink based on thirst. Tolvaptan carries a risk of serious liver injury. The FDA recommends that tolvaptan should not be used for durations longer than 30 days or in any patient with underlying liver disease. Monitoring parameters are equivalent to conivaptan the drug should be stopped promptly in patients with abnormal liver tests or symptoms of hepatotoxicity. In clinical studies, the average rise in serum Na after 4 days of therapy is 4.2 mEq/L and 5.5 mEq/L after 30 days of therapy. The vaptans are a substrate and potent inhibitor of cytochrome P-450 3A4 isoenzyme (CYP3A4). Prior to initiation of therapy drug-drug interactions should be reviewed with the pharmacists and vaptans are contraindicated with other CYP3A4 inhibitors.

Summary

Hyponatremia is a common electrolyte abnormality and is usually caused by decreased plasma osmolality. Accurate assessment of volume status is a key to determining the underlying cause and choosing the correct treatment approach. The biggest risk of hyponatremia and its treatment is the possibility of severe neurologic sequelae, including fatal cerebral edema and osmotic demyelination. Vanessa Ho, MD

CURRENT DIAGNOSIS

- Symptoms can be vague. Having heightened awareness is key to making an early diagnosis with resultant proper treatment.
- The diagnosis of hypopituitarism is based on a combination of brain imaging studies and demonstration of insufficiency of one or more pituitary hormones.
- Always confirm the diagnosis before initiating treatment.

CURRENT THERAPY

- Primary treatment of hypopituitarism is cortisol replacement.
- Treatment for hypopituitarism can be an emergency in severe cases because cortisol is responsible for supporting peripheral vascular function.
- Use higher doses of cortisol in cases of stress such as illnesses or high-risk surgeries to aid in proper recovery.

Epidemiology

In one study published in 2001 comprising a population of 146,000 in northwestern Spain, the prevalence of hypopituitarism is as high as 45.5 cases per 100,000 individuals. The incidence is estimated to be 4.2 per 100,000 per year. About 50% of patients had 3 to 5 pituitary hormonal deficiencies, with luteinizing hormone/follicle-stimulating hormone (LH/FSH) being the most prevalent. Patients with tumor-induced hypopituitarism showed a tendency to suffer growth hormone (GH) deficiency more frequently than those resulting from nontumor causes.

Risk Factors

The most common cause of hypopituitarism is pituitary tumors (61%), followed by nonpituitary tumors (9%) (Table 1). Thirty percent of cases are caused by nontumors. Nontumor causes include inflammatory diseases such as lymphocytic hypophysitis,

TABLE 1 Causes of Hypopituitarism

Pituitary and nonpituitary tumors
Pituitary surgery
Pituitary radiation
Inflammatory disease—lymphocytic hypophysitis, sarcoidosis, hemochromatosis, histiocytosis X
Infectious disease—tuberculosis, syphilis
Infarction—Sheehan's syndrome, also referred to as postpartum hypopituitarism, is attributed to infarction of the pituitary gland caused by hypovolemia from obstetric hemorrhage
Pituitary apoplexy—a potentially life-threatening syndrome that occurs as a result of hemorrhage, infarction, or hemorrhagic infarction within a pituitary tumor
Genetic diseases—multiple endocrine neoplasia-1 (MEN-1) is the most common; additional genetic problems are caused by pit-1 mutation
Traumatic brain injury
Stroke—both ischemic stroke and subarachnoid hemorrhage
Suppression of hypothalamic-pituitary axis by chronic exogenous steroid use

sarcoidosis, hemochromatosis, and histiocytosis X. Infectious causes include tuberculosis and syphilis. Over the last few years, awareness and detection rates of hypopituitarism after traumatic brain injury (TBI) and subarachnoid hemorrhage (SAH) have steadily increased. Various studies have shown that cases of hypopituitarism resulting from postradiotherapy radiation damage are also on the rise. With radiation doses of 30 to 50 Gy, the incidence of GH deficiency can reach 50% to 100%; long-term gonadotropin, TSH, and ACTH deficiencies occur in 20% to 30%, 3% to 9%, and 3% to 6% of patients, respectively. With higher dose cranial irradiation (>60 Gy), or after conventional irradiation for pituitary tumors (30–50 Gy), multiple hormonal deficiencies occur in 30% to 60% after 10 years of follow-up.

Some degree of hypopituitarism is found in 35% to 40% of patients who have suffered TBI. A rule of three-quarters can be applied clinically for hypopituitarism after TBI: three-quarters of cases are male <40 years of age, three-quarters of cases occur after road traffic accidents, and three-quarters of cases manifest within 1 year.

Hypopituitarism has been observed in 19% of patients with ischemic stroke and 47% of patients with SAH, presenting as an isolated deficiency in most cases. Major risk factors for developing hypopituitarism after ischemic stroke include certain clinical conditions, such as preexisting diabetes mellitus and medical complications during hospitalization. Patients with Alberta Stroke Programme early CT scores of 7 or less have a poorer prognosis and a higher risk of developing hypopituitarism after an ischemic stroke compared with those with a score greater than 7.

Chronic exogenous steroid use is also a known cause of hypopituitarism. In one study published in 2009, Dr. Lansang and colleagues presented cases of hypopituitarism followed by multiple intraarticular and epidural injections of steroids.

Pathophysiology

The pituitary gland is a pea-sized endocrine gland that sits at the base of the brain. Often referred to as the “master gland,” the pituitary gland synthesizes and releases various hormones that affect several organs throughout the body (Figure 1). It is composed of two functionally distinct structures that differ in embryologic development and anatomy: the adenohypophysis (anterior pituitary) and the neurohypophysis (posterior pituitary). The anterior pituitary is responsible for GH, prolactin, adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), lutein (LH),

and follicular-stimulating hormone (FSH). The posterior pituitary is responsible for vasopressin and oxytocin.

Therefore any damage to the pituitary gland can cause an array of symptoms ranging from generalized weakness, generalized fatigue, low blood pressure, electrolyte abnormalities, mental confusion, and even disorientation.

Prevention

In most cases, the condition is not preventable. Awareness can lead to early detection and proper treatment. As little as 7.5 mg of prednisone/prednisolone (Millipred) or 0.75 mg of dexamethasone (Decadron) daily for more than 3 weeks can suppress the HPA axis. This suppression may last for months after the exogenous steroid is stopped. Therefore, to reduce the risk of developing suppression of the HPA axis, we recommend the use of steroids for the shortest time possible and in the smallest dose possible, and to taper down the steroids slowly if used for longer than 2 weeks.

Clinical Manifestation

Signs and symptoms of hypopituitarism vary, depending on which pituitary hormones are deficient and how severe the deficiency is. They may include

- ACTH deficiency—generalized fatigue, generalized weakness, failure to thrive, tachycardia, hypotension, electrolyte abnormalities, confusion, and even disorientation
- TSH deficiency—fatigue, weight gain, cold intolerance
- Gonadotropin deficiency—decreased sex drive, infertility, hot flashes, irregular or no periods, inability to produce milk
- GH deficiency—failure to thrive and short stature in children; most adults are asymptomatic, but some may experience fatigue and weakness
- Anti-diuretic hormone (ADH) deficiency—polyuria, polydipsia, electrolyte abnormalities

Diagnosis

The diagnosis of hypopituitarism is based on a combination of high clinical suspicion, brain imaging studies, and demonstration of insufficiency of one or more pituitary hormones (Figure 2).

A. Corticotropin

1. Total cortisol level:

Normally, cortisol levels rise during the early morning hours and are highest at about 7 AM. They drop very low in the evening and during the early phase of sleep. Therefore cortisol level should be measured early morning and no later than 9 AM. The normal level is between 4.0 and 22.0 µg/dL. An early-morning serum cortisol level ≤3 µg/dL is abnormal. The next step is to repeat the test for confirmation and at the same time check a serum ACTH level to establish the diagnosis. A low or normal ACTH level is sufficient to make a diagnosis of hypopituitarism versus a high ACTH level that suggests a diagnosis of primary adrenal insufficiency. If the cortisol level is borderline between 4.0 and 10.0 µg/dL, an ACTH stimulation test should be performed to confirm the diagnosis.

2. ACTH stimulation tests:

- Metyrapone response test—or 11-Deoxycortisol (Compound S) test. The metyrapone test is used to evaluate inhibition of cortisol production with metyrapone (Metopirone) and a resultant increase of ACTH in response to the drop of cortisol. Metyrapone blocks cortisol production by inhibiting 11β-hydroxylase. The drop in cortisol stimulates ACTH secretion, which in turn increases plasma 11-deoxycortisol levels. The long version involves 24-hour inpatient admission because of the risk of hypotension. The short version involves the administration of a single dose of metyrapone at midnight and the measurement of serum cortisol in the morning. However, the inhibition of cortisol production may be partial, leading to a partial ACTH response and an inconclusive test result.

To conduct the metapyrone response test, metyrapone (30 mg/kg, maximum dose 3000 mg) is administered at

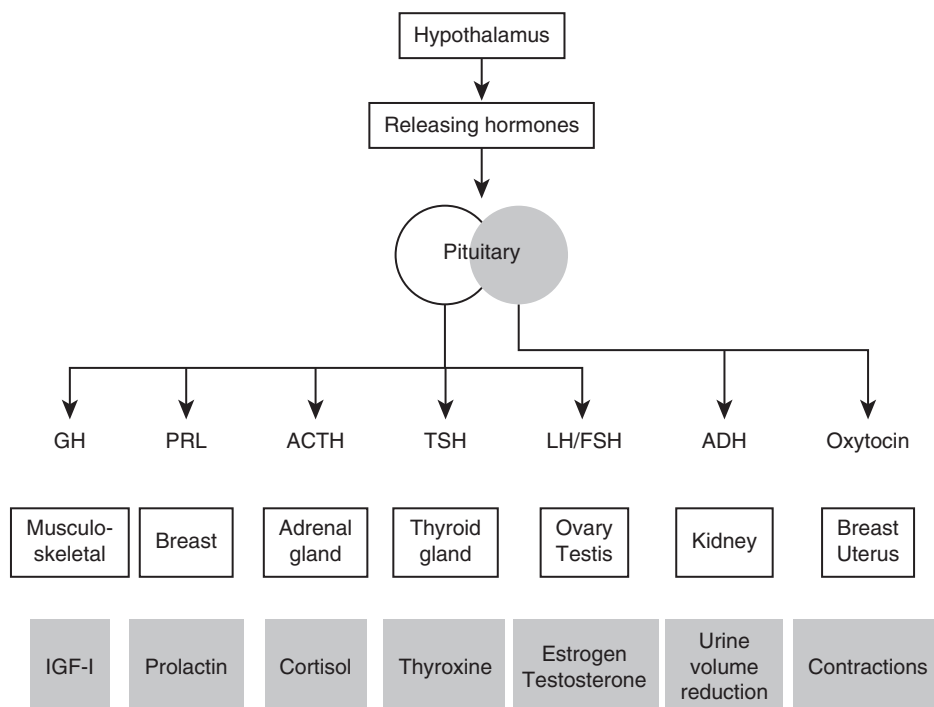

Figure 1 The pituitary gland.

Figure 2 The diagnosis of hypopituitarism.

midnight usually with a snack. The plasma cortisol and 11-deoxycortisol are measured the next morning between 8:00 and 9:00 AM. A plasma cortisol less than 220 nmol/L indicates adequate inhibition of 11 β -hydroxylase. In patients with an intact hypothalamo-pituitary-adrenal (HPA) axis, CRH and ACTH levels rise as a response to the falling cortisol levels. This results in an increase of the steroid precursors in the pathway, including 11-deoxycortisol. Therefore, if the ACTH level rises and 11-deoxycortisol levels do not rise and remain less than 7 μ g/dL, it is highly suggestive of impaired adrenal insufficiency. If neither ACTH or 11-deoxycortisol rise, it is highly suggestive of an impaired HPA axis at either the pituitary or hypothalamus.

- Cosyntropin (Cortrosyn) stimulation test—or ACTH stimulation test, is more appropriate than the metapyrone test to perform in an outpatient setting. It involves administering 0.25 mg of cosyntropin (Cortrosyn) to patients and measuring the serum cortisol level 60 minutes later. A 60-minute cortisol level of less than 18 μ g/dL is suggestive of abnormal pituitary response or hypopituitarism.
- B. Thyrotropin—Patients who have pituitary or hypothalamic diseases may have secondary hypothyroidism. In primary hypothyroidism caused by thyroid gland disorders, the TSH level will be high. In pituitary or hypothalamic disease, the TSH level will be low. Thus it is important to measure not only TSH but also “total T4” and “T3 uptake” or “free T4” levels to make the diagnosis.
- C. Gonadotropins—Patients who have pituitary or hypothalamic diseases may have secondary hypogonadism. The characteristics of secondary hypogonadism are a low estrogen level in women or a low testosterone level in men and low or normal FSH and LH. On the contrary, primary hypogonadism caused by ovarian or testicular failure would result in low estrogen or testosterone levels and likely elevated FSH and LH.
- D. GH—A measurement of basal serum GH concentration is not reliable. A diagnosis of GH deficiency is based on “serum IGF-1 concentration.” A concentration lower than the age-specific normal level confirms the diagnosis of GH deficiency. Alternatively, a provocative test of GH secretion such as the arginine-GHRH test can be performed. Suboptimal increases in the serum GH concentration (less than 4.1 ng/mL) confirm the diagnosis of GH deficiency.

Differential Diagnosis

The differential diagnoses of hypopituitarism consist of isolated primary organ failure and deficiencies such as adrenal insufficiency, thyroid gland disorders, and primary ovarian or testicular failure.

Hypopituitarism may manifest several years after radiation exposure and in chronic Sheehan's syndrome. In acute pituitary failure, as in Sheehan's syndrome, the ACTH stimulation test may be normal because the adrenal glands are not atrophied in the acute setting; adrenal atrophy may require at least 3 months to develop. For many women, the symptoms of Sheehan's syndrome, such as fatigue, are nonspecific and often attributed to other things. It is possible for a woman to be symptom-free with Sheehan's syndrome. A woman might not realize that she has Sheehan's syndrome until she requires treatment for thyroid or adrenal insufficiency. Some women unknowingly live for years with pituitary insufficiency, then

go into adrenal crisis triggered by extreme physical stressors, such as severe infection or surgery.

Treatment

Hypopituitarism can be an emergency in severe cases because of the risk of vascular collapse because cortisol is necessary for the maintenance of peripheral vascular function. Less severe cases can cause persistent hypotension and tachycardia.

The primary treatment of hypopituitarism is cortisol replacement. However, should the workup reveal other hormone deficiencies, replacement therapy for other hormones is indicated.

A. Corticosteroids

1. Oral hydrocortisone (Cortef) 15 to 25 mg a day in divided doses is the preferred treatment, because those doses are similar to physiologic daily production rates. Some patients, however, may need a higher or lower dose depending on the degree of severity. The problem with current hydrocortisone replacement regimens is that they are fixed doses given two to three times daily. Current regimens do not reflect the normal circadian pattern of physiological cortisol concentrations, which rise highest in the morning, to an intermediate level in the afternoon, and to low levels in the evening, with a cortisol-free interval at night. The current replacement regimens inevitably result in temporary over- or underreplacement and therefore result in a poor quality of life and increased mortality. Recent effort has studied sustained-release once-a-day hydrocortisone therapy versus a thrice-daily, weight-related dosing regimen. Plenadren is a recently licensed modified-release formulation of hydrocortisone that provides the potential for once-daily dosing. Plenadren provides cortisol concentrations in the afternoon but not in the evening; it does not provide an overnight rise in cortisol concentrations, such that patients have a long period of low cortisol concentrations from late afternoon to when they take their next morning dose. A pilot Chronocort² formulation demonstrated delayed release and an overnight rise in cortisol after about 4 hours of administering 30 mg at 10 PM. Pharmacokinetic modeling of Chronocort suggested that giving a 20-mg dose at 10 PM and a 10-mg dose at 7 PM could replicate the normal physiologic cortisol rhythm. Both are currently approved to be used in Europe and are in Phase 2 clinical trials in the United States.
2. Some authorities suggest prednisone or dexamethasone because of their longer duration of action. They can be given once a day, versus hydrocortisone, which is administered two to three times a day.
3. Patients may need a higher dose of hydrocortisone in times of illnesses or other stresses. Before planned surgeries, high-dose hydrocortisone (Solu Cortef) as stress doses for 1 to 3 days allows faster recovery (Table 2).
- B. Thyroid deficiency—Thyroid deficiency from hypopituitarism is treated with T₃ and T₄ in a fashion similar to the treatment of primary hypothyroidism. However, treatment of secondary hypothyroidism should not be administered until adrenal

²Not available in the United States.

TABLE 2 Recommended Perioperative Hydrocortisone Dosage for Patients on Long-Term Steroid Therapy*

SURGICAL RISKS	EXAMPLES	RECOMMENDATIONS
Minor surgery	Endoscopy, colonoscopy, inguinal herniography	Take the usual morning dose. Then take 25 mg/day for 1 day starting before surgery
Moderate surgery	Total joint replacement	Take the usual morning dose. Then take 50–75 mg/day for 1–2 days
Major surgery	Cardiopulmonary bypass	Take the usual morning dose. Then 100–150 mg/day for 2–3 days

From Shawn (2012).

*Based on the recommendations of Salem M, Tainsh RE Jr, Bromberg J, Loriaux DL, Chernow B. Perioperative glucocorticoid coverage: A reassessment 42 years after emergence of a problem. *Ann Surg* 1994; 219:416-425.

function is restored and found to be normal. Treatment of the hypothyroidism alone may suppress other hormones produced by the pituitary gland and worsen the severity of other deficiencies. Similarly, TSH cannot be used as a guide for thyroid replacement in hypopituitarism; dose adjustment should be based on free T_3 and free T_4 levels instead.

- C. Sex hormone deficiency—This includes testosterone, estrogen, and progesterone. The decision to initiate hormone therapy should be individualized. Risks and benefits should be discussed with patients extensively.
- D. GH deficiency—GH replacement is now available as somatropin injections (Accretropin, Genotropin, Humatrope). GH is indicated for treatment of pediatric patients who have growth failure or for treatment of short stature associated with Turner syndrome in pediatric patients whose epiphyses are not closed. GH is not indicated for treatment of adult onset deficiency.

Monitoring

Periodic serum cortisol levels are used to assess treatment adequacy and make adjustments as needed. Most studies use cortisol levels taken approximately 4 hours after the morning cortisol dose. The challenge of measuring serum cortisol levels is that cortisol sensitivity and concentrations vary between individuals. The total daily hydrocortisone dose should be based on the patient's clinical symptoms, not just cortisol level alone.

Complications

Most of the complications of hypopituitarism are caused by a failure to diagnose the condition. Having a high clinical suspicion is the key, especially after significant traumatic events such as cardiac arrests, acute emergency surgeries, or severe motor vehicle accidents. Inadequate replacement of hormone therapy can lead to persistent symptoms, whereas excessive replacement of hormones can lead to other conditions, such as Cushing's syndrome.

HYPOTHYROIDISM

Method of

William J. Hueston, MD

CURRENT DIAGNOSIS

- Hypothyroidism is more common in women as they age.
- The signs and symptoms of hypothyroidism are nonspecific and can mimic other diseases found in the elderly, so clinicians need to have a high index of suspicion.

- The key diagnostic test is to find a low free T_4 . The presence of an elevated TSH indicates primary hypothyroidism, and a low TSH indicates secondary hypothyroidism.
- There is insufficient evidence for screening for hypothyroidism in asymptomatic adults.

CURRENT THERAPY

- Thyroxine replacement with L-thyroxine (Synthroid, Levoxyl) is the treatment for hypothyroidism. Medication should be titrated to normalize the thyroid-stimulating hormone (TSH) level, which is usually achieved at an overall dose of 100 to 150 μg .
- Initial dosing for those with potential cardiac disease should be started low (25–50 $\mu\text{g}/\text{day}$) and advanced slowly every 6 to 8 weeks.
- Partial substitution of triiodothyronine (Cytomel) for thyroxine should be reserved for elderly patients with persistent neurocognitive dysfunction despite normalization of their TSH.
- Patients who have subclinical hypothyroidism with a TSH >10.0 should be considered for treatment. Patients with a TSH lower than this do not require therapy.

Epidemiology

Hypothyroidism is second only to diabetes in the prevalence of endocrine disorders in adults in the United States. Hypothyroidism occurs in up to 18/1000 population, with women outnumbering men by approximately 10:1. Rates of hypothyroidism increase dramatically with age, so that about 2% to 3% of all older women have hypothyroidism, and the prevalence is up to 5% in nursing home populations.

The prevalence of subclinical hypothyroidism, defined as an elevated TSH in the presence of normal free thyroxine (T_4) and triiodothyronine (T_3) levels increases with advancing age. Women, individuals over 65, and those from European heritage are at higher risk for subclinical hypothyroidism.

Risk Factors

Thyroid conditions are more common in patients who have a family history of thyroid disorders. In addition, hypothyroidism, as well as thyroid cancers, are more common in patients who had neck irradiation in childhood. However, most cases of hypothyroidism occur in people who have no risk factors.

Pathophysiology

Several conditions can lead to hypothyroidism (Box 1). Two categories, hypothyroidism after thyroiditis and iatrogenic hypothyroidism secondary to treatment of Graves' disease, account for the overwhelming majority of cases of hypothyroidism in the United States.

The most common non-iatrogenic condition causing hypothyroidism in the United States is Hashimoto's thyroiditis. Most idiopathic hypothyroidism also represents Hashimoto's thyroiditis that has followed an indolent course. Hashimoto's thyroiditis, also called chronic lymphocytic thyroiditis, is the most common of the inflammatory thyroid disorders and the most common cause of goiter in the United States. The prevalence of Hashimoto's thyroiditis has been increasing dramatically since the 1960s in the United States, but the cause for this rise is unknown. In patients with acute thyroiditis, either subacute granulomatous (also known as de Quervain's) and subacute lymphocytic (also known as silent or painless), transient hypothyroidism is common after an acute attack, and 10% of these patients also develop long-term hypothyroidism.

Another common cause of hypothyroidism is a medical intervention to treat Graves' disease or thyroidectomy for chronic fibrocytic thyroiditis (Riedel's struma). Radioactive iodine ablation of the

function is restored and found to be normal. Treatment of the hypothyroidism alone may suppress other hormones produced by the pituitary gland and worsen the severity of other deficiencies. Similarly, TSH cannot be used as a guide for thyroid replacement in hypopituitarism; dose adjustment should be based on free T_3 and free T_4 levels instead.

- C. Sex hormone deficiency—This includes testosterone, estrogen, and progesterone. The decision to initiate hormone therapy should be individualized. Risks and benefits should be discussed with patients extensively.
- D. GH deficiency—GH replacement is now available as somatropin injections (Accretropin, Genotropin, Humatrope). GH is indicated for treatment of pediatric patients who have growth failure or for treatment of short stature associated with Turner syndrome in pediatric patients whose epiphyses are not closed. GH is not indicated for treatment of adult onset deficiency.

Monitoring

Periodic serum cortisol levels are used to assess treatment adequacy and make adjustments as needed. Most studies use cortisol levels taken approximately 4 hours after the morning cortisol dose. The challenge of measuring serum cortisol levels is that cortisol sensitivity and concentrations vary between individuals. The total daily hydrocortisone dose should be based on the patient's clinical symptoms, not just cortisol level alone.

Complications

Most of the complications of hypopituitarism are caused by a failure to diagnose the condition. Having a high clinical suspicion is the key, especially after significant traumatic events such as cardiac arrests, acute emergency surgeries, or severe motor vehicle accidents. Inadequate replacement of hormone therapy can lead to persistent symptoms, whereas excessive replacement of hormones can lead to other conditions, such as Cushing's syndrome.

HYPOTHYROIDISM

Method of

William J. Hueston, MD

CURRENT DIAGNOSIS

- Hypothyroidism is more common in women as they age.
- The signs and symptoms of hypothyroidism are nonspecific and can mimic other diseases found in the elderly, so clinicians need to have a high index of suspicion.

- The key diagnostic test is to find a low free T_4 . The presence of an elevated TSH indicates primary hypothyroidism, and a low TSH indicates secondary hypothyroidism.
- There is insufficient evidence for screening for hypothyroidism in asymptomatic adults.

CURRENT THERAPY

- Thyroxine replacement with L-thyroxine (Synthroid, Levoxyl) is the treatment for hypothyroidism. Medication should be titrated to normalize the thyroid-stimulating hormone (TSH) level, which is usually achieved at an overall dose of 100 to 150 μg .
- Initial dosing for those with potential cardiac disease should be started low (25–50 $\mu\text{g}/\text{day}$) and advanced slowly every 6 to 8 weeks.
- Partial substitution of triiodothyronine (Cytomel) for thyroxine should be reserved for elderly patients with persistent neurocognitive dysfunction despite normalization of their TSH.
- Patients who have subclinical hypothyroidism with a TSH >10.0 should be considered for treatment. Patients with a TSH lower than this do not require therapy.

Epidemiology

Hypothyroidism is second only to diabetes in the prevalence of endocrine disorders in adults in the United States. Hypothyroidism occurs in up to 18/1000 population, with women outnumbering men by approximately 10:1. Rates of hypothyroidism increase dramatically with age, so that about 2% to 3% of all older women have hypothyroidism, and the prevalence is up to 5% in nursing home populations.

The prevalence of subclinical hypothyroidism, defined as an elevated TSH in the presence of normal free thyroxine (T_4) and triiodothyronine (T_3) levels increases with advancing age. Women, individuals over 65, and those from European heritage are at higher risk for subclinical hypothyroidism.

Risk Factors

Thyroid conditions are more common in patients who have a family history of thyroid disorders. In addition, hypothyroidism, as well as thyroid cancers, are more common in patients who had neck irradiation in childhood. However, most cases of hypothyroidism occur in people who have no risk factors.

Pathophysiology

Several conditions can lead to hypothyroidism (Box 1). Two categories, hypothyroidism after thyroiditis and iatrogenic hypothyroidism secondary to treatment of Graves' disease, account for the overwhelming majority of cases of hypothyroidism in the United States.

The most common non-iatrogenic condition causing hypothyroidism in the United States is Hashimoto's thyroiditis. Most idiopathic hypothyroidism also represents Hashimoto's thyroiditis that has followed an indolent course. Hashimoto's thyroiditis, also called chronic lymphocytic thyroiditis, is the most common of the inflammatory thyroid disorders and the most common cause of goiter in the United States. The prevalence of Hashimoto's thyroiditis has been increasing dramatically since the 1960s in the United States, but the cause for this rise is unknown. In patients with acute thyroiditis, either subacute granulomatous (also known as de Quervain's) and subacute lymphocytic (also known as silent or painless), transient hypothyroidism is common after an acute attack, and 10% of these patients also develop long-term hypothyroidism.

Another common cause of hypothyroidism is a medical intervention to treat Graves' disease or thyroidectomy for chronic fibrocytic thyroiditis (Riedel's struma). Radioactive iodine ablation of the

BOX 1 Conditions Causing Hypothyroidism**Thyroiditis**

Hashimoto's thyroiditis
 Subacute granulomatous thyroiditis (de Quervain's thyroiditis)
 Subacute lymphocytic thyroiditis (silent or painless thyroiditis)

Iatrogenic Hypothyroidism

Radioactive iodine treatment of Graves' disease
 Thyroidectomy

Secondary Hypothyroidism (Pituitary Dysfunction)

Pituitary surgery
 Intracranial radiation
 Congenital panhypopituitarism

Other Causes

Infiltrative diseases (sarcoidosis, amyloidosis, hemochromatosis)
 Drugs (lithium, interferon, amiodarone [Cordarone])
 Iodine deficiency

BOX 2 Symptoms and Signs of Hypothyroidism**Common Symptoms**

Lethargy
 Weight gain
 Constipation
 Slowed mentation, forgetfulness
 Depression
 Hair loss
 Dry skin
 Neck enlargement or goiter

Physical Examination Findings

Goiter
 Low blood pressure and slow pulse
 Hair thinning or loss
 Dry skin
 Confusion
 Depressed affect
 Non-pitting edema

thyroid for Graves' disease often results in underproduction of thyroxine in the remaining tissue, necessitating thyroid replacement.

A third uncommon cause of hypothyroidism that should not be overlooked is secondary hypothyroidism due to hypothalamic or pituitary dysfunction. These conditions are seen primarily in patients who have received intracranial irradiation or surgical removal of a pituitary adenoma.

Finally, a variety of other conditions including infiltration of the thyroid (amyloidosis, sarcoidosis), iodine deficiency, or medications (such as amiodarone [Cordarone] or interferon) can cause hypothyroidism.

Prevention

There are no known interventions to prevent hypothyroidism. According to their 2015 analysis, the US Preventive Services Task Force found insufficient evidence to support early detection through routine screening of asymptomatic persons.

Clinical Manifestations

Individual who have hypothyroidism can present with a variety of symptoms, many of which are not specific. Consequently, clinicians must have a high index of suspicion for hypothyroidism when patients come in with any one or combination of the symptoms that could signal hypothyroidism.

Symptoms of hypothyroidism include lethargy, weight gain, hair loss, dry skin, constipation, poor concentration, trouble thinking or forgetfulness, and depression (Box 2). In older patients, hypothyroidism easily can be confused with Alzheimer's disease or other conditions that cause dementia. Patients who present with depression also should have their thyroid function assessed.

The thyroid examination in most patients with hypothyroidism is completely normal. Patients might have a painless goiter; tenderness in the thyroid is generally a sign of active inflammation consistent with acute thyroiditis. Once the thyroid inflammation has subsided, thyroid function might return to normal. Other physical findings that can occur with hypothyroidism include low blood pressure, bradycardia, nonpitting edema, generalized hair loss especially along the outer third of the eyebrows, dry skin, and a lag in the relaxation phase of reflexes that can be assessed most easily in the ankle jerk reflexes.

Finally, there is an association between hypothyroidism and obstructive sleep apnea although it is unclear if this is a causal relationship.

Subclinical hypothyroidism usually has no, or very subtle clinical symptoms which could be explained by other conditions. The primary finding in subclinical hypothyroidism is the abnormal laboratory values. Subclinical hypothyroidism in pregnancy is associated with increases in pregnancy loss, premature rupture of membranes, and neonatal death, but limited evidence does

not show a reduction in these risks with thyroid supplementation during pregnancy.

Diagnosis

The diagnosis of hypothyroidism is based on finding a low free thyroxine (T_4) level, usually with an elevation in the thyroid stimulating hormone (TSH) levels. For patients with hypothyroidism due to pituitary dysfunction, also called secondary hypothyroidism, both the free T_4 and the TSH levels are low.

One situation where clinicians need to be wary is evaluating thyroid status in patients who are severely ill. During times of acute physiological stress, patients may have mildly elevated TSH levels that suggest hypothyroidism but are, in fact, euthyroid. This condition, called euthyroid sick syndrome, does not require treatment with thyroid replacement and resolves within a few weeks of recovery, but it may be difficult to distinguish from preexisting or new-onset hypothyroidism. Clinicians need to use other clinical symptoms to try to differentiate euthyroid sick syndrome from hypothyroidism. Even though it does not require treatment, the presence of euthyroid sick syndrome in a critically ill patient is a poor prognostic sign.

In contrast to hyperthyroidism, there is no role for thyroid scans or iodine uptake testing in patients with hypothyroidism. The only exception to this is when the clinician identifies a mass on physical examination. In that situation, scanning or other imaging is essential to determine the malignancy potential of the mass.

Differential Diagnosis

The differential diagnosis for hypothyroidism is broad and depends on the primary complaints given by patients. For patients with slowed mentation, depressed affect, or confusion, clinicians should suspect depression. Patients with lethargy and a slow pulse and low blood pressure might have adrenal insufficiency. Patients with constipation need to have colonic obstruction from a mass considered as well. In the elderly, common drugs that can cause depression (such as centrally acting antihypertensive agents), bradycardia (such as β -blockers or calcium channel blockers), constipation (calcium channel blockers), hair loss, or confusion also should be considered.

In patients with pituitary failure, other pituitary hormones are likely to be deficient as well, so clinicians should look for evidence of adrenal and gonadotropic failure.

Treatment

The treatment for hypothyroidism is thyroxine replacement (Synthroid, Levoxyl). The usual dose required to achieve full replacement is between 100 μ g and 150 μ g, although patients who are treated with radioactive iodine and have some remaining thyroid

activity might require lower doses. For patients with known heart disease or at risk for heart problems, doses should be initiated at 25 to 50 µg with increases of 25 µg every 4 to 6 weeks guided by TSH levels. Young patients who are at low risk for cardiac problems can be started at doses of 100 µg.

In choosing an agent to use for thyroid replacement, there is good evidence that generic substitutes are just as effective as brand-name drugs. A detailed study examining the metabolic effectiveness of a variety of generic drugs compared with a brand-name medication demonstrated no clinical or subclinical differences among preparations. So even though clinicians often hear that they should use a brand-name drug to maintain the stability of the replacement dose, this is not supported by the evidence.

One area of uncertainty is whether the addition of triiodothyronine (T₃, Cytomel) adds additional benefit to thyroid replacement with thyroxine. In some studies with elderly patients, subjects with continued neurocognitive dysfunction benefited from the addition of T₃ at a dose of 125 µg, with a concomitant decrease in the T₄ dose of 50 µg. However, subsequent studies of younger patients (aged 29–44 years) failed to find any benefits of partial T₃ substitution. Furthermore, studies of patients on doses of T₄ adequate to restore TSH levels to normal have been found to have normal T₃ levels. At this time, routine use of T₃ cannot be recommended; however, for selected elderly patients who have lingering confusion, depression, or slow mentation on adequate doses of T₄, a trial of T₃ partial substitution might be tried. Both the American Thyroid Association and European Thyroid Association recommend a trial of combination therapy for patients who are using single therapy with thyroxine alone who are persistently dissatisfied with their therapy.

Another situation where there is controversy is the use of thyroid replacement in patients with a mildly elevated TSH and a normal free T₄. This condition, called subacute hypothyroidism or mild hypothyroidism, is more common in white elderly women. Some studies have shown clinical improvement in symptoms when low doses of T₄ are given to these patients, although the patient populations tend to be those with preexisting thyroid disease (such as Graves' disease), and studies have had only a small number of patients. An expert panel has suggested using the TSH level as an indication for therapy. When the TSH is <7, almost half of all patients will revert to normal within 2 years. Patients with a TSH <10 do not require any therapy unless there are other individual patient risk factors such as existing cardiac disease or cognitive symptoms. Treatment is reasonable in those with a TSH level of 10.0 because these patients may be most symptomatic and have a progression to overt hypothyroidism of 5%.

Monitoring

In general, once a patient receives a full replacement dose of T₄ (usually between 100 and 150 µg) and has a TSH consistently in the normal range, there is little likelihood that their thyroid requirement will change over time. Although many advocate annual retesting of TSH to ensure patients are euthyroid, there is no evidence to show this is necessary.

Some conditions do warrant closer monitoring of the TSH level. Because T₄ and T₃ are highly protein bound, any conditions where a patient's serum protein status changes should prompt additional testing. This includes conditions that lower serum protein levels, such as liver disease, nephrotic syndrome, or malnutrition, as well as those where serum proteins are increased, such as pregnancy or initiation of estrogen therapy. Because patients' dietary protein usually decreases with advancing age, older patients whose diet declines can also require monitoring and a lowering of their T₄ dose over time.

Patients with subclinical hypothyroidism also might benefit from annual retesting of their free T₄ levels. Approximately 10% of patients with subacute hypothyroidism progress to hypothyroidism within 3 years of diagnosis. Because of this, yearly testing is recommended. Also, 50% of patients with subacute hypothyroidism have positive anti-thyroid antibodies; however, routine testing for these is not recommended.

Complications

Most of the complications of hypothyroidism are associated with undertreatment or overtreatment. Patients with inadequately treated hypothyroidism are at higher risk for cardiac disease. On the other hand, over-replacement of thyroxine increases the risk of both atrial fibrillation and osteoporosis.

In addition, Hashimoto's thyroiditis is associated with other endocrine autoimmune diseases such as Addison's disease and pernicious anemia. Clinicians should be aware of these associations and not overlook new endocrine disorders that might have clinical features similar to hypothyroidism.

Finally, patients with Hashimoto's hypothyroidism also are at higher risk for the future development of lymphoma. Clinicians should educate patients about the need to have newly enlarged lymph nodes evaluated and be aggressive about evaluating symptoms or signs consistent with the development of a lymphoma.

OBSESITY

Method of

Ana L. Creo, MD; and Seema Kumar, MD

CURRENT DIAGNOSIS

- Body mass index (BMI) is calculated as weight in kilograms divided by height in meters squared (kg/m²). BMI is currently the preferred method for determining whether a patient is obese.
- Patients with a BMI of 30 or greater are considered obese; those with a BMI between 25 and 29.9 are considered overweight. For Asians, overweight is a BMI between 23 and 24.9 kg/m² and obesity a BMI >25 kg/m².
- Abdominal circumference should also be measured to assess for abdominal obesity.
- A waist circumference of >102 cm (40 in) in men or >88 cm (35 in) in women is considered indicative of abdominal obesity. A waist circumference of >80 cm in Asian females and >90 cm in Asian males is considered abnormal.

CURRENT THERAPY

- Treatment of patients with obesity requires a multidisciplinary team approach.
- Lifestyle modifications, including dietary changes and increased physical activity, remain first-line treatment for patients with obesity.
- Adjuvant pharmacotherapy may be considered for patients with a BMI greater than 30 kg/m² or a BMI of 27 to 30 kg/m² with concomitant weight-related complications.
- Bariatric surgery should be considered for patients with a BMI of 40 kg/m² or greater and for those with a BMI of 35 kg/m² or

activity might require lower doses. For patients with known heart disease or at risk for heart problems, doses should be initiated at 25 to 50 µg with increases of 25 µg every 4 to 6 weeks guided by TSH levels. Young patients who are at low risk for cardiac problems can be started at doses of 100 µg.

In choosing an agent to use for thyroid replacement, there is good evidence that generic substitutes are just as effective as brand-name drugs. A detailed study examining the metabolic effectiveness of a variety of generic drugs compared with a brand-name medication demonstrated no clinical or subclinical differences among preparations. greater who have significant comorbidities such as severe diabetes, sleep apnea, or joint disease after nonsurgical weight loss attempts have failed.

Epidemiology

Obesity is a complex disease that represents a growing epidemic in the United States and worldwide. In the 2013–2014 National Health and Nutrition Examination Survey (NHANES), 35% of adult men and 40.4% of adult women were noted to be obese. The prevalence of obesity has increased among women from 2005 to 2014 but has not changed in men. There are disparities in the prevalence of obesity between ethnic groups, especially among women. In the United States, the prevalence of obesity is highest in non-Hispanic black women. The American Medical Association recently officially classified obesity as a disease due to its association with several comorbidities and increased mortality.

Diagnosis

Obesity is a condition marked by the accumulation of excess body fat. The body mass index (BMI) is the most practical way to evaluate the degree of excess weight. It is calculated from the weight (in kilograms) and the square of the height (in meters), as follows:

$$\text{BMI} = \frac{\text{Weight}}{\text{Height}^2}$$

The World Health Organization (WHO) and National Institutes of Health (NIH) define overweight as a BMI between 25 and 29.9 kg/m² and obesity as a BMI equal to greater than 30 kg/m² (Table 1). These guidelines apply to whites, Hispanics, and blacks. Because Asians can have higher percentage of body fat at a lower BMI, overweight for this particular ethnic group is a BMI between 23 and 24.9 kg/m², and obesity is a BMI equal to or greater than 25 kg/m². The BMI correlates with percentage of body fat and body fat mass, as well as with mortality. The BMI may, however, overestimate the degree of body fat in athletes. However, for a given BMI, the degree of body fatness tends to be higher in women compared with men, and it is higher in older compared with younger people. The relationship between BMI and mortality appears to form a J- or U-shaped curve, with the lowest mortality rate seen in those with a BMI of about 25 kg/m² (Figure 1).

Because people with abdominal (central) adiposity are more likely to develop many of the health conditions associated with obesity, waist circumference is an important adjunct measurement to obtain when screening for obesity. Waist circumference is measured at the level of the top of the iliac crest with the measuring tape snug against the skin. In adults with a BMI of 25 to 34.9 kg/m², a waist circumference greater than 102 cm (40 in) for men and 88 cm (35 in) for women is associated with a greater

risk of hypertension, type 2 diabetes, dyslipidemia, and coronary heart disease (CHD) (see Table 1). In patients with a BMI ≥ 35 kg/m², measurement of waist circumference is less helpful because it adds little to the predictive power of the disease risk classification of BMI; almost all individuals with this BMI also have an abnormal waist circumference. More precise measurement of abdominal fat can be made with abdominal computed tomography or magnetic resonance imaging. Alternative methods to assess body composition and degree of fatness include measurements of skin fold thickness, hydrostatic weighing, bioelectric impedance, and scanning by dual-energy x-ray absorptiometry. These methods require specialized equipment and trained personnel and are not used routinely in clinical practice.

Etiology and Pathophysiology

Obesity is a complex, multifactorial disease characterized by excessive caloric consumption and inadequate caloric expenditure. Many factors, including genetic and environmental influences, can contribute to the development of obesity. However, personal decisions regarding food choices, portion sizes, and level of activity also contribute to body size.

When evaluating a patient with obesity, it is important to rule out disorders such as Cushing's syndrome and hypothyroidism. Because many medications promote weight gain, including several antipsychotics, antidepressants, antiepileptics, sulfonylureas, and steroids (Table 2), it is prudent to obtain a complete medication history from any patient who is being evaluated for obesity. Single-gene mutations (e.g., in the melanocortin 4 receptor gene and leptin gene) and congenital syndromes (e.g., Prader-Willi, Bardet-Biedel, Cohen) typically cause early-onset obesity before 5 years of age.

Associated Comorbidities

Obesity is associated with a variety of other medical conditions that can increase morbidity and mortality. Comorbidities associated with obesity include metabolic syndrome and insulin resistance, type 2 diabetes, dyslipidemia, hypertension, coronary artery disease, degenerative joint disease, nonalcoholic fatty liver disease (NAFLD), and obstructive sleep apnea.

Insulin Resistance and Metabolic Syndrome

Insulin resistance is defined as a subnormal response to endogenous insulin. This results in pancreatic B-cell compensation with hypersecretion of insulin. Insulin resistance leads to various components of the metabolic syndrome, including low HDL cholesterol, high triglycerides, elevated blood pressure, and hyperglycemia. Patients may also manifest acanthosis nigricans and skin tags.

Type 2 Diabetes

The increasing prevalence of obesity has also resulted in an increasing prevalence of type 2 diabetes. More than 80% of type 2 diabetes can be attributed to obesity, but other factors, such as family

TABLE 1 Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Health Risk

CLASSIFICATION	BMI (kg/m ²)	DISEASE RISK*	
		WAIST ≤ 102 cm (≤ 40 in) IN MEN OR ≤ 88 cm (≤ 35 in) IN WOMEN	WAIST > 102 cm (> 40 in) IN MEN OR > 88 cm (> 35 in) IN WOMEN

*Disease risk for type 2 diabetes, hypertension, and cardiovascular disease relative to normal weight and waist circumference.

[†]Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

Figure 1 All-cause mortality versus body mass index (BMI) for each sex in the range of 15–50 kg/m² (excluding the first 5 years of follow-up). (From Whitlock G, Lewington S, Sherliker P, et al: Body-mass index and cause-specific mortality in 900,000 adults: Collaborative analyses of 57 prospective studies. *Lancet* 2009;373:1083–1096).

history, are also involved. Criteria for the diagnosis of type 2 diabetes include a fasting glucose level greater than 125 mg/dL or glucose levels greater than 200 mg/dL during a 2-hour oral glucose tolerance test.

Hypertension

Hypertension is a common chronic disease, and it has been estimated that obesity is a major risk factor for hypertension. Hypertension is associated with an increased risk for stroke, myocardial infarction, heart failure, and kidney disease. Even a modest weight loss (5%–10% of initial weight) can lead to a significant fall in blood pressure and, often, decreased need for antihypertensive medications.

Dyslipidemia

A variety of blood lipid abnormalities are seen frequently in obese patients. These include elevated levels of total cholesterol, LDL cholesterol, and triglycerides and decreased levels of HDL cholesterol. Patients with central adiposity are at particularly high risk for the development of hypertriglyceridemia and low HDL. Screening

for dyslipidemia should be done with a fasting lipid profile. However, if the testing opportunity is nonfasting, the total cholesterol and HDL values can still be measured.

Coronary Heart Disease

Comorbidities associated with obesity such as hypertension, insulin resistance, type 2 diabetes, and dyslipidemia lead to increased risk of cardiovascular disease in obese adults. Obesity is also associated with increased risk of CHD, heart failure, cardiovascular mortality, and all-cause mortality.

Respiratory Abnormalities

Obstructive sleep apnea is the most important respiratory problem associated with obesity. It is often underrecognized and inadequately treated. Patients may present with snoring, apneic episodes, excessive daytime somnolence, fatigue, irritability, and erectile dysfunction. Consequent nocturnal hypoxemia may result in arrhythmias, pulmonary hypertension, and right-sided heart failure. Treatment includes weight loss and use of continuous positive airway pressure at night. Other alterations in pulmonary

TABLE 2 Drugs that Cause Weight Gain and Some Alternatives

CATEGORY	DRUGS THAT CAUSE WEIGHT GAIN	POSSIBLE ALTERNATIVES
Antipsychotics		
Conventional	Thioridazine (Mellaril)	Haloperidol (Haldol)
Atypical	Olanzapine (Zyprexa), clozapine (Clozaril), quetiapine (Seroquel), risperidone (Risperdal)	Ziprasidone (Geodon), aripiprazole (Abilify)
Lithium	Lithium carbonate (Eskalith)	
Antidepressants		
Tricyclics	Amitriptyline (Elavil), clomipramine (Anafranil), doxepin (Sinequan), imipramine (Tofranil), nortriptyline (Pamelor)	Protriptyline (Vivactil)
Selective serotonin reuptake inhibitors	Paroxetine (Paxil)	Other SSRIs
Other	Mirtazapine (Remeron)	Bupropion (Wellbutrin), nefazodone (Serzone)
Anticonvulsant drugs	Valproate (Depakene), carbamazepine (Tegretol), gabapentin (Neurontin)	Topiramate (Topamax), lamotrigine (Lamictal), zonisamide (Zonegran)
Antidiabetic drugs	Insulin, sulfonylureas, metiglinide, thiazolidinediones	Metformin (Glucophage), alpha-glucosidase inhibitors
Serotonin and histamine antagonist	Pizotifen ¹	
Antihistamines	Cyproheptidine (Periactin)	
Beta-adrenergic blockers	Propranolol (Inderal), atenolol (Tenormin), metoprolol (Lopressor)	
Steroid hormones	Glucocorticoids Progestins: megestrol acetate (Megace), medroxyprogesterone acetate (Provera)

function that may occur, include higher residual lung volume associated with increased abdominal pressure on the diaphragm, decreased lung compliance and increased chest wall impedance, ventilation-perfusion abnormalities, reduced strength and endurance of respiratory muscles, depressed ventilatory drive, and bronchospasm.

Gastroesophageal Disease

Obesity is associated with an increased risk of gastroesophageal reflux disease symptoms, as well as erosive esophagitis, esophageal adenocarcinoma, and gastric carcinoma. It has been suggested that increased intragastric pressure and relaxation of the lower esophageal sphincter from gastric compression from surrounding adiposity contributes to the reflux rather than the type of diet consumed.

Hepatobiliary Disease

Obesity increases the risk of cholelithiasis and of NAFLD. The spectrum of NAFLD ranges from steatosis with mild disruption of the liver architecture by fat to steatohepatitis with varying degrees of fibrosis and cirrhosis. Increased liver transaminase levels and findings of steatosis on ultrasonography are both suggestive of NAFLD in obese patients. However, the definitive diagnosis remains histologic.

Osteoarthritis

The incidence of osteoarthritis is increased in obese subjects. Osteoarthritis commonly develops in the knees and ankles but can also affect non-weight-bearing joints. Weight loss results in decreased risk of osteoarthritis.

Cancer

For both men and women, increased BMI is associated with increased mortality from several cancers, such as those of the esophagus, colon and rectum, liver, gallbladder, pancreas, and

kidney, as well as non-Hodgkin lymphoma and multiple myeloma. Additionally, obese men are at increased risk of death from stomach and prostate cancer, and obese women are at increased risk of death from cancers of the breast, uterus, cervix, and ovary.

Psychosocial Function

Obese subjects often are subjected to discrimination in education, employment, and health care. Overweight women have been noted to have lower household incomes and higher rates of household poverty than women who were not overweight, independent of their baseline socioeconomic status and aptitude test scores. Depression has also been seen in association with severe obesity, particularly in younger patients and in women.

Economic Consequences of Obesity

Overweight and obesity and their associated health problems have a significant economic impact on the health care system. Health care costs are higher in obese subjects compared with their normal-weight counterparts. The higher costs are predominantly explained by the presence of CHD, hypertension, and diabetes.

Treatment

Patients must undergo a detailed history and physical examination before a treatment plan is initiated. Secondary causes of obesity, such as Cushing's syndrome and hypothyroidism, should be considered in the evaluation. A complete medication history is crucial to determining whether any medications may have promoted weight gain.

Laboratory studies should be directed at ruling out secondary causes in selected patients and ruling out comorbidities (fasting glucose, lipid profile, liver function tests). It is important that practitioners assess each patient's willingness to change and expectations for weight loss. Treatment should be based on the patient's BMI, risk factors, and willingness to lose weight. Patients who are in

the precontemplative phase (i.e., in the early stages of thinking about it) are not likely to be successful despite appropriate counseling. Health care providers must enforce the idea that even a modest weight loss improves complications associated with obesity.

Treatment of obesity requires a multidisciplinary team approach. Lifestyle modifications, including dietary change and increased physical activity, represent first-line treatment for patients with obesity. Pharmacotherapy and bariatric surgery may be used as adjuvant therapies in certain patients.

The goal of treatment is to prevent the complications of obesity. The initial target goal of weight loss therapy is to decrease body weight by 5% to 10%. Once this target is achieved, further weight loss can be attempted if indicated. The rationales for this initial goal of moderate weight loss are that:

- It can decrease the severity of obesity-associated risk factors.
- It can set the stage for further weight loss, if indicated.
- It is realistic and can be achieved and maintained over time.

A reasonable timeline for a 5% to 10% reduction in body weight is 6 months of therapy. A period of weight maintenance should then occur. Further weight loss may be considered if the initial goal is achieved and then maintained for at least 6 months. It is important to inform patients that it is preferable to maintain a moderate amount of weight loss over time than to lose more weight but later regain it.

Behavior Modification

Behavior modification is an integral part of any weight loss program. Motivational interviewing (MI) is a client-centered, collaborative decision-making approach that is helpful in facilitating lifestyle modifications. MI helps the health care provider provide nonjudgmental feedback to patients, allowing for patients' resistance to change and encouraging patients to develop their own arguments for engaging in health behavior change.

The goal of behavioral therapy is to help patients make long-term changes in their eating behavior by modifying and monitoring their food intake, increasing their physical activity, and controlling cues and stimuli in the environment that trigger eating. Maintaining food diaries and activity records for self-monitoring are key elements in any successful behavioral weight loss program. Stimulus control is considered a key element in a behavioral program. It focuses on gaining control over the environmental factors that activate eating and eliminating or modifying the environmental factors that facilitate overeating.

This requires the availability of trained personnel such as psychologists and therapists. The behavioral strategies taught are aimed at decreasing caloric intake and increasing physical activity in the long term.

Dietary Therapy

The goal of dietary therapy therefore is to reduce the total number of calories consumed. A principal determinant of weight loss appears to be the degree of adherence to the diet, irrespective of the particular macronutrient composition. Recent data suggest that the so-called Mediterranean diet and low-carbohydrate diets may represent effective alternatives to the low-fat diet for weight loss. Thus the macronutrient mix of the diet should be based on patient preferences to improve long-term adherence. Often patients revert to their previous habit of eating and can regain the weight that was lost. Diets that incorporate the patient's preference and culture to find the optimal mix of macronutrients will have the best chance of success.

Approximately 22 kcal/kg is required to maintain a kilogram of body weight in a normal adult. Thus the expected or calculated energy expenditure for a woman weighing 100 kg is approximately 2200 kcal/day. The variability of $\pm 20\%$ could give energy needs as high as 2620 kcal/day or as low as 1860 kcal/day. An average deficit of 500 kcal/day should result in an initial weight loss of approximately 0.5 kg/week (1 lb/week). However, after 3 to 6 months of weight loss, energy expenditure adaptations occur, which slow the body weight response to a given change in energy intake, thereby diminishing ongoing weight loss.

Patients should be counseled to avoid unnecessary calories from alcohol and sugary beverages such as soda and juice.

Very-low-calorie diets contain less than 800 kcal/day and are usually administered in the form of liquid supplements. Although these diets do produce significant and rapid weight loss, results are difficult to maintain in the long term. These diets require close monitoring by a health care professional. Side effects associated with very-low-calorie diets include fatigue, constipation, hair loss, and gallstones. These diets are strictly contraindicated in children and in pregnant and lactating women and are generally reserved for patients who require rapid weight loss for a specific purpose such as surgery.

Physical Activity

Physical activity is an integral component of therapy for obese patients and is most important in the prevention of weight regain. Physical activity also decreases the risks for cardiovascular disease and type 2 diabetes. Sedentary obese patients need to start their exercise program slowly and may require supervision from a health care professional. Initially, patients may be encouraged to increase their activities of daily living. For example, it may be suggested that they take the stairs instead of the elevator or that they park farther away from work or shopping. The intensity and duration of exercise should be increased gradually over time, with a goal of achieving 30 minutes of moderate-intensity activity on most days of the week to improve health (150 minutes/week) and 60 minutes of exercise of most days of the week to control body weight.

Ideally, adults should also perform muscle-strengthening exercises on 2 or more days per week. Patients should be encouraged to choose activities that they enjoy and to build these activities into their daily schedule. Sedentary activities, such as watching television, sitting in front of a computer screen, and playing video games, should be discouraged.

Pharmacotherapy

Pharmacotherapy (Table 3) is usually reserved for patients with a BMI greater than 30 kg/m² without complications or a BMI greater than 27 to 30 kg/m² with concomitant weight-related complications. These patients should have failed to achieve weight loss goals through diet and exercise alone. Pharmacotherapy must be used in conjunction with a program that includes dietary changes and physical activity.

The success may be measured by the degree of weight loss and improvement in associated risk factors. Weight loss should be more than 5% below baseline to be considered effective. A weight loss of 5% to 10% can significantly reduce the baseline risk factors for diabetes and cardiovascular disease and improvement in baseline risk factors after weight loss is an important criterion in the determination of whether to continue therapy.

Orlistat (Xenical) is recommended as the first-line drug for patients with dyslipidemia or diabetes. Orlistat is an inhibitor of pancreatic lipases that causes weight loss by limiting fat absorption. The recommended dose for adults is 120 mg PO three times daily with meals. A lower dose of 60 mg preparation (Alli) is available over the counter in the United States and several other countries. Orlistat has been shown to be effective for weight loss and prevention of weight regain. In a meta-analysis of 12 trials that included patients with and without diabetes and reported data with 12-month outcomes, patients randomly assigned to orlistat plus a behavioral intervention lost 5 to 10 kg (8% of baseline weight) compared with 3 to 6 kg in the control group (placebo plus behavioral intervention), for a mean placebo-subtracted difference of 3 kg. Weight loss was maintained with up to 24 to 36 months of orlistat treatment. Orlistat has also been shown to result in improved metabolic outcomes such as delay in development of type 2 diabetes in those that have impaired fasting glucose and improvement in blood pressure in hypertensive patients and in serum total and LDL cholesterol levels. Side effects associated with orlistat are mostly gastrointestinal and include cramping, flatus, fecal incontinence, oily spotting, and flatus with discharge. These side effects tend to decrease over time as patients learn to restrict their dietary

TABLE 3 Drugs Approved by the FDA for Treatment of Obesity

DRUG	DOSAGE	ADVERSE SIDE EFFECTS
Pancreatic Lipase Inhibitor Approved for Long-Term Use		
Orlistat (Xenical)	120 mg tid before meals	Cramps, flatulence, diarrhea, oily spotting
Appetite Suppressants Approved for Long-Term Use		
Serotonin agonist Lorcaserin hydrochloride (Belviq)	10 mg bid	Headache, dizziness, nausea, nasopharyngitis
GLP-1 analog approved for weight loss		
Liraglutide	0.6mg subq (doses escalated weekly with a max of 3mg)	Nausea, vomiting, diarrhea, constipation, hypoglycemia
Combination Drugs		
Bupropion/Wellbutrin	Week 1: one tablet daily (8 mg naltrexone 90 mg bupropion) Week 2: one tablet twice daily Week 3: two tablets in the am, one in the pm Week 4: two tablets twice daily	Nausea, headache, constipation, dizziness, and a dry mouth
Phentermine/topiramate (Qsymia)	7.5 mg/46 mg/d*	Dry mouth, tachycardia, depression, anxiety
Noradrenergic Drugs Approved for Short-Term Use		
Phentermine (Adipex-P)	Immediate release: 15–37.5 mg/d	Increase in blood pressure or in heart rate, insomnia, nervousness Dry mouth, constipation Abuse potential due to amphetamine-like effects
Ionamin ¹	Slow-release resin 15–30 mg/d	
Diethylpropion (Tenuate)	Immediate release: 25 mg tid Controlled release: 75 mg every morning	Same
Benzphetamine (Didrex)	25–50 mg tid	Same
Phendimetrazine (Bontril PDM)	17.5–70 mg tid Extended release: 105 mg/d	Same

*Maintenance dose.

intake to less than 30% fat. Severe cases of liver damage have been reported in patients taking orlistat. Orlistat may also interfere with the absorption of fat-soluble vitamins, so the use of a daily multivitamin supplement at bedtime is recommended.

Lorcaserin hydrochloride (Belviq) is a serotonin 2C receptor agonist that causes weight loss by causing appetite suppression. It appears to have fewer adverse effects than orlistat, although long-term safety data are limited. The recommended dosage is 10 mg twice daily. Lorcaserin should be discontinued if patients do not lose 5% of their body weight in 12 weeks. The efficacy of lorcaserin appears similar to that of orlistat (mean difference in weight loss between active and placebo-treated groups approximately 3–4 kg). Common side effects include nausea, headache, dizziness, nasopharyngitis, and fatigue. Lorcaserin may increase the risk of symptomatic hypoglycemia in patients with type 2 diabetes on oral agents, necessitating a reduction in the dose of diabetes medications. Lorcaserin should not be used in individuals with creatinine clearance <30 mL/minute. It is contraindicated during pregnancy. In addition, lorcaserin should not be used with other serotonergic drugs (e.g., selective serotonin reuptake inhibitors, selective serotonin-norepinephrine reuptake inhibitors, bupropion [Wellbutrin], tricyclic antidepressants, and monoamine oxidase inhibitors) because of the theoretical potential for serotonin syndrome.

Qsymia is a combination of phentermine (Adipex-P), an appetite suppressant, and topiramate, a medication used to treat epilepsy and migraine. The initial dose of phentermine/topiramate is 3.75/23 mg for 14 days, followed by 7.5/46 mg thereafter. If after 12 weeks, a 3% loss in body weight is not achieved, the dose can be increased to 11.25/69 mg for 14 days, and then to 15/

92 mg daily. If an individual does not lose 5% of body weight after 12 weeks on the highest dose, phentermine/topiramate should be discontinued gradually, as abrupt withdrawal of topiramate can cause seizures. Qsymia is contraindicated during pregnancy due to an increased risk of orofacial clefts in infants exposed to the combination drug during the first trimester of pregnancy. Women of child-bearing age should have a pregnancy test before starting this drug and monthly thereafter. It is also contraindicated in patients with glaucoma, hyperthyroidism, and individuals who have taken monoamine oxidase inhibitors within 14 days. Clinicians who prescribe phentermine/topiramate are encouraged to enroll in a risk evaluation and mitigation strategy, which includes an online or print formal training module detailing safety information. Pharmacies that dispense Qsymia also require a specific certification and have to provide patients with a medication guide and brochure each time the drug is dispensed, detailing the risks of birth defects.

Side effects for Qsymia include tachycardia, paresthesias, dizziness, altered taste sensation, insomnia, and constipation. Qsymia is not recommended in patients with cardiovascular disease (hypertension or CHD) and may be considered for obese postmenopausal women and men without cardiovascular disease, particularly those who do not tolerate orlistat or lorcaserin.

Contrave, a combination of bupropion, an antidepressant/anorectic with naltrexone, an opioid-receptor antagonist was approved by the Food and Drug Administration in September 2014 as an adjunct to diet and exercise in patients with BMI ≥ 30 kg/m² (or ≥ 27 kg/m² with comorbidities). The initial dose is one tablet (8 mg of naltrexone and 90 mg of bupropion) daily. After 1 week, the dose is increased to one tablet twice daily, and

by week 4 to two tablets twice daily. If after 12 weeks the patient has not lost at least 5% of baseline body weight, the drug should be discontinued because benefit is unlikely. Contraindications include concomitant use of other bupropion-containing products, long-term opioid use, uncontrolled hypertension, eating disorder, seizure disorders, and use within 14 days of taking monoamine oxidase inhibitors. Side effects for bupropion-naltrexone include nausea, headache, constipation, insomnia, vomiting, constipation, dizziness, and dry mouth.

Liraglutide (Saxenda) is a long-acting glucagon-like polypeptide-1 (GLP-1) receptor agonist that is recommended for long-term weight management in conjunction with reduced-calorie diet and physical activity. It is recommended for patients with BMI ≥ 30 kg/m² or ≥ 27 kg/m² if one weight-related comorbidity is present. Liraglutide is administered subcutaneously in the abdomen, thigh, or upper arm once daily. The initial dose is 0.6 mg daily for 1 week. The dose can be increased at weekly intervals (1.2, 1.8, 2.4 mg) to the recommended dose of 3 mg. If after 16 weeks a patient has not lost at least 4% of baseline body weight, liraglutide should be discontinued, because it is unlikely the patient will achieve clinically meaningful weight loss with continued treatment. Liraglutide is contraindicated in those with a personal history or family history of medullary thyroid cancer or multiple endocrine neoplasia type 2 or 2B. Side effects for liraglutide include headache, nausea, vomiting, diarrhea, and constipation which tend to be dose-related. Hypoglycemia can occur in non-diabetics but at a lower frequency than type 2 diabetics.

Several sympathomimetic drugs (phentermine, benzphetamine [Didrex], diethylpropion [Tenuate], and phendimetrazine [Bontril PDM]) are approved for the short-term (up to 12 weeks) treatment of obesity. These drugs can increase blood pressure and have a potential for abuse and therefore are contraindicated in patients with CHD, hypertension, or hyperthyroidism or in patients with a history of drug abuse.

Vagal blockade device is available in the United States for the treatment of adults with a BMI of 40 to 45 kg/m² or of 35 to 39.9 kg/m², with at least one obesity-related comorbidity (e.g., type 2 diabetes) who have failed a supervised weight management program within the past 5 years. The abdominal vagal nerve controls gastric emptying and signals the satiety center in the brain. Electric stimulation of the abdominal vagal nerve from the subcutaneously implanted device blocks vagal nerve conduction between the brain and the stomach, thereby reducing hunger. However, the specific mechanism for weight loss is unknown. Implantation of the device involves laparoscopically placing one lead on the anterior vagal trunk and the other on the posterior intraabdominal vagal trunk. Adverse events include pain at the neuroregulator site, vomiting, surgical complications, nausea, heartburn, belching and dysphagia. Implantation of the device is contraindicated in patients at high risk for surgical complications, patients with other permanent implanted devices (e.g., heart pacemaker, implanted defibrillator, neurostimulator), or patients likely to need magnetic resonance imaging (MRI) procedures.

Bariatric Surgery

Bariatric surgery should be considered for patients with a BMI >40 kg/m² or a BMI >35 kg/m² with significant comorbid conditions. Patients should be well informed and motivated and have failed a trial of nonsurgical weight loss. They should also be of acceptable risk for surgery. Contraindications to bariatric surgery include untreated major depression or psychosis, binge eating disorders, active drug or alcohol abuse, and the inability to comply with nutritional requirements including lifelong vitamin supplementation. A comprehensive preoperative evaluation and close extended follow-up after surgery are required. Bariatric surgery has been shown to result in a significant and sustained weight loss, as well as resolution of many obesity-related complications, in most patients. Patients may lose more than 60% of their excess weight after bariatric surgery. There is increasing interest in the role of bariatric surgery as a treatment for type 2 diabetes in obese patients who have a BMI <35 kg/m². Several unblinded trials

comparing bariatric surgery with medical therapy for type 2 diabetes have demonstrated significantly greater improvements in blood glucose control in patients who underwent bariatric surgery. However, long-term data are required before bariatric surgery procedures can be routinely recommended for the treatment of persistent hyperglycemia, resistant to multiple medications, in patients with mild obesity.

Bariatric procedures can be divided into three types: restrictive procedures, which decrease gastric volume and limit food intake; malabsorptive procedures, which alter digestion of food and decrease the effectiveness of nutrient absorption; and mixed procedures, which have components of both restriction and malabsorption. Currently, the most common procedures performed in the United States are the laparoscopic Roux-en-Y gastric bypass (RYGB), sleeve gastrectomy, and the laparoscopic adjustable band (a restrictive procedure) (Figure 2).

Roux-en-Y Gastric Bypass

The RYGB is characterized by a small (less than 30 mL) proximal gastric pouch that is divided and separated from the distal stomach and anastomosed to a Roux limb of small bowel, 75 to 150 cm in length. It is the most commonly performed bariatric procedure and involves the creation of a small pouch at the superior portion of the stomach. The pouch is then connected to the jejunum, bypassing the duodenum, where the majority of calories are absorbed. The mortality rate associated with gastric bypass is low ($<1\%$), but patients can have significant postoperative complications, including pulmonary emboli, deep vein thromboses, leaks from the gastrointestinal tract, gastric remnant distention, stomal stenosis, ulcers, gallstones, and hernias. Patients are required to take lifelong vitamin and mineral supplementation because absorption of iron, vitamin B₁₂/folate, and others are affected.

Laparoscopic Sleeve Gastrectomy

Laparoscopic sleeve gastrectomy (LSG), the second-most commonly performed bariatric procedure, is emerging as a single-stage bariatric procedure. It is a restrictive, nonreversible procedure involving removal of about 85% of the stomach so that the remainder takes the shape of a tube or sleeve. Recent studies have shown that LSG has equivalent results to other procedures. There is durability of results 5 to 9 years after the procedure, but there are no long-term data beyond this. Gastric-sleeve dilatations and staple-line leaks are the most common complications. LSG involves no foreign body, needs no invasive adjustments, and most likely avoids malabsorption of many micronutrients.

Laparoscopic Adjustable Gastric Band

Adjustable gastric banding is a purely restrictive procedure that compartmentalizes the upper stomach by placing a tight, adjustable prosthetic band around the entrance to the stomach. The gastric band consists of a soft, locking silicone ring that is connected to an infusion port placed in the subcutaneous tissue. The port can be accessed with a needle and syringe, and injection or removal of saline into the port may be used to manipulate the size of the band diameter, leading to greater or lesser degrees of restriction. Although weight loss with banding tends to be slower than with other weight loss procedures, the procedure is popular because it is performed laparoscopically and is reversible. Laparoscopic banding can also be associated with side effects such as stomal obstruction; band erosion, slippage, or prolapse; port malfunction; pouch or esophageal dilation; and infection.

Intragastric Balloon

The FDA has recently approved intragastric balloon devices to treat obesity in adults with a BMI ≥ 30 kg/m² who have failed previous weight loss attempts. The balloon promotes sensation of satiety and therefore, because the weight loss mechanism is primarily restrictive, the success is dependent on patient's adherence to lifestyle modifications. Adults with a BMI ≥ 40 kg/m² or a BMI ≥ 35 kg/m² with one or more comorbidities who qualify for bariatric surgery, but refuse or lack access to bariatric surgery, may also be

Figure 2 Techniques commonly used for the surgical treatment of obesity: Roux-en-Y gastric bypass (A), adjustable laparoscopic band (B), laparoscopic sleeve gastrectomy (C).

considered for the balloon. The intragastric balloon IBD may serve as a bridging therapy in the extremely obese patient who is not a bariatric surgical candidate due to excessive anesthesia risk.

Several intragastric balloons are available, and these differ in their volume, means of insertion and removal, duration in stomach, and adjustability. Common initial symptoms include nausea, vomiting, reflux, and abdominal pain. These symptoms tend to diminish in most patients. Total weight loss is intermediate between bariatric surgery and medical measures including drugs and lifestyle modifications.

Aspiration Therapy

Aspiration therapy is approved by the Food and Drug Administration for patients with BMI between 35–55 who have failed weight loss with nonsurgical therapy. Aspiration therapy induces weight loss by removing a portion of the ingested calories after each meal via a modified percutaneous endoscopic gastrostomy tube system. The patient is instructed to drain the stomach contents 20–30 minutes after each meal. There is a lack of long-term data on the efficacy of the aspiration therapy.

In conclusion, obesity is a growing public health problem that has significant short- and long-term consequences. Lifestyle modification with or without adjuvant therapies should be used to achieve a goal of modest weight loss. With modest weight loss, patients experience a decreased risk of mortality and improvement of obesity-related complications.

PARENTERAL NUTRITION IN ADULTS

Method of

Kris M. Mogensen, MS; and Malcolm K. Robinson, MD

CURRENT DIAGNOSIS

- Reserve parenteral nutrition (PN) for patients with intestinal dysfunction or failure.
- Reserve PN for conditions such as short-bowel syndrome, severe malabsorption, ileus or intestinal dysmotility, intractable vomiting, and severe diarrhea.
- Always reevaluate the need for PN and work toward a transition to enteral nutrition, or an oral diet, if possible, to limit complications associated with PN.

CURRENT THERAPY

- Correct electrolyte abnormalities and hyperglycemia prior to the initiation of PN.
- Start with no more than 150 to 200 g dextrose on the first day of PN; start with 100 to 150 g dextrose for patients with diabetes or patients at risk for the refeeding syndrome.
- Advance PN by 100 to 150 g dextrose daily until the goal is achieved.
- Maintain blood glucose <180 mg/dL.
- Monitor electrolytes, including phosphate and magnesium, until stable; the frequency of lab monitoring can be decreased based on stability.
- Monitor closely for complications associated with PN: electrolyte abnormalities, hyper/hypoglycemia, PN-associated liver disease, and central line infections.

Since the inception of parenteral nutrition (PN) in the 1960s, the science of PN has matured in a number of ways. The initial

Figure 2 Techniques commonly used for the surgical treatment of obesity: Roux-en-Y gastric bypass (A), adjustable laparoscopic band (B), laparoscopic sleeve gastrectomy (C).

considered for the balloon. The intragastric balloon IBD may serve as a bridging therapy in the extremely obese patient who is not a bariatric surgical candidate due to excessive anesthesia risk.

Several intragastric balloons are available, and these differ in their volume, means of insertion and removal, duration in stomach, and adjustability. Common initial symptoms include nausea, vomiting, reflux, and abdominal pain. These symptoms tend to diminish in most patients. Total weight loss is intermediate between bariatric surgery and medical measures including drugs and lifestyle modifications.

Aspiration Therapy

Aspiration therapy is approved by the Food and Drug Administration for patients with BMI between 35–55 who have failed weight loss with nonsurgical therapy. Aspiration therapy induces weight loss by removing a portion of the ingested calories after each meal via a modified percutaneous endoscopic gastrostomy tube system. The patient is instructed to drain the stomach contents 20–30 minutes after each meal. There is a lack of long-term data on the efficacy of the aspiration therapy.

In conclusion, obesity is a growing public health problem that has significant short- and long-term consequences. Lifestyle modification with or without adjuvant therapies should be used to achieve a goal of modest weight loss. With modest weight loss, patients experience a decreased risk of mortality and improvement of obesity-related complications.

PARENTERAL NUTRITION IN ADULTS

Method of

Kris M. Mogensen, MS; and Malcolm K. Robinson, MD

CURRENT DIAGNOSIS

- Reserve parenteral nutrition (PN) for patients with intestinal dysfunction or failure.
- Reserve PN for conditions such as short-bowel syndrome, severe malabsorption, ileus or intestinal dysmotility, intractable vomiting, and severe diarrhea.
- Always reevaluate the need for PN and work toward a transition to enteral nutrition, or an oral diet, if possible, to limit complications associated with PN.

CURRENT THERAPY

- Correct electrolyte abnormalities and hyperglycemia prior to the initiation of PN.
- Start with no more than 150 to 200 g dextrose on the first day of PN; start with 100 to 150 g dextrose for patients with diabetes or patients at risk for the refeeding syndrome.
- Advance PN by 100 to 150 g dextrose daily until the goal is achieved.
- Maintain blood glucose <180 mg/dL.
- Monitor electrolytes, including phosphate and magnesium, until stable; the frequency of lab monitoring can be decreased based on stability.
- Monitor closely for complications associated with PN: electrolyte abnormalities, hyper/hypoglycemia, PN-associated liver disease, and central line infections.

Since the inception of parenteral nutrition (PN) in the 1960s, the science of PN has matured in a number of ways. The initial

excitement of being able to feed basic nutrients, vitamins, and trace elements intravenously has been tempered by the realization that indiscriminant use of PN can be harmful. Although PN can still be lifesaving, it is imperative that it be used judiciously and only as long as necessary. This chapter discusses the current use of PN in adult patients.

Indications and Contraindications

Enteral nutrition (EN) is the preferred method of nutrition support, primarily because it is associated with fewer infectious and metabolic complications. However, total PN (TPN), which is the provision of all nutrient requirements intravenously, may be indicated when feeding through the gastrointestinal (GI) tract is not possible. PN may be appropriately initiated in those who cannot receive enteral nourishment and are malnourished or at risk for developing malnourishment. Malnourishment can be defined as unintentional loss of more than 10% of usual body weight or greater than 7 to 10 days of inadequate nutrient intake. The body stores of well-nourished persons are generally sufficient to provide the essential nutrients, resist infection, promote wound healing, and support other necessary physiologic functions for this time period. In patients who are anticipated not to be able to receive adequate EN for longer than 10 days, it is not necessary to wait 10 days before initiating PN. This may include patients with short-bowel syndrome and others who are expected to have prolonged GI dysfunction.

According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, EN is contraindicated in conditions such as diffuse peritonitis, intestinal obstruction, early stages of short-bowel syndrome, intractable vomiting, paralytic ileus, severe GI bleeding, and severe diarrhea and malabsorption syndromes. Other relative contraindications to EN include severe pancreatitis and enterocutaneous fistulas, although depending on the clinical circumstances, EN may be indicated. PN and EN may be provided concomitantly, although in patients who are critically ill, PN should not be started until all strategies to maximize enteral feeding (such as the use of postpyloric feeding tubes and motility agents) have been attempted. PN support is unlikely to benefit a patient who will be able to take EN within 4 or 5 days after the onset of illness or who has a relatively minor injury (Figure 1).

There are four key steps to consider before initiating PN, including assessing nutritional status, determining energy needs, evaluating GI function, and estimating the length of time a patient will require PN (Box 1).

Assessment of Nutritional Status

Nutrient depletion is associated with increased morbidity and mortality, and the prevalence of malnutrition in hospitalized patients is approximately 50%. Therefore it is imperative to identify patients who have or are at risk for developing protein-energy malnutrition or specific nutrient deficiencies. A patient's risk of developing malnutrition-related medical complications needs to be quantified, and it is necessary to monitor the adequacy of nutritional therapy.

Nutrition assessment begins with a thorough history and physical examination in conjunction with select laboratory tests aimed at detecting specific nutrient deficiencies in patients who are at high risk for future abnormalities. The nutrition assessment should establish whether the patient will need maintenance therapy or nutrition repletion and should assess the status of the patient's GI tract, especially if nutrition support will be required.

A thorough history includes an assessment of recent weight changes, dietary habits, GI symptoms, and changes in exercise tolerance or physical abilities that would indicate functional capacity deficiencies. The physical examination includes inspecting for a loss of subcutaneous fat and muscle wasting, which indicate a loss of body energy and protein stores; edema and ascites, which can also indicate altered energy demands or decreased energy intake; and signs of vitamin and mineral deficits such as dermatitis, glossitis, cheilosis, neuromuscular irritability, and coarse, easily pluckable hair.

Several laboratory measurements have been used as nutritional biomarkers to aid the nutritional assessment. The serum proteins

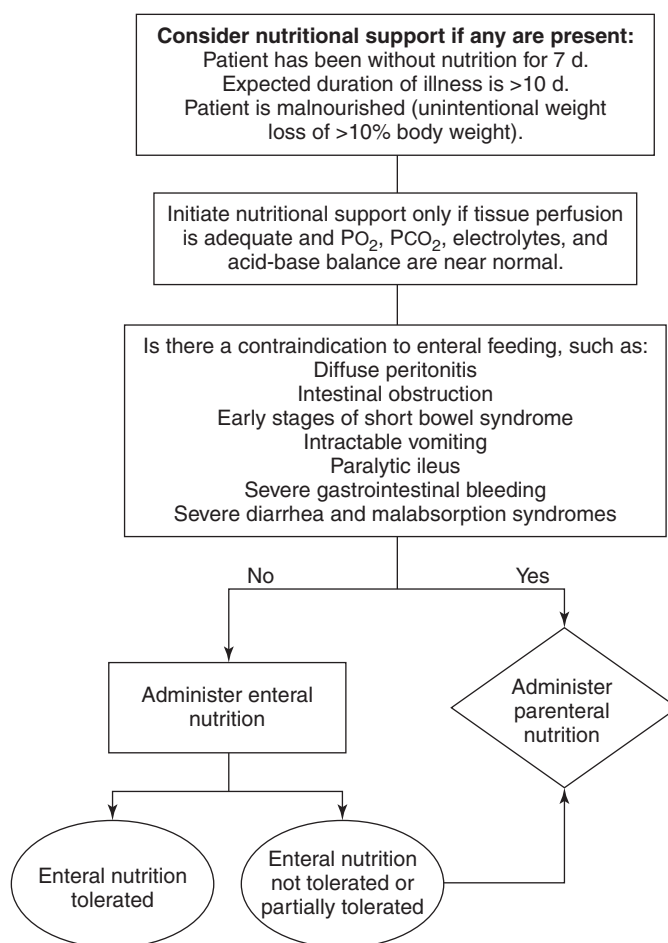

Figure 1 Determining route of feeding.

BOX 1

Decision-Making Steps When Initiating Parenteral Nutrition

Assess the patient's nutritional status. Nutrition support (PN or EN) should not be initiated in well-nourished patients unless they have received a suboptimal diet for more than 7 d.

Determine whether the patient has extreme energy needs (hypermetabolism) that warrant the early use of nutrition support (PN and/or EN) within 7 d of injury or illness. These are typically critically ill patients who have suffered severe burns or trauma.

Evaluate the function of the GI tract; if it is intact and can be used safely, PN should be avoided. PN support is indicated until enteral access is established and the patient can meet nutrient needs via tube feedings.

Estimate how long the patient will require PN support. If GI function is expected to return within 5 d, there is no known benefit of initiating PN.

Abbreviations: EN = enteral nutrition; GI = gastrointestinal; PN = parenteral nutrition.

prealbumin, transferrin, and retinol-binding protein have a rapid turnover rate and short half-lives and therefore may be used as indicators of recent nutritional intake. However, these proteins are affected by the metabolic responses to stress and illness, as well as other conditions, including iron status (transferrin) and renal status (retinol-binding protein, prealbumin). This can limit their usefulness during acute illness states.

Prealbumin is least affected by fluctuations in hydration status and by liver and renal function compared with other plasma

proteins. However, prealbumin levels drop in acute inflammatory conditions during which the liver switches to acute-phase protein production and decreases prealbumin synthesis. A rise in C-reactive protein, a protein synthesized by the liver as part of the acute-phase response, indicates inflammatory states. Thus C-reactive protein, when measured along with prealbumin, can help differentiate a low prealbumin due to nutritional inadequacy versus low prealbumin due to an acute-phase response.

The serum albumin concentration has traditionally been used as an indicator of nutritional status. Although it is a good preoperative predictor of outcome for patients undergoing surgery, it is affected by too many variables in the acute care setting to make it a reliable marker of nutritional status under such conditions or in the immediate postoperative period.

A simple and practical index of malnutrition is the degree of weight loss. Unintentional weight loss of greater than 10% within the previous 6 months indicates protein-energy malnutrition and is a good prognosticator of clinical outcome. Weight can also be compared with an ideal or desirable weight, or an index of body weight relative to height. The body mass index (BMI), reported as weight in kilograms divided by height in meters squared, is the best known such index and can be used to detect both undernutrition and overnutrition. This index is independent of height, and the same standards apply to both men and women. A BMI of 18.5 to 25 kg/m² is considered normal, 25 to 29.9 kg/m² is considered overweight, and greater than 30 kg/m² is considered obese. Patients with a normal or high BMI can still have nutrient deficiencies and therefore can be malnourished if they have recently lost a significant amount of weight. In addition, a BMI of 18 kg/m² or less in an adult indicates moderate malnutrition and a BMI less than 15 kg/m² is associated with increased morbidity.

Another practical tool for evaluating nutritional status is the subjective global assessment (SGA) that encompasses historical, symptomatic, and physical parameters. The SGA technique determines whether nutrient assimilation has been restricted because of decreased food intake, maldigestion, or malabsorption; whether any effects of malnutrition on organ function and body composition have occurred; and whether the patient's disease process influences nutrient requirements. The findings of the history and physical examination are subjectively weighted to rank patients as being well nourished, moderately malnourished, or severely malnourished and are used to predict their risk for medical complications (Box 2).

Estimating Nutritional Requirements

Historically, TPN often provided nutrients in excess of actual requirements. This was based on the assumption that patients requiring nutritional intervention were severely depleted and required aggressive repletion; hence, the misnomer "hyperalimentation." Overfeeding is associated with increased carbon dioxide production and difficulty weaning from a ventilator as well as metabolic complications, such as hyperglycemia, which can lead to increased infection, morbidity, and mortality. Thus nutritional support should be titrated to match actual metabolic requirements.

In addition, there are times when *underfeeding* calories may be necessary and beneficial. In such cases, this is referred to as "permissive" underfeeding to distinguish it from underfeeding that occurs due to the unintentional inadequate delivery of nutrients. For example, permissive underfeeding may be appropriate for some critically ill obese patients who are receiving adequate protein. Such permissive underfeeding for critically ill obese individuals is now the recommendation of ASPEN and the Society of Critical Care Medicine (SCCM).

Energy Requirements

There are four components of daily energy requirement. The first is the basal metabolic rate (BMR), which is the amount of energy expended under complete rest shortly after awakening and in a fasting state (12–14 hours). BMR varies with age, sex, and body size; correlates roughly with body surface area; and is proportional to lean tissue mass. This relationship holds true even among persons of different ages and sexes. Resting metabolic rate or resting

BOX 2 Subjective Global Assessment

Select the appropriate category with a checkmark, or enter a numeric value where indicated by #.

History

- Weight change
Overall loss in past 6 mo: amount = # _____ kg; % loss = # _____
Change in past 2 wk: _____ increase, _____ no change, _____ decrease
- Dietary intake change (relative to normal)
_____ No change
_____ Change duration = # _____ wk.
_____ Type: _____ suboptimal solid diet, _____ full liquid diet, _____ hypocaloric liquids, _____ starvation
- Gastrointestinal symptoms (that persisted for >2 wk)
_____ None, _____ nausea, _____ vomiting, _____ diarrhea, _____ anorexia
- Functional capacity
_____ No dysfunction (e.g., full capacity)
_____ Dysfunction duration = # _____ wk
_____ Type: _____ working suboptimally, _____ ambulatory, _____ bedridden
- Disease and its relation to nutritional requirements
Primary diagnosis (specify): _____
Metabolic demand (stress): _____ no stress, _____ low stress, _____ moderate stress, _____ high stress

Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe)

- # _____ Loss of subcutaneous fat (triceps, chest)
- # _____ Muscle wasting (quadriceps, deltoids)
- # _____ Ankle edema
- # _____ Sacral edema
- # _____ Ascites

SGA Rating (select one)

- _____ A = Well nourished
- _____ B = Moderately (or suspected of being) malnourished
- _____ C = Severely malnourished

energy expenditure (REE) represents the amount of energy expended 2 hours after a meal under conditions of rest and thermal neutrality. However, although it is often used synonymously with BMR, the REE is typically 10% higher.

The second component of daily energy expenditure is the thermic effect of exercise or the energy used in physical activity. The contribution of this component increases markedly during intense muscular work, and admission to a hospital generally results in a marked decrease in physical activity. Hospital activity in ambulatory patients accounts for a 20% to 30% increase in BMR. Critically ill patients who are on a ventilator generally have low activity levels (BMR increases by only 5%–10%) because the ventilator performs the work of breathing, and they are not ambulatory.

The third component of energy expenditure is diet-induced thermogenesis, the increase in BMR that follows food intake. The digestion and metabolism of exogenous nutrients, whether delivered to the gut or vein, result in an increase in metabolic rate. The magnitude of the thermic effect of food varies depending on the amount and composition of the diet and accounts for approximately 10% of daily energy expenditure.

Finally, acute illness adds an additional stress factor to the daily energy expenditure and correlates with disease severity. For example, a patient's metabolic rate increases by 10% to 30% after a major fracture, from 20% to 60% with severe infection, and from 40% to 110% with a severe third-degree burn. In addition, fever

accelerates chemical reactions, and the BMR rises approximately 10% for each degree Celsius increase in temperature. Alternatively, cooling of febrile patients produces a reduction in BMR of approximately 10% per degree Celsius.

The first step of estimating energy requirements is to estimate the BMR. This is usually accomplished using one of several predictive equations. The most commonly used method is based on the predictive equations reported by Harris and Benedict in 1919. The Harris-Benedict equations are as follows:

$$\text{BMR (men)} = 66.47 + 13.75(W) + 5.0(H) - 6.76(A)$$

$$\text{BMR (women)} = 655.1 + 9.56(W) + 1.85(H) - 4.68(A)$$

where W is weight in kg, H is height in cm, and A is age in years.

After the BMR is calculated, it is adjusted for the level of stress induced by injury or the disease process (Figure 2) and activity level. Activity factors for hospitalized patients are 1.0 to 1.1 for intubated patients, 1.2 for patients confined to bed, and 1.3 for patients out of bed. Therefore the patient's energy requirements (total energy expenditure [TEE]) are finally calculated:

$$\text{TEE} = \text{BMR} \times \text{Activity factor} \times \text{Stress factor}$$

The thermic effect of feeding is generally not included in the calculation of energy requirements for hospitalized patients.

Alternatively, some clinicians estimate energy requirements based on actual body weight. Thus 20 to 25 kilocalories (kcal)/kg is administered to the critically ill intubated patient, and 30 kcal/kg is given to nonventilated patients in whom excessive energy intake is not a major concern.

Predicting energy expenditure in obese patients can be difficult because using predictive formulas with actual body weight can lead to high TEE and potentially to overfeeding. A factor of 18 to 21 kcal/kg has been validated in obese patients, and the Harris-Benedict equation using the average of actual and ideal weight and a stress factor of 1.3 predicts REE in acutely ill obese patients with a BMI of 30 to 50 kg/m².

Indirect calorimetry is a more precise, clinically practical, and individualized method to determine energy expenditure, particularly in patients in whom estimating requirements through

predictive equations are difficult, such as those who continue to lose weight despite what appears to be an adequate caloric intake, who are critically ill, or who have rapidly changing energy needs.

Indirect calorimetry measures changes in oxygen consumption and carbon dioxide production to calculate the REE. Including a stress factor to account for injury is not necessary with indirect calorimetry because the measured energy expenditure accounts for the effects of disease state, stress, and trauma. However, the measurement occurs at rest, and therefore an activity factor of 1.0 to 1.3, depending on whether the patient is intubated, bedridden, or ambulatory, must be applied.

Nutrient Requirements

The recommended daily protein allowance for most healthy persons who are not hospitalized is 0.8 g/kg, or about 60 to 70 g of protein each day. The stressed, critically ill patient generally needs a higher dose of protein in the range of 1.0 to 1.5 g/kg/d. For most patients, providing protein beyond 1.5 g/kg/d is not beneficial. In fact, providing excess protein does not enhance uptake and can lead to increased ureagenesis, which can cause renal injury in some patients.

The calorie-to-nitrogen ratio for most PN solutions is typically about 150:1, with an acceptable range of 100:1 to 180:1. Nitrogen content is used as a marker for protein, and, hence, the two terms are used interchangeably. Usually, 6.25 g of protein is equal to 1.0 g of nitrogen. The conversion factor is slightly higher (6.4) for PN solutions, such as those with higher concentrations of crystalline amino acids.

Vitamin and mineral requirements are altered in certain disease states due to increased losses, greater use, or both. Guidelines for parenteral vitamin and trace elements, developed by the Nutrition Advisory Group of the American Medical Association, were approved by the US Food and Drug Administration (FDA) in 1979 and amended in 2000 (Table 1).

Composition of Central and Peripheral Venous Solutions

Central venous access is required for providing TPN because of the hypertonicity of the formulas infused (1900 mOsm/kg). The infusion of a hypertonic solution into a peripheral vein, known as *peripheral parenteral nutrition* (PPN), can result in thrombophlebitis and venous sclerosis unless the PN is drastically diluted to lower the tonicity. To minimize the hypertonicity of PPN solutions, dextrose is limited to 5% to 10%, and amino acids are limited to 2.5% to 3.5%. Lipids are isotonic and therefore provide a significant portion of the caloric substrate of PPN formulas.

Central venous solutions, which are prepared by the hospital's pharmacy, typically combine carbohydrate in the form of dextrose, protein as crystalline amino acids, and lipids from polyunsaturated long-chain triglycerides such as soybean oil or a safflower/soybean oil emulsion. Vitamins, electrolytes, and trace elements are added to the formulation as needed. Typical substrate profiles of carbohydrate, protein, and lipids in central PN are shown in Table 2. A usual PN prescription administers 1 to 2 L of a solution each day. Administration of 500 mL of a 20% fat emulsion 1 day each week is sufficient to prevent essential fatty acid deficiency. Alternatively, if additional calories from lipids are needed on a daily basis, they can be administered as a separate infusion or most commonly as part of the mixture of dextrose and amino acids, a technique known as *triple mix* or *three-in-one*.

Including lipid injectable emulsion into a parenteral admixture changes the conventional nutritional solution into an emulsion. Various electrolytes and micronutrients can adversely influence emulsion stability, and therefore their concentration in three-in-one solutions is limited to prevent "cracking" of the PN solution, in which microscopic or macroscopic precipitates are formed. The higher the cation valence, the greater the destabilizing influence to the emulsifier. Therefore trivalent cations such as ferric ion (iron dextran) are more disruptive than divalent cations such as calcium or magnesium ions, which are more disruptive than monovalent

Figure 2 Percentage change in metabolic rate due to injury. (Adapted from Wilmore DW: *The Metabolic Management of the Critically Ill*, New York, Plenum Medical Books, 1977.)

TABLE 1 Recommended Daily Doses of Parenteral Vitamins and Trace Elements

MICRONUTRIENT	PARENTERAL DOSE
Vitamins	
Vitamin A	3300 IU
Vitamin D	200 IU
Vitamin E	10 IU
Vitamin K	150 µg
Ascorbic acid (vitamin C)	200 µg
Folic acid	600 µg
Niacin	40 mg
Riboflavin (vitamin B ₂)	3.6 mg
Thiamine (vitamin B ₁)	6 mg
Pyridoxine (vitamin B ₆)	6 mg
Cyanocobalamin (vitamin B ₁₂)	5 µg
Pantothenic acid	15 mg
Biotin	60 µg
Trace Elements	
Zinc	2.5–5 mg
Copper	0.3–0.5 mg
Chromium	10–15 µg
Manganese	60–100 µg
Selenium	20–60 µg

Data from American Medical Association, Department of Foods and Nutrition: Multivitamin preparations for parenteral use. A statement by the Nutrition Advisory Group, JPEN J Parenter Enteral Nutr 1979;3:258–62; Food and Drug Administration: Parenteral multivitamin products: Drugs for human use: Drug efficacy study implementation: Amendment, Federal Register 2000;65 (77):21200–21201.

TABLE 2 Central Vs. Peripheral Parenteral Nutrition

PROPERTY	CENTRAL NUTRITION	PERIPHERAL NUTRITION
Daily calories	2000–3000	1000–1500
Protein	Variable	56–87 g
Volume of fluid required (mL)	1000–3000	2000–3500
Duration of therapy (d)	>7	5–7
Route of administration	Dedicated central venous catheter	Peripheral vein or multiuse central catheter
Substrate profile	55%–60% carbohydrate 15%–20% protein 25% fat	30% carbohydrate 20% protein 50% fat
Osmolarity (mOsm/L)	~2000	~600–900

cations such as sodium or potassium. No concentration of iron dextran is safe in triple-mix formulations. In-line filtration is necessary for all PN solutions, including triple-mix solutions, because it is impossible to visually detect precipitates until they are grossly incompatible and unsafe for infusion.

Once the basic solution is created, electrolytes are added as needed (Table 3). Sodium or potassium salts are given as chloride or acetate depending on the patient's requirements. Normally, equal amounts of chloride and acetate are provided. However, if chloride losses from the body are increased, which can occur in patients who have nasogastric tubes, then most of the salts should be given as chloride. Similarly, more acetate should be given to patients when additional base is required because acetate generates bicarbonate when it is metabolized. Sodium bicarbonate is incompatible with PN solutions and cannot be added to the mixture. Phosphate may be given as the sodium or potassium salt. Lipid injectable emulsions contain an additional 15 mmol/L of phosphate.

Commercially available preparations of fat-soluble and water-soluble vitamins, minerals, and trace elements are added to the nutrient mix unless they are contraindicated. Adequate thiamine is essential for patients receiving PN and can be provided separately. Vitamin K is now a component of standard IV multivitamin preparations; vitamin preparations without vitamin K are also available for those patients who may need a vitamin K restriction (e.g., patients on warfarin). Trace element preparations that include zinc, copper, manganese, and chromium are added to the PN solution in amounts consistent with the American Medical Association guidelines (see Table 1). Manganese accumulation can be toxic, and overexposure can lead to progressive neurodegenerative damage. Manganese is usually supplied in the PN solution at a daily dose of 0.5 mg as part of a multiple trace element additive. Because manganese is primarily eliminated via biliary excretion, patients with biliary obstruction or cholestasis can accumulate potentially toxic levels of manganese. Hence, manganese should be removed from the PN of patients with hyperbilirubinemia. Higher doses, 10 to 15 mg/d, of zinc are provided to patients with excessive GI losses.

Iron is not a part of commercial additive preparations because it is incompatible with triple-mix solutions and can cause anaphylactic reactions when it is given intravenously. Patients who need this trace element should receive it orally or by injection. Iron is not given to patients who are critically ill because hyperferremia can increase bacterial virulence, alter polymorphonuclear cell function, and increase host susceptibility to infection.

PPN is less commonly used than central PN and can be disadvantageous. Because of the low concentration of dextrose, greater volumes (typically >2 L/d) are required to provide sufficient calories, which might not be feasible in fluid-restricted patients. PPN generally does not approximate a patient's energy needs because PPN provides only 1000 to 1500 kcal/d, and a large percentage of the calories (60%) are derived from fat. High-fat infusions are undesirable because they are associated with impaired reticuloendothelial system function and are potentially immunosuppressive. There is no evidence that lipid injectable emulsions improve outcomes or significantly decrease nitrogen losses. Generally, PPN should be avoided unless it is combined with enteral feeding in patients who cannot tolerate full enteral feeding, patients who cannot get a central venous catheter, or patients with low body weights in whom PPN can meet at least two-thirds of estimated needs.

Administration and Venous Access

Typically, central PN solutions are administered into the superior vena cava. Access to this vein can be achieved by cannulation of the subclavian or internal jugular veins. Peripherally inserted central venous catheters (PICCs), typically inserted via an antecubital vein and advanced into the superior vena cava, are the most commonly used central venous access devices for providing PN. PICC placement offers the advantage of central venous access, while avoiding the risks associated with accessing the subclavian or jugular veins, such as hemothorax, pneumothorax, and arterial injury.

Tunneled catheters or catheters with indwelling ports should be considered for patients who will need prolonged central venous nutrition (e.g., >6 weeks). Patients who will be using their catheters solely for daily central PN and who require home IV feeding

TABLE 3 Electrolyte Concentrations in Parenteral Nutrition

ELECTROLYTE	RECOMMENDED CENTRAL PN DOSES	RECOMMENDED PERIPHERAL PN DOSES	USUAL RANGE OF DOSES
Potassium (mEq/L)	30	30	0–120 (CVC) 0–80 (PV)
Sodium (mEq/L)	30	30	0–150
Phosphate (mmol/L)	15	5	0–20
Magnesium (mEq/L)	5	5	0–16
Calcium (mEq/L) (as gluconate)	4.7	4.7	0–10
Chloride (mEq/L)	50	50	0–150
Acetate (mEq/L)	40	40	0–100

Abbreviations: CVC=central venous catheter; PN=parenteral nutrition; PV=peripheral vein.

may be best served by a tunneled catheter rather than an indwelling port. Tunneled catheters may be more easily manipulated and cared for, which can minimize the risk of infection.

Inserting a dedicated line for infusing hypertonic solutions requires strict aseptic technique and maximal barrier protection: hat, mask, gown, and gloves must be worn. The position of the catheter tip in the superior vena cava is confirmed by chest x-ray before any concentrated solutions are administered. Once the position of the tip has been confirmed, the line should be used exclusively for administering the hypertonic nutrient solution.

Multiple-lumen central venous catheters are most commonly used. Although at least one lumen is dedicated to the infusion of the PN solutions, the other(s) may be used for monitoring, blood drawing, or medication. The rate of catheter sepsis associated with multiple-port catheters may be the same as or slightly greater than the rate associated with the use of single-port catheters. However, multiple-port PICCs are used to infuse PN solutions for a shorter time, which can minimize their inherent risk. Multiple-port catheters should be carefully maintained, including dressing changes, maintaining the dedicated lumen, careful handling of the other lumens, and removing the catheter as soon as it is no longer needed.

Infusion and Patient Monitoring

It is advisable to start with 1 L of central PN and increase the volume as needed, depending on the patient's metabolic stability. Blood glucose levels should be closely monitored and maintained at <180 mg/dL, tissue perfusion should be adequate, and PO₂, PCO₂, electrolytes (especially potassium, phosphate, and magnesium) and acid-base balance should be near normal before starting or advancing to the goal solution. The solutions should be administered using a volumetric pump set at a constant rate. It is important not to modify the infusion rate during any given day to try to compensate for excess or inadequate administration of the PN solution, such as when the PN solution arrives later than expected. A cyclic schedule (10–16 h/d) for patients requiring long-term PN can be initiated once the patient is metabolically stable. In situations when the central PN solution must be suddenly discontinued, a 10% dextrose solution may be given at the same infusion rate as was used for the PN unless the patient is severely hyperglycemic. PN solutions may be administered at one-half the infusion rate to patients who are undergoing surgical procedures because circulating glucose and electrolyte levels are easier to control.

In addition to hyperglycemia, metabolic complications include hyper- and hypophosphatemia, hyper- and hypokalemia, hyper- and hypomagnesemia, and hyper- and hypocalcemia. Thus it is important to monitor the patient's serum electrolytes closely, especially when initiating TPN. Once the patient has stabilized on the individual nutritional prescription, serum chemistries should be

obtained at least twice weekly to measure chloride, CO₂, potassium, sodium, blood urea nitrogen, creatinine, calcium, and phosphate levels and once weekly for a full profile that includes liver function, magnesium, and triglyceride levels. Stable home PN patients may have less frequent chemistry monitoring, typically starting with once per week monitoring, then decreasing to twice per month and then monthly, depending on overall stability and clinical status.

Patients with Special Needs

Glucose Intolerance

Hyperglycemia is the most common metabolic complication related to PN, and glucose regulation may be especially difficult in patients who have diabetes mellitus or who develop insulin resistance in response to severe stress or infection. Control of blood glucose levels is important for all patients who receive PN because uncontrolled hyperglycemia may be associated with complications such as fluid and electrolyte disturbances and increased infection risk due to impairment of host defenses, including decreased polymorphonuclear leukocyte mobilization, chemotaxis, and phagocytic activity. Intensive insulin therapy, maintaining blood glucose concentrations between 80 and 110 mg/dL, was once considered standard practice for critically ill patients. However, other studies have demonstrated significant morbidity and mortality with this approach. For critically ill patients, a target blood glucose of 110 to 150 mg/dL is preferred, and for ambulatory patients, a target blood glucose of 140 to 180 mg/dL is recommended.

Patients with difficult glycemic control may best be managed by continuous insulin infusion, which is safe, effective, and more timely than subcutaneous insulin therapy. Hypoglycemia that occurs during this type of infusion generally is short lived and more easily corrected than hypoglycemia resulting from subcutaneous insulin administration. A separate IV insulin infusion can be used rather than adding incremental doses of insulin to the PN bag every 24 hours in patients for whom glycemic control is difficult. Many intensive care units (ICUs) have an insulin drip infusion protocol in which there are frequent checks of serum glucose and adjustments of the insulin infusion drip (e.g., every 1–2 hours) to maintain target glucose levels. The conventional approach of using sliding scale insulin to cover high blood glucose levels may be unsafe and ineffective, and repetitive doses of subcutaneous insulin in the edematous patient can have a cumulative effect leading to prolonged hypoglycemia. In addition, adjusting insulin in the PN bag every 24 hours might not achieve the desired rapid correction of hyperglycemia deemed appropriate based on the literature, which indicates worse outcomes for those with poor glucose control.

Abrupt discontinuation of PN can lead to hypoglycemia and should be avoided. Instead, it is recommended to decrease the PN infusion rate by one-half for the last hour of infusion prior to discontinuation to prevent rebound hypoglycemia.

Pancreatitis

Most cases of pancreatitis are mild, and nutritional support is not needed. However, 10% to 20% of patients with pancreatitis develop severe disease that results in a hypermetabolic, hyperdynamic, systemic inflammatory response syndrome that creates a highly catabolic stress state. In an evidence-based report evaluating nutrition support in acute pancreatitis patients, EN delivered to the small intestine (distal to the ligament of Treitz) is preferred over PN; EN patients are less likely to suffer from multiorgan failure, systemic infections, and death.

Initiation of PN should be delayed in patients with acute pancreatitis who cannot tolerate EN even though they might eventually require PN. Providing PN within 24 hours of admission has been shown to worsen outcome, and providing PN after resuscitation and abatement of the acute inflammatory process appears to improve outcome compared with standard therapy. Consequently, if EN is not feasible, the initiation of PN should be delayed for at least 5 days after admission to the hospital, when the peak period of inflammation has abated.

Acute Kidney Injury and Chronic Kidney Disease

Acute kidney injury (AKI) is associated with severe nutritional deficits. Most patients with AKI are catabolic and have energy requirements 50% to 100% greater than resting requirements, likely the result of other coexisting conditions such as sepsis, trauma, and burns. Energy is provided to patients with AKI in sufficient quantities to minimize protein degradation, generally in the range of 25 to 35 kcal/kg/day. Lipid injectable emulsions can be used as a source of concentrated energy in patients who require a fluid restriction.

Protein loss is accelerated and protein synthesis is impaired in patients with AKI. Loss of amino acids in the dialysate and renal replacement therapies add to the protein deficit and increase individual protein needs. Approximately 10 to 12 g of amino acids are lost with each dialysis therapy, depending on the type of dialyzer membrane, blood flow rate, and dialyzer reuse procedure, and approximately 10 to 16 g/day of amino acids are lost through continuous renal replacement therapies (CRRT). The provision of protein at 1.0 to 1.4 g/kg/day and 1.5 to 2.5 g/kg/day is recommended for AKI patients receiving hemodialysis and CRRT, respectively.

Protein is provided with a standard solution containing both essential and nonessential amino acids. Although some data suggest essential amino acids alone may be beneficial compared to a mixture of both essential and nonessential amino acids, the efficacy of using essential amino acid solutions remains uncertain. The goal is to provide adequate protein while treating the patient aggressively with dialysis to prevent the accumulation of nitrogenous waste products.

Fluid and electrolyte balance are often impaired in patients with AKI. The amount of fluid from the PN might need to be adjusted daily, depending on the phase of AKI, whether the patient is receiving dialysis, and whether dialysis is continuous or intermittent. Serum potassium and phosphate levels typically rise in patients with AKI until dialysis is initiated, at which time levels might drop, especially with the provision of PN. Potassium, phosphate, and magnesium levels need close monitoring and adjusting to correct imbalances. Acetate salts of potassium or sodium can be administered to help correct a metabolic acidosis.

Standard doses of the water-soluble vitamins and additional folic acid (1 mg/day total) and pyridoxine (vitamin B₆) (10 mg/day) might need to be added to the solution for patients who are being dialyzed because these vitamins are lost from the body in the dialysate bath. Thiamine losses are increased with CRRT and repletion (100 mg/day) must be provided for patients receiving this therapy. The dose of vitamin C might need to be restricted to 100 mg/day to prevent oxalate deposits. However, additional vitamin C (250 mg/day) should be provided to patients receiving CRRT. The supplementation of fat-soluble vitamins is usually not required, especially in patients who also are eating, because excretion of fat-soluble vitamins is reduced in renal failure. For example, serum vitamin A levels may be elevated in ARF due to enhanced hepatic release

of retinol and retinol-binding protein, decreased renal catabolism, and decreased degradation of vitamin A transport protein by the kidneys. Vitamin D levels may be decreased because of impaired activation of 1,25-dihydroxycholecalciferol in the kidneys. In anuric patients, trace elements may be withheld from the PN solution; however, for prolonged PN, trace elements and fat-soluble vitamins should be monitored and replaced accordingly.

Patients with chronic kidney disease (CKD) also have nutritional deficits due to anorexia, amino acid losses into the dialysate, concurrent illness, metabolic acidosis, and endocrine disorders. However, unlike those suffering from AKI, patients with CKD have normal energy requirements. Protein intake generally is restricted in predialysis patients to 0.6 g/kg/day or 0.75 g/kg/day if the patient is malnourished. Protein is required in higher amounts in patients on dialysis, depending on the type of dialysis: 1.2 g/kg/day for hemodialysis; 1.2 to 1.5 g/kg/day for peritoneal dialysis. Predialysis patients who become acutely ill should be given protein 1.2 to 1.5 g/kg/day even if this precipitates the need for dialysis. Starvation from insufficient calories or protein in the patient with renal dysfunction increases the risk of nutritionally related complications and should be avoided in the severely ill patient regardless of the potential need for dialysis.

Intradialytic PN is the provision of IV amino acids, carbohydrates, and fat directly into the venous drip chamber of the hemodialysis unit during treatment. It is a method of providing additional calories and protein in malnourished chronic hemodialysis patients. It is associated with significant increases in body weight and serum albumin in patients with end stage renal disease. However, intradialytic PN is expensive and the benefits have not been fully elucidated. A typical solution contains about 1100 kcal and 50 g of protein, which is provided three times per week with hemodialysis. For example, intradialytic PN provides a patient with energy and protein requirements of 2500 kcal and 70 g of protein/day, respectively, only 20% of the weekly calorie and 30% of the weekly protein needs. Thus, intradialytic PN is reserved for patients with CRF who cannot ingest sufficient nutrients by mouth and who are not candidates for nutritional support via EN or PN due to GI intolerance or venous access problems or for other reasons. Appropriate use of intradialytic PN should be limited to a very small fraction of people who are on hemodialysis.

Hepatic Dysfunction and Liver Failure

Hepatic dysfunction is associated with a variety of abnormalities including metabolic abnormalities, malabsorption, maldigestion, anorexia, and early satiety due to ascites. Dietary restrictions also can contribute to malnutrition.

Protein intake in patients with stable chronic liver disease depends on the patient's nutritional status and protein tolerance. Nutritionally depleted patients can require as much protein as 1.5 g/kg estimated dry weight. In a minority of patients who have protein-sensitive hepatic encephalopathy, protein intake might need to be decreased to 0.5 to 0.7 g/kg/day and gradually increased to 1.0 to 1.5 g/kg/day, as tolerated. These patients have deranged plasma amino acid profiles, with increased concentrations of aromatic amino acids (phenylalanine, tyrosine, and tryptophan) and methionine and decreased branched-chain amino acids (leucine, isoleucine, and valine). Randomized, controlled trials that provided parenteral or enteral formulas enriched with branched-chain amino acids have been inconsistent and have had results including no benefit, improved morbidity, no change in mortality, and improvement in encephalopathy. These specialty products should be reserved for patients with disabling encephalopathy who do not tolerate standard proteins and have not responded to other therapies, such as lactulose or neomycin administration.

Energy requirements are difficult to predict in patients with liver failure. Whereas most patients have a normal metabolic rate, up to one-third may be hypermetabolic. Although providing 25 to 30 kcal/kg/day is a guideline for providing energy needs, basing requirements on indirect calorimetry is often recommended.

Fluid restriction due to ascites and edema often necessitates increasing the dextrose concentration in the PN so as to maintain

sufficient calories in a restricted volume. Sodium is reduced in the formula because liver-failure patients excrete nearly sodium-free urine. Vitamin and mineral deficiencies often occur as a result of suboptimal nutrient intake, decreased absorption, decreased storage, and in some cases alcohol use, which decreases thiamine (vitamin B₁) and folate absorption. Copper and manganese may be contraindicated because a major route of excretion for these substances is the biliary system. Zinc deficiency is common in cirrhotic patients, and supplementation of this mineral may be necessary, especially if there are excessive GI losses.

Acute Respiratory Distress Syndrome

Patients with protein-calorie malnutrition have an increased incidence of pneumonia, respiratory failure, and acute respiratory distress syndrome (ARDS). Nutritional support is indicated in patients with ARDS, and underfeeding and overfeeding can be detrimental to pulmonary function.

Overfeeding calories, and particularly glucose, can lead to increased minute ventilation, increased dead space, and increased carbon dioxide production and ultimately to difficulty weaning from a ventilator. Hypercapnia from increased carbon dioxide production is the result of glucose combustion causing more carbon dioxide production and excess calories triggering lipogenesis. A healthy person increases ventilation in response to increased calories and thus avoids hypercapnia. However, patients with compromised ventilatory status might not be able to compensate with increased ventilation and can develop respiratory distress, acute respiratory failure, and difficulty weaning from mechanical ventilation. Thus, the use of indirect calorimetry measurements to determine energy expenditure is imperative in patients with ARDS.

Critically Ill Obese Patients

Obesity is a growing problem worldwide, and management of critically ill obese patients poses many challenges. These patients are at risk for hyperglycemia, hyperlipidemia, and hypercapnea, all of which can be exacerbated by metabolic changes associated with critical illness. As with any critically ill patient, obese patients will preferentially use protein and carbohydrate for energy and cannot effectively draw upon adipose tissue for energy. These patients require nutrition support to minimize loss of lean body mass.

The concept of “hypocaloric feeding” has emerged as the preferred way to feed critically ill obese patients. Energy delivery is restricted to approximately 60% to 70% of estimated energy requirements and protein delivery is high (typically >2 g/kg ideal body weight [IBW]). This is to avoid hyperglycemia, hyperlipidemia, and hypercapnea while providing the protein required to spare lean body mass and support recovery. Small-scale studies employing this feeding method have demonstrated that patients can achieve positive nitrogen balance; one study found decreased ICU length of stay, decreased antibiotic days, and a trend toward decreased mechanical ventilation days.

Energy and protein delivery for critically ill obese patients is guided by BMI. The ASPEN-SCCM guidelines recommend providing 11 to 14 kcal/kg actual weight or 22 to 25 kcal/kg IBW for patients with a BMI >30 kg/m². In comparing these recommendations to our experience with measuring REE in this population, we have found that this should be refined further by BMI. For patients with a BMI of 30 to 50 kg/m², 11 to 14 kcal/kg closely represented 60% to 70% of measured REE. For patients with a BMI >50 kg/m², 22 to 25 kcal/kg IBW represents 60% to 70% of measured REE. For protein delivery, ASPEN and SCCM recommend protein provision of ≥2 g/kg IBW for patients with class I and class II obesity (BMI of 30 to 35 kg/m² and 35 to 40 kg/m², respectively) and for patients with class III obesity (BMI >40 kg/m²) protein provision should be ≥2.5 g/kg IBW.

Other Conditions and Nutritional Treatments

The catabolic response to major surgery, trauma, burn, and sepsis is characterized by a net breakdown of body protein stores to provide substrates for gluconeogenesis and acute-phase protein

synthesis. Adequate nutrition can attenuate whole-body catabolism but rarely, if ever, prevents or reverses the loss of lean body mass during the acute phase of injury. Several strategies to prevent the loss of lean body mass have been investigated, including growth hormone, growth factors, and conditionally essential amino acids, such as glutamine.

Growth hormone is a potent anabolic agent, and administration to humans increases the rate of wound healing, decreases rates of wound infection, and decreases the catabolism and muscle wasting of critical illness. However, a large European trial found increased morbidity and mortality in patients with prolonged critical illness who received high doses of growth hormone. Thus, the use of growth hormone in patients who are in the acute phase of critical illness is not recommended.

Alternative anabolic agents such as oxandrolone (Oxandrin)¹ and testosterone¹ are being pursued to induce positive nitrogen balance and enhance wound healing in critically ill patients. These anabolic steroid hormones increase protein synthesis and can reduce the rate of protein breakdown. In a study of patients with alcoholic hepatitis, administration of oxandrolone was associated with lower mortality compared with patients receiving placebo. The patients receiving oxandrolone had improvements in the severity of their liver injury and the degree of malnutrition. Several studies have demonstrated a benefit of oxandrolone use in the burn patient population. Other anabolic steroid hormones, such as methandienone² and nandrolone decanoate (Deca Durabolin),² have been shown to increase protein anabolism and nitrogen balance in hospitalized patients.

Growth factors should be reserved for patients with major burns and documented impaired healing; patients who have large wounds or enterocutaneous fistulae and who have impaired healing; and patients with muscle wasting and weakness associated with AIDS; other failure to thrive conditions; and, in general, patients who have not responded to aggressive nutritional support but whose underlying disease processes are controlled. Growth factors have not been shown to decrease length of time on a respiratory in ICU patients. In fact, such factors can increase ventilator time and worsen outcome.

Glutamine-supplemented PN solutions administered to trauma or stressed patients can improve overall nitrogen balance, enhance muscle protein synthesis, improve intestinal nutrient absorption, decrease gut permeability, improve immune function, and decrease hospital stays and costs in some patient populations. A review of 14 randomized trials in surgical and critically ill patients found that glutamine supplementation was associated with reduced mortality, lower rates of infectious complications, and a decreased hospital stay. The greatest benefit was in patients receiving high-dose (>0.29 g/kg/day) parenteral glutamine.

However, a recent randomized trial of glutamine and antioxidant micronutrient supplementation in critically ill patients showed a trend toward increased 28-day mortality and significant in-hospital and 6-month mortality in patients receiving glutamine supplementation. There were limitations in this study in that baseline glutamine levels were not checked for all patients; in a subset of 66 patients with plasma glutamine levels evaluated, all had normal levels at baseline. This suggests that glutamine supplementation may not be appropriate for all critically ill patients. In addition, patients received approximately 50% of goal energy requirements and approximately 45% of goal protein delivery from glutamine. The total amount of glutamine given in this study was significantly higher than the dose of glutamine usually recommended. This raises the possibility that there is an optimal “therapeutic window” for glutamine administration: giving too little glutamine may not be efficacious and giving too much may be toxic. Further study is required before a definitive recommendation can be given based on this study alone.

¹Not FDA approved for this indication.

²Not available in the United States.

Patients with intestinal dysfunction requiring PN, such as those with short-bowel syndrome or mucosal damage following chemotherapy and/or irradiation, might benefit from glutamine-containing PN. Glutamine-containing PN might also be beneficial in patients with immunodeficiency syndromes, including AIDS, immune-system dysfunction associated with critical illness, and bone marrow transplantation; patients with severe catabolic illness, such as major burns; patients with multiple trauma; and patients with other diseases associated with a prolonged ICU stay. Glutamine-supplemented solutions should not yet be considered routine care and should not be used in patients with significant renal insufficiency or in patients with significant hepatic failure. A recent ASPEN position paper

summarizes recommendations for use of both enteral and IV glutamine.

Common Complications and Management Catheter Sepsis

Central venous catheter-related bloodstream infection ranges from 3% to 20% in hospitalized patients and is the most common complication of central venous catheters. The migration of microorganisms along the external surface of the catheter is likely the most common cause, followed by intraluminal contamination from manipulation of the catheter hub or IV connectors. The most common organisms associated with catheter-related bloodstream infections include *Staphylococcus epidermidis*, *Staphylococcus aureus*,

TABLE 4 Possible Etiologies and Treatment of Common Complications of Central Parenteral Nutrition

PROBLEM	POSSIBLE ETIOLOGY	TREATMENT
Glucose		
Hyperglycemia, glycosuria, hyperosmolar nonketotic dehydration, or coma	Excessive dose or rate of infusion, inadequate insulin production, steroid administration, infection	Decrease the amount of glucose given, increase insulin, administer a portion of calories as fat
Diabetic ketoacidosis	Inadequate endogenous insulin production and/or inadequate insulin therapy	Give insulin Decrease glucose intake
Rebound hypoglycemia	Persistent endogenous insulin production by islet cells after long-term high-carbohydrate infusion	Give 5%–10% glucose before parenteral infusion is discontinued
Hypercarbia	Carbohydrate load exceeds the ability to increase minute ventilation and excrete excess CO ₂	Limit glucose dose to 5 mg/kg/min Give greater percentage of total caloric needs as fat (up to 30%–40%)
Fat		
Hypertriglyceridemia	Rapid infusion Decreased clearance	Decrease rate of PN infusion Allow clearance (~12 h) before testing blood
Essential fatty acid deficiency	Inadequate essential fatty acid administration	Administer essential fatty acids in doses of 4%–7% of total calories
Amino Acids		
Hyperchloremia metabolic acidosis	Excessive chloride content of amino acid solutions	Administer Na ⁺ and K ⁺ as acetate salts
Prerenal azotemia	Excessive amino acids with inadequate caloric supplementation	Reduce amino acids Increase the amount of glucose calories
Miscellaneous		
Hypophosphatemia	Inadequate phosphorus administration with redistribution into tissues	Give 15 mmol phosphate/1000 IV kcal Evaluate antacid and Ca ²⁺ administration
Hypomagnesemia	Inadequate administration relative to increased losses (diarrhea, diuresis, medications)	Administer Mg ²⁺ (15–20 mEq/1000 kcal)
Hypermagnesemia	Excessive administration; renal failure	Decrease Mg ²⁺ supplementation
Hypokalemia	Inadequate K ⁺ intake relative to increased needs for anabolism; diuresis	Increase K ⁺ supplementation
Hyperkalemia	Excessive K ⁺ administration, especially in metabolic acidosis; renal decompensation	Reduce or stop exogenous K ⁺ If ECG changes are present, treat with calcium gluconate, insulin, diuretics, and/or Kayexalate
Hypocalcemia	Inadequate Ca ²⁺ administration; reciprocal response to phosphorus repletion without simultaneous calcium infusion	Increase Ca ²⁺ dose
Hypercalcemia	Excessive Ca ²⁺ administration; excessive vitamin D administration	Decrease Ca ²⁺ and/or vitamin D administration
Elevated liver transaminases or serum alkaline phosphatase and bilirubin	Enzyme induction secondary to amino acid imbalances or overfeeding	Reevaluate nutritional prescription Cycle TPN Avoid overfeeding calories Consider administering carnitine

Abbreviations: ECG = electrocardiogram; PN = parenteral nutrition; TPN = total parenteral nutrition.

Enterococcus spp., *Candida albicans*, and *Enterobacter* spp. as well as resistant strains such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci. Primary catheter sepsis occurs when there are signs and symptoms of infection and the indwelling catheter is the only anatomic focus of infection. Secondary catheter infections are associated with another focus or multiple infectious foci that cause bacteremia and seed the catheter.

Management of patients with catheter infection depends on their clinical condition. With extremely ill patients with high fevers who are hypotensive or who have local signs of infection around the catheter site, the catheter should be removed, its tip cultured, and peripheral and central venous blood cultures obtained. In catheter-related bloodstream infection, the organisms that grow from the catheter tip are the same those identified in the peripheral blood culture, and typically more than 10^3 organisms are grown from cultures of the catheter tip.

Specific therapy should be initiated against the primary source in patients in whom a source of infection, other than the catheter tip, is present. Peripheral blood cultures should be obtained and blood cultures should not be taken from the central venous catheter port dedicated for PN because this increases the risk of contaminating the line. If the infection resolves, central venous feedings can be continued. If a secondary source is not identified and the symptoms persist, the catheter should be removed and its tip should be cultured. If the culture of the catheter tip returns positive or if the index of suspicion is high, appropriate antibiotic therapy is initiated. Central venous feeding can be resumed, maintaining euglycemia.

Occasionally, the situation arises in which a site of infection, other than the catheter, is identified, but signs and symptoms persist despite what is assumed to be adequate therapy. Again, if blood cultures are positive, the safest course of action may be to remove the catheter. If peripheral blood cultures are negative, the catheter may be changed over a guidewire and the catheter tip cultured to determine if it was contaminated. Central venous feedings may be continued during this interval if the patient is stable. If the catheter tip returns positive, a new catheter should be inserted at a different site. Changing the central venous catheter over a guidewire can also facilitate the diagnosis of primary catheter infections. Changing the site of catheter location, rather than guidewire exchange, is recommended in patients in whom infection is suspected.

Other Complications

Common complications, their etiologies, and treatments are outlined in Table 4. Prolonged administration of PN can result in altered hepatic function and changes in liver pathologic conditions that can lead to liver failure. One to 2 weeks after initiating PN, transaminases may be elevated, but this often resolves without any change in the composition of PN or rate of administration. However, in patients receiving long-term PN (>20 days), prolonged elevations of alkaline phosphatase followed by elevated levels of serum transaminases can occur, even after therapy is discontinued.

Serum levels of alkaline phosphatase and bilirubin initially remain normal, but they rise in many patients who receive long-term PN. Patients who do not receive lipids in the PN solution have more frequent and severe hepatic abnormalities, most likely due to higher carbohydrate loads. Excess glucose increases insulin secretion, which stimulates hepatic lipogenesis and results in hepatic fat accumulation. Fatty infiltration is the initial histopathologic change; it is readily reversible and might not be accompanied by altered liver function tests.

Longer PN therapy may be associated with cholestasis, cholelithiasis, steatosis, and steatohepatitis and can progress to active chronic hepatitis, fibrosis, and eventual cirrhosis. The management of PN-related liver dysfunction is summarized in Box 3.

Complications are minimized and nutritional therapy maximized when the care of patients who require specialized nutritional support is supervised by a nutrition support team. Ideally, the nutrition support team consists of a pharmacist, dietitian, nurse, and physician.

BOX 3

Management of Parenteral Nutrition-Related Liver Dysfunction

Have the patient eat, if possible.
Avoid administering large amounts of glucose or protein calories.
Supply IV fat emulsions (up to 30% of total calories).
Cycle the parenteral nutrition, infusing for 10–12 h/d.
Reevaluate energy needs; reduce energy delivery if liver dysfunction persists.

PHEOCHROMOCYTOMA

Method of

Melissa K. Gonzales, BS; and Karel Pacak, MD, PhD, DSc, FACE

CURRENT DIAGNOSIS

- Hypertension is the most common clinical sign.
- A triad of headaches, palpitations, and sweating (sometimes associated with paleness), with or without hypertension, indicates the possibility of a pheochromocytoma.
- Biochemical diagnosis of pheochromocytoma should be based on the determination of plasma free or urine fractionated metanephrines.
- Localization of pheochromocytomas should consist of anatomic imaging, preferably computed tomography (CT) or magnetic resonance imaging (MRI), followed by specific functional imaging using positron emission tomography (PET).

Enterococcus spp., *Candida albicans*, and *Enterobacter* spp. as well as resistant strains such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci. Primary catheter sepsis occurs when there are signs and symptoms of infection and the indwelling catheter is the only anatomic focus of infection. Secondary catheter infections are associated with another focus or multiple infectious foci that cause bacteremia and seed the catheter.

Management of patients with catheter infection depends on their clinical condition. With extremely ill patients with high fevers who are hypotensive or who have local signs of infection around the catheter site, the catheter should be removed, its tip cultured, and peripheral and central venous blood cultures obtained. In catheter-related bloodstream infection, the organisms that grow from the catheter tip are the same those identified in the peripheral blood culture, and typically more than 10^3 organisms are grown from cultures of the catheter tip.

Specific therapy should be initiated against the primary source in patients in whom a source of infection, other than the catheter tip, is present. Peripheral blood cultures should be obtained and blood cultures should not be taken from the central venous catheter port dedicated for PN because this increases the risk of contaminating the line. If the infection resolves, central venous feedings can be continued. If a secondary source is not identified and the symptoms persist, the catheter should be removed and its tip should be cultured. If the culture of the catheter tip returns positive or if the index of suspicion is high, appropriate antibiotic therapy is initiated. Central venous feeding can be resumed, maintaining euglycemia.

Occasionally, the situation arises in which a site of infection, other than the catheter, is identified, but signs and symptoms persist despite what is assumed to be adequate therapy. Again, if blood cultures are positive, the safest course of action may be to remove the catheter. If peripheral blood cultures are negative, the catheter may be changed over a guidewire and the catheter tip cultured to determine if it was contaminated. Central venous feedings may be continued during this interval if the patient is stable. If the catheter tip returns positive, a new catheter should be inserted at a different site. Changing the central venous catheter over a guidewire can also facilitate the diagnosis of primary catheter infections. Changing the site of catheter location, rather than guidewire exchange, is recommended in patients in whom infection is suspected.

Other Complications

Common complications, their etiologies, and treatments are outlined in Table 4. Prolonged administration of PN can result in altered hepatic function and changes in liver pathologic conditions that can lead to liver failure. One to 2 weeks after initiating PN, transaminases may be elevated, but this often resolves without any change in the composition of PN or rate of administration. However, in patients receiving long-term PN (>20 days), prolonged elevations of alkaline phosphatase followed by elevated levels of serum transaminases can occur, even after therapy is discontinued.

Serum levels of alkaline phosphatase and bilirubin initially remain normal, but they rise in many patients who receive long-term PN. Patients who do not receive lipids in the PN solution have more frequent and severe hepatic abnormalities, most likely due to higher carbohydrate loads. Excess glucose increases insulin secretion, which stimulates hepatic lipogenesis and results in hepatic fat accumulation. Fatty infiltration is the initial histopathologic change; it is readily reversible and might not be accompanied by altered liver function tests.

Longer PN therapy may be associated with cholestasis, cholelithiasis, steatosis, and steatohepatitis and can progress to active chronic hepatitis, fibrosis, and eventual cirrhosis. The management of PN-related liver dysfunction is summarized in Box 3.

Complications are minimized and nutritional therapy maximized when the care of patients who require specialized nutritional support is supervised by a nutrition support team. Ideally, the nutrition support team consists of a pharmacist, dietitian, nurse, and physician.

PHEOCHROMOCYTOMA

Method of

Melissa K. Gonzales, BS; and Karel Pacak, MD, PhD, DSc, FACE

CURRENT DIAGNOSIS

- Hypertension is the most common clinical sign.
- A triad of headaches, palpitations, and sweating (sometimes associated with paleness), with or without hypertension, indicates the possibility of a pheochromocytoma.
- Biochemical diagnosis of pheochromocytoma should be based on the determination of plasma free or urine fractionated metanephrines.
- Localization of pheochromocytomas should consist of anatomic imaging, preferably computed tomography (CT) or magnetic resonance imaging (MRI), followed by specific functional imaging using positron emission tomography (PET).

- If a pheochromocytoma gene panel is not available, a cost-effective alternative is genetic screening guided by family history, clinical features, and a biochemical phenotype, which should be performed on most patients. The identification of a causative mutation should lead to presymptomatic genetic testing in a patient's relatives.

CURRENT THERAPY

- The optimal therapy for a pheochromocytoma is prompt surgical removal of the tumor.
- At least 1 to 2 weeks before the operation, there should be adequate control of blood pressure using mainly α -adrenoceptor blockers and, if tachyarrhythmia is present, β -adrenoceptor blockers; less commonly, calcium channel blockers and metyrosine (Demser) may be used if indicated.
- For most pheochromocytomas, laparoscopy is the procedure of choice.
- Adrenal cortex-sparing surgery should be advocated in all patients with hereditary (except *SDHB* gene mutation) and bilateral adrenal pheochromocytomas, if feasible.
- Clinical follow-up should be lifelong, especially in cases of an underlying germline mutation or with a large primary tumor greater than 4–5 cm, which has a higher likelihood to develop a metastasis.
- Management of metastatic tumors requires a multidisciplinary approach, in which pharmacologic treatment, targeted radiotherapy, chemotherapy, and surgery play an important role.

The 2017 WHO classification of endocrine tumors defines pheochromocytoma* as a tumor of chromaffin cells that arises in the adrenal medulla. Pheochromocytomas arise exclusively in the adrenal glands, whereas functionally similar tumors arising in extra-adrenal paraganglia are classified as paragangliomas. Pheochromocytomas and paragangliomas are characterized by the synthesis, metabolism, storage, and usually, but not always, secretion of catecholamines, metanephrines, and/or methoxytyramine.

Parasympathetic paragangliomas are mainly located along cranial and vagus nerves. Glomus or carotid body tumors, for example—head and neck paragangliomas—can be locally invasive but rarely develop metastases and usually do not secrete norepinephrine/normetanephrine, but up to 70% secrete dopamine/methoxytyramine.

Sympathetic paragangliomas mainly arise in the abdomen from chromaffin tissue neighboring or inside sympathetic ganglia. Less often, they originate from the pelvis and infrequently from the mediastinum (2%) and neck (1%). In the abdomen, they often derive from the organ of Zuckerkandl, a collection of chromaffin tissue around the origin of the inferior mesenteric artery (Figure 1).

Epidemiology

Pheochromocytomas can occur at any age, including in childhood, but most often they are detected in the fourth and fifth decades. There is no gender preference. In Western countries the prevalence of pheochromocytoma is estimated between 1:6500 and 1:2500, with an annual incidence of 3 to 8 cases per 1 million in the general population, although autopsies show a higher incidence. The pheochromocytoma-to-paraganglioma ratio is about 0.80 to 0.20. About 35% are familial, and 3% to 50% are malignant, depending on their genetic background.

Genetics

There are no lifestyle-related risk factors that increase the risk of pheochromocytoma. However, understanding of the role of

*For the purpose of this chapter, the term *pheochromocytoma* also refers to paraganglioma unless otherwise specified.

Figure 1 Anatomic distribution of chromaffin tissue. (Adapted from Lack E: Tumors of the adrenal gland and extra-adrenal paraganglia. In *Armed Forces Institute of Pathology: Atlas of Tumor Pathology*. Washington, DC, Armed Forces Institute of Pathology, 1997, 261–267.)

genetics has dramatically increased over the last several years. Up to 35% of pheochromocytomas are hereditary, and a significant number of patients (approximately 20%) with apparently sporadic tumors carry a germline mutation. Thus, gene mutations are the largest risk factor involved in the development of pheochromocytoma.

At present, at least 22 well-known susceptibility genes have been discovered that fall into two categories: major susceptibility genes and minor susceptibility genes. Major susceptibility genes represent about 85% to 90% of all hereditary tumors: the *VHL* gene, which causes von Hippel–Lindau syndrome; the *RET* gene, for multiple endocrine neoplasia (MEN) types 2A and 2B; the *NF1* gene in neurofibromatosis type 1; and the *SDHB* and *SDHD* genes in familial paraganglioma syndromes. Minor susceptibility genes include *SDHA*, *SDHC*, *SDHAF2*, *FH*, *MAX*, *TMEM127*, *PHD1*, *EGLN1/PHD2*, *IDH1*, *KIF1B β* , *HIF2A* (*EPAS1*), *MDH2*, and *DNMT3A* which represent 10% to 15% of hereditary tumors. Approximately 30 to 35% of pheochromocytomas can have somatic mutations in any of the aforementioned genes. The list of susceptibility genes is constantly growing, with recently reported genes having a very low incidence; therefore some of their characteristics have not yet been fully elucidated. We expect more genes to be reported in connection with familial pheochromocytoma, but their relevance must be confirmed. The characteristics of hereditary tumors are described in Table 1.

Pheochromocytomas can occur as part of several syndromes, which are associated with additional clinical conditions (Box 1). A recently described Pacak–Zhuang syndrome connects novel mutations in the gene encoding hypoxia-inducible factor 2 α (*HIF2A* or *EPAS1*) with paraganglioma, polycythemia, somatostatinoma, and retinal abnormalities. Other rare syndromes that include pheochromocytomas are Carney triad and Carney–Stratakis syndrome, which are characterized by gastrointestinal stromal tumors and

TABLE 1 Characteristics of Known Hereditary Pheochromocytomas

SYNDROME	MUTATION	GENE	PROTEIN FUNCTION	PENETRANCE	BILATERAL PHEO	MALIGNANT	PHEO OR PGL	PEAK AGE (Y)	BIOCHEMICAL PHENOTYPE
MEN2	10q11.2	RET	Receptor tyrosine kinase	~50%	50%–80%	Rarely malignant	Mainly PHEO	40	Adrenergic
VHL	3p25-26	VHL	von Hippel–Lindau protein/E3 ubiquitin protein ligase	10%–30%	50%	< 5%	Mainly PHEO	30	Noradrenergic
NF-1	17q11	NF-1	Neurofibromatosis-related protein	1%–2%	16%	~10%	Mainly PHEO	50*	Adrenergic
PGL5	5p15	SDHA	Catalytic flavoprotein; A subunit of SDH	Has not been studied consistently	Has not been studied consistently	0%–14%	Mainly PGL	40	Has not been studied consistently
PGL4	1p36	SDHB	Catalytic iron-sulfur protein; B subunit of SDH	80%–100% [†] (by age 70 y)	Rarely	31%–71%	Mainly PGL	30	Noradrenergic and/or dopaminergic; sometimes silent
PGL3	1q21	SDHC	Membrane-spanning protein; C subunit of SDH	Has not been studied consistently	Has not been studied consistently	Rarely malignant	Mainly PGL	38	Noradrenergic and/or dopaminergic; often silent as HNPG
PGL1	11q23	SDHD	Membrane-spanning subunit; D subunit of SDH	90% [†] if paternally transmitted (by age 70 y)	Has not been studied consistently	< 5%	Mainly PGL	35–40	Noradrenergic and/or dopaminergic; often silent as HNPG
PGL2	11q12.2	SDHAF2/SDHD5	Assembly factor for SDHA	~100% if paternally transmitted		Malignancy was not reported	Only PGL reported	30–40	Has not been studied consistently
	2q11.2	TMEM127	Transmembrane protein	Has not been studied consistently	33%	< 5%	Mainly PHEO	43	Mixed adrenergic and noradrenergic
	14q23	MAX	bHLHLZ transcription factor	Has not been studied consistently (probably paternal transmission only)	67%	~25%	Mainly PHEO	32	Mixed adrenergic and noradrenergic

*Seldom seen in children.

[†]Our unpublished observations show lower penetrance.

Note: An adrenergic phenotype represents either an increase only in metanephrine or both metanephrine and normetanephrine; a noradrenergic phenotype represents an increase only in normetanephrine; a mixed phenotype represents an increase in both metanephrine and normetanephrine.

Abbreviations: bHLHLZ = basic helix–loop–helix leucine zipper; HNPG = head and neck paraganglioma; MEN = multiple endocrine neoplasia; NF = neurofibromatosis; PGL = paraganglioma; SDH = succinate dehydrogenase; VHL = von Hippel–Lindau.

BOX 1

Main Clinical Features of Syndromes Associated With Pheochromocytoma

von Hippel–Lindau Syndrome**Type 1 (No Pheochromocytoma)**

Renal cell cysts and carcinomas
 Retinal and CNS hemangioblastomas
 Pancreatic neoplasms and cysts
 Endolymphatic sac tumors
 Epididymal cystadenomas

Type 2 (with Pheochromocytoma)

Type 2A: Retinal and CNS hemangioblastomas

- Pheochromocytomas
- Endolymphatic sac tumors
- Epididymal cystadenomas

Type 2B: Renal cell cysts and carcinomas

- Retinal and CNS hemangioblastomas
- Pancreatic neoplasms and cysts
- Pheochromocytomas
- Endolymphatic sac tumors
- Epididymal cystadenomas

Type 2C: Pheochromocytomas only

Multiple Endocrine Neoplasia Type 2

Type 2A (medullary thyroid carcinoma)

- Pheochromocytomas
- Hyperparathyroidism
- Cutaneous lichen amyloidosis

Type 2B (medullary thyroid carcinoma)

- Pheochromocytomas
- Multiple neuromas
- Marfanoid habitus

FMTc: familial medullary thyroid carcinoma only

Neurofibromatosis Type 1

Multiple benign neurofibromas on skin and mucosa

Café au lait skin spots

Iris Lisch nodules

Learning disabilities

Skeletal abnormalities

Vascular disease

CNS tumors

Malignant peripheral nerve sheath tumors

Pheochromocytomas

Paraganglioma Syndromes

Head and neck tumors

- Carotid-body tumors
- Vagal, jugular, and tympanic paragangliomas

Abdominal and/or thoracic paragangliomas

Pheochromocytomas

Renal cell carcinoma (SDHB)

Gastrointestinal stromal tumor (SDHB and SDHD)

Gastrointestinal stromal tumor (SDHB and SDHD)

Carney–Stratakis syndrome

Carney triad

Pituitary adenoma (SDHx)

Pacak–Zhuang syndrome

Polycythemia

Abbreviations: CNS = central nervous system; SDH = succinate dehydrogenase.

paragangliomas in an SDH gene cluster carrier or due to hypermethylation of the *SDHC* promoter. It is well established that renal cell carcinomas are also related to SDH gene cluster mutations.

Genetic counseling is recommended for all patients with pheochromocytoma, but it would be neither appropriate nor cost-effective to test for each disease-causing gene in every patient with

a pheochromocytoma. Currently a pheochromocytoma gene panel or exome sequencing are preferred methods to test for about 22 pheochromocytoma susceptibility genes. However, in some countries where these modalities are not available or too costly, an algorithm that takes family history, clinical characteristics, and a biochemical phenotype into consideration is shown in [Figure 2](#). In cases of confirmation of a hereditary disorder, one should offer specific genetic tests and genetic counseling to the patient's family members. Disease screening should be offered to presymptomatic relatives who have a diagnosed mutation, especially because familial syndromes are also associated with other types of tumors, and early diagnosis improves the prognosis of these patients. If a genetic syndrome can be established by genetic diagnosis, patient management can be individually tailored based on the specific characteristics of the syndrome.

Presymptomatic genetic testing in minors can raise ethical and legal issues, partly owing to the potential emotional impact of the results and the difficulty of obtaining individual informed consent for the testing of minors. To address these issues, the criteria for proper genetic testing should include several steps ([Box 2](#)). The advent of next-generation sequencing methods has the potential to decrease the cost of sequencing and enable all patients with pheochromocytoma to be screened as described above.

Clinical Manifestations

The signs and symptoms of pheochromocytoma are mostly the result of the hemodynamic and metabolic actions of the often inconsistent and disorderly secreted catecholamines on α - and β -adrenoceptors. Most symptoms are nonspecific, including dyspnea, nausea, weakness, weight loss, visual disturbances, arrhythmias, and anxiety or nervousness, but when a triad of headaches, palpitations, and sweating (sometimes with paleness) is accompanied by hypertension, pheochromocytoma should immediately be suspected. The typical episodic symptoms of catecholamine secretion seen in patients (e.g., palpitations, sweating, headache) may be caused by manipulation of the tumor, endoscopy, anesthesia, ingestion of food or beverages that contain tyramine, and certain medications like current antidepressants. However, very often these symptoms occur spontaneously. Often, many patients exhibit no symptoms or only minor ones. The diagnosis can therefore be easily missed. This is especially true in elderly patients.

Pheochromocytoma can also be discovered during preventive screening, as a result of signs and symptoms related to a mass effect of the tumor, and as incidental findings during imaging studies.

The primary clinical indicators for the diagnosis of pheochromocytoma are summarized in [Box 3](#).

Differential Diagnosis

Pheochromocytoma is often referred to as “the great mimic” because it has signs and symptoms that are common in numerous other clinical conditions. As a result, this often leads to the misdiagnosis of pheochromocytoma. Consideration should be given to other conditions that are associated with sympathomedullary activation (e.g., hyperadrenergic hypertension, renovascular hypertension, panic disorders, pseudopheochromocytoma, temporal epilepsy, and some other neuroendocrine tumors that may release vasoactive substances), because they mimic pheochromocytoma most closely. This overlap can be excluded by a normal response to the clonidine suppression test.

Biochemical Diagnosis

Missing a pheochromocytoma can have a fatal outcome. Therefore tests with high sensitivity are needed to safely exclude a pheochromocytoma without using expensive and unnecessary biochemical follow-up or imaging studies.

Pheochromocytomas can secrete all, none, or any combination of catecholamines (epinephrine, norepinephrine, dopamine). After multiple studies at the National Institutes of Health (NIH), measurement of plasma free metanephrines (the O-methylated metabolites of parent catecholamines), which represent metabolism of catecholamines, but not their secretion, showed superior combined

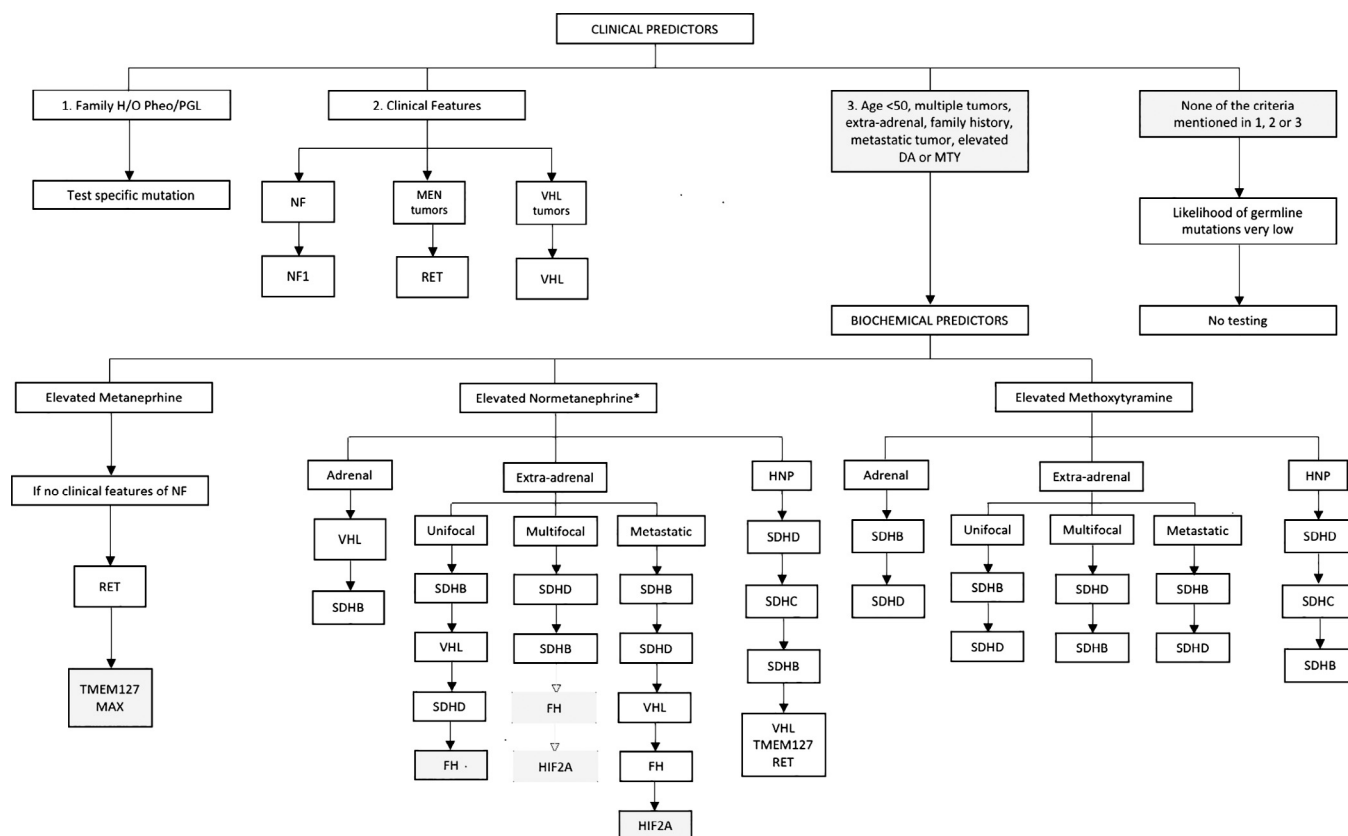

Figure 2 Suggested algorithm for genetic analysis in patients affected by pheochromocytoma or paraganglioma. If both normetanephrine and methoxytyramine are elevated, follow the algorithm for methoxytyramine. If both normetanephrine and metanephrine are elevated, follow the algorithm for metanephrine. *SDHAF2* mutation screening should be considered in patients who suffer exclusively from head and neck paragangliomas and who have familial antecedents, multiple tumors, or a very young age of onset and in whom the *SDHB/C/D* genes have been shown to be negative for mutations. In patients older than 50 years with benign adrenal tumors and no family history, consider *TMEM127* testing. *In a patient with elevated normetanephrine in whom clinical features and investigations do not clearly indicate which gene to test, perform immunohistochemistry before proceeding with testing. *Abbreviations:* DA = dopamine; FH = fumarate hydratase; HIF2A = hypoxia-inducible factor 2A; HNP = head and neck paraganglioma; H/O = history of; MEN = multiple endocrine neoplasia; MTY = methoxytyramine; NF = neurofibromatosis; VHL = von Hippel-Lindau. (Adapted from Karasek D, Shah U, Fryszak Z, et al. An update on the genetics of pheochromocytoma. *J Hum Hypertens.* 2012 May 31 27(3):141–147, 2013. doi: <https://doi.org/10.1038/jhh.2012.20>.)

BOX 2 Criteria for Proper Genetic Testing in Minors

Decision should be made by both parents after appropriate consultation with a geneticist.

Parents should be advised about how to inform their child about the hereditary disease and the reason for genetic testing.

The discussion of the most appropriate time for testing for each child should take into account the potential medical benefits and the minor's schedule (school schedule, birthdays, etc.).

Periods of medical examinations or hospitalization for the carrier parent should be avoided where possible.

Adapted from Lahlou-Laforet K, Consoli SM, Jeunemaitre X, Gimenez-Roqueplo AP. Pre-symptomatic genetic testing in minors at risk of paraganglioma and pheochromocytoma: Our experience of oncogenetic multidisciplinary consultation. *Horm Metab Res* 2012;44:354–358.

BOX 3 Patients Who Should Be Evaluated for Pheochromocytoma or Paraganglioma

- Anyone with a triad of headaches, sweating, and tachycardia, whether or not the subject has hypertension.
- Anyone with a known mutation of one of the susceptibility genes or a family history of pheochromocytoma and paraganglioma.
- Anyone with an incidental adrenal mass.
- Anyone whose blood pressure is poorly responsive to standard therapy.
- Anyone who has had hypertension, tachycardia, or arrhythmia in response to anesthesia, surgery, or medications known to precipitate symptoms in patients with pheochromocytoma and paraganglioma.

diagnostic sensitivity (98%) and specificity (92%) over all other tests. Analysis of free metanephrines and methoxytyramine in plasma is currently the method of choice to both detect and exclude the disease. In addition, 24-h urine collections may be used and are considered a good alternative to plasma tests when these tests are not available. The decision to rule out pheochromocytoma should be based on normal values of these tests, respecting for age-adjusted reference ranges.

The conditions under which blood samples are collected can be crucial to the reliability and interpretations of test results. The optimal circumstances are noted in [Box 4](#). Besides these conditions, numerous foods and medications can cause direct or indirect interference in the measurement of catecholamines and metanephrines. This should be kept in mind when interpreting a positive test result. Any antidepressants, particularly tricyclic ones, α -methyl dopa (Aldomet), mesalamine (Pentasa)/sulfasalazine (Azulfidine), phenoxymethylamine (Dibenzylamine), acetaminophen, monoamine oxidase inhibitors, sympathomimetics, levodopa, cocaine, and other

BOX 4 Optimal Conditions for Blood Collection of Plasma Free Metanephrines or Catecholamines

Patient is supine for at least 15–20 minutes before sampling.
 Samples are collected through a previously inserted IV to avoid stress associated with the needle stick.
 Patient has abstained from nicotine, alcohol, and vigorous exercise for at least 12 hours.
 Patient has fasted overnight before blood sampling.

TABLE 2 Medications That Interfere With Testing of Fractionated Plasma or Urinary Metanephrines

MEDICATION	METANEPHRINE	NORMETANEPHRINE
Acetaminophen ^a	-	↑↑
α-Methyldopa ^a	-	↑↑
Tricyclic antidepressants	-	↑↑
Mesalamine ^a /sulfasalazine ^a	-	↑↑
Phenoxybenzamine	-	↑
Monoamine oxidase inhibitors ^b	↑↑	↑↑
Sympathomimetics ^b	↑	↑
Cocaine ^b	-	↑↑
Levodopa ^{a,b,c}	↑	↑

Symbols: ↑↑, clear increase (≥ 3 -fold above the upper limit depending on the dose and duration of administration); ↑, mild increase (< 3 -fold above the upper limit); -, no increase. Adapted from Lenders et al.³

^aWhether these drugs interfere with the measurement or elevate fractionated plasma or urinary metanephrines depends on the assay and should be withdrawn 5 days before testing. Drug interference is not an issue when mass spectrometry–based assays are used.

^bMonoamine oxidase inhibitors, sympathomimetics, and cocaine can increase catecholamines (thereby metanephrines through peripheral conversion).

^cLevodopa elevates dopamine and thereby methoxytyramine (its measured metabolite), which elevates metanephrine and normetanephrine using non-mass spectrometry-based assays.

(From Hannah-Shmouni F, Pacak K, Stratakis CA. Metanephrines for evaluating palpitations and flushing. *JAMA*. 2017 Jul 25 318(4):385–386. doi: <https://doi.org/10.1001/jama.2017.5926>.)

drugs, interfere with test results. The effects of these medications on metanephrine levels are summarized in Table 2. Patients with chronic kidney disease, particularly those on dialysis, commonly have elevated plasma metanephrines (but usually not more than 3–4x above the upper reference limit), even in the absence of pheochromocytoma. Use of liquid chromatography tandem mass spectrometry (LCMS/MS) is the recommended detection method because it can remove potentially interfering substances. It is also faster, cheaper, and more specific than other techniques.

Besides the initial biochemical tests, which can exclude the disease, follow-up tests are required to establish the diagnosis. This is necessary because although the initial tests are specific, the diagnosis of pheochromocytoma is so rare that there are many false-positive results. Options for biochemical follow-up testing are repeated plasma or urinary metanephrine tests, additional sampling for plasma free or urinary fractionated catecholamines, and the clonidine (Catapres) suppression test. Biochemical follow-up testing is not necessary for patients with increases above four times the upper reference limit (URL) of plasma free metanephrines, which are almost always diagnostic for the presence of pheochromocytoma, unless they are on antidepressants, which can falsely produce results with highly elevated levels. The previously used glucagon stimulation test should be abandoned because this test is insufficiently sensitive and can lead to hypertensive complications.

With the increasing proportion of familial tumors, it is important to highlight their different catecholamine profiles. The biochemical profile of a tumor can help guide genetic testing, as reflected in the genetic testing algorithm depicted in Figure 2. Biochemical measurements can also help identify metastatic tumors; a recent study introduced the O-methylated metabolite of dopamine, plasma methoxytyramine, as an accurate biomarker for discriminating between patients with and without metastases. Several previous studies suggested that increased dopamine could have prognostic significance for metastatic pheochromocytomas, but later methoxytyramine was shown to be a more sensitive biomarker of a tumor's dopamine production than either plasma or urinary dopamine.

Based on these findings, an algorithm for biochemical diagnosis was designed and is shown in Figure 3.

Localization of Pheochromocytoma

Imaging studies to locate pheochromocytoma should be initiated once there is clear biochemical evidence. For optimal results, anatomic imaging studies such as CT or MRI should be combined with high-specificity functional imaging studies. Computed tomography (CT) rather than magnetic resonance imaging (MRI) was suggested as the first-choice imaging modality because of its excellent spatial resolution of the thorax, abdomen, and pelvis. Use of MRI (T2-weighted) is recommended in patients with metastatic pheochromocytoma, for detection of skull base and neck paragangliomas in patients with surgical clips, in patients with an allergy to CT contrast, and for patients in whom radiation exposure should be limited (children, pregnant women, patients with known germline mutations, and those with recent excessive radiation exposure).

Initial imaging should be focused on the adrenals. Negative imaging of the adrenals should be followed by CT or MRI scans of the abdomen and pelvis, where paragangliomas are most commonly located. If these scans are negative, chest and neck images should be obtained. Ultrasound is not recommended to localize pheochromocytoma. Exceptions include children and pregnant women when MRI is not available. Recently, there have been some suggestions to use rapid-sequence MRI without contrast, but larger and more definitive studies are needed to validate this approach for accuracy to detect this tumor, especially metastatic lesions.

After anatomic imaging, which lacks the specificity to indisputably identify a mass as a pheochromocytoma, functional imaging methods can confirm a tumor as a pheochromocytoma. Functional imaging also detects most cases of metastatic and multifocal disease. They include ¹²³I-MIBG scintigraphy, PET, and somatostatin receptor modality, at present ⁶⁸Ga-DOTATATE PET/CT. PET scanning is preferred for comprehensive localization of metastatic disease. The most commonly used radiopharmaceuticals in PET scanning are currently ¹⁸F-3,4-dihydroxyphenylalanine (¹⁸F-FDOPA), ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG), and recently ⁶⁸Ga-DOTATATE PET/CT. Different circumstances require different radiopharmaceuticals (Figure 4). The ¹⁸F-FDOPA PET/CT is recommended as the imaging modality for head and neck paragangliomas if ⁶⁸Ga-DOTATATE PET/CT is not available. ⁶⁸Ga-DOTATATE PET/CT or ¹⁸F-FDG PET/CT is recommended for metastatic pheochromocytomas. The use of ¹²³I-MIBG scintigraphy in patients with known metastatic pheochromocytoma should be limited to the evaluation of whether a patient qualifies for ¹³¹I-MIBG treatment. A combined PET/MRI scan has been introduced and might represent a novel advantageous imaging modality.

The algorithm described in Figure 4 provides the basis for diagnostic localization of pheochromocytoma.

If all tests return negative, it is advised to repeat noninvasive localization after 2 to 6 months.

Treatment

The optimal therapy for a pheochromocytoma is prompt surgical removal of the tumor, because an unresected tumor represents a time bomb waiting to explode with a lethal hypertensive crisis. In patients with extensive or metastatic disease, surgery can reduce the hormone secretion and prevent critical anatomic

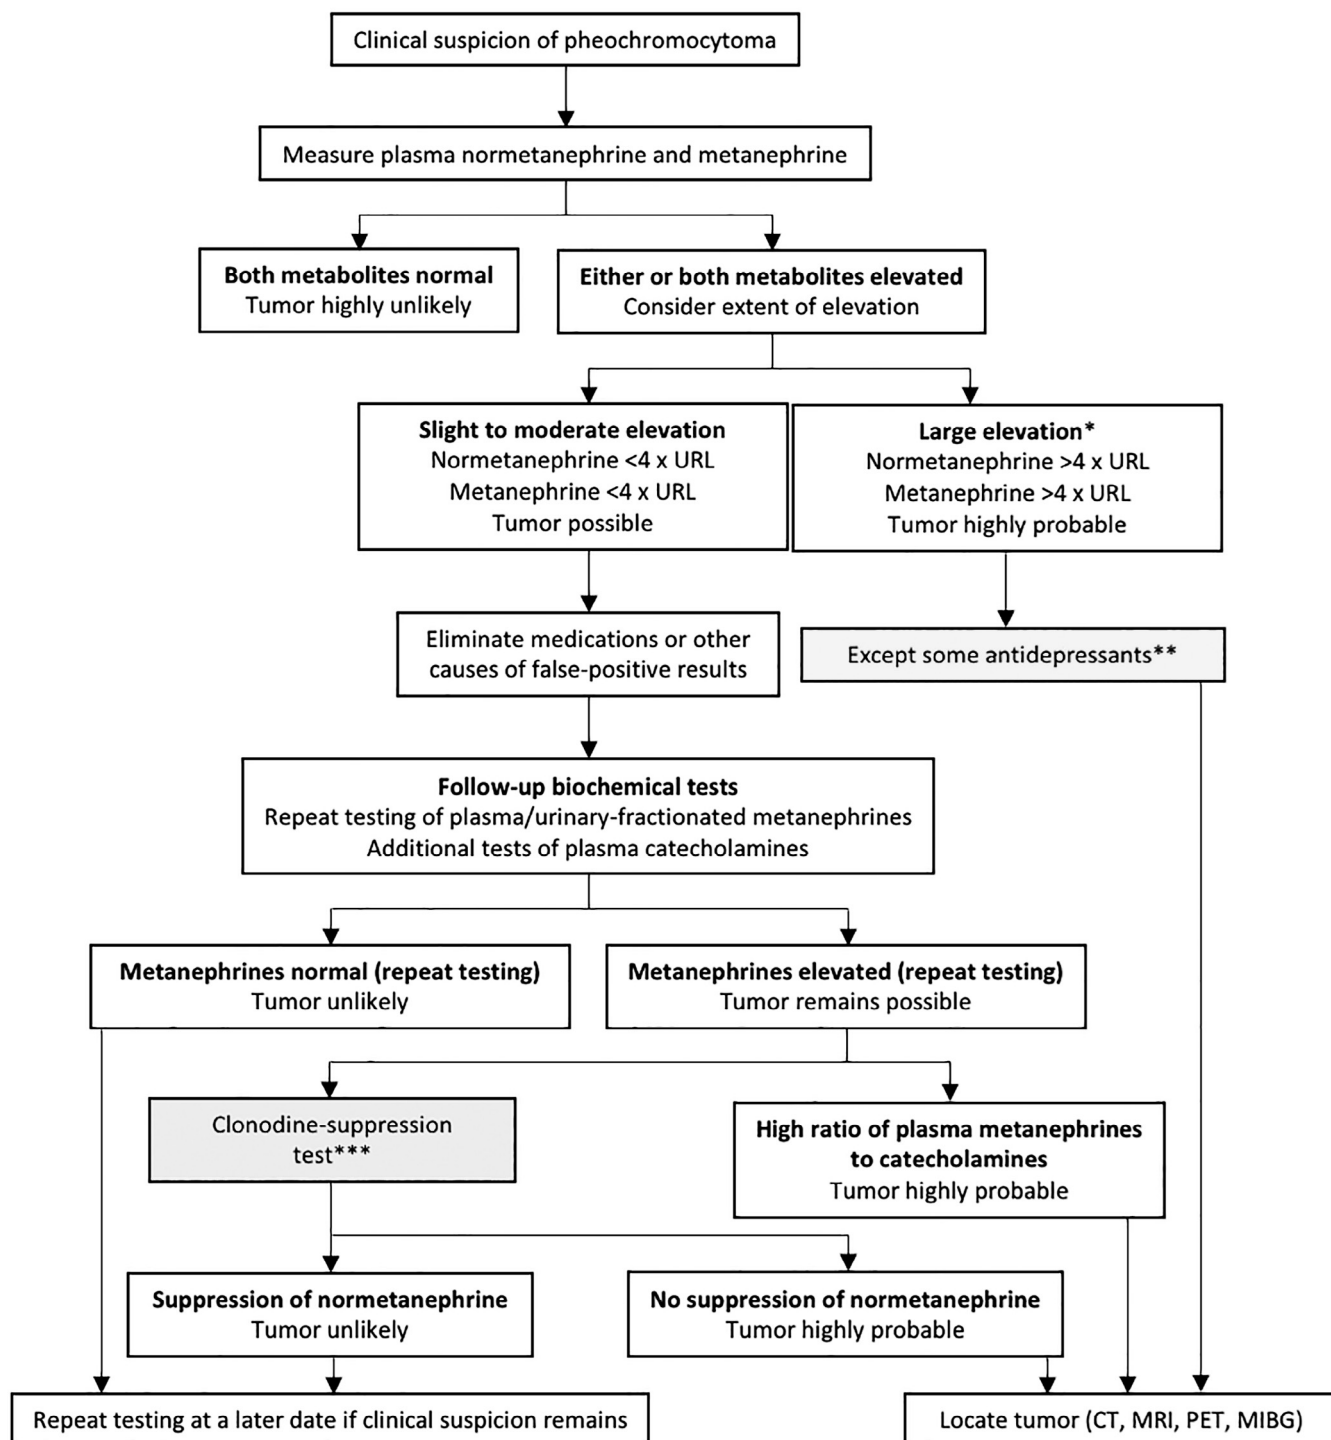

Figure 3 Algorithm for biochemical diagnosis. *It has been reported that venlafaxine (a serotonin-norepinephrine reuptake inhibitor) can cause an increase of more than four times the URL of normetanephrine. **Some antidepressants, especially those with a combination of norepinephrine and serotonin reuptake inhibition, can elevate plasma normetanephrine levels to four times above the upper reference limit. ***This test can only be predictive for normetanephrine and/or norepinephrine secreting tumors. *Abbreviations:* MIBG = meta-iodobenzylguanidine; MRI = magnetic resonance imaging; PET = positron emission tomography; URL = upper reference limit.

complications, such as urinary tract or cord compression or cardiac obstruction. Safe surgical removal requires the efforts of a team made up of an internist, an anesthesiologist, and a surgeon, preferably in a center experienced with this demanding surgery.

Medical Therapy and Preparation for Surgery

The goal of preoperative medical treatment is to control hypertension, maintain stable blood pressure during surgery, minimize adverse effects during anesthesia, and reduce other clinical signs and symptoms caused by high plasma levels of catecholamines.

As soon as the diagnosis is made, blood pressure should be adequately treated for at least 2 weeks before the operation. With satisfactory pretreatment, perioperative mortality has fallen to less than 3%. α -Adrenergic blockade is the basis of medical management and preoperative preparation. The most commonly used nonselective α -adrenoceptor blocker is phenoxybenzamine (Dibenzylamine), which is also used for nonhypertensive patients. Other possibilities include α -blocking agents such as prazosin (Minipress), terazosin (Hytrin), and doxazosin (Cardura). Though these have a shorter duration of action and more often cause hypotension

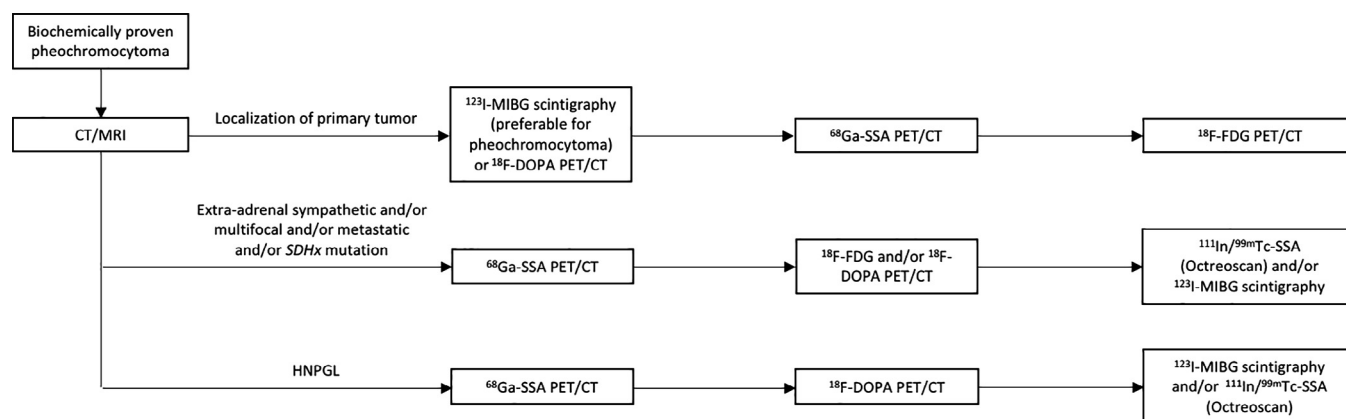

Figure 4 Recommended imaging studies for the localization of pheochromocytoma. *Abbreviations:* CT = computed tomography; ^{18}F -FDG = ^{18}F -fluorodeoxyglucose; ^{18}F -FDOPA = ^{18}F -3,4-dihydroxyphenylalanine; HNPGL = head and neck paraganglioma; MIBG = metaiodobenzylguanidine; MRI = magnetic resonance imaging; PET = positron emission tomography; SSA = somatostatin analogues.

when initially administered for preoperative blood-pressure control, postoperative hypotension is more often seen with phenoxybenzamine. In addition to α -blockers, one can use β -blockers (especially when cardiac tachy- and other arrhythmias occur) and calcium-channel blockers such as nicardipine (Cardene). α -Methyl-L-tyrosine or metyrosine (Demser) has limited use as a premedication. Diuretics should be avoided.

β -Blockers should never be used until α -adrenoceptor blockers have been administered for at least 2 to 3 days because this can result in severe hypertensive crisis in patients with pheochromocytoma, which is believed to result from inhibition of β_2 -adrenoceptor-mediated vasodilation (in the presence of catecholamine stimulation of incomplete α -adrenoceptor blockage). It might be presumed that cardioselective β_1 -adrenoceptor-blocking drugs might be administered without adverse effect. Indeed, almost all adverse reactions to β -blockers in pheochromocytoma patients have involved nonselective β -blockers. Therefore cardioselective β -blockers, such as atenolol (Tenormin), esmolol (Brevibloc), and metoprolol (Lopressor), are favored over nonselective blockers for the management of patients with pheochromocytoma. Nevertheless, because of incomplete specificity and likelihood of some actions on β_2 -adrenoceptors, even β -blockers deemed to be cardioselective should only be administered to patients with pheochromocytoma once there is adequate control of blood pressure by α -adrenoceptor blockade or other means. In patients with persistent tachyarrhythmia, newly introduced drugs, such as ivabradine (Corlanor),¹ can be used.

Patients can be recommended a salt- and fluid-rich diet. A proposed algorithm for preoperative treatment is given in Figure 5.

Operative and Postoperative Management

After extensive preoperative preparation, surgery should be performed by an experienced surgical and anesthesiology team.

To ensure adequate preoperative preparation, several criteria have been proposed. First, targeted blood pressure should be below 140/90 mm Hg for at least 24 hours. Orthostatic hypotension should be present, but not below 80/45 mm Hg. In some cases, Doppler or conventional echocardiography are indicated in addition to ECG to detect the presence of cardiomyopathy or coronary artery disease. In patients with a large left adrenal pheochromocytoma, splenectomy is likely; therefore vaccinations against *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis* should be given preoperatively.

An experienced anesthesiologist should be aware of potential catecholamine release either as a side effect of the drugs used or as a result of tumor manipulation during the surgery.

A minimally invasive approach is the accepted standard for small, noninvasive, nonmetastatic pheochromocytomas and retroperitoneal paragangliomas because of its significant postoperative benefits. Locoregional invasion is difficult to establish preoperatively; therefore it has been recommended that potentially invasive tumors should be initially explored by laparoscopy or retroperitoneoscopy followed by conversion to open surgery in cases of critical adhesion. To prevent permanent glucocorticoid deficiency in patients with bilateral pheochromocytomas, adrenal cortex-sparing surgery is advocated (except in *SDHB*-related pheochromocytoma). There are multiple potential hazardous events and situations involved in surgery, including anesthesia induction, tumor manipulation, hypotension, and hypoglycemia. The treatment of hypotension with pressor agents is not recommended, especially when long-acting β -blockers or metyrosine have been used; these paralyze the vascular bed in a dilated state. Instead, volume replacement is the treatment of choice.

Postoperative hypertension can indicate incomplete tumor resection. However, during the first 24 hours after surgery, hypertension is most likely attributed to pain, volume overload, or autonomic instability, all of which are treated symptomatically. If hypertension persists, any attempts to collect specimens for biochemical evidence of an incompletely resected tumor should be delayed for at least 5 to 7 days after surgery to ensure that the large increases in both plasma and urinary catecholamines produced by surgery have dissipated.

Close monitoring of blood glucose in the postoperative period is recommended, because its level can be decreased due to decreased glucose production and increased glucose utilization in the absence of the previous catecholamine excess and persistence of α -adrenoceptor blockers.

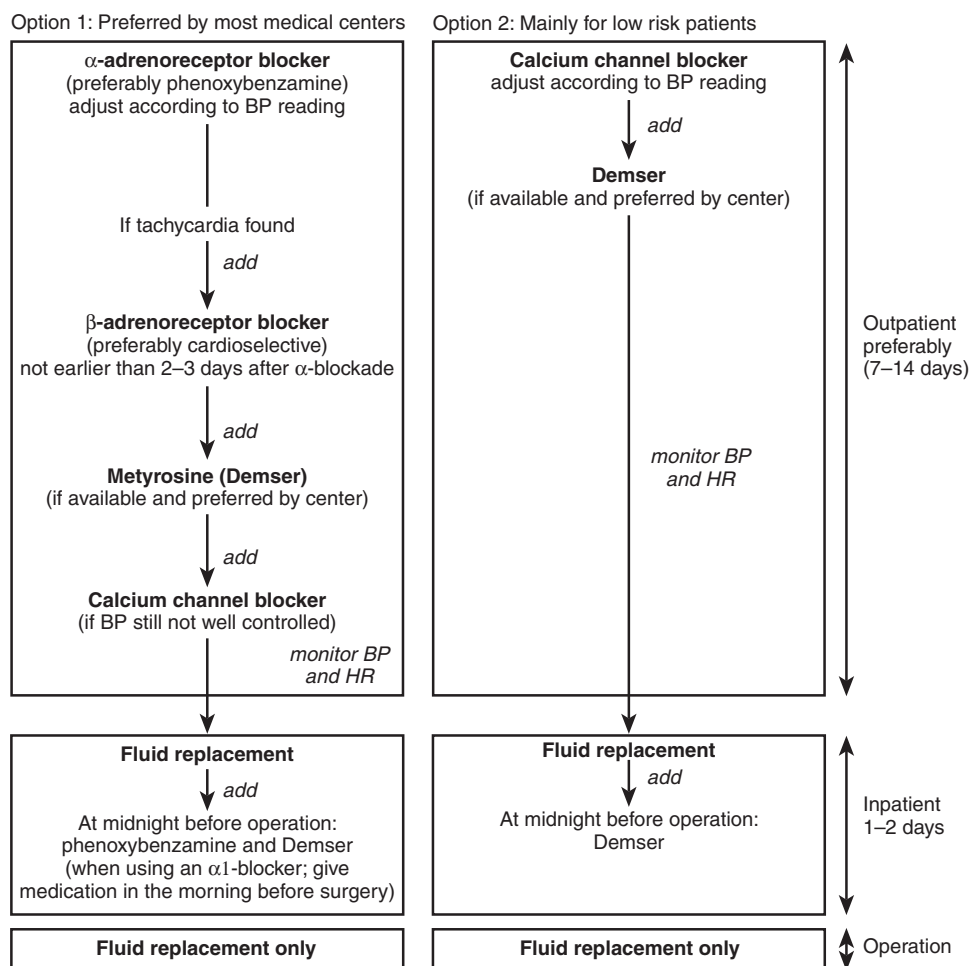

If the patient is hypotensive, hemorrhage should be excluded first; however, the most likely cause of hypotension is the prolonged effect of the α -adrenoceptor blockers in the presence of reduced plasma catecholamine levels.

Hypertensive Crisis

The most dangerous complication of pheochromocytoma is the occurrence of a hypertensive crisis. Hypertensive crisis can manifest as a severe headache, visual disturbances, acute myocardial infarction, congestive heart failure, or a cerebrovascular accident. It is treated with an intravenous bolus of 5 mg phentolamine (Regitine), a reversible nonselective α -adrenergic antagonist. Phentolamine has a very short half-life, and therefore the same dose can be repeated every 2 minutes until hypertension is adequately controlled. Phentolamine can also be given as a continuous infusion. Continuous intravenous infusion of sodium nitroprusside (Nitro-press) or Labetalol (Trandate) can also be given to control hypertension.

¹Not FDA approved for this indication.

Figure 5 Current recommended preoperative treatment algorithms in patients with pheochromocytoma. Abbreviations: BP = blood pressure; HR = heart rate. (Adapted from Pacak K: Preoperative management of the pheochromocytoma patient. *J Clin Endocrinol Metab* 2007;92:4069–4079.)

Malignant Pheochromocytoma

Malignant pheochromocytoma is established only by the presence of metastases at sites where chromaffin cells are normally absent, which is only in lymph nodes or bones based on the current 2017 WHO definition. Paragangliomas are malignant more commonly than pheochromocytomas (25% vs. 7%).

Pheochromocytoma metastasizes via hematogenous or lymphatic routes, and the most common metastatic sites are lymph nodes, bones, lung, and liver. About one-half of malignant tumors are found at original presentation, and the other half develop at a median interval of 5.6 years, but they can be delayed up to 24 years. Based on the localization of the metastatic lesions, there are short-term and long-term survivors.

Up to 50% of malignant pheochromocytomas develop because of a germline mutation. *SDHB* mutations with the presence of pheochromocytoma represent about 70% or even more of the risk of malignancy (both in children and adults). Currently, there are several other independent factors of malignancy, including extra-adrenal localization (paragangliomas), the size of the primary tumor (larger than 5 cm), and possibly high methoxytyramine level. Owing to the substantial amounts of methoxytyramine produced by a significant portion of metastatic pheochromocytomas, this measurement should also offer utility in patient management as a surrogate biomarker to assess tumor burden, disease progression, and response to treatment.

Malignant disease is often complicated by clinical manifestations of catecholamine excess and is invariably fatal. The 5-year survival probability after the diagnosis of the first metastasis is reported to be 36% in *SDHB* carriers and 67% in the absence of this mutation.

Successful management of malignant pheochromocytoma requires a multidisciplinary approach, where pharmacologic treatment, targeted radiotherapy, chemotherapy, and surgery can all

play a part. While external-beam radiation has been used for inoperable tumors or for symptom palliation, especially in the treatment of bone lesions, surgical debulking is considered the mainstay of palliative treatment. About 30% of patients receiving CVD (cyclophosphamide [Cytoxan]¹, vincristine [Oncovin]¹, and dacarbazine [DTIC-Dome]¹) exhibit clinical benefits; this number is much higher in patients with *SDHB*-related malignant tumors (about 70%–80%). Limited documented experience with other chemotherapeutic regimes is available. Somatostatin analogues can be used as an alternative option (for example, ¹⁷⁷Lu-DOTATATE [Lutathera]¹). Nowadays, a lot is expected from the novel molecular targeted therapies. In fact, some therapies have already been tested in clinical settings with new possible targets emerging, especially in HIF genes, the mTOR pathway and Hsp90. Individualized treatment should be performed with the intention to cure limited disease and achieve palliation for advanced disease. Figure 6 shows a proposed algorithm for the treatment of metastatic pheochromocytoma.

Prognosis and Monitoring

The long-term survival of patients after successful removal of a benign pheochromocytoma is essentially the same as that of age-adjusted normal subjects. Findings from a large study with a long-term follow-up showed a recurrence rate of 17%, with half the patients showing signs of malignant disease. Recurrences occur more often in patients with extra-adrenal disease and in patients with a hereditary disorder. At least 25% of patients remain hypertensive after treatment, but this is usually easily controlled with medication.

¹Not FDA approved for this indication.

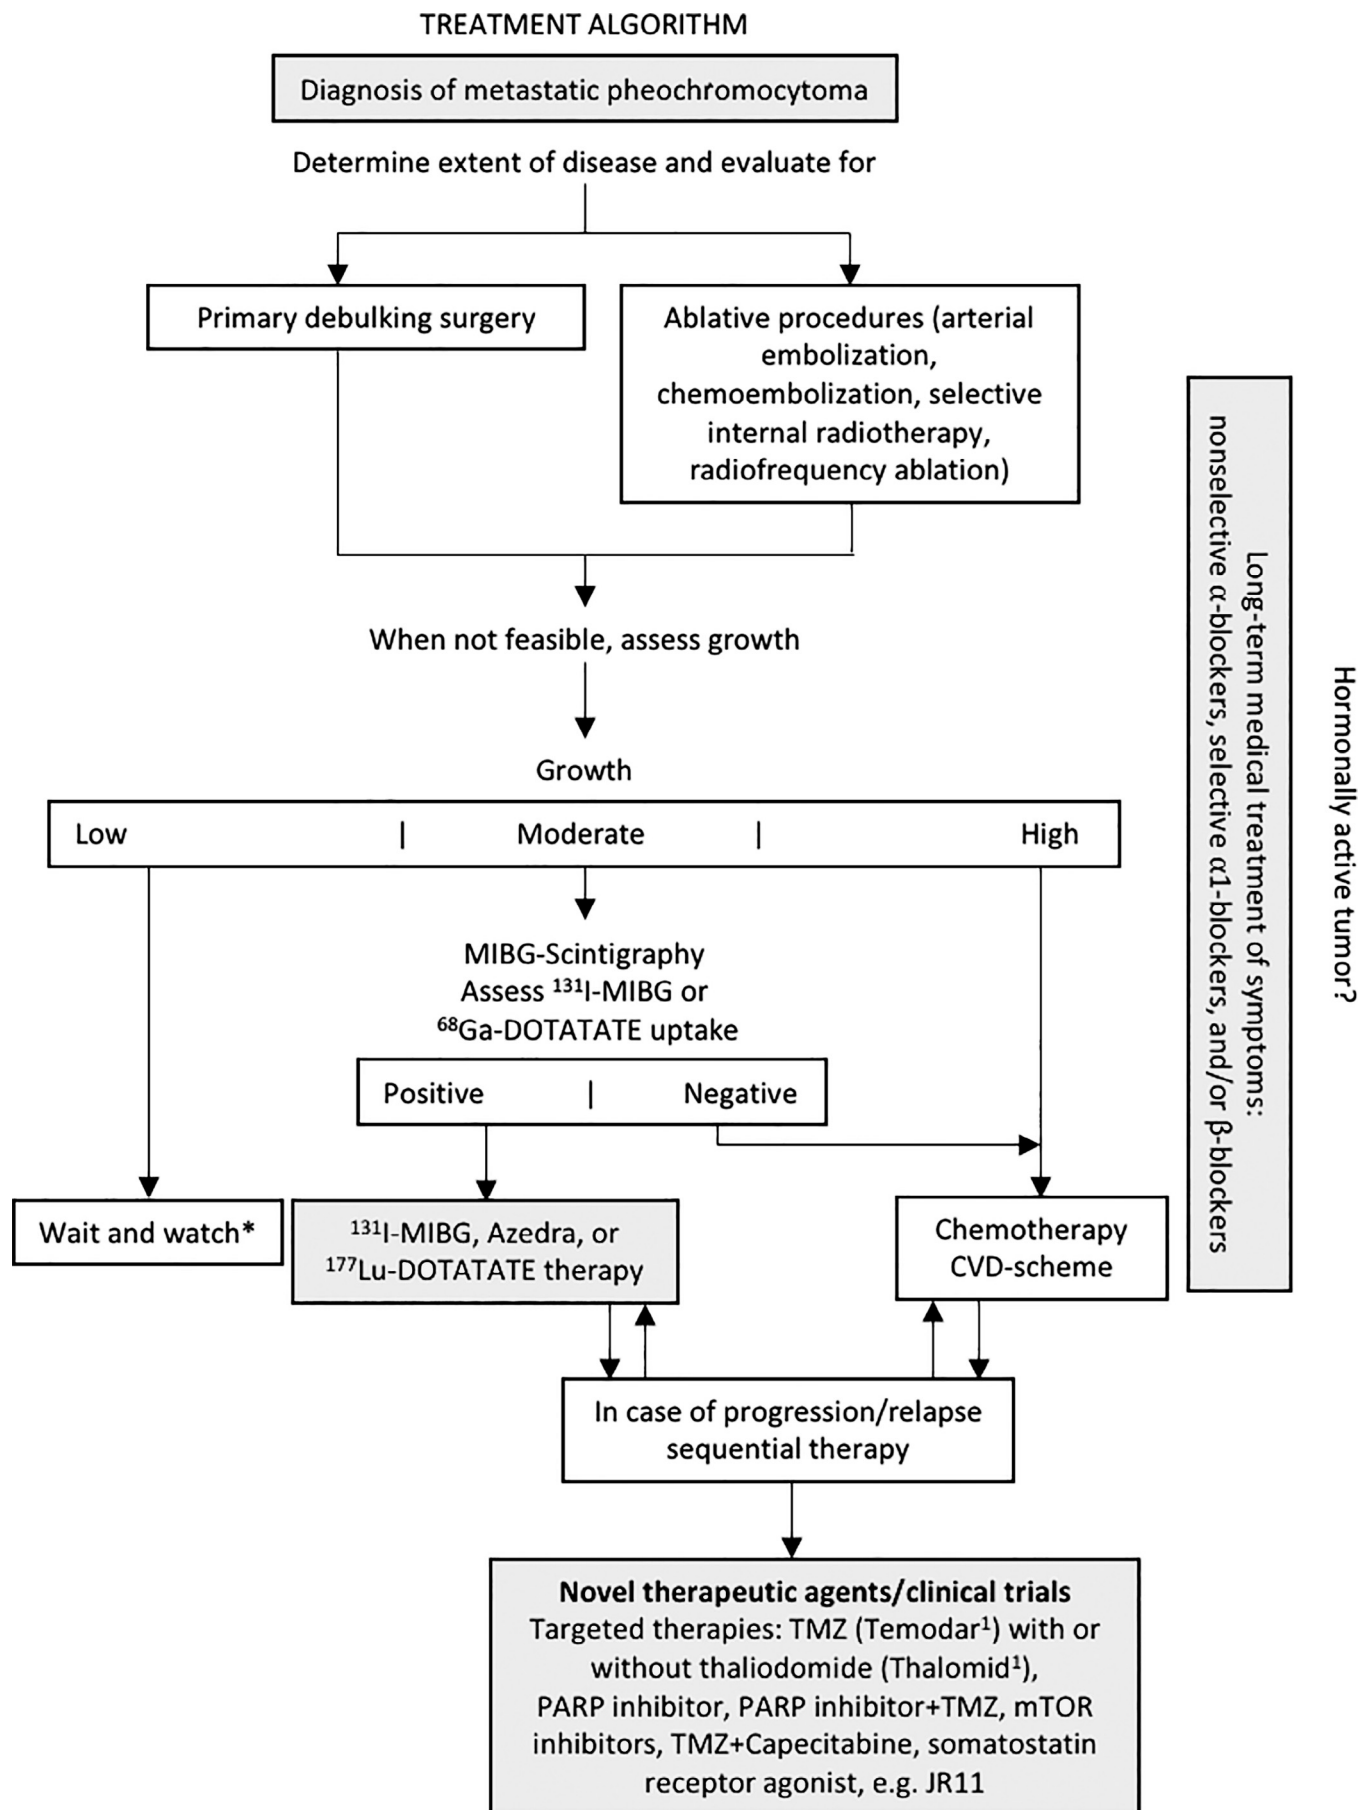

Figure 6 Treatment algorithm for metastatic pheochromocytoma. Asterisk indicates that the risk of side effects from therapy exceeds the chance of benefit. *Abbreviations:* CVD = cyclophosphamide, vincristine, and dacarbazine [chemotherapy]; JR11 = ^{nat}Ga-NODAGA-JR11; MIBG = metaiodobenzylguanidine; mTOR = mammalian target of rapamycin; PARP = poly ADP ribose polymerase; TMZ = temozolomide. (Adapted from Adjallé R, Plouin PF, Pacak K, Lehnert H: Treatment of malignant pheochromocytoma. *Horm Metab Res* 2009;41:687–896.)

Clinical follow-up should be lifelong for all patients, but especially in those with an underlying hereditary disorder. The frequency of checkups, once a year or more often, and the kind of diagnostic measurements, only biochemical tests or also imaging studies, should depend on the characteristics of the pheochromocytoma. Follow-up must be more intensive in patients with hereditary and malignant pheochromocytoma.

THYROID CANCER

Method of

Mark E. Zafereo, MD; and Randal S. Weber, MD

CURRENT DIAGNOSIS

- Thyroid nodules are typically recognized when a physician or patient palpates a central neck mass, or they are discovered incidentally on imaging studies performed for other reasons.
- Ninety-five percent of thyroid nodules are benign, and thyroid ultrasound scanning is the best overall imaging study to evaluate characteristics of thyroid nodules and to determine which nodules may require fine-needle aspiration biopsy.
- Ultrasound-guided fine-needle aspiration biopsy is often performed at the time of thyroid ultrasound for thyroid nodules that have suspicious sonographic features.
- Fine-needle aspiration histopathology can aid in diagnosis of thyroid cancer, but fine-needle aspiration cytology reports often fall into an indeterminate thyroid lesion/neoplasm category.
- Thyroid cancer does not typically affect thyroid hormone levels, but thyroid-stimulating hormone (TSH) should be measured in the workup of a thyroid nodule and to assess thyroid function prior to consideration of thyroid surgery.
- Medullary thyroid carcinoma is a rare type of thyroid cancer that can be diagnosed by fine-needle aspiration biopsy or elevated serum calcitonin and carcinoembryonic antigen (CEA) levels in the presence of a thyroid mass.
- Twenty percent of medullary thyroid carcinoma is hereditary and associated with autosomal dominant mutations in the RET proto-oncogene (MEN syndrome); therefore all patients with medullary thyroid carcinoma should undergo RET genetic testing and evaluation for pheochromocytoma before surgery.
- Anaplastic thyroid carcinoma is a rare and extremely aggressive form of thyroid cancer that presents as a very rapidly growing thyroid mass.

CURRENT THERAPY

- Observation with follow-up ultrasound is the most appropriate treatment recommendation for thyroid nodules that are suspected to be benign unless the patient is having compressive symptoms related to a large benign thyroid tumor or goiter.
- Thyroid nodules that are indeterminate for malignancy on fine-needle aspiration biopsy may be treated with short-term observation, thyroid lobectomy, or total thyroidectomy.
- Micropapillary thyroid carcinomas (tumors <1 cm) can be treated with short-term observation, thyroid lobectomy, or total thyroidectomy, depending on patient age and preference.
- Well-differentiated thyroid cancers (papillary and follicular thyroid cancers) may be treated with thyroid lobectomy or total thyroidectomy, with or without central compartment lymph node dissection.
- For patients with intermediate or high risk well-differentiated thyroid cancers who undergo total thyroidectomy, radioactive iodine and thyroid hormone suppression may be considered following surgery.

Clinical follow-up should be lifelong for all patients, but especially in those with an underlying hereditary disorder. The frequency of checkups, once a year or more often, and the kind of diagnostic measurements, only biochemical tests or also imaging studies, should depend on the characteristics of the pheochromocytoma. Follow-up must be more intensive in patients with hereditary and malignant pheochromocytoma.

THYROID CANCER

Method of

Mark E. Zafereo, MD; and Randal S. Weber, MD

CURRENT DIAGNOSIS

- Thyroid nodules are typically recognized when a physician or patient palpates a central neck mass, or they are discovered incidentally on imaging studies performed for other reasons.
- Ninety-five percent of thyroid nodules are benign, and thyroid ultrasound scanning is the best overall imaging study to evaluate characteristics of thyroid nodules and to determine which nodules may require fine-needle aspiration biopsy.
- Ultrasound-guided fine-needle aspiration biopsy is often performed at the time of thyroid ultrasound for thyroid nodules that have suspicious sonographic features.
- Fine-needle aspiration histopathology can aid in diagnosis of thyroid cancer, but fine-needle aspiration cytology reports often fall into an indeterminate thyroid lesion/neoplasm category.
- Thyroid cancer does not typically affect thyroid hormone levels, but thyroid-stimulating hormone (TSH) should be measured in the workup of a thyroid nodule and to assess thyroid function prior to consideration of thyroid surgery.
- Medullary thyroid carcinoma is a rare type of thyroid cancer that can be diagnosed by fine-needle aspiration biopsy or elevated serum calcitonin and carcinoembryonic antigen (CEA) levels in the presence of a thyroid mass.
- Twenty percent of medullary thyroid carcinoma is hereditary and associated with autosomal dominant mutations in the RET proto-oncogene (MEN syndrome); therefore all patients with medullary thyroid carcinoma should undergo RET genetic testing and evaluation for pheochromocytoma before surgery.
- Anaplastic thyroid carcinoma is a rare and extremely aggressive form of thyroid cancer that presents as a very rapidly growing thyroid mass.

CURRENT THERAPY

- Observation with follow-up ultrasound is the most appropriate treatment recommendation for thyroid nodules that are suspected to be benign unless the patient is having compressive symptoms related to a large benign thyroid tumor or goiter.
- Thyroid nodules that are indeterminate for malignancy on fine-needle aspiration biopsy may be treated with short-term observation, thyroid lobectomy, or total thyroidectomy.
- Micropapillary thyroid carcinomas (tumors <1 cm) can be treated with short-term observation, thyroid lobectomy, or total thyroidectomy, depending on patient age and preference.
- Well-differentiated thyroid cancers (papillary and follicular thyroid cancers) may be treated with thyroid lobectomy or total thyroidectomy, with or without central compartment lymph node dissection.
- For patients with intermediate or high risk well-differentiated thyroid cancers who undergo total thyroidectomy, radioactive iodine and thyroid hormone suppression may be considered following surgery.

- Total thyroidectomy with central compartment dissection is the recommended treatment for patients with medullary thyroid cancer.
- Postoperative external beam radiation therapy is rarely indicated for patients with well-differentiated thyroid cancer or medullary thyroid cancer unless disease is significantly invasive.
- Cytotoxic chemotherapy is not effective for well-differentiated thyroid cancer, but select molecular targeted therapies have been approved by the Food and Drug Administration (FDA) for patients with progressive systemic disease.

Epidemiology

Thyroid nodules are very common, affecting approximately 20% of the population. The vast majority (approximately 95%) of thyroid nodules are benign. The incidence of thyroid nodules increases with age, and thyroid nodules are more common in females. The clinical importance of thyroid nodules lies in the need to exclude thyroid cancer, present in approximately 5% to 10% of thyroid nodules. Thyroid cancer represents the most rapidly increasing cancer (>5% increase per year in both men and women) in the United States and the most common endocrine malignancy. Thyroid cancer is more common in females, representing the fifth most common malignancy in women in the United States (6% of estimated cancer diagnoses in females in 2016); and is also relatively more common in young adults, representing 15% of overall U.S. cancer diagnoses among persons aged 20 to 34. However, the increasing incidence of thyroid cancer in the United States is largely attributed to higher rates of detection with increasing use of imaging such as neck ultrasonography. A recent study estimated that almost one-half of papillary thyroid cancers diagnosed in women and men less than 50 years old in the United States may be clinically irrelevant. Fortunately, thyroid cancer is most often an indolent malignancy, and many patients with thyroid cancer can live unknowingly with disease for years or even decades. Despite increased incidence, mortality from thyroid cancer remains very low (approximately 5%). Patients who die of thyroid cancer most often present with aggressive histopathology, high tumor burden, and distant metastases.

Risk Factors

Ninety-five percent of thyroid cancers are not associated with any known risk factor. History of ionizing radiation to the thyroid is the only known environmental factor associated with increased risk of thyroid cancer, but this risk factor accounts for less than 1% of thyroid malignancies. Only 5% to 10% of patients with nonmedullary differentiated thyroid cancer have a familial occurrence, and well-differentiated thyroid cancer is generally not considered familial (familial follicular cell–derived differentiated thyroid cancer) unless three or more first-degree relatives are affected. Therefore routine screening for thyroid cancer with thyroid ultrasound is not recommended unless the patient has a specific genetic syndrome that may be associated with differentiated thyroid cancer, such as phosphate and tensin homolog hamartoma

tumor syndrome (PTEN), Cowden disease, familial adenomatous polyposis (FAP), or Carney complex. On the other hand, approximately 20% of patients with medullary thyroid carcinoma (MTC) have multiple endocrine neoplasia (MEN) types 2A and 2B hereditary syndromes, and therefore patients with MTC should routinely undergo genetic testing.

Pathophysiology

The thyroid gland has two distinct hormone-producing cell types from which tumors arise: follicular cells and neuroendocrine parafollicular C cells. The follicular cells secrete thyroid hormone and are the origin of five types of thyroid cancer: papillary thyroid cancer, follicular thyroid cancer, Hurthle cell thyroid cancer, poorly differentiated thyroid cancer, and anaplastic thyroid cancer. Medullary thyroid carcinoma, on the other hand, arises from the calcitonin-secreting parafollicular C cells (Table 1).

Differentiated Thyroid Cancers

Papillary and follicular cancers are collectively referred to as differentiated thyroid cancers, indicating cells that maintain a microscopic appearance more similar to normal thyroid tissue. Differentiated thyroid cancer collectively makes up 95% of thyroid cancer. Papillary thyroid cancer is the most prevalent thyroid cancer subtype, and 70% have genetic alterations causing activation of the mitogen-activated protein kinase (MAPK) pathway. The MAPK pathway is most typically initiated by activation of the tyrosine kinase receptor. Activation of the MAPK pathway often leads to oncogenic conversion of BRAF, which is the most common genetic event in papillary thyroid cancer. Therefore tyrosine kinase and BRAF inhibition represent two foci of targeted drug therapy for rare cases of advanced or metastatic differentiated thyroid cancer. The two most common genetic mutations associated with follicular thyroid cancer are renin-angiotensin system (RAS) and paired box 8/peroxisome proliferator-activated receptor gamma (PAX8-PPARG) mutations.

Hurthle cell carcinomas are considered variants of differentiated follicular thyroid cancer that are distinguished by an accumulation of Hurthle cells. Thyroid Hurthle cells (also called oncocytic cells) are characterized by abundant eosinophilic granular cytoplasm as a result of accumulation of altered mitochondria. This phenomenon of Hurthle cell change in the thyroid occurs in inflammatory disorders such as thyroiditis and Graves disease, and the notation of Hurthle cells is therefore common with fine-needle aspiration biopsies in which there is associated thyroiditis. The proliferation of oncocytes also may give rise to hyperplastic and neoplastic nodules termed Hurthle cell neoplasms.

Dedifferentiated Thyroid Cancers

Dedifferentiated thyroid cancers are very rare and include poorly differentiated and anaplastic thyroid cancers. Many tumors with poorly differentiated and anaplastic thyroid carcinoma exhibit areas or separate foci of papillary or follicular carcinoma, suggesting that these tumors may arise from preexisting well-differentiated tumors. Poorly differentiated thyroid cancers include tumors with

TABLE 1 Classification, Genetics, and Incidence of Thyroid Cancers

TYPE OF THYROID CANCER	CELL TYPE	DIFFERENTIATED?	COMMON GENETIC MUTATIONS	ESTIMATED % OF CASES
Papillary	Follicular	Yes	TKR, BRAF	80
Follicular	Follicular	Yes	RAS, PAX8-PPARG	15
Hurthle cell	Follicular	Yes	–	2*
Poorly differentiated	Follicular	No	RAS, TP53	1
Anaplastic	Follicular	No	TP53, BRAF, RAS	1
Medullary	Parafollicular (C cell)	No	RET	3

*Included among follicular thyroid cancers

Abbreviation: TKR = tyrosine kinase receptor.

solid/trabecular/insular growth patterns, absence of typical nuclear features of papillary thyroid carcinoma, high mitotic figures, and extensive tumor necrosis. Anaplastic thyroid cancers are similarly thought to derive from a terminal dedifferentiation of carcinoma of the thyroid follicular cell, often with loss of p53 and other genetic mutations. Histopathologically, anaplastic thyroid cancers appear as necrotic and hemorrhagic tumors with cytologic anaplasia showing bizarre tumor cells, high mitotic rate, and significant angioinvasion. Dedifferentiated thyroid cancers exhibit rapid growth, high rates of distant metastases, and overall poor prognosis; anaplastic thyroid carcinomas are almost uniformly fatal.

Medullary Thyroid Cancers

MTCs originate from the neuroendocrine parafollicular C cells of the thyroid gland. Approximately 20% of MTC is hereditary, associated with germline mutations in the RET proto-oncogene, leading to MEN. Ninety-five percent of hereditary MTC is related to MEN2a (50% incidence parathyroid hyperplasia, 100% incidence MTC, and 33% incidence pheochromocytoma), whereas approximately 5% results from MEN2b (85% incidence MTC, 50% incidence pheochromocytoma, 80% incidence marfanoid body habitus, 100% incidence mucosal neuromas). Approximately 50% of patients with sporadic MTC have somatic RET mutations. The M918T mutation portends the worst prognosis in both hereditary and sporadic MTC.

Clinical Manifestations

The diagnosis of thyroid cancer is often made after incidental discovery of a nonpalpable thyroid nodule on radiology scans performed for unrelated reasons (eg, CT of the neck in the emergency room for a young woman in an automobile accident, or screening carotid ultrasound for an elderly woman with atherosclerosis). Some patients may undergo thyroid ultrasound after self-palpating a thyroid nodule or neck mass, or after their primary care physician palpates a thyroid nodule on routine physical examination. Patients with larger thyroid cancers may have presenting symptoms of hoarseness (caused by recurrent laryngeal nerve paralysis), dysphagia (caused by esophageal compression or invasion), difficulty breathing, or pain. Patients with advanced medullary thyroid cancer can have diarrhea, Cushing syndrome, or facial flushing because of high serum levels of calcitonin and other hormonally active peptides. However, the vast majority of small thyroid cancers are asymptomatic.

Diagnosis

Serum TSH should be measured in the evaluation of a thyroid nodule, as rarely thyroid nodules can be hyperfunctioning. If serum TSH is subnormal in the presence of a thyroid nodule a radionuclide thyroid scan may be considered; “hot” nodules, that is those with uptake greater than the surrounding thyroid tissue, very rarely represent malignancy and do not require cytologic evaluation.

All patients with thyroid nodules should be evaluated with thyroid ultrasound. Ultrasound-guided fine-needle aspiration biopsy is the gold standard in diagnosis of thyroid neoplasia. However, not all thyroid nodules require biopsy. The vast majority of thyroid cancers are solid, and purely cystic nodules are very rarely malignant. Nodules greater than 1 cm with suspicious sonographic features (e.g., solid nodules with irregular margins, microcalcifications, and/or increased central internal vascularity) are recommended for biopsy, but nodules less than 1 cm are rarely recommended for biopsy. Incidental thyroid nodules that are discovered as fluorodeoxyglucose-avid on positron emission tomography (PET) imaging (“PET incidentalomas”) are recommended to undergo fine-needle aspiration biopsy, as PET-avid nodules have approximately 40% malignancy risk.

Thyroid cytologic classification is according to the criteria and terminology of the Bethesda system and includes the following general diagnostic categories (with associated malignancy risk): nondiagnostic (20% risk), benign (2% risk), follicular lesion (5%–10% risk), follicular neoplasm (15%–20% risk), atypical cells of undetermined significance (25% risk), suspicious for malignancy (90% risk), and

malignant (99% risk). Papillary thyroid carcinoma can be diagnosed cytologically based on atypical nuclear features such as nuclear grooves and nuclear inclusions. In contrast to papillary thyroid carcinomas, follicular and Hurthle cell carcinomas can rarely be diagnosed on fine-needle aspiration biopsy, because the diagnostic criterion for diagnosis of malignancy requires demonstration of capsular or vascular invasion. Nondiagnostic fine-needle aspiration biopsies fail to meet criteria for cytologic analysis, and repeat biopsy is recommended. Thyroid fine-needle aspirations (FNAs), which fall into the indeterminate category (follicular lesion, follicular neoplasm, atypical cells of undetermined significance) may be further evaluated with molecular testing by one of several commercially available gene expression classifier tests (eg, Afirma) or individual mutational analysis (e.g., BRAF).

If thyroid cytology is suspicious for medullary thyroid carcinoma, serum calcitonin and CEA should be measured. Although CEA may be elevated with a number of malignancies, calcitonin is more specific to medullary thyroid carcinoma, and calcitonin can rarely be elevated in association with other conditions. Patients with MTC should undergo genetic testing prior to surgery to rule out hereditary MTC since a coexisting pheochromocytoma has the potential to cause hypertensive crisis during thyroid surgery. Often patients with hereditary MTC with associated pheochromocytoma will undergo resection of the pheochromocytoma before their thyroid surgery.

Treatment

Differentiated Thyroid Cancer

Initial Management

Treatment algorithms for nondiagnostic, benign, indeterminate, and differentiated malignant thyroid nodules are illustrated in [Box 1](#). For patients with indeterminate thyroid nodules a molecular gene expression classifier test or individual mutational analysis may be considered to further characterize preoperative risk of malignancy. Determination of observation versus thyroid lobectomy

BOX 1 Management of Thyroid Neoplasms and Cancers Based on Fine-Needle Aspiration Cytology

Nondiagnostic

Repeat ultrasound-guided fine-needle aspiration biopsy in 3 months

If repeat biopsy nondiagnostic: Observation (with initial follow-up ultrasound 3–6 months) **or** thyroid lobectomy

Benign

Observation, may repeat ultrasound in 12 months

Indeterminate (Follicular lesion or follicular neoplasm or atypical cells of undetermined significance)

Observation (with initial follow-up ultrasound 3–6 months) **or** thyroid lobectomy

- May consider gene expression classifier test

Suspicious or Malignant Differentiated Thyroid Cancer

Thyroid lobectomy **or** total thyroidectomy with possible central compartment lymph node dissection

- Observation may be considered for older patients with intrathyroidal micropapillary (<1 cm) carcinomas
- Thyroid hormone suppression and radioactive iodine may be considered postoperatively if total thyroidectomy performed

Medullary Thyroid Cancer

Total thyroidectomy with central compartment dissection

- Measure serum calcitonin/CEA and perform genetic testing (rule out MEN2 with associated pheochromocytoma) preoperatively

must primarily take into account patient preference after discussion of risks, implications, and benefits of both approaches.

Differentiated thyroid cancer is generally treated with surgery, with the exception of intrathyroidal micropapillary carcinomas (tumors <1 cm), which may be observed with follow-up ultrasound, especially in older patients. With micropapillary thyroid carcinoma, risk of rapid growth is low, and many of these lesions demonstrate relatively little growth over the course of 5- or 10-year follow-up.

For tumors between 1 and 4 cm, thyroid lobectomy may be considered in the absence of central compartment lymphadenopathy; total thyroidectomy is recommended for tumors greater than 4 cm. Central compartment (i.e., level VI paratracheal) lymph node dissection should be performed for patients with lymph node metastases, and may be performed electively for patients with larger tumors because of the risk of occult lymph node metastases. Intraoperative frozen section evaluation of central compartment lymph nodes may also be useful to guide the decision regarding central compartment lymph node dissection. Patients with lateral neck (most commonly levels II, III, IV, and VB) lymph node metastases should undergo selective comprehensive lateral neck dissection of aforementioned compartments. Single node plucking or “berry-picking” is not recommended, because this increases potential morbidity with any subsequent surgery to remove remaining lymph nodes.

Monitoring total thyroidectomy patients with well-differentiated thyroid cancer is recommended for thyroid hormone suppression (suppression of TSH), because TSH is a trophic hormone that stimulates growth of thyroid follicular cells. Additionally, patients with distant metastases or higher-risk tumors may be considered for postoperative radioactive iodine therapy. Postoperative external beam radiation therapy is very rarely indicated for well-differentiated thyroid cancer, but it is only indicated with particularly aggressive and invasive disease in patients who would not be candidates for future revision surgery (e.g., laryngotracheal invasion, or esophageal invasion). Traditional cytotoxic chemotherapeutic agents are ineffective for well-differentiated thyroid cancer, but select targeted molecular therapies may be considered for patients with progressive and/or symptomatic disease. Sorafenib and lenvatinib are two small molecule kinase inhibitors that have been approved by the US Food and Drug Administration for advanced or metastatic thyroid cancer refractory to radioactive iodine.

Long-term Management

Approximately 25% of patients undergoing thyroid lobectomy will require thyroid hormone replacement, in addition to all patients undergoing total thyroidectomy. These patients require follow-up to check thyroid function tests, and also surveillance testing to detect potential recurrent differentiated thyroid cancer. Depending on prognostic variables, up to 30% of patients with well-differentiated thyroid cancer may develop recurrence over the course of several decades following initial therapy. Thyroid/cervical ultrasound and serum thyroglobulin measurement (for patients who have had total thyroidectomy) are the two primary methods of long-term follow-up for patients with history of well-differentiated thyroid cancer. Whole body diagnostic radioactive iodine scans are less sensitive for detecting recurrent disease but can be useful for localizing disease in the presence of detectable/rising thyroglobulin in the absence of thyroid bed/neck disease (as assessed by ultrasound or computed tomography [CT] imaging), or in select high risk patients whose serum thyroglobulin is unreliable for detection of thyroid disease because of the presence of thyroglobulin antibodies. Serum thyroglobulin can be measured while the patient is on thyroid hormone, or under conditions of stimulation, either by thyroid hormone withdrawal, or administration of recombinant TSH. Stimulated thyroglobulin is more sensitive for detecting residual thyroid tissue or recurrent disease.

Ultrasound-guided fine-needle aspiration biopsy can be performed for recurrent thyroid bed or lateral neck nodules/lymph nodes. Small burden recurrent locoregional or distant disease may be monitored for a period of time, because the majority of well-differentiated thyroid cancer is slow growing and

asymptomatic in the absence of large tumor burden. Alternatively, surgery may be performed for larger recurrent nodules/lymph nodes, and radioactive iodine and/or targeted molecular therapy may be considered for progressive distant disease.

Medullary Thyroid Cancer

Initial Management

As with differentiated thyroid cancer, surgery is the mainstay of treatment for medullary thyroid cancer. Infants and children with hereditary MTC diagnosed on genetic testing require special consideration; patients with intermediate risk mutations may be recommended for prophylactic thyroidectomy by 5 years of age, whereas patients with MEN2b and high risk mutations may be recommended for prophylactic thyroidectomy in the first year of life.

Occult cervical lymph node metastases with MTC are common, and therefore total thyroidectomy and bilateral central compartment paratracheal lymph node dissection is the generally recommended surgery. For patients with evidence of lateral neck disease on preoperative imaging, a systematic unilateral or bilateral selective or modified radical neck dissection should be performed, preserving important neurovascular structures unless they are invaded with disease. Most commonly cervical levels II, III, IV, and VB are dissected, although patients may rarely have metastases to other levels of the lateral neck. For patients without preoperative lateral neck disease, observation of the lateral neck is appropriate, as these patients can undergo subsequent lateral neck surgery if they were to later develop lateral neck metastases. Some surgeons, however, recommend elective unilateral or bilateral lateral neck dissection at the time of the thyroid surgery for patients with serum calcitonin greater than 20 (elective unilateral dissection) or 200 (elective bilateral dissection).

External beam radiation therapy is only indicated postoperatively for patients with particularly aggressive and invasive disease who would not be candidates for future revision surgery (e.g., laryngotracheal invasion or esophageal invasion). Because medullary thyroid cancer is not a follicular neoplasm, there is no indication for thyroid hormone suppression postoperatively. Patients should be managed with appropriate thyroid hormone supplementation so that their TSH is maintained in the euthyroid range. Radioactive iodine is not indicated in the postoperative treatment of medullary thyroid cancer because parafollicular C cells (and thereby medullary thyroid cancer cells) do not take up radioactive iodine.

Long-Term Management

Measurement of serum calcitonin and CEA is the primary method of surveillance for recurrence or distant metastases and should be measured approximately 3 months postoperatively and at regular intervals thereafter. Rising tumor markers should prompt further evaluation with cross-sectional imaging of the neck, chest, and abdomen, in addition to consideration of bone scan. Higher levels of calcitonin (>1000) are associated with distant metastases, and shorter calcitonin doubling time has been associated with overall poorer prognosis.

Medullary thyroid cancers have variable growth rates, and locoregionally recurrent and distant disease may be monitored in the absence of significant progression or symptoms. Patients with progressive or symptomatic recurrent or distant disease may be treated surgically (for patients with operable locoregional recurrence) or with systemic targeted molecular therapy. Vandetanib and cabozantinib are tyrosine kinase inhibitors with activity against RET and vascular endothelial growth factor receptor (VEGFR) with US FDA approval for use in advanced medullary thyroid cancer. Patients with symptomatic diarrhea resulting from markedly elevated serum calcitonin should be treated with antimotility agents such as loperamide, diphenoxylate/atropine, or codeine.

Anaplastic Thyroid Cancer

Because of rapid growth (doubling time often measured in weeks) and frequent distant metastases, anaplastic thyroid cancer is almost

always uniformly fatal. Patients with anaplastic thyroid cancer often have rapid onset of speech, swallowing, and breathing difficulties, and the decision for a tracheotomy in these patients is based on discussion of risks and implications with the patient. Anaplastic cancers confined to the thyroid gland are rare, but surgery and postoperative chemoradiation therapy can be effective to control disease in this very select group of patients with anaplastic thyroid cancer. Unfortunately, the vast majority of patients with anaplastic thyroid cancer present with massive tumor burden beyond the thyroid gland or distant metastases, and surgery is generally not effective to control disease in these situations. These patients may be treated palliatively with radiation, chemotherapy, or both; or they may elect for supportive/hospice care.

Complications

Because thyroid cancer is generally treated surgically, operative treatment complications are most common. Significant care must be taken to identify and preserve the bilateral recurrent laryngeal nerves during thyroid surgery; injury to unilateral or bilateral recurrent laryngeal nerves may result in temporary or permanent postoperative hoarseness (unilateral paralysis), or breathing difficulty (bilateral paralysis). Patients with a bilateral vocal cord paralysis may require a temporary or permanent tracheostomy tube. Permanent unilateral recurrent laryngeal nerve paralysis occurs after approximately 1% to 2% of thyroid surgeries.

A second postoperative complication associated with total thyroidectomy is hypocalcemia related to hypoparathyroidism. Care must be taken during thyroid surgery to preserve the bilateral superior and inferior parathyroid glands along with their respective vascular pedicle. Although one normal-functioning parathyroid gland is generally considered sufficient for long-term parathyroid function, many patients become temporarily hypoparathyroid, and hypocalcemic when multiple parathyroid glands are removed and/or devascularized during thyroid and central compartment surgery. Since the inferior parathyroid gland is usually interspersed with central compartment lymph nodes, this gland is often devascularized with central compartment surgery. Any devascularized parathyroid gland should be reimplanted, generally in an adjacent muscle such as the sternothyroid or sternocleidomastoid muscle. Patients who undergo total thyroidectomy should have their calcium and/or parathyroid hormone level checked in the immediate postoperative period prior to discharge. If calcium or parathyroid hormone level is low, an appropriate calcium replacement protocol should be initiated. Most postoperative hypocalcemia and hypoparathyroidism is temporary, with permanent hypoparathyroidism occurring in approximately 3% of thyroid surgery.

Patients who undergo lateral neck surgery in association with thyroid surgery have additional risks of neurovascular injury, which includes shoulder weakness (cranial nerve 11 injury), tongue weakness (cranial nerve 12 injury), lower lip weakness (marginal mandibular nerve injury), and chyle leak.

Risks of radioactive iodine include sialadenitis, dry mouth, and altered taste. There are also rare reports of second cancers that may be associated with cumulative high doses of radioactive iodine. Women who are nursing or pregnant should not receive radioactive iodine, and patients are recommended that close contact with others, especially children, should be avoided for several days following administration of radioactive iodine.

Conclusion

Thyroid nodules are very common and 95% are benign. The gold standard for evaluation of a thyroid nodule is ultrasound-guided fine-needle aspiration biopsy. Benign and many indeterminate nodules may be observed, although thyroid cancer is generally treated with surgery. Most well-differentiated thyroid cancers (papillary and follicular) have good prognosis with surgery (either thyroid lobectomy or total thyroidectomy), and some patients are recommended for postoperative radioactive iodine and thyroid hormone suppression. Medullary thyroid cancer is typically treated with total thyroidectomy and central compartment lymph node dissection. Approximately 20% of medullary thyroid carcinomas are

hereditary, associated with MEN2, and mutation in the RET proto-oncogene; patients with medullary thyroid cancer should therefore undergo genetic testing prior to surgery. Postoperative radiation therapy is rarely indicated for well-differentiated or medullary thyroid cancers unless the disease is particularly aggressive and invasive. Anaplastic thyroid cancer is a very aggressive and almost uniformly fatal rare type of thyroid cancer that is commonly treated with palliative radiation therapy, and/or chemotherapy.

THYROIDITIS

Method of

Leigh M. Eck, MD

CURRENT DIAGNOSIS

- Thyroiditis is a term used to describe a diverse group of disorders associated with thyroid inflammation.
- Thyroiditis can be associated with a euthyroid state, thyrotoxicosis, or hypothyroidism.
- The clinical presentation of thyroiditis will direct the evaluation with useful testing to include measurement of thyroid hormone levels, thyroid antibody testing, white blood cell count, erythrocyte sedimentation rate, thyroid scintigraphy, and thyroid ultrasound.

CURRENT THERAPY

- Abnormalities of thyroid hormone levels resulting from thyroiditis may be transient and require no or only short-term therapy.
- If symptomatic thyrotoxicosis is present, beta-blocker therapy should be initiated.
- Thyroiditis associated with persistent hypothyroidism is managed with synthetic thyroxine (T4, Levoxyol, Synthroid).
- Thyroid pain associated with subacute thyroiditis is managed with a nonsteroidal antiinflammatory drug or, if ineffective, glucocorticoid therapy.
- Acute suppurative thyroiditis requires immediate parenteral antibiotic therapy as well as surgical drainage, if indicated.

Thyroiditis is a term used to describe a diverse group of disorders characterized by inflammation of the thyroid gland (Table 1). Presentation of thyroiditis is variable depending on the etiology. The most common thyroid disorder in the United States, Hashimoto's thyroiditis, most often presents with hypothyroidism. Other forms

always uniformly fatal. Patients with anaplastic thyroid cancer often have rapid onset of speech, swallowing, and breathing difficulties, and the decision for a tracheotomy in these patients is based on discussion of risks and implications with the patient. Anaplastic cancers confined to the thyroid gland are rare, but surgery and postoperative chemoradiation therapy can be effective to control disease in this very select group of patients with anaplastic thyroid cancer. Unfortunately, the vast majority of patients with anaplastic thyroid cancer present with massive tumor burden beyond the thyroid gland or distant metastases, and surgery is generally not effective to control disease in these situations. These patients may be treated palliatively with radiation, chemotherapy, or both; or they may elect for supportive/hospice care.

Complications

Because thyroid cancer is generally treated surgically, operative treatment complications are most common. Significant care must be taken to identify and preserve the bilateral recurrent laryngeal nerves during thyroid surgery; injury to unilateral or bilateral recurrent laryngeal nerves may result in temporary or permanent postoperative hoarseness (unilateral paralysis), or breathing difficulty (bilateral paralysis). Patients with a bilateral vocal cord paralysis may require a temporary or permanent tracheostomy tube. Permanent unilateral recurrent laryngeal nerve paralysis occurs after approximately 1% to 2% of thyroid surgeries.

A second postoperative complication associated with total thyroidectomy is hypocalcemia related to hypoparathyroidism. Care must be taken during thyroid surgery to preserve the bilateral superior and inferior parathyroid glands along with their respective vascular pedicle. Although one normal-functioning parathyroid gland is generally considered sufficient for long-term parathyroid function, many patients become temporarily hypoparathyroid, and hypocalcemic when multiple parathyroid glands are removed and/or devascularized during thyroid and central compartment surgery. Since the inferior parathyroid gland is usually interspersed with central compartment lymph nodes, this gland is often devascularized with central compartment surgery. Any devascularized parathyroid gland should be reimplanted, generally in an adjacent muscle such as the sternothyroid or sternocleidomastoid muscle. Patients who undergo total thyroidectomy should have their calcium and/or parathyroid hormone level checked in the immediate postoperative period prior to discharge. If calcium or parathyroid hormone level is low, an appropriate calcium replacement protocol should be initiated. Most postoperative hypocalcemia and hypoparathyroidism is temporary, with permanent hypoparathyroidism occurring in approximately 3% of thyroid surgery.

Patients who undergo lateral neck surgery in association with thyroid surgery have additional risks of neurovascular injury, which includes shoulder weakness (cranial nerve 11 injury), tongue weakness (cranial nerve 12 injury), lower lip weakness (marginal mandibular nerve injury), and chyle leak.

Risks of radioactive iodine include sialadenitis, dry mouth, and altered taste. There are also rare reports of second cancers that may be associated with cumulative high doses of radioactive iodine. Women who are nursing or pregnant should not receive radioactive iodine, and patients are recommended that close contact with others, especially children, should be avoided for several days following administration of radioactive iodine.

Conclusion

Thyroid nodules are very common and 95% are benign. The gold standard for evaluation of a thyroid nodule is ultrasound-guided fine-needle aspiration biopsy. Benign and many indeterminate nodules may be observed, although thyroid cancer is generally treated with surgery. Most well-differentiated thyroid cancers (papillary and follicular) have good prognosis with surgery (either thyroid lobectomy or total thyroidectomy), and some patients are recommended for postoperative radioactive iodine and thyroid hormone suppression. Medullary thyroid cancer is typically treated with total thyroidectomy and central compartment lymph node dissection. Approximately 20% of medullary thyroid carcinomas are

hereditary, associated with MEN2, and mutation in the RET proto-oncogene; patients with medullary thyroid cancer should therefore undergo genetic testing prior to surgery. Postoperative radiation therapy is rarely indicated for well-differentiated or medullary thyroid cancers unless the disease is particularly aggressive and invasive. Anaplastic thyroid cancer is a very aggressive and almost uniformly fatal rare type of thyroid cancer that is commonly treated with palliative radiation therapy, and/or chemotherapy.

THYROIDITIS

Method of

Leigh M. Eck, MD

CURRENT DIAGNOSIS

- Thyroiditis is a term used to describe a diverse group of disorders associated with thyroid inflammation.
- Thyroiditis can be associated with a euthyroid state, thyrotoxicosis, or hypothyroidism.
- The clinical presentation of thyroiditis will direct the evaluation with useful testing to include measurement of thyroid hormone levels, thyroid antibody testing, white blood cell count, erythrocyte sedimentation rate, thyroid scintigraphy, and thyroid ultrasound.

CURRENT THERAPY

- Abnormalities of thyroid hormone levels resulting from thyroiditis may be transient and require no or only short-term therapy.
- If symptomatic thyrotoxicosis is present, beta-blocker therapy should be initiated.
- Thyroiditis associated with persistent hypothyroidism is managed with synthetic thyroxine (T4, Levothy, Synthroid).
- Thyroid pain associated with subacute thyroiditis is managed with a nonsteroidal antiinflammatory drug or, if ineffective, glucocorticoid therapy.
- Acute suppurative thyroiditis requires immediate parenteral antibiotic therapy as well as surgical drainage, if indicated.

Thyroiditis is a term used to describe a diverse group of disorders characterized by inflammation of the thyroid gland (Table 1). Presentation of thyroiditis is variable depending on the etiology. The most common thyroid disorder in the United States, Hashimoto's thyroiditis, most often presents with hypothyroidism. Other forms

TABLE 1 Causes of Thyroiditis

Autoimmune thyroiditis: Hashimoto's thyroiditis, postpartum thyroiditis, silent thyroiditis
Subacute thyroiditis, also known as de Quervain's thyroiditis or subacute granulomatous thyroiditis
Suppurative thyroiditis, also known as infectious thyroiditis or pyrogenic thyroiditis
Riedel's thyroiditis, also known as fibrous thyroiditis
Therapy induced thyroiditis: amiodarone (Cordarone), interferon-alpha, interleukin-2, lithium, tyrosine kinase inhibitors, radioactive iodine

of thyroiditis may present with thyrotoxicosis because of inflammation in the thyroid gland resulting in the release of stored hormone. Painful thyroiditis is seen with subacute, suppurative and radiation-induced thyroiditis, while other variants are most often painless.

Epidemiology

The most common cause of hypothyroidism in iodine-sufficient areas of the world is *Hashimoto's thyroiditis*, also known as *chronic autoimmune thyroiditis*. Elevated serum antithyroid peroxidase antibody concentrations are found in ~ 5% of adults and ~ 15% of older women; overt hypothyroidism is seen in up to 2% of the population. A variant of chronic autoimmune thyroiditis, *postpartum thyroiditis*, is a destructive thyroiditis induced by an autoimmune mechanism that occurs within 1 year of parturition. Postpartum thyroiditis occurs in up to 10% of women in the United States. *Silent thyroiditis* is indistinguishable from postpartum thyroiditis, with the exception of lack of temporal relationship to pregnancy. Silent thyroiditis may account for about 1% of all cases of thyrotoxicosis. Many medications are associated with an alteration in thyroid function testing; however, only a few are known to provoke an autoimmune or destructive inflammatory thyroiditis, including amiodarone (Cordarone), lithium, interferon alfa, interleukin-2, tyrosine kinase inhibitors, and checkpoint inhibitor immunotherapy. *Riedel's thyroiditis* is a progressive fibrosis of the thyroid gland with a prevalence of only 0.05% among patients with thyroid disease requiring surgery. *Subacute thyroiditis* is the most common cause of thyroid pain. It occurs in up to 5% of patients with clinical thyroid disease. *Suppurative thyroiditis*, most commonly caused by bacterial infection, is rare because of the thyroid gland's encapsulation, high iodine content, rich blood supply, and extensive lymphatic drainage. *Radiation-induced thyroiditis* occurs in approximately 1% of patients who receive radioactive iodine therapy for hyperthyroidism.

Risk Factors

Hashimoto's thyroiditis is more common in women, particularly older women. Hashimoto's thyroiditis is associated with several gene polymorphisms, suggesting a role for genetic susceptibility. Subacute thyroiditis frequently follows an upper respiratory tract infection, with its incidence highest in summer. Suppurative thyroiditis is most likely to occur in patients with preexisting thyroid disease, those with congenital anomalies such as pyriform sinus fistula, and those who are immunosuppressed.

Pathophysiology

Hashimoto's thyroiditis, postpartum thyroiditis, and silent thyroiditis all have an autoimmune basis. The antithyroid immune response begins with activation of thyroid antigen-specific helper T cells. Once helper T cells are activated, they induce B cells to secrete thyroid antibodies; thyroid antibodies most frequently measured are those directed against thyroid peroxidase and against thyroglobulin. The mechanism for autoimmune destruction of the thyroid likely involves both cellular immunity and humoral immunity. Riedel's thyroiditis is the local involvement of the

thyroid in a systemic disease, multifocal fibrosclerosis; the etiology of Riedel's thyroiditis is not known. Although a viral cause of subacute thyroiditis has been proposed, clear evidence for this proposed etiology is lacking. Suppurative thyroiditis is most often associated with a bacterial pathogen; however, fungal, mycobacterial, or parasitic infections may also be the cause. Although rare, radiation-induced thyroiditis may occur following the treatment of hyperthyroidism with radioactive iodine because of radiation-induced injury and necrosis of thyroid follicular cells and associated inflammation.

Clinical Manifestations

A symmetrical, painless goiter is frequently the initial finding in Hashimoto's thyroiditis. The usual course of Hashimoto's thyroiditis is gradual loss of thyroid function. Among patients with this disorder who have subclinical hypothyroidism, overt hypothyroidism occurs at a rate of about 5% per year. The classic presentation of postpartum thyroiditis occurs in only approximately 30% of afflicted women, with the characteristic sequence of hyperthyroidism, followed by hypothyroidism, and then recovery. Persistent hypothyroidism is seen in up to 30% of women following an episode of postpartum thyroiditis. Silent thyroiditis is marked by a similar characteristic sequence of thyroid hormone dysfunction. However, it is not temporally associated with pregnancy; 20% will have residual hypothyroidism. *Medication-induced thyroiditis* is variable in its presentation. Amiodarone (Cordarone), rich in iodine, is associated with hypothyroidism and hyperthyroidism; type 2 amiodarone-induced thyrotoxicosis is due to a destructive thyroiditis process. Lithium is more commonly associated with hypothyroidism. Interferon-alfa and interleukin-2 can cause both permanent and transient hypothyroidism likely related to the ability of these substances to induce or exacerbate thyroid autoimmune disease. Riedel's thyroiditis presents with neck discomfort or tightness, dysphagia, hoarseness, and a diffuse goiter that is hard, fixed, and often not clearly separable from the adjacent tissues. Generally, patients are euthyroid, and their antithyroid antibody concentrations are often high. Subacute thyroiditis manifests with a prodrome of myalgias, pharyngitis, low-grade fever, and fatigue with subsequent fever and neck pain, and up to 50% of patients have symptoms of thyrotoxicosis. Patients with suppurative thyroiditis are usually acutely ill with fever, dysphagia, dysphonia, anterior neck pain with erythema, and a tender thyroid mass. Radiation-induced thyroiditis presents 5 to 10 days following radioactive iodine treatment with neck pain and tenderness. In addition, there can be a transient exacerbation of hyperthyroidism.

Diagnosis and Differential Diagnosis

The diagnostic approach to suspected thyroiditis can be focused based on an association with thyroid pain and circulating thyroid hormone status (Figure 1). Hashimoto's thyroiditis is diagnosed when a goiter is found on examination with a subsequently noted elevation of thyroid antibodies or when subclinical or overt hypothyroidism is detected with associated elevated thyroid antibodies. Screening for postpartum thyroiditis with a measurement of TSH and free thyroxine should be undertaken in women presenting with symptoms of thyroid dysfunction in the postpartum period. If hyperthyroidism is present, thyroid scintigraphy (if not contraindicated, e.g., breastfeeding) or measurement of thyroid-stimulating immunoglobulins is helpful in the differentiation of postpartum thyroiditis from Graves' disease. The diagnostic approach to silent thyroiditis is similar. The laboratory hallmark of subacute thyroiditis is a markedly elevated erythrocyte sedimentation rate; the leukocyte count is normal or slightly elevated. Thyrotoxicosis may be present; if so, thyroid scintigraphy will reveal a low iodine uptake state. Thyroid antibody testing is typically normal. Thyroid ultrasound reveals a hypoechogenic gland with low to normal vascularity. Suppurative thyroiditis is typically associated with normal thyroid function. Leukocyte counts and erythrocyte sedimentation rates are elevated. Fine-needle aspiration with Gram stain and culture is the diagnostic test of choice. Radiation-induced thyroiditis should be considered if a temporal relationship to radioactive

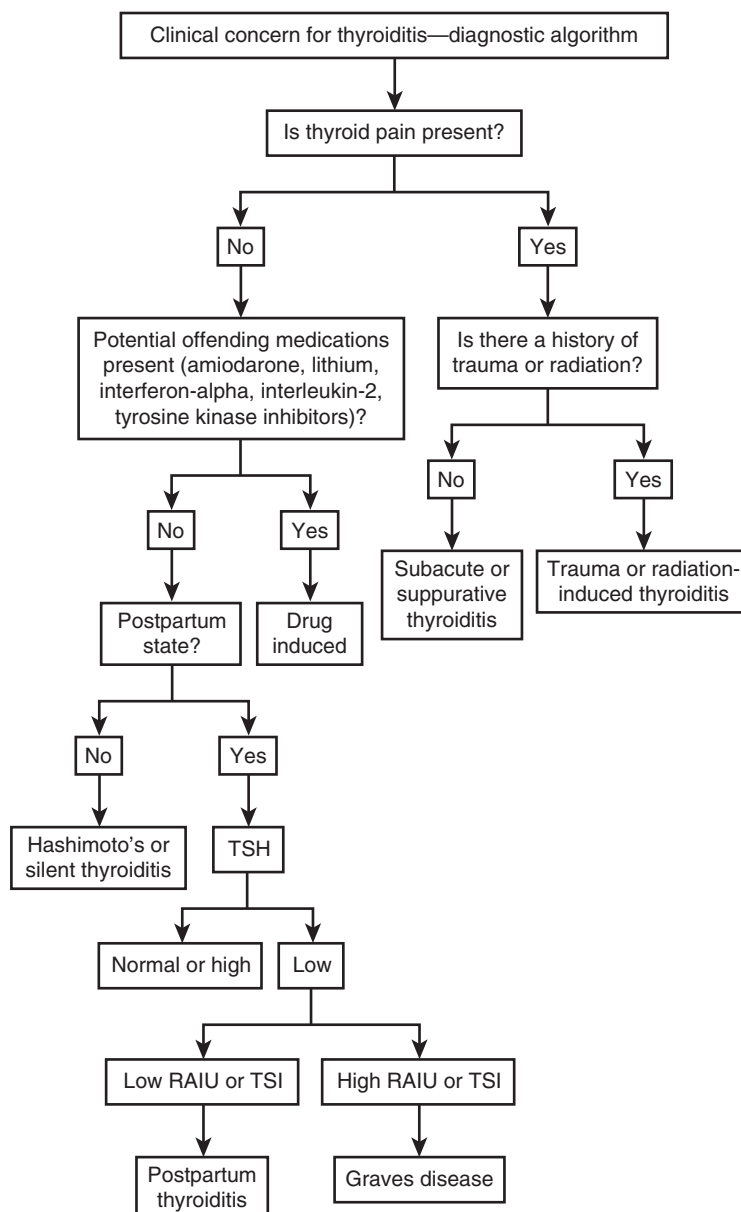

Figure 1 Clinical concern for thyroiditis—diagnostic algorithm. Abbreviations: RAIU = radioactive iodine uptake; TSI = thyroid-stimulating immunoglobulins.

iodine treatment is present. If there is an exacerbation of hyperthyroidism immediately following radiation treatment for the same, consideration of radiation-induced thyroiditis due to the release of preformed thyroid hormone associated with destruction of follicular cells should be considered as an etiology of thyrotoxicosis in addition to the underlying disease process.

Treatment

Once overt hypothyroidism is present in the patient with Hashimoto's thyroiditis, treatment with synthetic L-thyroxine (Levoxyl, Synthroid) therapy is indicated. The average replacement dose of thyroxine in adults is approximately 1.6 mcg/kg body weight per day. Adjustment of dosage is undertaken every 6 weeks until a euthyroid status is achieved. The majority of women with postpartum thyroiditis will not need treatment during either the hyperthyroid or hypothyroid phase. If symptomatic hyperthyroidism is present, beta-blocker therapy can be used; antithyroid medications have no utility in the management of postpartum thyroiditis. Women with symptomatic hypothyroidism should be treated with synthetic thyroxine therapy; in asymptomatic women, initiation of thyroxine therapy should be considered if TSH is >10 mU/L.

Management of silent thyroiditis is the same as that for postpartum thyroiditis. Symptoms associated with Riedel's thyroiditis may be relieved with prednisone; a small case series associated improvement and even resolution of the process with tamoxifen (Nolvadex)¹ therapy. Surgery is indicated in Riedel's thyroiditis if compressive symptoms are present. The goal of therapy in subacute thyroiditis is to provide symptom relief. Nonsteroidal antiinflammatory medications are often adequate to control pain; if insufficient, glucocorticoid therapy should be initiated. Beta-blockade therapy can ameliorate symptoms of thyrotoxicosis if indicated. Suppurative thyroiditis is managed with appropriate antibiotics and drainage of any abscess; the disease may prove fatal if diagnosis and treatment are delayed. Pain associated with radiation-induced thyroiditis can be managed with nonsteroidal antiinflammatory therapy or, if ineffective, a short course of glucocorticoid therapy. Radiation-induced thyroiditis is a self-limited process and will resolve spontaneously within days to weeks.

¹Not FDA approved for this indication.

Monitoring

In the patient with Hashimoto's thyroiditis with a euthyroid state, routine TSH testing should be undertaken given the risk of development of overt hypothyroidism at 5% per year. Any woman who has had postpartum thyroiditis should be monitored very closely for thyroid dysfunction with future pregnancies, as reoccurrence is likely. For women who have fully recovered from postpartum thyroiditis, yearly TSH measurements should be considered because of underlying chronic autoimmune thyroiditis and risk for overt hypothyroidism. Although overall recurrence rates for silent thyroiditis have not been well established, a similar monitoring plan is warranted for this variant of chronic autoimmune thyroiditis. Subacute thyroiditis recurs in only about 2% of patients. Routine monitoring following resolution of process has not been defined.

ACUTE LEUKEMIA IN ADULTS

Method of

William Blum, MD; and Clara Bloomfield, MD

CURRENT DIAGNOSIS

- Diagnosis of acute leukemia is made based on the presence of myeloid (acute myeloid leukemia; AML) or lymphoid (T- or B-cell acute lymphoblastic leukemia; ALL) blasts in blood and/or bone marrow. Acute leukemia may uncommonly have ambiguous lineage or mixed phenotype.
- Medical history taking should identify risk factors such as prior exposure to chemotherapy for other malignancies, antecedent hematologic disorders, familial hematologic disorders, or other inherited genetic disorders (e.g., Down syndrome, others).
- Clinical examination should identify extramedullary sites of involvement such as meninges/central nervous system (CNS), active infection, hemorrhage, or disseminated intravascular coagulation.
- AML requires the presence of $\geq 20\%$ blasts in blood or marrow, except in selected subsets of disease with specific cytogenetic aberrations associated with more favorable clinical outcomes, which do not require $\geq 20\%$ blasts. These favorable subsets are t(8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13;q22), or t(15;17)(q22;q12). Testing for additional cytogenetic and molecular aberrations is critical for diagnosis, prognosis, and therapy.
- Acute promyelocytic leukemia (APL) with *PML-RARA* gene fusion, detected by genetic methods or cytogenetics showing t(15;17), is a unique entity requiring different therapy; APL has a favorable prognosis.
- ALL is subcategorized based on B-lymphocyte or T-lymphocyte lineage. For B-ALL (also in mixed phenotype acute leukemia), identification of the Philadelphia chromosome t(9;22)(q34.1;q11.2) or its *BCR-ABL1* gene fusion is essential for proper diagnosis and treatment. As with AML, testing for an established group of other specific chromosomal and molecular aberrations is standard.

CURRENT THERAPY

- AML is typically treated with intensive initial therapy (induction) followed by repetitive cycles of intensive postremission therapy (consolidation). Induction chemotherapy most commonly consists of anthracycline plus cytarabine (Cytosar). Several acceptable postremission approaches are used; often these are repetitive high-dose cytarabine based regimens.
- APL is uniquely treated with all-*trans*-retinoic acid (tretinoin [Vesanoid]) and arsenic trioxide (Trisenox), instead of

chemotherapy, though cases with high presenting white blood cell count may require chemotherapy for cytoreduction.

- ALL is treated with multidrug regimens for induction and postremission therapies. Postremission therapies include further intensification cycles and prolonged lower-dose maintenance therapy. CNS-directed therapy is a critical component of treatment, even in patients without clear involvement. Most acute leukemias of ambiguous lineage are treated with ALL-type regimens, although clinical outcomes are poor.
- The use of pediatric ALL regimens in adolescents and young adults has improved outcomes.
- Older patients or those with medical infirmities may require less intensive treatment regimens; because of more resistant disease and also higher toxicities, such patients fare worse than younger patients.
- Because of high relapse risks, allogeneic hematopoietic stem cell transplantation (alloHCT) in first remission is an important consideration for all eligible patients with AML except those with favorable-risk disease. High-risk older patients with ALL are also offered early transplantation. All patients who relapse should be considered for transplantation, if remission is again achieved.
- Several subsets of acute leukemia can be treated by new, effective therapies that target specific aberrant signaling or enzymatic activities, or which are directed to unique biologic targets of disease. Most important among these are the use of tyrosine kinase inhibitors in acute leukemia (typically ALL) with *BCR-ABL1*.
- Advances in immunology have rapidly and dramatically improved the options for treatment, especially for those with relapsed B-ALL. Novel antibody constructs and genetically engineered autologous cellular products directed to eliminate B-lymphocytes can induce durable remissions in B-ALL.

Epidemiology

The incidence of AML in the United States is 4.2 per 100,000 per year, with an estimated 21,380 new cases in 2017 per data from the National Institutes of Health. AML accounts for about 1.3% of all new cancer cases and 31% of all new leukemia cases, according to the American Cancer Society. AML is far more common than ALL in adult patients. Although AML affects all age groups, the incidence increases with advancing age, presenting at a median age of 67 years. ALL has a bimodal distribution across ages, with a peak in early childhood and a second peak around age 70 years.

Risk Factors

Most cases of acute leukemia in adults have no established cause. Genetic predisposition, drugs, and radiation have been associated with the development of acute leukemia, particularly AML. Several rare genetic syndromes have increased risk for development of acute leukemia, including Down syndrome, Fanconi anemia, Bloom syndrome, neurofibromatosis type I, and ataxia telangiectasia. AML with germline predisposition represents an uncommon

but important subset of disease. Germline mutations associated with increased risk of developing a myeloid neoplasm include *CEBPA*, *DDX41*, *RUNX1*, *ANKRD26*, *ETV6*, and *GATA2*. Down syndrome–associated AML and ALL have increased risk of toxicity with standard chemotherapy and require dose adjustment (and expert management).

Anticancer drugs are the leading cause of therapy-associated AML. Alkylating agent–associated leukemias typically occur 4 to 6 years after exposure; affected individuals often have multilineage dysplasia and monosomy/aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor–associated leukemias typically occur with shorter latency, 1 to 3 years after exposure; affected individuals often have AML with monocytic features and aberrations involving chromosome 11q23.

Pathophysiology

Acute leukemias are hematologic malignancies arising from hematopoietic progenitor (stem) cells in the bone marrow. Clonal immature cells accumulate in the blood, bone marrow, and occasionally extramedullary tissues. These malignant cells divide and proliferate, but they do not differentiate into functional cells (ie, neutrophils, lymphocytes, others). Patients with acute leukemia are immunocompromised and have impaired oxygen-carrying capacity (anemia) and bleeding diathesis (because of thrombocytopenia or disrupted coagulation).

Patients experience complications directly from the accumulation of abnormal immature blasts or indirectly from the reduction in functional hematopoietic cells in the marrow and blood. Leukemic involvement of the bone marrow often results in pancytopenia—patients may present with cytopenias in all hematopoietic cell lineages. Patients typically require transfusions of red blood cells and platelets and are at risk of life-threatening infectious complications because of neutropenia. Most patients with acute leukemia die from infection or, less frequently, hemorrhage.

Patients with morphologically similar acute leukemias may experience vastly different clinical outcomes. Increasingly, this is understood by karyotyping or genetic sequencing studies that demonstrate marked heterogeneity in the cytogenetic and mutational profiles among patients with acute leukemia. It is clear that morphology and cytochemical staining alone to establish diagnosis does little to explain the pathophysiology of these varied hematologic cancers. Genetic sequencing studies demonstrate common dysregulation of several critical cellular pathways but also a myriad of genetic differences that occur in only small (or very small/unique) subsets. In adults, most cases of AML ultimately arise in the backdrop of a limited number of mutations that accumulate with advancing age. As noted above, cases with a clear cause such as germline predisposition or drug exposure are rare. The Cancer Genome Atlas (cancergenome.nih.gov) and other databases have shown that up to 5% to 6% of healthy individuals over 70 years of age have blood cells with potentially “pre-malignant” mutations that are associated with clonal expansion. There appear to be a variety of “final insults” that transform these expanded clones to AML. However, how all these genetic aberrations contribute to leukemic transformation remains incompletely understood. Although the number of mutations/cell in AML is relatively few (median of 13 mutations) compared with other cancers (e.g., melanoma and non-small cell lung cancer may have several hundred mutations/cell), great heterogeneity exists in the mutations identified between individual patients with AML. The same can be said of ALL. Indeed, dramatic differences in mutations/genetic signatures have been observed between patients with childhood, adolescent, young adult, and older adult ALL, respectively.

Great heterogeneity exists not just between patients with different types of acute leukemia but within each individual patient. Each patient has several leukemic clones and subclones that have slightly different mutational profiles. The presence of genetically different clones and subclones helps explain why a patient may achieve remission but then experience relapse with more resistant disease—sensitive clones are eliminated by chemotherapy, whereas surviving clones are more resistant to subsequent treatment.

Furthermore, persisting clones after treatment may emerge with additional novel mutations.

Clinical Manifestations

Patients with any type of acute leukemia present with similar symptoms. Most have vague symptoms that are consequences of pancytopenia. Typically, the onset of illness is no more than 3 months before diagnosis. Fatigue is common, as are anorexia and weight loss. Fever or infection are also common but not universal at presentation. Patients may have evidence of abnormal hemostasis (bleeding, easy bruising). Bone pain, lymphadenopathy, nonspecific cough, headache, and diaphoresis (excessive sweating) may also occur. Bone pain, typically vaguely localized to the pelvis or back, is frequent. Patients with ALL (as compared with AML) are more likely to have lymphadenopathy, splenomegaly, or other sites of extramedullary involvement such as testicles or CNS. However, involvement at any of these sites is not exclusive to ALL; their presence is not diagnostic of that type. Rarely, patients present with primary symptoms caused by extramedullary leukemia. Extramedullary disease in AML is known as a myeloid sarcoma (also called a *granulocytic sarcoma* or *chloroma*). This is a tumor mass consisting of myeloid blasts and is most commonly seen in the skin, lymph node, gastrointestinal tract, soft tissue, or testis. Patients who present with isolated myeloid sarcoma typically develop blood or marrow involvement quickly thereafter; such patients thus require systemic (not solely surgical or local radiation) treatment. CNS involvement at initial presentation (headache, cranial nerve palsies) is uncommon. Patients with ALL, however, have increased risk of CNS disease and thus should be given intrathecal chemotherapy as prophylaxis even without such symptoms (or detectable CNS involvement).

Severe hemorrhagic complications are relatively infrequent at presentation but are most commonly encountered in APL. Recognition of this risk at the time of initial presentation is critical, as replacement of fibrinogen or plasma may be lifesaving. Patients with APL often present with disseminated intravascular coagulation (DIC)–associated hemorrhage and may have intracranial hemorrhage or bleeding at other sites. Thrombosis is a less frequent but well-recognized feature of APL. Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other acute leukemias. Retinal hemorrhage caused by thrombocytopenia and extreme leukocytosis is detected in approximately 15% of patients.

Laboratory parameters are quite variable with any type of acute leukemia. Although many patients present with leukocytosis and high levels of circulating blasts, it is important to note that presenting with low white blood cell (WBC) counts or even no circulating blasts is not rare. Typically, though, review of the peripheral blood smear identifies the classic blast—fine, lacy chromatin, with one or more nucleoli, and high nucleus-to-cytoplasm ratio that is characteristic of immature cells. The presence in blasts of abnormal rod-shaped granules called *Auer rods* on light microscopy indicates a diagnosis of AML.

Anemia is usually observed at diagnosis but is not severe. Decreased erythropoiesis often results in a reduced reticulocyte (immature red blood cell) count, and red blood cell survival may be shortened through accelerated destruction. Most patients present with at least mild thrombocytopenia (below the normal lower limit value of 150,000/ μ L).

Diagnosis

When acute leukemia is clinically suspected, in addition to morphologic and flow cytometric analyses, cytogenetic and genetic tests are mandatory to aid rapid diagnosis, assess prognosis, and inform the best approach to treatment. That said, clinical features also remain important. These include history of antecedent hematologic disorder or prior chemotherapy, advanced age, and strong family history of acute leukemia or related hematologic disorder (all favoring AML); all of these have an adverse prognosis. In ALL, high WBC at presentation ($>100,000/\mu$ L for B-ALL and $>30,000/\mu$ L for T-ALL) and T-cell phenotype have an adverse prognosis.

Initial assessments should evaluate cardiovascular, pulmonary, hepatic, and renal systems; patients should also be evaluated and treated for infection or DIC. Preparation for transfusion of blood or platelets requires blood type and crossmatch to be determined, and human leukocyte antigen (HLA) testing is required early in the treatment course (before chemotherapy) in consideration of future alloHCT. Cytogenetic analysis typically requires bone marrow. Genetic testing (from blood or marrow) continues to evolve and is critical for successful diagnosis, prognosis, and therapy.

The diagnosis of AML is based on a finding of at least 20% myeloid blasts by histology, cytochemistry or flow cytometry. However, this 20% threshold is not required for the diagnosis if any of the following recurrent cytogenetic abnormalities is present: t(15;17), t(8;21), inv(16) or t(16;16). Myeloid blasts stain positive for myeloperoxidase; by flow cytometry, myeloid blasts are typically positive for CD13 and CD33. A prognostic schema developed by the European LeukemiaNet assigns prognostic risk based on cytogenetic and genetic features of disease (Table 1). Some morphologic features associate with specific cytogenetic or molecular

findings such as t(15;17) and APL, or dysplastic eosinophils and inv(16) or t(16;16). Expression of B-cell markers (CD19, PAX5, cytoplasmic CD79a) is not infrequent in t(8;21).

The diagnosis of ALL likewise requires at least 20% lymphoid blasts. By immunohistochemical methods, lymphoid blasts stain positive for terminal deoxynucleotidyl transferase (TdT); by flow, lymphoid blasts are typically positive for CD10, CD19, CD22, CD20 (variable) for B-ALL and CD3, CD7, CD4, and CD8 for T-ALL.

Patients may uncommonly present with acute leukemia of ambiguous lineage (undifferentiated or mixed phenotype). However, more common are AML cases that express an aberrant B or T cell marker (e.g., CD7 on myeloid blasts); this is called an aberrant immunophenotype. Likewise, B-ALL may aberrantly express CD13 or CD33.

Molecular testing is an important component of diagnosis. For AML, molecular testing should include assessment of *FLT3* (with allelic ratio), *NPM1*, *CEBPA* (bi-allelic), *IDH1*, *IDH2*, *RUNX1*, *ASXL1*, and *TP53*. For ALL, testing is equally complex but still evolving in terms of commercial availability for important molecular analyses. Critical to initial assessment of ALL is testing for the *BCR-ABL1* fusion by molecular methods that are widely available; tyrosine kinase inhibitors (TKIs) targeting this lesion are now an important part of treatment. Likewise, testing by interphase fluorescence in situ hybridization for the major recurrent cytogenetic abnormalities seen in ALL, including *ETV6-RUNX1*, *TCF3-PBX1*, and *KMT2A* rearrangements, among others, is mandatory. Although not yet widely available, testing in B-ALL for the “*BCR-ABL1*-like” genetic signature identifies a subset of patients with adverse prognosis but potential responsiveness to TKI therapies. *BCR-ABL1*-like disease as a subset has several common genetic features including dysregulation of B-lymphoid transcription factors including *IKZF1*, *CRLF2*, *JAK2*, and others. Diagnostic testing guidelines for both AML and ALL are delineated and annually updated by the National Comprehensive Cancer Network (NCCN.org).

Cytogenetic analysis should be performed on the bone marrow aspirate taken at diagnosis in any patient suspected to have acute leukemia. Prognosis is determined on the presence of structural or numeric chromosomal abnormalities and then more fully informed by additional genetic testing. Broadly speaking, patients with AML with t(15;17), known as APL as described earlier, have an excellent prognosis, with 80% to 90% cured. Patients with t(8;21) or inv(16) also have a favorable prognosis. Patients with no cytogenetic abnormalities (cytogenetically normal AML; CN-AML) have an intermediate prognosis. Patients with a complex karyotype, t(6;9), inv(3) or -7 (absence of chromosome 7) have an adverse prognosis, with few cures, particularly in older patients. Genetic testing provides valuable additional information, especially in CN-AML. Favorable-genetic risk is observed in those with *NPM1* mutations without a high allelic ratio of *FLT3* internal tandem duplications (*FLT3*-ITD) and also in those with bi-allelic *CEBPA* mutations. Conversely, *TP53* mutations (often but not exclusively observed in the setting of complex karyotypes) are associated with adverse risk. *IDH2* and *IDH1* mutations may contribute to prognostication but, more importantly, identify patients likely to respond to novel therapies that target these aberrant pathways.

Cytogenetic testing for ALL allows classification into several groups, including, for example, *BCR-ABL1* fusion disease. This fusion, known cytogenetically as t(9;22) and called colloquially the Philadelphia (Ph) chromosome, based on the city where it was originally identified, has a poor prognosis. However, the incorporation into multiagent regimens of TKIs that target the aberrantly active kinase has improved clinical outcomes. Other important ALL subsets include *KMT2A* rearrangements at chromosome 11q23 (with various translocation partners but often chromosome 4 in B-ALL). Both *BCR-ABL1* and *KMT2A* aberrant ALL are associated with unfavorable prognosis. Many other subsets of ALL exist in the World Health Organization (WHO) classification. Favorable-risk is seen in patients with B-ALL with t(12;21)(p13.2;q22.1); the *ETV6-RUNX1* fusion. T-ALL is characterized by activation mutations in *NOTCH1* (present in about

TABLE 1 2017 European LeukemiaNet Risk Stratification by Genetics for Acute Myeloid Leukemia*

RISK CATEGORY [†]	GENETIC ABNORMALITY

*This table excludes acute promyelocytic leukemia. Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated.

[†]Prognostic impact of a marker is treatment-dependent and may change with new therapies.

[‡]Low, low allelic ratio (<0.5); high, high allelic ratio (≥0.5); semi-quantitative assessment of *FLT3*-ITD allelic ratio (using DNA fragment analysis) is determined as ratio of the area under the curve (AUC) “*FLT3*-ITD” divided by AUC “*FLT3*-wild type”; recent studies indicate that acute myeloid leukemia with *NPM1* mutation and *FLT3*-ITD low allelic ratio may also have a more favorable prognosis and patients should not routinely be assigned to allogeneic hematopoietic-cell transplantation.

[§]The presence of t(9;11)(p21.3;q23.3) takes precedence over rare, concurrent adverse-risk gene mutations.

^{¶¶}Three or more unrelated chromosome abnormalities in the absence of one of the World Health Organization–designated recurring translocations or inversions, ie, t(8;21), inv(16) or t(16;16), t(9;11), t(v;11)(v;q23.3), t(6;9), inv(3) or t(3;3); AML with *BCR-ABL1*.

[¶]Defined by the presence of one single monosomy (excluding loss of X or Y) in association with at least one additional monosomy or structural chromosome abnormality (excluding core-binding factor AML).

^{**}These markers should not be used as an adverse prognostic marker if they co-occur with favorable-risk AML subtypes.

^{††}*TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

Adapted from Döhner H, Estey E, Grimwade D et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel. *Blood* 2017;129:424–447.

60% of cases) and deregulation of a number of transcription factors; immunophenotyping showing an early T-cell precursor (ETP) phenotype (low expression of CD1a, CD8, CD5) has been associated with adverse prognosis.

Historically, the diagnosis and classification of acute leukemia was based on the French–American–British morphologic and cytochemical criteria, which assigned patients with AML to 1 of 8 groups, designated M0–M7. Likewise, ALL was classified into L1, L2, and L3 groups. These categories, while still in the vernacular on the clinical wards, are practically obsolete. Diagnosis and classification is based instead on the complex morphologic, flow, cytogenetic, and molecular characterization schemas outlined by the WHO for myeloid neoplasms and acute leukemia.

Differential Diagnosis

The differential diagnosis for acute leukemia includes many bone marrow disorders that present with pancytopenia. However, the presence of excess blasts in the blood or marrow limits the diagnosis to AML, ALL, or acute leukemia of ambiguous lineage. For patients without circulating blasts in the blood, highest in the differential diagnosis of pancytopenia are other hematologic cancers with marrow infiltration, or bone marrow failure syndromes such as aplastic anemia. Advanced myeloproliferative disorders with bone marrow fibrosis can also present similarly, occasionally with rare circulating blasts. Rarely, the pancytopenia caused by the displacement of hemopoietic bone marrow tissue by fibrosis, tumor, or granuloma (called myelophthisis) mimics acute leukemia (but without blasts). Examples include solid organ cancers with extensive marrow involvement and granulomatous disease such as tuberculosis. However, essentially only acute leukemia is the appropriate diagnosis in patients with high-level circulating blasts visualized on light microscopy.

Treatment of AML

Treatment of the newly diagnosed adult patient with AML is usually divided into two phases: (1) induction and (2) consolidation (i.e., postremission management). The aim of induction chemotherapy is complete remission (CR), defined as fewer than 5% blasts on a bone marrow aspirate, with recovery of blood counts (absolute neutrophil count > 1000/ μ L AND platelet count > 100,000/ μ L). At CR, additional defining criteria include absent circulating blasts and no detectable extramedullary disease. Achievement of CR (or failure to do so) is the best predictor for long-term clinical outcome. The definition of CR is further refined based on the detection of measurable residual disease (MRD) by cytogenetic or molecular testing. Marrow response *without* full blood count recovery meets lesser response definitions, but not CR; patients with such responses have outcomes inferior to those with CR. Blood count recovery occurs approximately 4 weeks after initiating intensive induction chemotherapy. CR is achieved in 60% to 90% of younger patients (depending on molecular risk), and in approximately 40% to 60% of older patients (>60 years). Notably, for older patients this estimate is from the subset limited to those who are actually offered intensive therapy; many older patients are not treated intensively (or at all) due to medical comorbidities. Such patients would likely fare even worse than the estimates provided if offered intensive treatment. Long-term survival estimates are approximately 60% for younger patients with favorable-risk disease (Table 1), 40% for intermediate-risk disease, and 20% for adverse-risk disease. Older patients do poorly in each group; indeed, for older patients with adverse-risk disease, there are very few long-term survivors.

Induction and consolidation therapies are chosen based on the patient's age, overall fitness, and cytogenetic/molecular risk. Intensive induction therapy is the norm in younger patients (<60 years). In older patients, the benefit of intensive therapy is more controversial in all but favorable-risk patients; novel approaches for selecting patients predicted to be responsive to treatment and new therapies remain under investigation. Notably, large datasets have demonstrated that even more infirm older patients with AML benefit from treatment, as compared with only palliative care.

Standard induction therapy for AML consists of cytarabine (cytosine arabinoside, AraC; Cytosar), 100 to 200 mg/m² per

day administered as a continuous infusion for 7 days, and daunorubicin (Cerubidine), 60 to 90 mg/m² per day for 3 days, commonly known as the 7+3 schedule. Idarubicin (Idamycin; 12 mg/m²/day) is equivalent to daunorubicin. Resistant disease is more frequent in older patients and those with prior hematologic disorders, therapy-related AML, or cytogenetic and genetic abnormalities that adversely impact clinical outcome (which are more frequent in older patients). In older patients, the long-term outcome is generally poor due to a higher frequency of resistant disease plus an increased rate of treatment-related mortality. As an alternative to intensive induction, unfit or adverse-risk older patients may instead receive lower-intensity therapy with a hypomethylating agent (such as decitabine [Dacogen]¹ or azacitidine [Vidaza]¹). All older patients should be considered for clinical trials, but older patients in adverse-risk groups should ideally be offered investigational approaches whenever available.

Induction of first CR (CR1) is critical to long-term survival in AML. However, without further therapy, virtually all patients in CR will eventually relapse. Patients are estimated to have 10¹² leukemic cells at diagnosis, which intensive induction chemotherapy reduces by 4 to 5 orders of magnitude. Although this reduces the disease burden by 99.9%, approximately 10⁸ residual leukemic cells still remain after successful induction therapy. These residual cells cannot be measured at all or can only be measured by sensitive techniques such as multiparameter flow cytometry or quantitative reverse transcriptase polymerase chain reaction (RT-PCR). They cannot be detected by morphology alone. Thus postremission therapy is designed to eradicate residual (typically undetectable) leukemic cells to prevent relapse and prolong survival. As for induction, the type of postremission therapy in AML is selected for each individual patient based on age, fitness, and cytogenetic/molecular risk.

Postremission treatment options include chemotherapy or transplantation. The choice between consolidation with chemotherapy or transplantation is complex and based on age, risk, and practical considerations. In younger patients receiving chemotherapy, postremission therapy with intermediate/high-dose cytarabine for two to four cycles is standard practice. It is clear that alloHCT is the best relapse prevention strategy currently available for AML. However, the benefit of alloHCT in relapse risk reduction is offset somewhat by increased morbidity and mortality from complications including graft-versus-host disease. Given that relapsed AML is typically resistant to chemotherapy, alloHCT in CR1 is a favored strategy for patients at high risk for relapse. Transplantation is generally recommended for physically fit patients age <75 years who do not have favorable-risk disease and who have a suitable donor. Donors are typically HLA-matched (related or unrelated) or, increasingly, haploidentical (half-matched sibling, parent, or child). Prognostic factors help select the appropriate post-remission therapy in patients in CR1. Generally speaking, patients with favorable-risk AML in CR1 are treated with chemotherapy alone; patients with adverse-risk disease should proceed to alloHCT at CR1 if possible. The decision for alloHCT versus chemotherapy in CR1 for intermediate-risk patients remains in debate.

APL is uniquely treated with all-*trans*-retinoic acid (tretinoin [Vesanoid]) and arsenic trioxide (Trisenox), instead of chemotherapy, although cases with high presenting WBC count (>10,000/ μ L) may require chemotherapy for cytoreduction. Cases with high WBC count are at increased risk for fatal hemorrhage and other complications. Low-risk patients (WBC <10,000/ μ L) have virtually nonexistent frequency of resistant disease. Patients with APL require expert management to address complications of DIC and hemorrhage and the so-called APL syndrome (formerly differentiation syndrome, retinoic acid syndrome). APL syndrome is marked by rising WBC count, fever, hypoxia, shortness of breath, and fluid accumulation, occurring 1 to 18 days after treatment initiation. It is common, especially in higher WBC presentations, and requires urgent therapy consisting of steroids, diuresis, and possibly cytoreduction.

¹Not FDA approved for this indication.

Treatment of ALL

Standard chemotherapy treatment of ALL is of much more extended duration and regimen complexity than that of AML. However, the same general principles apply—achievement of CR1 with initial therapy is the critical first step for long-term survival. Postremission therapy in ALL is broken into different segments of various intensity, including interim maintenance, delayed intensification, and prolonged (24 months) maintenance. CNS-directed therapy (systemic chemotherapy with intrathecal chemotherapy, or cranial radiotherapy) is an important mandatory feature of ALL treatment. Generally, treatment approaches include variations on a five-drug induction combination of cyclophosphamide (Cytosan), prednisone¹ or dexamethasone (Decadron)¹, anthracycline (doxorubicin [Adriamycin]; or daunorubicin [Cerubidine]), PEGylated asparaginase (Oncaspar), and vincristine (Oncovin). The principle of therapy is continuous exposure to multiple chemotherapy agents with non-overlapping resistance mechanisms; all ALL regimens use alternating chemotherapy regimens given over extended time. Additional agents include methotrexate, cytarabine, 6-mercaptopurine (Purinethol), and others. Examples of treatment strategies are the BFM (Berlin-Frankfurt-Munster) approach and the hyper-CVAD regimen.

Unfortunately, although children with B-ALL have favorable long-term survival in the 80% to 90% range, adults fare far worse. Estimated long-term survival rates for adults with ALL are only 30% to 40%. Encouraging data have come from recent cooperative group studies: adolescents and young adults (age 16–40 years) treated with “pediatric-inspired” regimens have outcomes far better than those treated with “adult” regimens. Pediatric regimens have a greater focus on less myelotoxic therapies such as PEGylated asparaginase, vincristine, and steroids. Unfortunately, older adults (>40 years) have difficulty tolerating such approaches.

As noted previously, the identification of the Ph chromosome t(9;22) or the *BCR-ABL1* fusion is a very important part of the initial diagnosis of B-ALL or mixed-phenotype acute leukemia. The introduction of TKI for Ph+ patients into multiagent induction and postremission treatment has dramatically improved outcomes and is now standard. Whether Ph+ B-ALL should have mandatory alloHCT in CR1 is now controversial. Imatinib (Gleevec) is a standard TKI; second- or third-generation TKI such as dasatinib (Sprycel), nilotinib (Tasigna)¹, or ponatinib (Iclusig) are also commonly used for Ph+ acute leukemia.

Additional advances to traditional approaches over the last 5 years include use of CD20 monoclonal antibodies (rituximab [Rituxan]¹) for patients with B-ALL whose lymphoid blasts express this surface marker, and nelarabine (Arranon) in T-ALL. Nelarabine is a purine analogue with increased activity in T-lymphoid blasts and 30% response rates in the relapsed setting; it is being incorporated into front-line multiagent trials. AlloHCT in adult ALL is more controversial than in AML, although most offer alloHCT in CR1 for high-risk disease.

Immune-Based Therapies in Acute Leukemia

Beyond use of alloHCT, recent years have seen remarkable progress in immunologic therapies for acute leukemia. The US Food and Drug Administration recently approved two exciting engineered cellular therapies for relapsed malignancies of B-lymphocytes: chimeric antigen receptor (CAR) T-cells that target CD19 (in B-ALL and non-Hodgkin's lymphoma). In these cases, autologous B-cells are collected by apheresis from the patient, genetically engineered ex vivo to target CD19, then infused back into the patient to treat CD19+ malignancy (typically after some type of lymphodepleting therapy). High response rates and long-term remissions have been reported in patients with ALL with highly refractory disease using CAR T-cell therapy; complete response rates in the range of 70% to 90% have been observed in CD19+ cancers: ALL, chronic lymphocytic leukemia, and diffuse large B-cell lymphoma (Figure 1). Challenges of CAR T-cells include issues with uncontrolled immune

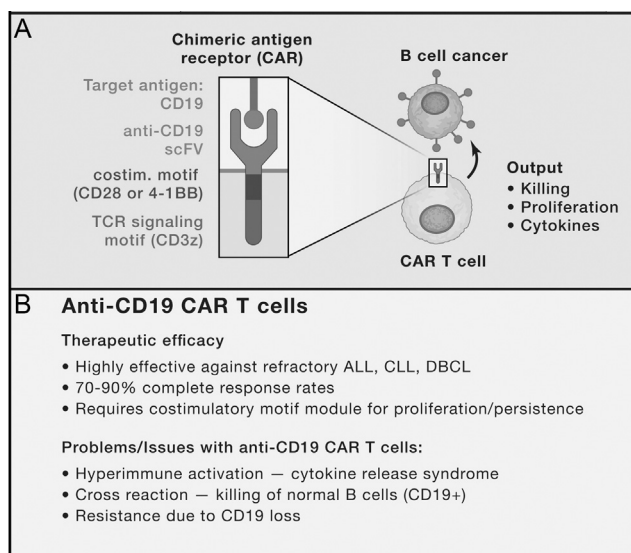

Figure 1 Chimeric antigen receptor (CAR) T cells. (Reprinted with permission from Lim WA and June CH. The Principles of Engineering Immune Cells to Treat Cancer. *Cell* 168:724–740, 2017.)

cell activation, killing of normal CD19+ B-cells, and resistance due to loss of CD19 expression on leukemic cells. Whether CAR retargeting can be successfully applied to other hematologic targets beyond CD19 remains to be seen.

Several novel antibodies have also recently been approved. Inotuzumab ozogamicin (Besponsa; targeting CD22 in B-ALL) and gemtuzumab ozogamicin (Mylotarg; targeting CD33 in AML) are antibody–drug conjugates that deliver the toxin calicheamicin to lymphoid or myeloid blasts, respectively. Blinatumomab (Blin-cyto) is a CD3-CD19 bi-specific antibody.

Monitoring

Measurement of residual disease is an important component of management in acute leukemia. It is not surprising that initial responsiveness to chemotherapy is a useful predictor for long-term outcome. Lack of early clearance of blasts (by day 7 to 14) has adverse prognostic value (especially in ALL). Persistence of abnormal karyotype after induction among patients in CR is also associated with poor clinical outcomes. For patients in morphologic CR, measurement of MRD is an emerging standard (ALL) and research (AML) area. More sensitive methods of MRD measurement beyond light microscopy and cytogenetics are increasingly used to aid decision making. Examples of sensitive MRD assessment include immunophenotyping to detect minute populations of blasts or quantitative RT-PCR to detect leukemia-associated molecular abnormalities. Particularly in B-ALL, early clearance of MRD is favorable. In ALL and in APL, MRD assessment is a very useful and reliable tool to assess prognosis, detect early relapse, and direct initiation of additional therapy.

Management of Complications

The treatment of acute leukemia involves repeated cycles of myelotoxic or immunosuppressive chemotherapy, requiring intensive supportive care. The emergence of multidrug-resistant organisms is a growing concern. In addition, invasive fungal infections are associated with early death. Standard infection precautions include reverse isolation, air filtration, and prophylactic antimicrobials. Recommendations on the latter are best tailored based on institutional antibiograms.

Transfusion of red blood cells and platelets is a common and necessary part of treatment. Blood products should ideally be leukodepleted (done by the American Red Cross in the United States) to reduce the risk of febrile transfusion reaction and alloimmunization. Particularly in ALL, it is clear that management of complications yet still proceeding with on-time administration of subsequent therapy improves outcomes.

¹Not FDA approved for this indication.

APLASTIC ANEMIA

Method of

Eva C. Guinan, MD

CURRENT DIAGNOSIS

- Patient must all meet hematologic criteria.
- Assess severity.
- Adequate cytogenetic analysis is essential.
- Consider diagnoses with treatment implications:
 - Causes of transient pancytopenia.
 - Evaluate for inherited bone marrow failure syndromes, paroxysmal nocturnal hemoglobinuria, myelodysplastic syndromes.
 - Evaluate for malignancy (leukemia, lymphoma), HIV.

CURRENT THERAPY

- Minimize interval between diagnosis and initiation of treatment.
- Determine if an MSD is available.
- If the patient is young and has an MSD, proceed to HCT with non-TBI regimen.
- If the patient has no MSD or is older, proceed to IST with CSA/ATG/steroid.
- For treatment failure, reconsider IST versus HCT options.

Abbreviations: ATG = antithymocyte globulin; CSA = cyclosporine; HCT = hematopoietic cell transplantation; IST = immunosuppressive therapy; MSD = matched sibling donor; TBI = total body irradiation.

The survival of patients with aplastic anemia has improved dramatically in the past several decades. Improved testing for underlying acquired and congenital genetic defects has served to better segregate patients with idiopathic aplastic anemia from those with the very different prognoses associated with inherited bone marrow failure syndrome (IBMFS) and myelodysplasia (MDS). For patients in the idiopathic (or acquired) aplastic anemia group, advances in transfusion medicine and other supportive care have also certainly contributed. Refinements in both major arms of treatment, immunosuppressive therapy (IST), and allogeneic hematopoietic cell transplantation (HCT), have also contributed to current outcomes (Figure 1). Although IST survival curves have been stable in the last decade, survival after HCT regardless of donor

Figure 1 The actuarial survival of 2479 patients with acquired severe aplastic anemia. Group A received immunosuppressive therapy (IST) (solid line) as first-line therapy and Group B underwent hematopoietic stem cell transplant (BMT) (dashed line). Ten-year survival was 73% with BMT and 68% with IST ($P < .002$). (Data from Locasciulli A, Oneto R, Bacigalupo A, et al: Outcome of patients with acquired aplastic anemia given first-line bone marrow transplantation or immunosuppressive treatment in the last decade: A report from the European Group for Blood and Marrow Transplantation [EBMT]. *Haematologica* 2007;92:11–18.)

source has continued to improve. Greater understanding of pathophysiology and long-term treatment outcomes are having the largest impact on triage of therapy and standards of practice.

Definition

There is no pathognomonic diagnostic test for aplastic anemia. Accordingly, aplastic anemia continues to be diagnosed by a combination of inclusion and exclusion criteria. The definition established by the International Agranulocytosis and Aplastic Anaemia Study states that patients must have bone marrow hypocellularity with two or more of the following: hemoglobin of less than 10 g/dL, platelet count of less than $50 \times 10^9/L$, and neutrophil count of less than $1.5 \times 10^9/L$. Most commonly, patients said to have aplastic anemia in fact have severe aplastic anemia, which is defined by the absolute neutrophil count (ANC) as shown in Box 1. Severity grading has become part of the diagnostic algorithm and is increasingly used as one predictor of outcome.

Differential Diagnosis

Because many conditions can fulfill these inclusion criteria, care must be taken to consider infectious, metabolic, and toxic

exposures that could result in transient pancytopenia. Specific considerations are listed in many current reviews. These diagnoses are wide ranging and include hypoplastic presentations of lymphoma, leukemia, and MDS (including the subtype refractory cytopenia of childhood); anorexia; and transient severe bone marrow suppression due to drug exposure or, albeit rarely, a spectrum of acute viral illnesses.

Patients should be carefully evaluated for other conditions that can require an alternative management approach. A fraction of pancytopenic and hypocellular patients have clonal cytogenetic abnormalities despite well-reviewed histology that appears to be free of any evidence of dysplasia or infiltrative disease. Accordingly, best practice should include both fluorescent in situ hybridization (FISH) and routine cytogenetics, because the yield for the latter analysis may be inadequate given the hypocellularity of the bone marrow compartment.

Although the prognostic relevance of clonal cytogenetics remains somewhat debatable, evidence of clonality at diagnosis should certainly provoke consideration of MDS as an alternative diagnosis and mandate an aggressive plan of follow-up and determination of HCT donor status. Clonality also potentially alters immediate treatment depending on the clinical setting and most current literature. Among infectious problems, perhaps the most important consideration from a diagnostic and management perspective is HIV. However, viruses rarely cause a true aplastic picture, and their diagnosis, at present, does not have much therapeutic importance. Aplastic anemia can occur or recur during pregnancy and can resolve with either delivery or termination.

The most important alternative diagnosis is an inherited bone marrow failure syndrome (IBMFS) (Table 1), which should be considered in virtually all patients and certainly in all pediatric patients. Such a diagnosis has important implications for medical management of the extended family, for genetic counseling, for the choice of therapy, for prognosis of the patient, and, in the setting of HCT, for donor evaluation. A meticulous patient and family history and physical examination should be performed, although uninformative results do not eliminate the possibility of an IBMFS. IBMFS diagnosis by functional testing for cell surface molecules, telomere length, and chromosomal breakage has markedly improved. Genetic testing is available for some IBMFSs; however, it is clear that these syndromes are polygenic, and not all relevant genetic defects have been defined. Therefore testing might not be diagnostic. Moreover, new genetic defects associated with aplastic anemia are still being discovered. As additional mutations are described and their epidemiology becomes better elucidated, this information should be of increasing value.

In addition to IBMFS, an evaluation for paroxysmal nocturnal hemoglobinuria (PNH) should be undertaken. A small clonal

population of cells deficient in glycosylphosphatidylinositol (GPI)-linked proteins that characterize PNH can be found in 20% to 50% of both children and adults with aplastic anemia without a concurrent history of clotting or hemolysis. The presence of such cells does not imply a diagnosis of classic PNH, although some patients with apparent aplastic anemia do develop classic PNH. Ongoing clinical investigation into the relation of aplastic anemia and PNH might yield further information that will assist in therapeutic decision making.

Supportive Care

The goals of supportive care in aplastic anemia are alleviating symptoms of anemia and addressing the risks of hemorrhage and infection that result from pancytopenia. Appropriate precautions for minimizing alloimmunization should be taken, such as use of leukodepletion techniques and conservative transfusion goals.

Preemptive counseling can play as important a role as symptom management. There are few evidence-based guidelines for activities of daily living, such as the quality of diet, extent of exercise, and travel restrictions. The best standard is frequent, open communication between physician and patient. Some practical issues, however, are common. For example, the menstrual status of female patients should be ascertained immediately on diagnosis. Because severe menorrhagia can occur in the setting of protracted thrombocytopenia, use of hormonal therapy to suppress menstruation should be addressed with patients and with families of younger patients. Particular regard should be paid to anticipation of menarche in pubertal girls.

With regard to infectious risks, standards widely vary by practitioner and institution. Although the largest single cause of death in patients undergoing either HCT or IST is infection, there is no current standard for infection prophylaxis in aplastic anemia. Clinical trials to define the best possible approaches to this issue, including the role of novel broad-spectrum anti-infective drugs and their schedule of use, would be very important. At the least, a detailed history taken in the context of exposure and lifestyle issues should be used to develop a plan for fever and infection prophylaxis with which the patient can be compliant.

Benefit from the use of hematopoietic growth factors to support the ANC, or indeed any lineage, has been unclear in patients with idiopathic aplastic anemia. Prior concerns about the association of long-term use of granulocyte colony-stimulating factor (G-CSF) (Neupogen)¹ by pediatric aplastic anemia patients, in particular, and subsequent development of MDS and acute myelogenous leukemia (AML) have not been confirmed in recent multicenter data.

¹Not FDA approved for this indication.

TABLE 1 Inherited Bone Marrow Failure Syndromes Commonly Associated with Pancytopenia*

SYNDROME	COMMON HEMATOLOGIC FINDINGS	DIAGNOSTIC TESTS AVAILABLE [†]
Amegakaryocytic thrombocytopenia	Thrombocytopenia with absent or hypolobulated megakaryocytes Macrocytosis Progressive pancytopenia with marrow hypoplasia	Gene mutation analysis
Dyskeratosis congenita	Macrocytosis Thrombocytopenia Progressive pancytopenia with marrow hypoplasia	Gene mutation analysis Telomere length (markedly shortened)
Fanconi anemia	Macrocytosis Single, bilineage, or trilineage cytopenia Progressive pancytopenia with marrow hypoplasia	Abnormal chromosomal breakage or sister-chromatid exchange in the presence of DNA cross-linkers Abnormal cell cycle progression Gene mutation analysis
Shwachman-Diamond syndrome	Neutropenia Progressive pancytopenia with marrow hypoplasia	Radiologic bony abnormalities Serum trypsinogen and isoamylase levels (may be decreased) Gene mutation analysis

*Diamond-Blackfan anemia, as well as less common disorders such as Pearson, Seckel, and Noonan syndromes; cartilage-hair hypoplasia; and reticular dysgenesis, can progress to marrow failure meeting the definition of aplastic anemia.

[†]Clinically approved mutation testing is becoming increasingly available, but not all genetic defects have been defined for any of these disorders.

Monitoring of iron status should be routine for patients with ongoing red cell transfusion needs. Chelation should be initiated according to accepted guidelines to minimize complications of iron overload.

Treatment

Observation is not a successful treatment option for patients with severe aplastic anemia; older, retrospective data demonstrate a 1-year mortality with supportive care alone of more than 80%, although current transfusion and support strategies should improve on this outcome. Nonetheless, a recent large report from the European Group for Blood and Marrow Transplantation demonstrates that decreased time from diagnosis to treatment, whether IST or HCT, is a highly significant predictor of survival. A triage of therapy is shown in Figure 2.

Immunosuppressive Therapy

It is generally held that a significant percentage of aplastic anemia has an immune pathogenesis. A variety of data on immune effector cell function and repertoire, cell surface phenotype, and cytokine production support this belief. In practice, this hypothesis is also supported by the observation that IST with cyclosporine (Neoral)¹ (CSA), antithymocyte globulin (ATG), and corticosteroids results in response in roughly 75% of patients. Horse ATG was shown to be superior to rabbit ATG in a recent randomized trial.

Younger patients generally have a higher likelihood of response. Children (<16 years) on IST with very severe aplastic anemia have better survival rates than similarly affected adults. Age does not affect the relative survival rate of patients with less severe aplastic anemia.

Randomized studies have demonstrated better response when IST agents are used in combination. Meta-analysis has also shown decreased all-cause mortality. In addition to their general immunomodulatory capacity, the immunologic effects of IST may be specific, because direct lympholytic and bone marrow stimulatory activities have been described. The addition of further immunosuppressive medications, such as mycophenolate or sirolimus, to this regimen has thus far not improved outcomes.

IST responses can be of varying degree and duration and can take 3 to 6 months to become evident. Often, responding patients continue to manifest some evidence of bone marrow failure, with mild degrees of cytopenia or residual macrocytosis commonly observed. Slow taper of CSA in IST responders is advisable, generally over longer than 6 months, and a significant fraction of patients demonstrate prolonged dependence on CSA for persistent hematologic improvement. A second course of IST in patients who failed a first course can produce response in 12% to 50% of patients. Complete or partial loss of response occurs in an appreciable number of patients, approximately one third, and can become manifest years after cessation of IST or immediately on CSA taper. Re-treatment with the same or a similar regimen is often successful.

Recent studies demonstrate that eltrombopag (Promacta), a thrombopoietin mimetic, has potential for multilineage efficacy in patients with severe aplastic anemia refractory to IST, and it has been FDA-approved for this indication.

Hematopoietic Cell Transplantation

HCT is the only truly curative therapy for aplastic anemia and produces stable survival rates in the range of 65% to 90%, depending on donor type and other HCT variables (Figure 3). In young patients with matched sibling donors (MSDs), a short interval from diagnosis to HCT, and little prior therapy, survival rates up to 97% have been recently reported. Conversely, prior IST or excessive transfusion (or both) are associated with worse outcome. Thus the general recommendation is for young patients with MSDs to proceed to HCT as soon as the diagnosis is confirmed. The age cut-off for this decision varies somewhat, but the recommendation certainly holds for patients younger than 30 years and is often implemented for those younger than 40 years.

HCT for aplastic anemia from MSD can be successfully achieved with radiation-free preparative regimens, of which the most standard and widely used is cyclophosphamide (Cytosan)¹ (CY) and ATG conditioning. CSA and short-course methotrexate (Trexall)¹ (MTX) provide highly effective graft-versus-host disease (GVHD)

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

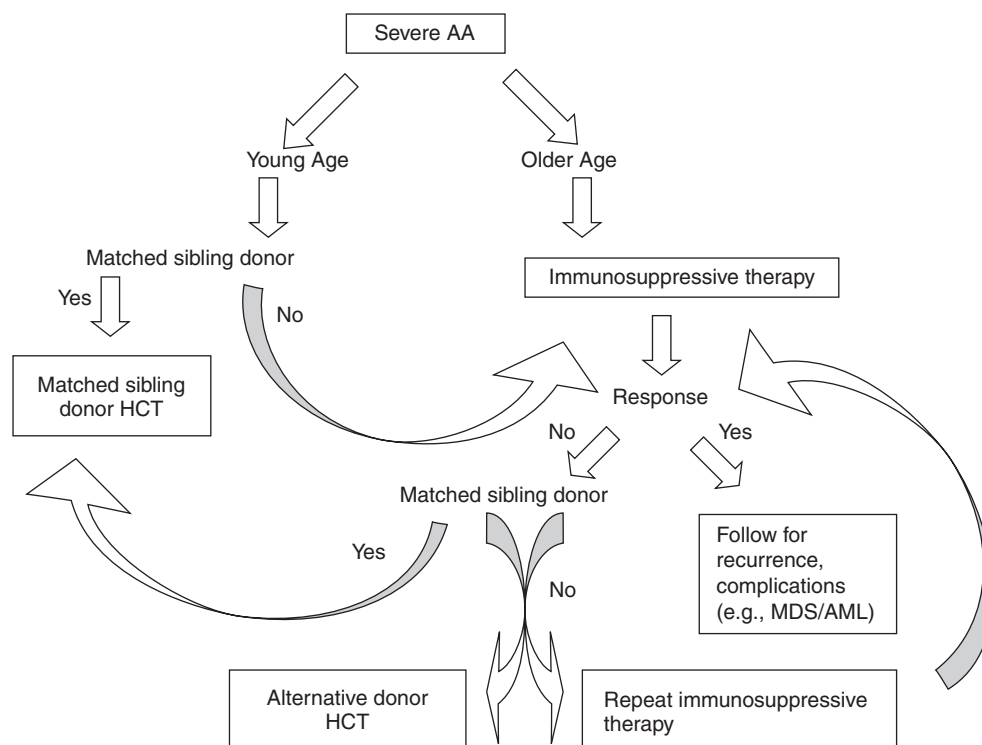

Figure 2 Triage of aplastic anemia (AA) therapies. The age limit suggested by young/old is variable from report to report, but generally sits in the 30- to 40-year-old range. *Abbreviations:* AML = acute myelogenous leukemia; HCT = hematopoietic cell transplant; MDS = myelodysplasia.

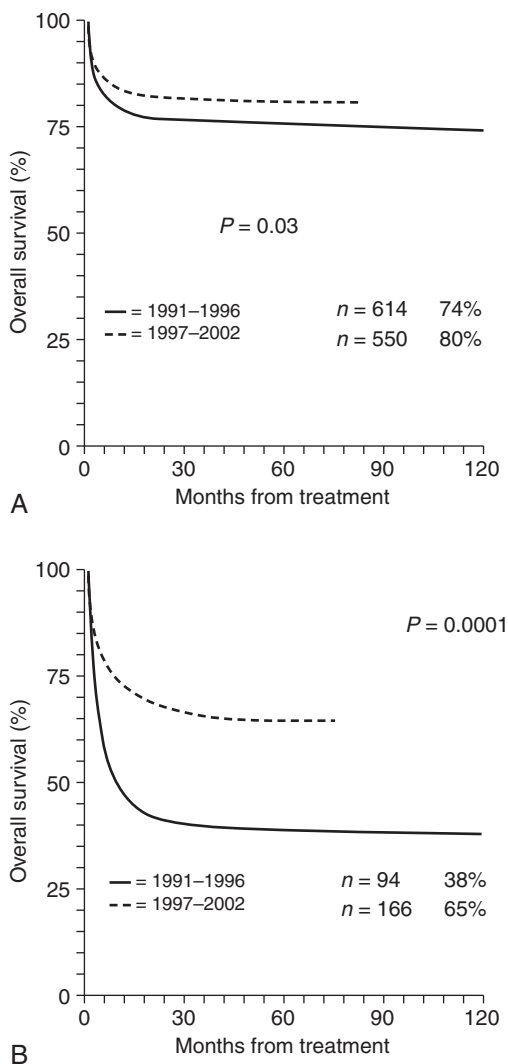

Figure 3 The actuarial survival of patients undergoing hematopoietic cell transplantation (HCT) from matched sibling donors (A) or alternative donors (B) by time periods. Results improved for both donor groups in the later time period (matched sibling donors 74% vs 80%, $P = .03$) and alternative donors (38% vs 65%, $P = .0001$). (Data from Locasciulli A, Oneto R, Bacigalupo A, et al. Outcome of patients with acquired aplastic anemia given first line bone marrow transplantation or immunosuppressive treatment in the last decade: A report from the European Group for Blood and Marrow Transplantation [EBMT]. *Haematologica* 2007;92:11-18.)

prophylaxis in this setting. In a group of adults and children undergoing MSD allogeneic HCT, this classic CY/ATG/CSA/MTX regimen produced a 96% rate of sustained engraftment, 3% rate of severe acute GVHD, 26% rate of chronic GVHD, and overall survival of 88% at median follow-up of 9 years. A recent study suggests that ATG may not be as essential to this outcome as previously thought. All stem cell sources, including sibling umbilical cord blood, have been used successfully, although use of peripheral blood stem cells appears to result in an unacceptably high rate of chronic GVHD and is not currently advised.

The dearth of alternative therapies for those who fail to respond to IST, coupled with the success of MSD HCT, have encouraged the use of alternative-donor HCT for aplastic anemia. Originally, patients coming to alternative-donor HCT were often late in their clinical course with significant aplastic anemia-associated morbidity and more aggressive regimens than those used for MSD engendered more regimen-related toxicity. Outcomes were somewhat disappointing. Results have improved significantly over the past decade, and even more so over the past 5 years (see Figure 3B). Moving HCT treatment earlier in therapeutic triage, coupled with

improvements in histocompatibility and supportive care, and the successful implementation of reduced-intensity regimens and alternative immunosuppressive strategies have produced encouraging results, with an overall survival in excess of 70% in some reports. However, the best results are seen when patients are younger, with worse outcomes in those older than 40 years.

Long-Term Complications of Treatment

All aplastic anemia treatments can be associated with significant morbidity, be it the iron-overload of long-term transfusion or the more protean problems of IST or HCT. These include, in both cases, significant regimen-related end-organ toxicity. The development of clonal cytogenetic abnormalities after IST is well described and occurs in patients of all ages, regardless of treatment response, and over a broad time frame. The rate of progression to frank AML is not predictable, although progression is most common in those with monosomy 7 or complex cytogenetic abnormalities. Patients with aplastic anemia who undergo HCT generally experience fewer toxicities than does the overall HCT population, in part due to the reduced intensity of aplastic anemia regimens. Growth and fertility may be well preserved, but persistent infectious complications, pulmonary insufficiency, dermatologic pathology, avascular necrosis, other bone and joint issues, hypothyroidism or other endocrine disturbances, and secondary malignancies can occur. Some of these conditions reflect the sequelae of chronic GVHD itself, and others reflect the toxicity of drugs used to manage GVHD. The toll of GVHD is real; decreased quality of life and overall survival are observed in the nearly one half of patients with aplastic anemia experiencing chronic GVHD.

Conclusions

Improvements in diagnosis, supportive care, IST, and HCT have led to significant improvements in survival for patients with severe aplastic anemia. However, there are still controversies over the optimal choice of therapy for individual patients, and any given choice can lead to a number of serious regimen-related toxicities. Further insights into the pathophysiology of bone marrow failure, increased diagnostic accuracy for IBMFS, greater appreciation of the risk and epidemiology of late complications, and steady progress in therapeutics will hopefully combine to yield increasingly well-targeted and more-successful treatment.

BLOOD COMPONENT THERAPY AND TRANSFUSION REACTIONS

Method of

Theresa Nester, MD

CURRENT DIAGNOSIS

- Fever greater than 1°C rise during or within 4 hours after transfusion should prompt evaluation of the patient and consideration of a transfusion reaction.
- Fever and pain are the most common manifestations of an acute hemolytic transfusion reaction.
- The point of the transfusion reaction laboratory investigation is to evaluate for hemolysis, either intravascular or extravascular. The majority of reactions are negative for hemolysis.
- The differential diagnosis of a transfusion reaction with respiratory symptoms includes febrile nonhemolytic and circulatory overload (common), allergic or anaphylactic reaction, transfusion-related acute lung injury, acute hemolytic reaction, and bacterial contamination (rare).

CURRENT THERAPY

- The decision to transfuse red blood cells to a patient should depend more on the clinical state of the patient than on an absolute trigger for hemoglobin or hematocrit.
- A transfusion trigger of less than 7 g/dL is recommended for hospitalized adult patients who are hemodynamically stable, including critically ill patients. A transfusion trigger of 8 g/dL is recommended for patients undergoing orthopedic or cardiac surgery, as well as those with preexisting cardiovascular disease.
- For severe autoimmune hemolytic anemia, maintenance of hemoglobin at greater than 4 g/dL in younger patients and greater than 6 g/dL in older patients or patients with cardiovascular disease is appropriate.
- Platelets are not typically indicated in thrombotic thrombocytopenic purpura, autoimmune thrombocytopenic purpura (ITP), and heparin-induced thrombocytopenia (HIT) unless the patient has significant bleeding.
- Currently available coagulation tests are not very useful for predicting bleeding in patients with end-stage liver disease. These patients establish a new equilibrium between coagulation, anticoagulation, and fibrinolysis that results in relatively less bleeding than predicted by the international normalized ratio.

- The goal during massive transfusion scenarios should be to prevent marked acidosis, hypothermia, and coagulopathy. The latter is often achieved with replacement of coagulation factors using plasma or cryoprecipitate within the first hour of the resuscitation.
- Cryoprecipitate is useful as a source of concentrated fibrinogen. In a patient who is actively bleeding and has a fibrinogen less than 100 mg/dL, cryoprecipitate is indicated.
- Fibrinogen concentrates are available for select patient populations.

Therapeutic Use of Blood Components

The community blood supply depends on two types of donors: whole blood donors and apheresis donors. Units of whole blood are centrifuged and then separated into components within a closed system. Using apheresis techniques, individual components of whole blood can be collected. Citrate is used to keep blood components from clotting.

The decision to transfuse blood to a patient should always include a consideration of the risks versus the benefits. Risks of transfusion-transmitted diseases are small with current testing standards. Transfusion reactions do occur; the most common ones are not life-threatening unless the patient cannot tolerate tachycardia or hypertension. Rarely, a patient experiences a life-threatening reaction. Thus it is important to ensure that the need for the blood component outweighs the risks. Additionally, in a bleeding patient, it is important to check coagulation parameters (platelet count, prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [aPTT], fibrinogen) in addition to hematocrit (Hct) to ensure that the component that will best address the bleeding is being used.

Red Blood Cells

Indications

Red blood cells should be given to increase oxygen-carrying capacity. The hemoglobin (Hb) and Hct levels alone should not be used to determine the need for transfusion; instead, the patient's clinical picture should drive the decision to transfuse. The patient's intravascular volume status, cardiopulmonary function, and baseline vital signs in the presence of anemia should all be considered. When anemia has persisted over weeks and months, transfusion is often not indicated because compensatory mechanisms have had time to work.

Transfusion Triggers

The most recent clinical practice guideline from AABB (formerly known as the American Association of Blood Banks) has the following recommendations: in hospitalized adult patients who are hemodynamically stable, including critically ill patients, a transfusion threshold of 7 g/dL is acceptable. In patients undergoing orthopedic or cardiac surgery, and those with preexisting cardiovascular disease, a transfusion threshold of 8 g/dL is recommended. The recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia, or chronic transfusion dependent anemia, because of insufficient evidence.

Dosage

One unit of packed red blood cells will increase the hemoglobin by 1 g/dL and hematocrit by 3% in the patient who is not bleeding or experiencing hemolysis (Table 1).

Autoimmune Hemolytic Anemia

Special Situation

When the autoantibody responsible for autoimmune hemolytic anemia reacts at body temperature, all red blood cell units can appear incompatible. This is because the antibody binds to an epitope common to all red blood cells, such as the band 3 protein. The clinician needs to decide when to transfuse the (apparently) incompatible units. In a patient who has never received a transfusion or been pregnant, there is little possibility of red blood cell alloantibodies in circulation, and the chance of hemolysis (beyond that being caused

Therapeutic Use of Blood Components

The community blood supply depends on two types of donors: whole blood donors and apheresis donors. Units of whole blood are centrifuged and then separated into components within a closed system. Using apheresis techniques, individual components of whole blood can be collected. Citrate is used to keep blood components from clotting.

The decision to transfuse blood to a patient should always include a consideration of the risks versus the benefits. Risks of transfusion-transmitted diseases are small with current testing standards. Transfusion reactions do occur; the most common ones are not life-threatening unless the patient cannot tolerate tachycardia or hypertension. Rarely, a patient experiences a life-threatening reaction. Thus it is important to ensure that the need for the blood component outweighs the risks. Additionally, in a bleeding patient, it is important to check coagulation parameters (platelet count, prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [aPTT], fibrinogen) in addition to hematocrit (Hct) to ensure that the component that will best address the bleeding is being used.

Red Blood Cells

Indications

Red blood cells should be given to increase oxygen-carrying capacity. The hemoglobin (Hb) and Hct levels alone should not be used to determine the need for transfusion; instead, the patient's clinical picture should drive the decision to transfuse. The patient's intravascular volume status, cardiopulmonary function, and baseline vital signs in the presence of anemia should all be considered. When anemia has persisted over weeks and months, transfusion is often not indicated because compensatory mechanisms have had time to work.

Transfusion Triggers

The most recent clinical practice guideline from AABB (formerly known as the American Association of Blood Banks) has the following recommendations: in hospitalized adult patients who are hemodynamically stable, including critically ill patients, a transfusion threshold of 7 g/dL is acceptable. In patients undergoing orthopedic or cardiac surgery, and those with preexisting cardiovascular disease, a transfusion threshold of 8 g/dL is recommended. The recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia, or chronic transfusion dependent anemia, because of insufficient evidence.

Dosage

One unit of packed red blood cells will increase the hemoglobin by 1 g/dL and hematocrit by 3% in the patient who is not bleeding or experiencing hemolysis (Table 1).

Autoimmune Hemolytic Anemia

Special Situation

When the autoantibody responsible for autoimmune hemolytic anemia reacts at body temperature, all red blood cell units can appear incompatible. This is because the antibody binds to an epitope common to all red blood cells, such as the band 3 protein. The clinician needs to decide when to transfuse the (apparently) incompatible units. In a patient who has never received a transfusion or been pregnant, there is little possibility of red blood cell alloantibodies in circulation, and the chance of hemolysis (beyond that being caused

TABLE 1 Component Therapy: Dosage and Expected Increment

COMPONENT	DOSE	EXPECTED INCREMENT	AVERAGE VOLUME
Red blood cells	1 unit	Hct 3%, Hb 1 g/dL	250 mL
Whole blood platelets	1 unit	Platelet count increased by 5000–10,000/ μ L	50 mL/unit (1 pool of 6 = 300 mL)
Apheresis platelet	1 unit	Platelet count increased by 20,000–60,000/ μ L	300 mL/unit
Plasma	10 mL/kg	Factor levels increased by 20%	300 mL/unit
Cryoprecipitate	1 unit	Fibrinogen increased by 5 mg/dL	15 mL/unit
Prepooled cryoprecipitate	1 6-unit pool	Fibrinogen increased by 45 mg/dL	120 mL/pool

Abbreviations: Hb = hemoglobin; Hct = hematocrit.

by the autoantibody) is low. For the patient who has received a transfusion or who has been pregnant in the past, the risk that a circulating red blood cell alloantibody is present and is being masked by the autoantibody is higher; special studies are available to reduce the risk of an alloantibody being overlooked. The transfusion trigger depends on whether the anemia is acute or chronic. For acute severe anemia, maintenance of hemoglobin at greater than 4 g/dL in younger patients and greater than 6 g/dL in older patients or patients with cardiovascular disease is appropriate.

Platelets

Platelets are required as part of normal clotting. The first stage of clot formation is development of a platelet plug over the site of endothelial injury.

Indications

The indications for platelet transfusion may be divided into prevention of bleeding and treatment of bleeding in the setting of thrombocytopenia or platelet dysfunction.

Transfusion Triggers

Prevention of Bleeding. In a stable patient with normal platelet function, transfusion is appropriate if the platelet count is less than 10,000/ μ L. One randomized, controlled trial has shown that transfusion at platelet counts of 5000/ μ L to 10,000/ μ L prevents bleeding in the stable patient. In a stable patient with other hemostatic abnormalities (e.g., on anticoagulation), transfusion is appropriate with a platelet count less than 50,000/ μ L.

Before a planned invasive procedure such as lumbar puncture, transfusion is appropriate with a platelet count of 50,000/ μ L. A patient undergoing major surgery should receive platelets if the count is less than 50,000 to 100,000/ μ L. The transfusion should take place as close to the procedure as possible so the platelets remain in circulation while the procedure is occurring.

Treatment of Bleeding. Platelets may be transfused with a major hemorrhage (e.g., gastrointestinal or genitourinary) and a platelet count less than 30,000 to 50,000/ μ L. For bleeding with major surgery or trauma, transfusion is appropriate for counts less than 80,000/ μ L. For bleeding into critical areas (e.g., central nervous system bleeding or diffuse alveolar hemorrhage), platelets may be given for counts less than 100,000/ μ L.

Dosage

Dosage is determined on the basis of the baseline platelet count, desired platelet count, and estimated blood volume. For a 70-kg patient, 3×10^{11} platelets (four to six units of pooled whole blood platelets or one unit of apheresis platelets) increases platelet count by approximately 30,000 to 50,000/ μ L in the absence of alloimmunization or excessive consumption. For prophylactic therapy, lower dosages have been shown to be as effective as higher dosages in the prevention of bleeding.

Out of ABO Group Platelet Transfusion

Because platelets can only be stored for a maximum of 7 days following collection, and the community platelet supply is collected from volunteer donors, a platelet product that is identical to the patient's ABO type might not be available (Table 2 and Box 1). Thus it may be necessary to infuse a small volume of incompatible plasma (suspending the platelets) to the patient. There is therefore a small risk of hemolysis of the patient's red blood cells if the isoagglutinin (anti-A or anti-B) titer in the donated plasma is high. Studies of healthy blood donors indicate that these antibody titers are typically low and do not precipitate hemolysis. Transfusion services often have policies that limit the amount of incompatible plasma a patient has received with platelet transfusion. Alternatively, some centers measure the antibody titer in the donated product and give high-titer products only to patients whose red blood cells lack the corresponding ABO antigen.

Unresponsiveness to Platelet Transfusion

A number of clinical factors can result in a patient's less-than-optimal response to platelet transfusion. In addition to consumption, some of these factors include splenomegaly, fever, and antifungal therapy. Patients who have been sensitized to foreign human leukocyte antigens through prior pregnancy or transfusion can also have a poor response to platelet transfusion. Transfusion medicine consultation regarding the evaluation of refractoriness to platelet transfusion may be indicated.

TABLE 2 ABO Compatibility*

PATIENT'S ABO	ANTIBODIES IN CIRCULATION	COMPATIBLE PACKED RED BLOOD CELLS	COMPATIBLE PLASMA
O	anti-A, anti-B	O	O, A, B, AB
A	anti-B	O or A	A or AB
B	anti-A	O or B	B or AB
AB	None	O, A, B, AB	AB

*For platelet compatibility, see text.

BOX 1 Rh(D) compatibility

Rh(D) negative patients should receive Rh negative red blood cells and platelet units.*†

Rh(D) positive patients can receive Rh positive or Rh negative red blood cells and platelet units.

Rh compatibility does not apply to acellular components (plasma and cryoprecipitate).

Only 15% of blood donors are Rh negative.

*In times of shortage, it becomes necessary to preserve the Rh(D) negative red blood cell inventory for females of childbearing potential (< 50 years old).

†Platelet components contain very few red blood cells; Rh(D) immune globulin (RhGAM) may be administered if prevention of anti-D formation is deemed appropriate. Consult with a transfusion medicine physician if further discussion is needed.

Special Situations

Uremia. Patients who are dialysis dependent might have an acquired platelet defect as a result of the uremic environment. Transfusion of platelets into this environment will render the transfused platelets dysfunctional. Thus if optimal platelet function is desired, dialysis should be performed frequently. Consider performing dialysis without heparin if the patient is actively bleeding.

Purpura and Thrombocytopenia. In patients with autoimmune thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP), or heparin-induced thrombocytopenia (HIT), platelet transfusion is not indicated unless the patient has significant bleeding. Other therapies, such as steroid administration for ITP and plasma exchange for TTP, should be initiated to address the condition.

Plasma

Plasma contains all of the coagulation proteins needed for clot formation, as well as all of the fibrinolytic proteins that prevent systemic thrombosis. There are currently several kinds of plasma, such as fresh frozen, FP24, thawed, and liquid. All contain hemostatic levels of coagulation factors as long as they are stored appropriately. The effect of plasma transfusion on the PT and INR is 4 to 6 hours, owing to the short half-life of coagulation factor VII. Thus other, longer-lasting means of restoring coagulation factors, such as vitamin K administration, should be undertaken.

When replacing coagulation factors with plasma, it is not necessary to have 100% factor replacement as the goal. Hemostasis is typically able to occur if circulating coagulation factor levels are between 40% and 50%. It is important to understand that the relationship between the INR and the percentage factor level is a logarithmic, rather than a linear, relationship (Figure 1). Thus whether the INR is 9 or 1.8, the initial dosage of plasma should be 10 to 20 mL/kg, with recheck of the laboratory values a few minutes after infusion. The more prolonged the INR, the more significant the impact of the dose on the INR.

Transfusion Triggers

For bleeding or imminent surgery that cannot be corrected in a timely manner by vitamin K administration, use plasma to correct an INR greater than 1.5 to 2.0. The exception is patients with end-stage liver disease (see later).

Dosage

At a dosage of 10 mL/kg, each unit has an average of 300 mL (3–5 units in a 70-kg adult). This dosage should increase circulating coagulation factors by 20% immediately after infusion.

Special Situations

Liver Disease. The INR is a less useful test in patients with end-stage liver disease. The destruction of liver tissue leads to decreased production of coagulation and fibrinolytic proteins such that a new

Figure 1 American Association of Blood Banks international normalized ratio (INR) compared with percentage factor levels. (Reprinted with permission from Nester T, AuBuchon J: Hemotherapy decisions and their outcomes. In Roback JD (ed): AAB Technical Manual, 17th ed. Bethesda, MD, American Association of Blood Banks, 2011, p 592.)

balance is established. Patients with end-stage liver disease have been shown to have normal levels of circulating thrombin and reduced levels of certain anticoagulant proteins (e.g., protein C), which could explain why they do not bleed as often as predicted with the elevation in INR. Thus the prophylactic use of plasma to correct a mildly prolonged laboratory value in the absence of bleeding is not indicated. It will lead to unnecessary plasma infusion, and the risk of volume overload and transfusion reactions outweighs the benefit in these patients.

Massive Transfusion. In trauma patients, patients with ruptured aortic aneurysms, and patients with other arterial bleeding, massive transfusion may be necessary. The basic principles of such a scenario include taking steps early into the resuscitation to prevent the patient from becoming too cold, acidotic, or coagulopathic to reverse the situation. Some plasma (and cryoprecipitate, if the fibrinogen is very low) should be infused early into the resuscitation to help prevent coagulopathy. Red blood cells and plasma should be infused through a blood warmer, if possible.

Isolated Prolonged aPTT. Other than a deficiency in coagulation factor XI, bear in mind that the differential of an isolated prolonged aPTT includes entities that do not typically require plasma (refer to Figure 2). Hemophilia A, hemophilia B, and von Willebrand disease are no longer treated by plasma but can require factor concentrates to prevent bleeding. Systemic administration of heparin must be reversed by protamine, if fast reversal is desired. Note that plasma transfusion will not reverse the effect of heparin. One of the most common causes of a prolonged aPTT is a lupus anticoagulant; this is an antibody directed against phospholipids that typically leads to thrombosis rather than hemorrhage.

Intracranial Hemorrhage or Life-Threatening Bleeding. Reversal of anticoagulation in the setting of intracranial hemorrhage or life-threatening bleeding depends on the anticoagulant. For patients taking warfarin (Coumadin), refer to Box 2.

Prothrombin complex concentrates (PCCs) may be used to replenish factors II, IX, and X rapidly. Two types of PCCs are available in the United States. A 4-factor PCC will replenish factors II, VII, IX, and X, and has been FDA approved for this indication. A 3-factor PCC lacks factor VII, thus a small dose of plasma will also be required. Inquire with a transfusion medicine physician or hematologist to determine whether such a protocol exists in your facility. For reversal of dabigatran (Pradaxa), a direct oral anticoagulant (DOAC), idarucizumab (Praxbind) is approved by the Food and Drug Administration (FDA) as a reversal agent. For other DOAC types, reversal may be significantly more difficult.

Cryoprecipitate

Cryoprecipitate contains fibrinogen, coagulation factors VIII and XIII, and von Willebrand factor. The most common current use

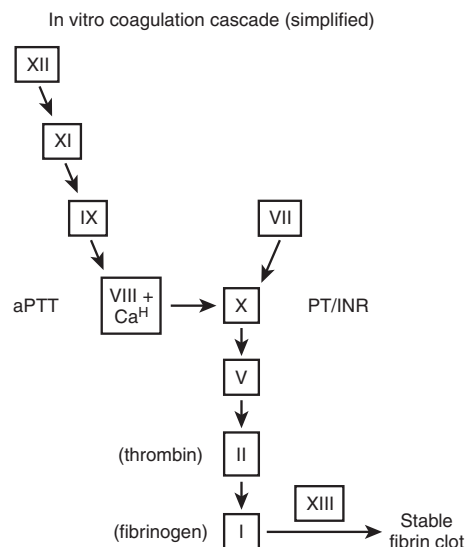

Figure 2 Coagulation cascade.

BOX 2**Guidelines for Correction of Excessive Warfarin Anticoagulation****INR Higher than Therapeutic but <5, No Significant Bleeding**

Lower anticoagulant dosage.
Temporarily discontinue drug, if necessary.

INR >5 but <9, No Significant Bleeding

Omit 1 or 2 doses, monitor INR, resume when INR is in therapeutic range.

Alternative if patient is at increased risk of hemorrhage:

- Omit 1 dose
- Give 1–2.5 mg vitamin K orally.

For rapid reversal before urgent surgery:

- Give 2–4 mg vitamin K orally.
- Give 1–2 mg at 24 hours if INR remains elevated.

INR >9, No Significant Bleeding

Omit warfarin; give 2.5–5.0 mg vitamin K orally.
Closely monitor INR; give additional vitamin K, if necessary.
Resume warfarin at lower dose when INR is within therapeutic range.

Serious Bleeding at Any Elevation of INR

Omit warfarin.
Give 10 mg vitamin K by slow IV infusion.
Supplement with plasma or prothrombin complex concentrate depending on urgency of correction.
Vitamin K infusions may be repeated every 12 hours.

Life-Threatening Hemorrhage

Omit warfarin.
Give prothrombin complex concentrate with 10 mg vitamin K by slow IV infusion.
Repeat as necessary, depending on INR.

Abbreviation: INR = international normalized ratio.

From Nester T, AuBuchon J: Hemotherapy decisions and their outcomes. In Roback JD (ed): AAB Technical Manual, 17th ed. Bethesda, MD, American Association of Blood Banks, 2011, p 571–616.

is as a source of concentrated fibrinogen. It may also be used to treat hemorrhage in the rare patient with factor XIII deficiency.

Indications

Clinical scenarios that increase probability for low fibrinogen include any clinical situation where disseminated intravascular coagulation (DIC) may be present. These include obstetric bleeding, trauma involving head injury or crush injury, and sepsis. Clinical events that can lead to an isolated decrease in serum fibrinogen concentration include administration of L-asparaginase (Elspar) and surgeries that disrupt bladder or salivary gland endothelium. Fibrinogen concentrates are available for patients who will not accept cryoprecipitate.

Transfusion Triggers

Transfusion is appropriate in patients with low serum fibrinogen, typically less than 100 mg/dL. In cases of massive transfusion, a trigger of 150 mg/dL is considered practical, so that the patient becomes less coagulopathic in the time that it takes to draw and review new laboratory values. New evidence indicates that a fibrinogen level of less than 300 mg/dL predicts severe postpartum hemorrhage, as a normal postpartum fibrinogen level is in the 600 mg/dL range. Because component therapy aims to replete coagulation factors to hemostatic (rather than completely normal) levels, consensus guidelines suggest maintaining a fibrinogen level greater than 200 mg/dL during a postpartum hemorrhage.

Dosage

Dosage depends on the type of cryoprecipitate available. If the product requires resuspension in saline before pooling, then one

TABLE 3**Transfusion Reactions**

MOST-COMMON REACTIONS	INCIDENCE
Allergic reaction of mild severity	1:33 to 1:100
Febrile nonhemolytic reaction	1:100 to 1:1000 with leukocyte reduction
Transfusion-related circulatory overload	< 1:100
MOST DANGEROUS REACTIONS	INCIDENCE
Acute hemolytic reaction	1:38,000 to 1:70,000
Anaphylactic reaction	1:20,000 to 1:50,000
Transfusion-related acute lung injury	1:1200 to 1:190,000
Bacterial contamination of red cell unit with gram-negative organisms	1:1,000,000

unit (average 15 mL volume) will increase fibrinogen by 5 mg/dL. If the product has been pooled in plasma before freezing, then one unit will increase fibrinogen by 7 to 8 mg/dL; a six-unit pool will increase fibrinogen by 45 mg/dL. Check with the transfusion service laboratory regarding which product is available and the expected increment.

Special Situation

DIC is a state where fibrinogen is consumed at a faster rate than other circulating coagulation factors. This is because DIC is typically a thrombin-generating process (thrombin cleaves fibrinogen into fibrin for clot formation). Thus, although all coagulation factors are being consumed in DIC, timely repletion of fibrinogen by use of cryoprecipitate can result in more-timely cessation of bleeding in a patient with active DIC. The target value is fibrinogen at least 100 mg/dL. If the PT and INR are still prolonged with fibrinogen greater than 100 mg/dL, administration of plasma will replete other coagulation factors being consumed.

Transfusion Reactions

Reactions to transfusion are relatively common; life-threatening reactions are rare (Tables 3 and 4).

Because fever is a feature of both common and dangerous reactions, a transfusion reaction evaluation should be initiated with fever greater than 1°C above patient's baseline temperature at the start of the transfusion. The infusion of product should cease, at least until the laboratory results are known and the patient has responded to treatment. The main point of the laboratory investigation is to evaluate the plasma for abnormal (usually red) color in an effort to detect intravascular hemolysis as quickly as possible. If the hemolysis, clerical, and direct antiglobulin test checks are negative, one might consider restarting the transfusion with careful surveillance of the patient. A direct antiglobulin test is also performed to detect the presence of antibody coating red blood cells in circulation; a positive result could indicate extravascular hemolysis, which is not as dangerous as intravascular hemolysis.

Most-Common Reactions**Febrile Nonhemolytic Reaction**

Presentation. A febrile nonhemolytic transfusion reaction manifests as fever greater than a 1°C rise above the patient's baseline, often accompanied by rigors. Hypertension, tachypnea, and transient decrease in oxygen saturation can also occur until the symptoms are treated. Evidence of hemolysis will be absent on laboratory evaluation. These reactions can manifest during or 2 to 3 hours after the transfusion.

Pathophysiology. Cytokines produced by white blood cells present in cellular blood components (red blood cell and platelet units) are responsible for the clinical presentation. Platelets also secrete cytokines; thus leukoreduction of platelet units might not be successful in preventing the reaction.

TABLE 4 Transfusion Reactions with Respiratory Symptoms

REACTION	CLASSIC SIGNS	RELATIVE FREQUENCY	ACUTE MANAGEMENT (TRANSFUSION STOPPED IN ALL CASES)
Febrile nonhemolytic reaction	Transient tachypnea in the presence of rigors and fever	Common	Antipyretic ± meperidine (Demerol) ¹
Circulatory overload	Hypoxia Crackles in lower lung fields Increased BP Chest radiograph consistent with volume overload	Common	Diuresis
Allergic reaction of moderate severity	Wheezes Possible perioral or periorbital edema Possible hives	Uncommon	IV antihistamines and possibly epinephrine (Adrenalin)
Allergic reaction of marked severity	Wheezes, swollen lips, tongue, uvula Stridor or other signs of airway compromise Very decreased BP	Rare	Epinephrine IV fluids and airway management Bronchodilators and glucagon (GlucaGen) ¹ for patient on β-blockers
Transfusion-related acute lung injury	Tachypnea and hypoxia during or within 6 of transfusion Persisting for several hours Chest radiograph consistent with bilateral white out	Rare	Respiratory support of noncardiogenic pulmonary edema
Acute hemolytic reaction	Red urine and red serum Hypotension and diffuse oozing may be present Tachypnea (10% of patients)	Rare	Supportive (possibly ICU) care Administration of crystalloid solution Blood component therapy if DIC is present
Bacterial contamination with Gram-negative organism	Very decreased BP Fever Nausea, vomiting Possible tachypnea	Rare	Intensive care for support of Gram-negative sepsis

Abbreviations: BP = blood pressure; DIC = disseminated intravascular coagulation; ICU = intensive care unit.

¹Not FDA approved for this indication.

Acute Management. Administration of an antipyretic is the routine treatment; meperidine (Demerol)¹ may be required to address severe rigors. Slow IV push of 25 mg as a first dose is recommended; an additional 25-mg dose can be given 10 to 15 minutes later if rigors persist.

Prevention with Future Transfusion. Antipyretic may be administered prior to transfusion. Ordering leukoreduced red blood cells and platelets (if the hospital inventory is not entirely composed of leukoreduced components) is also a preventive measure. For recurring reactions with platelets, volume reduction of the component can reduce the incidence.

Allergic Reaction of Mild Severity

Presentation. Urticaria or flushing occurs during a transfusion. Evidence of hemolysis is absent on laboratory evaluation.

Pathophysiology. Allergic reactions are immunoglobulin (Ig)E-mediated reactions against some allergen in the donor plasma. Because all blood components have some amount of plasma, it is possible to experience an allergic reaction with any blood product.

Acute Management. Slowing the infusion rate may be all that is required to alleviate the reaction. Antihistamine administration also addresses the symptoms.

Prevention with Future Transfusion. A reaction of this type may be a one-time event. For patients with recurrent reactions, transfusing the blood product more slowly (maximum of transfusion over 4 hours), or premedication with antihistamines will reduce the incidence.

Transfusion Associated Circulatory Overload (TACO)

Presentation. The patient has respiratory distress, typically during the transfusion, and increase in blood pressure unless cardiac decompensation occurs. Tachycardia, tachypnea, and decrease in

oxygen saturation are often present. Jugular venous distension may be seen. Radiographic findings include pleural effusions, perihilar edema, and increased vascular pedicle width.

Pathophysiology. The reaction results in cardiogenic pulmonary edema.

Acute Management. Diuretic should be administered. Supplemental oxygen may be required temporarily to improve oxygen saturation.

Prevention with Future Transfusion. Slowing the infusion rate with a maximum time of transfusion over 4 hours can prevent the reaction. Diuretic administration may be necessary in patients with poor heart function.

Most-Dangerous Reactions

Acute Hemolytic Transfusion Reaction (AHTR)

Presentation. The most common signs include fever with or without rigors and pain. The more commonly reported sites of pain include flank, back, chest, or abdomen. Nausea and vomiting and dyspnea can also occur. In more-severe presentations, hemodynamic instability is present, accompanied by oozing from line sites or petechial hemorrhage if DIC is occurring. Red or cola-colored urine is another manifestation of an acute hemolytic transfusion reaction and represents overwhelming of the kidneys' ability to recirculate free heme.

Pathophysiology. Red blood cells have proteins and carbohydrates on the cell surface that are antigenic. These epitopes are categorized into blood groups based on structure and sharing of a parent protein. A patient who lacks particular epitopes can develop antibodies through pregnancy or transfusion. Such red blood cell alloantibodies can then lyse transfused red blood cells that possess the cognate antigen. When time allows for pretransfusion testing, the antibodies are identified, and antigen-negative units are provided. The ABO blood group system is unusual in that almost all patients older than 4 months have naturally occurring antibodies to the

¹Not FDA approved for this indication.

A and B antigens that they did not inherit. These antibodies are capable of activating complement and causing intravascular lysis when bound to their cognate antigen. Thus it is of utmost importance to avoid transfusing red blood cells against the ABO antibody in circulation. Refer to the ABO compatibility table (see Table 1).

Acute Management. Management is largely supportive. The end result of intravascular hemolysis and activation of the complement cascade can be shock, uncontrolled bleeding secondary to DIC, and renal failure. Therefore prompt infusion of intravenous crystalloid solutions are indicated to maintain blood pressure and renal perfusion. The goal for urine flow rate should be more than 1 mL/kg per hour. Coagulation laboratory values should be obtained to determine whether DIC is present; if so, component therapy to reverse the DIC is indicated. If the reaction is severe, intensive care is appropriate, because cardiac monitoring and mechanical ventilation may be necessary to support the patient.

Prevention with Future Transfusion. An acute hemolytic reaction is one of the most feared complications of transfusion. It is also often one of the most preventable. Great care should be given to the pretransfusion blood sample draw, comparing the label to the patient's unique identifiers, and labeling the tube at the patient's bedside as soon as the blood is in the tube. Just before transfusion, the unit label attached to the blood product should be compared with the patient's armband to ensure that the product is intended for this particular patient. To prevent intravascular hemolysis from antibodies directed against non-ABO antigens, pretransfusion testing (antibody screen or crossmatch) should be done in advance of the need for red cell transfusion for any patient whose clinical situation indicates a likelihood of needing blood. The exception is a patient who is hemodynamically unstable because of acute red blood cell loss, where uncrossmatched red blood cells are indicated. If the patient's identity is known, a call to the hospital transfusion service in this situation is warranted; explain that the patient needs uncrossmatched red blood cells and ask if there are transfusion records that indicate a need for antigen-negative units.

Allergic Reaction of Marked Severity (Anaphylaxis)

Presentation. Significant drop in blood pressure occurs, typically early into the transfusion. Wheezes, difficulty breathing, and stridor may be present. Tongue or facial edema and hives may be observed.

Pathophysiology. Anaphylaxis is an IgE-mediated reaction against an allergen in the donor plasma. In a patient with absolute IgA deficiency, naturally occurring anti-IgA can precipitate this reaction on binding IgA in the plasma. Anti-haptoglobin antibodies can also induce a severe reaction.

Acute Management. Airway and blood pressure support should be provided with the patient recumbent and the lower extremities elevated. The treatment of choice is epinephrine (Adrenalin) 1 mg/mL, also labeled as 1:1000 or 0.1%, using an adult dosage of 0.3 to 0.5 mg per single dose, typically administered intramuscularly to the mid-quadriceps area. If symptoms persist, the dose may be repeated every 5 to 15 minutes for a maximum of three times, unless palpitations, tremors, or extreme anxiousness occurs. Supplemental oxygen should be administered and the airway maintained. Intravenous fluid administration is also recommended. Bronchodilators such as albuterol can be given as adjunctive treatment for bronchospasm that does not appear to respond to epinephrine. For patients on β -blockers, the addition of intravenous glucagon¹ (GlucaGen) 1 to 5 mg administered over 5 minutes, followed by infusion of 5 to 15 μ g/minute, may be required. The addition of glucocorticoids can help prevent the biphasic reaction that occurs in some patients.

Prevention with Future Transfusion. Slow administration with careful observation of any transfusion is required. Premedication with intravenous antihistamines is appropriate. Steroids may be administered, although their effectiveness has not been confirmed through controlled trials. Epinephrine should be available at the

bedside. For severe allergic reactions, a discussion with the transfusion service physician regarding washed components is appropriate.

Transfusion-Related Acute Lung Injury

Presentation. The signs of transfusion-related acute lung injury (TRALI) are difficulty breathing, tachypnea, and hypoxia during or within 6 hours of a transfusion of any blood component. Ideally, signs of underlying lung disease or circulatory overload are absent. Chest radiograph may show diffuse bilateral opacities (white-out). Diuretic administration does not result in improvement. The hypoxemia can progress to the point that the patient requires mechanical ventilation, and thus the patient should be closely monitored while the reaction is occurring.

Pathophysiology. The factors that result in TRALI are not entirely known. In a portion of cases, antibodies against white blood cell antigens are present in donor plasma. These antibodies are believed to bind the cognate antigens on the patient's white blood cells, leading to degranulation and a capillary leak syndrome involving the lungs. Other theories regarding the pathophysiology of TRALI exist. One such theory implicates biologically active substances such as lipids and cytokines in the stored blood products. These substances are believed to prime the patient's granulocytes and activate pulmonary endothelium, setting the stage for an additional trigger to cause acute lung injury. Regardless of the cause of TRALI, the end result is an increase in pulmonary vascular permeability and noncardiogenic pulmonary edema. The estimated mortality rate from TRALI is 5% to 8%.

Acute Management. Management consists of supportive care, with particular regard to respiratory support. With adequate supportive care, the process most often reverses over 48 to 96 hours.

Prevention with Future Transfusion. Marked respiratory compromise is occasionally due to white blood cell antibodies in the patient, which bind cognate antigens in the donated red blood cells or platelet unit ("reverse TRALI"). In these cases, leukoreduction of cellular blood products may reduce the severity of subsequent transfusions, although solid evidence to support this is lacking. For TRALI caused by white blood cell antibodies in the donated product, there are no preventive measures for the clinician to take. The majority of US blood suppliers provide plasma from only male donors, in an effort to reduce the incidence of TRALI caused by multiparous women with white blood cell antibodies.

Bacterial Contamination of a Blood Component

Presentation. The most-common presentation includes fever and rigors, nausea and vomiting, and possible onset of moderate hypotension during or after a platelet transfusion. Rarely, presentation includes signs of overt septic shock, including marked hypotension, typically early into the transfusion of a red blood cell or platelet component. Bacterial contamination of plasma or cryoprecipitate is extremely rare.

Pathophysiology. The most-common organisms to contaminate a platelet product are gram-positive organisms such as *Staphylococcus epidermidis*. These organisms are thought to be introduced into the collection bag via a skin plug that results from phlebotomy using a large-gauge needle when sterilization of the phlebotomy site has been ineffective.

The most common organisms to contaminate a red blood cell unit are gram-negative, endotoxin-producing organisms such as *Yersinia enterocolitica*. This organism is introduced into the blood product as a result of asymptomatic bacteremia in the donor, from sources such as the gastrointestinal tract. The donor-screening questionnaire and vital sign assessment at the time of donation help to make collection from such a donor a very rare event. Transfusion of a bacterially contaminated red blood cell unit is most often a fatal event. It is important to remember that platelets can also be contaminated by the same gram-negative, endotoxin-producing organisms; in this case, signs of septic shock may be manifest.

Acute Management. Blood cultures from the patient should be drawn, and then prompt intravenous antibiotic administration should begin. Supportive care including inotropic agents and close nursing attention may be required.

¹Not FDA approved for this indication.

Prevention with Future Transfusion. Bacterial contamination is associated with a donor product, and thus preventive measures for the patient do not apply. Blood suppliers perform bacterial detection tests on platelet components, and transfusion services have strict policies related to visual inspection of all blood products before they are issued to a patient-care area. However, these measures are not completely effective. The FDA recently approved pathogen inactivation technology for platelets, which may further lower the risk.

Other Reactions

Delayed Hemolytic Transfusion Reaction

Presentation. The main finding with a delayed hemolytic transfusion reaction is usually an unexplained decrease in hematocrit within 2 to 7 days after transfusion. The patient often remains symptom free unless the decline in hemoglobin is poorly tolerated. Jaundice can occur, and laboratory values consistent with hemolysis may be positive (elevated indirect bilirubin, elevated lactate dehydrogenase, decreased haptoglobin). Rarely, signs of intravascular hemolysis can occur.

Pathophysiology. The most common source of this reaction is a red blood cell alloantibody that the patient developed with prior transfusion or pregnancy; the antibody titer wanes over time such that pretransfusion testing does not detect the antibody. A unit of red blood cells positive for the cognate antigen is then transfused, and within a few days the patient's memory B cell response produces the antibody again. Transfused cells are then cleared, most often by an extravascular mechanism.

Acute Management. Most transfusion services have a policy to notify the clinician that a serologic delayed hemolytic transfusion reaction is present on testing a new plasma sample from the patient. If the patient's hematocrit has declined, it may be useful to determine a clinical correlation by obtaining the laboratory values just described. This is of particular importance when the distinction between hemolysis and bleeding will lead to different management strategies for the patient. Although extravascular clearance of hemoglobin is fairly well tolerated by the kidneys, the conservative approach is to increase renal perfusion with intravenous crystalloid solutions if possible.

Prevention with Future Transfusion. For a patient who routinely receives care through one hospital system, the transfusion service will keep a record of the red blood cell alloantibody and provide antigen-negative cells for transfusion. The prevention, then, is to plan ahead for transfusion when possible, so that fully compatible units can be provided. Uncrossmatched red blood cells may be positive for the cognate antigen.

Allergic Reaction of Moderate Severity

Presentation. The patient has labile blood pressure, either hyper- or hypotension, accompanied by at least one of the following: throat scratchiness, respiratory wheezes, or perioral or periorbital edema. Hives may be present. Gastrointestinal symptoms such as crampy abdominal pain may also be present.

Pathophysiology. This is an IgE-mediated reaction against an allergen in the plasma of the donated product.

Acute Management. Treatment is administration of intravenous antihistamines. If the respiratory component does not resolve, consider epinephrine administration and treat similarly to anaphylaxis (see previous section).

Prevention with Future Transfusion. Slower infusion of blood products can reduce further episodes of this type of reaction. If the patient is atopic, intravenous antihistamines may be administered as a premedication. If the patient requires chronic transfusion and experiences this type of reaction on a repeated basis, discussion with the transfusion service regarding washed components may be warranted.

Hypotensive Transfusion Reaction

Presentation. The patient has isolated hypotension (drop in systolic BP greater than 30 but less than 80 mm Hg) that responds quickly to cessation of the transfusion. The reaction classically occurs within the first 15 minutes of infusion of the blood product.

Pathophysiology. Pathophysiology is unclear. Some research indicates that the patient may have slower ability to metabolize bradykinin compared to other individuals.

Acute Management. Stop the transfusion.

Prevention with Future Transfusion. Prevention is unclear. In the author's experience, rate of infusion has a role. Slower infusion may help to prevent this type of reaction.

Transfusion Associated Dyspnea

Presentation. Mild respiratory distress that occurs within 24 hours of cessation of transfusion.

Pathophysiology. Pathophysiology is unclear.

Acute Management and Prevention with future transfusion. Management is supportive and prevention is unclear.

CHRONIC LEUKEMIAS

Method of

Katarzyna Jamieson, MD

CURRENT DIAGNOSIS

Chronic Myelogenous Leukemia

- Clinical symptoms
 - Constitutional symptoms
 - Splenomegaly (abdominal discomfort, early satiety)
- Laboratory parameters
 - Increased white blood cell count, commonly $>100,000/\mu\text{L}$, with differential counts showing granulocytes in all stages of differentiation, and two peaks involving neutrophils and myelocytes
 - Absolute basophilia
- Genetic parameters
 - Demonstration of *bcr-abl* by standard cytogenetic analysis, fluorescent in situ hybridization, or polymerase chain reaction

Chronic Lymphocytic Leukemia

- Clinical symptoms
 - B symptoms (fever, night sweats, and weight loss)
 - Lymphadenopathy and organomegaly
 - Recurrent infections
- Laboratory parameters
 - Increased white blood cell count with absolute lymphocytosis
 - Anemia, thrombocytopenia
- Immunophenotypic analysis (flow cytometry)
 - Demonstration of monoclonal population of light chain–restricted mature B lymphocytes expressing CD19, CD20 (dim), and CD23 and coexpressing pan-T cell antigen CD5

Prevention with Future Transfusion. Bacterial contamination is associated with a donor product, and thus preventive measures for the patient do not apply. Blood suppliers perform bacterial detection tests on platelet components, and transfusion services have strict policies related to visual inspection of all blood products before they are issued to a patient-care area. However, these measures are not completely effective. The FDA recently approved pathogen inactivation technology for platelets, which may further lower the risk.

CURRENT THERAPY

Chronic Myelogenous Leukemia: Chronic Phase

- Initial therapy
 - Imatinib mesylate (Gleevec) 400–600 mg daily
 - Dasatinib (Sprycel)
 - Nilotinib (Tasigna)
- Second-line therapy:
 - Imatinib mesylate 800 mg daily
 - Dasatinib (Sprycel)
 - Nilotinib (Tasigna)
 - Bosutinib (Bosulif)
 - Ponatinib (Iclusig)
 - Omacetaxine (Synribo)
- High risk for failure:
 - Allogeneic stem cell transplantation

Chronic Lymphocytic Leukemia

- Chemotherapy drugs
 - Fludarabine (Fludara)
 - Deoxycoformycin (Pentostatin [Nipent])
 - Cyclophosphamide (Cytoxan)
 - Chlorambucil (Leukeran)
 - Bendamustine (Treanda)
- Targeted therapy drugs
 - Idelalisib (Zydelig)
 - Ibrutinib (Imbruvica)
- Immunotherapy (monoclonal antibodies):
 - Rituximab (Rituxan)
 - Alemtuzumab (Campath)
 - Ofatumumab (Arzerra)
 - Obinutuzumab (Gazyva)

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is a chronic myeloproliferative disorder defined by the presence of a chimeric gene, *bcr-abl*, encoded by translocation between chromosomes 9 and 22, the Philadelphia chromosome. Discovered in 1960, the Philadelphia chromosome was the first chromosomal abnormality implicated in carcinogenesis. This was followed by decades of unraveling of leukemogenic process, which culminated in a development of the *bcr-abl* inhibitor imatinib mesylate (Gleevec). As a result, in 2001 CML became the first human neoplasm in which the rationally designed therapeutic agent to target a carcinogenic pathway demonstrated great clinical efficacy.

Epidemiology and Risk Factors

CML accounts for 7% to 15% of all cases of leukemia in adults. The median age at diagnosis is 45 to 55 years. The disease is extremely rare in children and the overall incidence increases with age. There is slight male predominance, with a male-to-female ratio of 1.4 to 1.0. There is no association with geographic distribution or race. The etiology of CML is unknown. High-dose radiation exposure is the only well-established environmental risk factor. No genetic predisposition is thought to play any role in pathogenesis of CML.

Pathogenesis

bcr-abl is created by a reciprocal translocation of genetic material between the long arm of chromosome 9 (containing the protooncogene *c-abl*) and the long arm of chromosome 22 (containing the *bcr* gene). This is the Philadelphia chromosome, and it is correctly annotated t(9;22)(q34.1;q11.21). The translocation results in constitutive upregulation of tyrosine kinase activity of *abl*, which triggers downstream transduction pathways of a signaling cascade of oncogenic events.

The natural course of CML is one of inevitable progression from an initial chronic phase to a more-aggressive accelerated phase and eventually to a rapidly fatal myeloid or lymphoid blast phase. It is thought that the transformation proceeds as a consequence of the accumulation of additional molecular changes in genetically unstable *bcr-abl*-containing cells. Supportive of this hypothesis, up to 80% of patients with advanced CML have secondary cytogenetic abnormalities.

Clinical and Laboratory Characteristics

CML is a clonal myeloproliferative disorder that develops through accumulation of maturing cells of myeloid, erythroid, and megakaryocytic origin. CML has a biphasic or triphasic clinical course. Patients usually present in the initial chronic phase, exhibiting a cluster of specific clinical and laboratory features (listed in the [Current Diagnosis](#) box). More than half of patients with CML diagnosed in the chronic phase are asymptomatic, and the diagnosis is established following the incidental discovery of elevated white blood cell (WBC) count on a routine screening test.

The median time to the development of terminal blast phase is 3 to 6 years. The disease typically progresses through slow evolution into an accelerated phase and then blast phase, but it can transform rapidly directly into the blast phase. The detection of a change in the pace of the disease may be difficult and therefore definitions of accelerated phase vary and are imprecise. The blast phase is defined by the presence of extramedullary disease or at least 30% blasts or blasts and promyelocytes in the bone marrow or peripheral blood. Leukemic cells in blast phase are characterized by arrested maturation, and they proliferate rapidly, similar to acute leukemia cells. The symptoms of blast phase are also those typically seen in acute leukemia.

Diagnosis

The diagnosis of CML can be usually made with reasonable certainty based on the results of peripheral blood cell counts and examination of the peripheral blood smear (see the [Current Diagnosis](#) box). The detection of the Philadelphia chromosome or *bcr-abl* by cytogenetic analysis, fluorescent in situ hybridization (FISH), or polymerase chain reaction (PCR) confirms the diagnosis: all patients positive for the Philadelphia chromosome by standard cytogenetic analysis will have a *bcr-abl* fusion gene detectable by FISH or PCR; however, in approximately 5% of patients with *bcr-abl* detectable by FISH or PCR, the Philadelphia chromosome could not be appreciated by standard cytogenetics. The bone marrow biopsy is usually not necessary for diagnosis but should be performed for staging purposes in all patients with newly diagnosed CML.

Differential Diagnosis

At presentation, the differential diagnosis of CML usually involves distinction from leukemoid reaction. Among hematologic malignancies, CML may be difficult to differentiate from other myeloproliferative disorders (essential thrombocythosis, polycythemia vera, and mutagenic myeloid metaplasia), chronic neutrophilic leukemia, chronic myelomonocytic leukemia, juvenile chronic myeloid leukemia, and eosinophilic leukemia. In most cases, the detection of *bcr-abl* is sufficient to make the distinction. However, the differentiation between CML presenting in lymphoid-blast phase and Philadelphia chromosome–positive acute lymphoblastic leukemia might not be possible.

Prognosis

Before the effective therapies became available, the expected median survival of patients with CML was 39 to 47 months, with less than 20% surviving longer than 8 years. Allogeneic stem cell transplantation (SCT) and interferon (IFN) α -2b (Intron-A)¹

¹Not FDA approved for this indication.

or INF alfa 2a (Roferon-A) in the 1990s improved median survival to 60 to 65 months. However, the availability of tyrosine kinase inhibitors (TKIs) in 2000s transformed CML into a chronic disease associated with near-normal life expectancy: The 8-year update of the IRIS trial (International Randomized Study of Interferon and STI-571) reported 85% overall survival and 93% survival in patients with only CML-related deaths. At this time, it is still unclear if TKIs are capable of curing CML; and continuation of therapy to maintain the remission is generally considered the standard of care. However, the increasing body of evidence suggests that as many as 30% of imatinib-treated patients who stopped the treatment after 2 years or more of undetectable minimal residual disease by conventional PCR may be able to sustain their remission off treatment. Patients who are suboptimal responders, who are poor responders, or whose disease is refractory to imatinib have poorer prognosis than patients who met expected response criteria (Table 1). The Sokal prognostic score, originally derived from 800 patients treated in the early 1960s and 1970s, still helps to identify patients who are at high risk for failure in the era of TKI.

Definitions of Response and Monitoring of Therapeutic Efficacy

The goal of CML therapy is the maximum possible reduction of leukemia burden. The status of the response is routinely evaluated by peripheral blood counts, cytogenetic analysis and FISH, and real-time quantitative PCR (RQ-PCR). The uniform criteria for hematologic, cytogenetic, and molecular responses have been developed to guide therapy and facilitate meaningful analysis of efficacy data across clinical trials (Tables 1 and 2). Close follow-up of response is critically important to predict when other therapies, such as alternative TKIs or transplantation, should be considered. Selective testing for bcr-abl kinase domain mutations is recommended for all patients who fail to respond to the first-line agent.

Treatment

Chronic Phase

Throughout most of the 20th century CML was considered incurable. The principal options for treating CML included busulfan (Myleran, Busulfex) or hydroxyurea (Hydrea). Such therapy, although successful in alleviating symptoms, did not alter the natural course of the disease. Introduction of allogeneic SCT in 1980s for the first time offered CML patients a prospect of cure. However, the high treatment-related morbidity and mortality associated with this procedure greatly limited its use to patients who were

young and fit and for whom an HLA-identical donor could be identified. The alternative was treatment with IFN alfa 2b (Intron-A)¹ or IFN alfa 2a (Roferon-A), which offered prolongation of survival but generally only to a minority of patients who could tolerate it.

First-Line Therapy. In 2001, imatinib mesylate (Gleevec), the first selective bcr-abl tyrosine kinase inhibitor, was introduced into clinical practice. The trial that established imatinib as the treatment of choice for newly diagnosed CML in the chronic phase was the International Randomized Study of Interferon Alpha Versus STI571 (IRIS). Between June 2000 and January 2001 IRIS accrued and randomized 1106 patients to imatinib 400 mg daily versus what was then the standard of care, interferon alfa plus subcutaneous cytarabine (Cytosar). After a median of 5 years, 382 of the 553 patients (69%) randomized to imatinib were still receiving it. The estimated progression-free survival was 83% and overall survival was 89%. The responding patients whose disease did not progress in any way in their first 3 years were unlikely to relapse and unlikely to suffer from late-onset side effects.

The recommended dose of imatinib for patients with CML in the chronic phase is 400 mg orally once daily. The drug is well tolerated by the majority of patients; the most common side effects are nausea, vomiting, edema (fluid retention), muscle cramps, skin rash, diarrhea, heartburn, and headache. Hematologic toxicity is quite common, particularly in patients with advanced CML, and the package insert contains exact guidelines for its management. Occasional severe hepatotoxicity has been reported.

Most patients with CML in the chronic phase today achieve and maintain excellent disease control with imatinib and seem to enjoy near-normal survival and quality of life. Given that continuation of TKI in a majority of patients seems necessary to maintain the remission, adherence to therapy is crucial and has recently become an avid focus of clinical investigations.

Since introduction of imatinib, three more second-generation TKIs have been developed and approved for treatment of CML: dasatinib (Sprycel), nilotinib (Tasigna) and bosutinib (Bosulif). All three have been studied extensively and demonstrated efficacy in the setting of imatinib failure. Dasatinib and nilotinib have subsequently been studied and received Food and Drug Administration (FDA) approval for use as first-line agents. Phase III studies comparing dasatinib (DASISION) or nilotinib (ENESTnd) to imatinib as initial therapy for CML in the chronic phase demonstrated

¹Not FDA approved for this indication.

faster and deeper responses; however, a longer follow-up will be required to determine if this is going to translate into clinically significant long-term benefits such as improved survival. At this time the choice of a front line TKI is often determined by the patient's tolerance of the drug, as each of the TKIs has some unique and non-overlapping toxicities. Bosutinib has not yet been approved in the first-line setting. A randomized study comparing bosutinib to imatinib (BELA) in newly diagnosed patients indicated comparable response rates but higher rate of gastrointestinal toxicity associated with bosutinib. Neutropenia, musculoskeletal events, and edema were less frequent.

A fourth-generation TKI, ponatinib (Iclusig), is the newest agent of this class granted accelerated FDA approval after demonstrating high levels of response rates on the PACE trial in heavily pretreated patients, including those carrying the T315I mutation. Soon after its approval ponatinib received a black box warning in highlighting the increased risk of serious vascular events and hepatic toxicity. More recently an increased risk of serious complications associated with the long-term use of the other second-generation TKI have also been reported, emphasizing the relative safety of the first drug in this class, namely imatinib.

The long-term follow-up of patients in the IRIS trial indicates that despite the favorable toxicity profile and efficacy, as many as 30% of patients will eventually fail imatinib therapy. Patients who are intolerant to first-line TKIs should be offered, and may be able to tolerate and respond to, other TKIs. Consensus recommends that patients who fail imatinib by progression or relapse should be screened for other medications that could affect metabolism and thus compromise the clinical efficacy of TKIs, for compliance and for *abl* mutations. More than 50 mutations in *bcr-abl* have been described, detection of which may help guide selection of second-line TKI therapy. Younger and otherwise fit patients should be evaluated for an allogeneic SCT.

Other Therapeutic Options. Patients who fail imatinib and/or second-generation TKI have particularly poor prognoses. Those who are not transplant candidates may be treated with omacetaxine (Synribo), which has recently been approved for patients resistant and/or intolerant to two or more tyrosine kinase inhibitors.

Advanced Phase

Imatinib mesylate is indicated for advanced CML in accelerated phase and blast phase. The recommended dosages are higher: 600 mg daily for CML accelerated phase and 800 mg daily for CML in the blast phase. Patients who satisfy criteria for acceleration are a heterogeneous group, because the disease biologically varies from slightly more advanced than late chronic phase to

verging on blast phase. Up to 80% of patients achieve a hematologic remission, and approximately 40% achieve a complete cytogenetic response, which is considered a prerequisite to long-term survival. All second- and third-generation TKIs are approved for treatment of advanced CML: dasatinib at 140 mg once daily (or 70 mg twice daily), nilotinib at 400 mg twice daily, bosutinib 500 to 600 mg once daily, and ponatinib 45 mg once daily. Patients who progress to the accelerated phase on the first-line TKI should be screened for *bcr-abl* mutations. In general the likelihood of response to a second-line TKI is 30% to 40%, and the identification of a mutation and selection of the second-line agent accordingly may improve those odds. Ponatinib is the only TKI with significant activity in CML associated with T315I mutation. Once the maximum response has been realized, patients who are suitable transplant candidates are offered an allogeneic stem cell transplantation.

Patients presenting in blast phase require a more-aggressive approach and are generally treated with a combination of TKI and chemotherapy or with a second-generation tyrosine kinase inhibitor with or without chemotherapy. Patients who achieve responses are immediately evaluated for an allogeneic SCT. The outcome of allogeneic SCT in advanced CML is much worse than in the chronic phase, but a minority of patients can definitely be cured.

Allogeneic Stem Cell Transplantation

The curative potential of allogeneic SCT is well established, and transplantation remains the widely accepted regimen for patients who failed imatinib. Historically, in the pre-imatinib era the allogeneic SCT has been reported to produce long-term survival between 50% and 60%—and even as high as 80% for larger, more experienced centers—in patients who underwent transplantation in the chronic phase.

Chronic Lymphocytic Leukemia

CLL has historically been considered an indolent disease of older patients. The general approach to treatment was conservative and the few therapies available were only marginally effective; since the 1990s, new treatments, namely purine analogues and monoclonal antibodies, started to change the face of this disease. Intensive research over the past several years provided greatly improved insight into the pathogenesis of CLL and led to the development of several targeted treatment approaches that will likely dramatically change the way we treat CLL. The availability of novel agents that are less toxic and more effective has rekindled hope that treatments with higher curative potential can be developed.

Epidemiology and Risk Factors

The median age at diagnosis is 70 years. The incidence is higher in men, and the male-to-female ratio is 1.7:1. It is the most common leukemia in the Western world; it is rare in Asian people and remains rare in people of Japanese origin who live in Hawaii, suggesting a genetic rather than environmental predisposition. An increased risk of developing the disease has been described in first-degree relatives of patients with CLL.

Pathogenesis

CLL develops by progressive accumulation of genetically altered mature lymphocytes in the blood, bone marrow, and lymphoid tissue. The CLL cell of origin is a B cell arrested in its pathway of differentiation, intermediate between a pre-B cell and mature B cell. One of the most important genetic parameters defining clinical behavior and prognosis is the mutation status of the variable segments of immunoglobulin heavy chain *VH* gene: CLL with unmutated *VH* shows an unfavorable course with rapid progression, whereas CLL with mutated *VH* typically shows slow progression and long survival.

FISH detects genetic aberrations in more than 80% of patients with CLL. The FISH CLL panel typically includes probes for 13q, 11q, 17p, and 6q deletions and for 12q duplication. The most common abnormality is deletion of 13q, which occurs in more than 50% of patients. Persons showing 13q14 abnormalities have a relatively benign disease that usually manifests as stable or slowly progressive isolated lymphocytosis. Trisomy 12 is associated with atypical morphology and progressive disease. Deletions of bands 11q22-q23 are associated with extensive lymph node involvement, aggressive disease, and shorter survival. Deletion of 17p results in loss of function of *p53* and is associated with a particularly poor prognosis.

Clinical Manifestations

The clinical features of CLL are variable and depend on the stage of the disease. Up to 30% of patients with CLL are asymptomatic, and the diagnosis is established following the incidental discovery of leukocytosis and/or absolute lymphocytosis on routine screening tests. The remaining patients present with lymphadenopathy, splenomegaly, or B symptoms (fever, night sweats, and weight loss), alone or in combination. Anemia and thrombocytopenia are considered late signs of the disease but can be present at the time of diagnosis. Due to their immunocompromised state, patients can present with recurrent or persistent infections.

Diagnosis

The diagnosis of CLL requires demonstration of absolute lymphocytosis of greater than 5000/mL and an immunophenotypic evidence of monoclonal population of mature B cells expressing CD19, CD20 (dim), and CD23 and coexpressing pan-T-cell antigen CD5. The malignant cells express low density of monoclonal surface immunoglobulin (IgM or IgD) with either κ or λ light chain. Patients are evaluated and grouped prognostically based on physical examination and complete blood count. The bone marrow biopsy and computed tomography scans are not required for diagnosis but may be indicated based on symptoms.

Differential Diagnosis

The immunophenotypic profile of CLL is quite characteristic, but at times it has to be differentiated from other low-grade lymphoproliferative disorders: hairy cell leukemia, prolymphocytic leukemia, (splenic) marginal zone lymphoma, and lymphoplasmacytic lymphoma. Most importantly, CLL needs to be differentiated from mantle cell lymphoma, which also coexpresses CD5 but is characteristically CD23 negative and cyclin D1 positive by immunohistochemical staining.

Prognosis

The natural history of CLL is extremely variable, with survival times ranging from 2 to 20 (or more) years. Clinical staging using the Rai or Binet system provides a good estimate of prognosis but is not very reliable in an individual patient; for example, among

patients presenting with early clinical stage disease, up to 30% never progress and eventually die of causes unrelated to CLL, and another 30% progress much more rapidly than expected. A number of additional prognostic factors are considered in estimating prognosis in an individual case: clinical characteristics such as age, sex, and performance status; laboratory parameters reflecting the tumor burden or disease activity such as lymphocyte count, lactate dehydrogenase (LDH), bone marrow infiltration pattern, or lymphocyte doubling time; serum markers such as soluble CD23 and β_2 -microglobulin; and genetic markers such as genetic aberrations (see earlier), the *VH* mutation status, or its surrogate markers (CD38, ZAP-70).

Treatment

Early alkylating drug-based treatment strategies in CLL offered control of symptoms but little impact on the natural course of the disease. The introduction of purine analogues in the 1980s represented definite progress but it was not until they were combined with monoclonal antibodies that deeper and more meaningful remissions were experienced. The analysis of historical series suggests that immunotherapeutic regimens offer a modest prolongation of survival. The BCR pathway kinase inhibitors approved in the past few years are certainly very promising in this regard. However at present, short of allogeneic stem cell transplant, CLL is still considered incurable. Asymptomatic patients with CLL are followed expectantly. The treatment is initiated upon progression of the disease or appearance of symptoms such as rapid lymphocyte doubling time, bulky lymphadenopathy or organomegaly, disease-related B symptoms, and autoimmune or nonautoimmune cytopenias. CLL is quite sensitive to many chemo- and immunotherapeutic agents. However, remissions are rarely durable. The disease follows a remitting and relapsing pattern, and most patients receive at least a few different regimens throughout the course of their disease.

First-Line Therapy

The first-line treatment usually consists of the purine analogue fludarabine (Fludara)-based chemotherapy in combination with the anti-CD20 monoclonal antibody rituximab (Rituxan). FR (fludarabine and rituximab) and FCR (fludarabine, cyclophosphamide [Cytosan], and rituximab) are the chemoimmunotherapy combinations used most commonly. The overall response rates for these regimens are, respectively, 90% and 95%. FCR offers a higher complete remission rate of 70% versus 47% for FR; however, FR offers a more acceptable toxicity profile. Median overall survival with each of these regimens seems comparable: approximately 5 years. FCR may be particularly effective in CLL associated with del(11q). However, in general the choice between the regimens is made based on the patient's characteristics and the goals of therapy. The treatment cycles are administered every 28 days for up to 6 cycles.

Other treatment options used in the newly diagnosed progressive disease setting include PCR (deoxycoformycin [Pentostatin (Nipent)],¹ cyclophosphamide, and rituximab); bendamustine (Treanda); the anti-CD25 antibody alemtuzumab (Campath); or chlorambucil (Leukeran). Deoxycoformycin is another purine analogue, and the PCR regimen offers an alternative to FCR. The fludarabine-based regimens are only marginally effective in high-risk disease defined by the presence of del(17p). Patients with del-(17p) either do not respond to initial treatment or relapse soon after achieving remission. Therefore, other therapies, including investigational therapies, are often offered in this setting. Alemtuzumab is the only FDA-approved agent that has demonstrated activity in cells lacking *p53* function, as seen in patients with deletion of chromosome 17p.

Bendamustine (Treanda) is an alkylating agent approved for treatment of CLL in March 2008. Based on the results of a randomized trial, like fludarabine, it offers a higher response rate and progression-free survival in comparison to single agent

¹Not FDA approved for this indication.

chlorambucil. The toxicity of bendamustine seems intermediate between that of fludarabine and chlorambucil. In the past few years the combination of bendamustine and rituximab (BR) has become an acceptable alternative for patients who are unable to tolerate fludarabine due to co-morbid conditions or due to age. Many older patients too frail to tolerate either fludarabine or bendamustine could still be treated with chlorambucil combined with a novel anti-CD20 antibody either obinutuzumab (Gazyva) or ofatumumab (Arzerra). Both antibodies have been approved for this indication based on greater improvement in response rates and progression-free survival demonstrated in randomized trials. The initial results of those trials also suggest a benefit in overall survival.

Other Therapeutic Options

Relapsed disease occurs in a patient who achieved at least a partial remission that lasted more than 6 months after completion of treatment. Many of those patients can be re-treated successfully with the same medications or can be switched to an alternative strategy. Specifically, it has been demonstrated that patients initially treated with fludarabine often achieve another durable response upon re-treatment. Whether patients treated with fludarabine-containing combination regimens or other newer therapies such as alemtuzumab or bendamustine will respond to re-treatment equally well is not yet known.

Patients who fail to achieve at least a partial remission or whose disease progresses within 6 months from completion of treatment have refractory disease, which is associated with a poor prognosis. Patients refractory to fludarabine historically had expected median survival of 48 weeks and only an 11% likelihood of responding to other therapies, which included alkylating drugs, other purine analogues, high-dose steroids, or monoclonal antibodies (rituximab, alemtuzumab, ofatumumab). The year 2014 was remarkable for FDA approval of two novel agents for treatment of relapsed/refractory CLL. Ibrutinib (Imbruvica) is an oral BTK inhibitor. A randomized trial in relapsed/refractory CLL confirmed a superior response rate and survival when compared with ofatumumab. The drug produces a rapid and sustained decrease in lymphadenopathy coupled by lymphocytosis. Idelalisib (Zydelig) is an oral inhibitor of PI3K kinase, which in combination with rituximab was shown to have a superior therapeutic activity over rituximab. A phase III randomized trial was stopped prematurely after it demonstrated improved response rate and improved survival over rituximab alone.

Both drugs can be taken by mouth and are well tolerated. Interestingly both drugs generally induce only partial remission, yet, they translate to prolongation of survival. Furthermore it appears that continuation of the drugs is necessary to maintain remissions.

At this time it is still unclear what role these new drugs will play in treatment of CLL.

Patients are encouraged to participate in clinical trials. Those who are potential transplant candidates are considered for an allogeneic stem cell transplant.

Allogeneic stem cell transplantation remains the only potentially curative treatment modality. Unfortunately, data on the use of allogeneic stem cell transplantation are limited to small case series. Allogeneic stem cell transplantation is associated with considerable treatment-related morbidity and mortality and is usually not considered until definitive evidence of poor prognosis.

Complications

Major complications of CLL include cytopenias and immune dysfunction. Anemia and thrombocytopenia can result from direct infiltration of the bone marrow and hypersplenism, in which case response to treatment usually results in improvement. Splenectomy obtained either surgically or via splenic irradiation is clinically useful in patients with splenomegaly and profound cytopenias unresponsive to chemotherapy. Autoimmune hemolytic anemia and thrombocytopenia seen in a significant percentage of patients often respond to steroids. Danazol,¹ high-dose intravenous

immunoglobulin (IVIg) (Gammagard),¹ cyclosporine (Neoral),¹ and rituximab¹ have all also been used in this setting.

Infections are the major cause of mortality in CLL. They result from hypogammaglobulinemia, impaired T-cell function, and neutropenia. Patients with repeat major bacterial infections are candidates for treatment with high-dose IVIg.¹ Patients treated with purine analogues and alemtuzumab are at high risk for opportunistic infections by herpes simplex virus and herpes zoster virus, *Listeria monocytogenes*, *Pneumocystis jiroveci*, and cytomegalovirus and should be offered prophylaxis with acyclovir (Zovirax),¹ trimethoprim-sulfamethoxazole (Bactrim), or aerosolized pentamidine (NebuPent) and antifungal agents. Patients receiving alemtuzumab should be monitored for cytomegalovirus reactivation or disease.

Patients with CLL have been reported to have a higher risk of developing other hematologic and solid malignancies. It is unknown how much of this increased risk is due to the underlying disease and accompanying chronic immunosuppression and how much is due to the treatments given. In 5% to 10% of patients with CLL, the disease transforms into an aggressive large-cell lymphoma (Richter's transformation) or polymorphocytic leukemia.

¹Not FDA approved for this indication.

DISSEMINATED INTRAVASCULAR COAGULATION

Method of

Jaime Morales-Arias, MD

CURRENT DIAGNOSIS

- Disseminated intravascular coagulation (DIC) occurs in the presence of a life-threatening underlying illness and is characterized by systemic pathologic activation of the coagulation system.

¹Not FDA approved for this indication.

- Symptoms may be secondary to either the underlying disease or to DIC, the most common manifestation being a bleeding diathesis.
- A combination of clinical and laboratory findings aid in making an accurate diagnosis.
- Depending on the underlying condition, laboratory abnormalities can vary. The most common laboratory findings are thrombocytopenia, elevated fibrin degradation products, elevated D-dimer assay, prolonged prothrombin time, prolonged activated partial thromboplastin time, low fibrinogen, and microangiopathic hemolytic anemia.
- A validated objective scoring system for the diagnosis of overt DIC based solely on laboratory data is available.

CURRENT THERAPY

- Prompt and efficacious treatment of the underlying condition is crucial.
- Aggressive supportive care measures are required.
- Platelet and factor replacement with fresh frozen plasma and cryoprecipitate may be indicated.
- Anticoagulation with heparin is used for selected cases.
- Activated protein C concentrates (drotrecogin alfa [Xigris]) are useful in disseminated intravascular coagulation secondary to severe sepsis.

Disseminated intravascular coagulation (DIC) is an acquired clinicopathologic syndrome that typically occurs as a consequence of a serious underlying condition. It is characterized by systemic activation of the coagulation system. This process initiates a cascade of events that includes the formation of fibrin clots and microthrombi with secondary end-organ ischemia and failure and concomitant consumption of coagulation factors and platelets that can result in hemorrhagic manifestations.

Epidemiology

DIC is a secondary thrombohemorrhagic phenomenon that occurs as a consequence of a multitude of disorders that pathologically activate and dysregulate the intravascular coagulation system. The most common causes are sepsis, cancer, and trauma. DIC is estimated to occur in approximately 1% of hospitalized patients, but it may be present in up to 30% to 50% of those with severe sepsis. DIC carries a high morbidity and mortality risk, usually depending on the severity of the underlying disease and the degree of the hematologic and thrombotic manifestations. Mortality rates have been reported to range from 31% to as high as 86% in some series. Advanced age is associated with a worse outcome.

Risk Factors

The main factor for the occurrence of DIC is the presence of a life-threatening underlying condition that abnormally activates the coagulation process. Severe sepsis (bacterial, viral, fungal) is the major cause. Additionally, serious trauma, especially head trauma, has a high correlation with DIC. Several pregnancy complications have also been implicated in the pathogenesis of DIC. [Box 1](#) summarizes the most common causes.

Pathophysiology

The most common initiating event in DIC is the exposure of blood to tissue factor, which can be secondary to vascular endothelial damage or to activation of tissue factor by circulating monocytes in response to inflammatory cytokines. As a result, this aberrant exposure to tissue factor produces increased amounts of thrombin. In DIC, thrombin generation becomes so excessive that it cannot be counterregulated by the natural antithrombotic pathways, such as tissue factor pathway inhibitor and antithrombin III. Because thrombin activates fibrin, these events create a widespread systemic

- Eclampsia

Protein C and S deficiencies (purpura fulminans)

Kasabach-Merritt syndrome

Severe hemolytic transfusion reactions

Toxin exposures (snake and spider bites)

Severe pancreatitis

deposition of fibrin, thus stimulating the formation of microthrombi and end-organ ischemia and damage.

Thrombin promotes the release of tissue plasminogen activator from damaged endothelium. This phenomenon causes a secondary activation of the fibrinolytic pathway, generating fibrin degradation products that in turn interfere with fibrin polymerization and have a deleterious effect on platelet aggregation.

There is generalized consumption of fibrinogen, platelets, and coagulation factors (II, V, VIII), thus promoting bleeding. Coagulation inhibitors such as protein C also get depleted, further impairing the capacity to control the thrombotic manifestations. DIC can also induce a secondary microangiopathic hemolytic anemia, mostly due to intravascular fibrin causing mechanical damage and fragmentation of red blood cells.

Clinical Manifestations

Symptoms may be secondary to either the underlying disease or to DIC. The most common manifestation is that of a bleeding diathesis. A patient might initially have excessive oozing from venipuncture sites or mucosal surfaces, but more severe hemorrhages can also occur. Both venous and arterial thrombosis are seen in DIC and can manifest with secondary organ damage. Other signs include renal, hepatic, and neurologic impairment. Pulmonary hemorrhage and acute respiratory distress syndrome have been reported in severe cases. [Table 1](#) summarizes the most common symptomatology in DIC.

Diagnosis

No single test is diagnostic for DIC, but rather a combination of clinical and laboratory findings can aid in making an accurate diagnosis. Depending on the underlying condition, laboratory

Shock	14
Thrombosis	7
Neurologic dysfunction	2

abnormalities can vary. However, the most common findings, in decreasing order of frequency, are thrombocytopenia, elevated fibrin degradation products or D-dimers, prolonged prothrombin time (PT), prolonged activated partial thromboplastin time (aPTT), and low fibrinogen. Thrombocytopenia occurs in 98% of patients with DIC, and the platelet count is less than 50,000 per microliter in 50% of them, making this an extremely sensitive, though non-specific, marker. The PT and aPTT are prolonged in 75% and 60% of patients, respectively, reflecting the degree of consumption of coagulation factors.

Low fibrinogen is another marker for DIC, but its sensitivity has been reported to be as low as 28%. This may be due in part to the fact that fibrinogen is an inflammatory marker and may be falsely elevated in some conditions that cause DIC. Fibrin degradation products and D-dimers are elevated owing to the increased activation of the fibrinolytic pathway. The D-dimer assay has been shown to be more specific for DIC than the measurement of fibrin degradation products. In addition, the thrombin time may be elevated secondary to the increase in fibrin degradation products as well as to the hypofibrinogenemia. Measurement of anticoagulant proteins such as antithrombin III and protein C can demonstrate decreased levels in DIC, but there are limitations owing to the lack of availability of these assays in most centers. In addition, a review of the blood smear can reveal fragmented red blood cells in cases where DIC has caused a microangiopathic hemolytic anemia.

An objective scoring system for the diagnosis of overt DIC based solely on laboratory data has been established by the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis (Box 2). It has been demonstrated to have a sensitivity of 91% and a specificity of 97% and to be an independent prognostic factor for mortality. Following the guidelines of the scoring system, patients with sepsis and DIC have been shown to have a mortality of 43%, as compared with only 27% for those without DIC.

Treatment

To control DIC, the precipitating disease needs to be treated vigorously and promptly. Additionally, aggressive supportive care measures, usually in an intensive care setting, are of utmost importance. In some cases this can indeed be enough. In other instances, a more specific treatment approach, such as replacing platelets or coagulation factor, may be necessary. This should not be based on laboratory parameters alone but rather on the clinical scenario and whether there is active bleeding, thrombosis, or organ dysfunction.

Platelet transfusions in nonbleeding patients are not usually indicated. They should be reserved for patients with a count of

<50,000/ μ L and active bleeding or those who are perceived to be at an increased risk for bleeding, for example, in a preoperative or postoperative setting. A higher platelet count may be desired in specific situations, such as neurotrauma. Platelet support may also be considered in nonbleeding patients if the count is significantly low (<20,000–30,000/mL).

The same rule applies to factor replacement with fresh frozen plasma. For patients without active bleeding, fresh frozen plasma is rarely indicated. However, in patients with a prolongation of the PT and aPTT and bleeding, or those perceived to be at an increased risk for bleeding or who are undergoing an invasive procedure, fresh frozen plasma should be considered. If the fibrinogen level is significantly low (<1 g/L), cryoprecipitate may be administered.

The use of anticoagulant therapy with heparin in patients with DIC has been controversial. Its use can potentiate the bleeding risks. However, heparin should be considered in cases where thrombosis predominates and is likely to lead to severe tissue injury. For example, heparin or other anticoagulant therapy should be given in the presence of dermal or acral ischemia that might rapidly progress to gangrene, as occurs in purpura fulminans and in some types of bacteremia. Indeed, anticoagulation has been demonstrated to reduce mortality from 90% to 18% in patients with purpura fulminans. Other instances in which heparin may be of benefit include DIC related to metastatic cancers, aortic aneurysms, retained dead fetus syndrome, and acute promyelocytic leukemias that are unresponsive to initial standard therapy. In addition, heparin therapy may be indicated in the presence of large vessel clots or in cases where intensive replacement of blood products alone has not been effective.

Replacement of anticoagulant factors, including administration of activated protein C (drotrecogin alfa [Xigris] and antithrombin concentrates (Thrombate III, ATryn),¹ is another strategy that has been evaluated. Clinical studies have shown a survival advantage for patients with severe sepsis and DIC using activated protein C, but there was a minor increased risk of bleeding (3.5% vs 2% in placebo), and caution should be exercised in this regard. After several clinical trials studying its potential efficacy in DIC, antithrombin administration has not been demonstrated to decrease mortality.

Antifibrinolytic therapy is usually contraindicated in DIC because of its risk of promoting thrombosis, but it may be considered in patients with severe bleeding whose primary process is a hyperfibrinolytic state. Agents include aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron).¹

Potential treatment agents undergoing trials include recombinant thrombomodulin, recombinant tissue factor pathway inhibitor, activated factor VII (Novoseven), and recombinant nematode anticoagulant protein c2.

¹Not FDA approved for this indication.

BOX 2

Scoring System for Overt Disseminated Intravascular Coagulation

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?
 - Yes: Proceed
 - No: Do not use this algorithm
2. Order global coagulation tests (platelet count, fibrin markers, PT, fibrinogen).
3. Score results.
 - Platelet count: >100 = 0, <100 = 1, <50 = 2
 - Elevated fibrin markers such as D-dimers or FDP: No increase = 0, moderate increase = 2, strong increase = 3
 - Prolonged PT: <3 sec = 0, >3 sec but <6 sec = 1, >6 sec = 2
 - Fibrinogen level: >1 g/L = 0, <1 g/L = 1
4. Calculate score:
 - ≥ 5 : compatible with overt DIC. Repeat score daily.
 - <5: Suggestive (not conclusive) for nonovert DIC. Repeat score in next 1 or 2 days.

Abbreviations: DIC = disseminated intravascular coagulation; FDP = fibrin degradation product; PT = prothrombin time.

HEMOCHROMATOSIS

Method of

Paul C. Adams, MD

CURRENT DIAGNOSIS

- Consider the diagnosis in patients with Northern European ancestry.
- Initial testing is transferrin saturation or unsaturated iron binding capacity and serum ferritin.
- Secondary testing is the C282Y genetic test.
- More than 90% of typical hemochromatosis patients are homozygotes for the C282Y mutation.
- If genetic testing is not typical, reassess the diagnosis and consider secondary iron overload related to cirrhosis, alcoholism, viral hepatitis, or an iron-loading anemia.
- A number of other hemochromatosis genetic mutations are relevant to only a minority of patients.
- Not all patients need a liver biopsy.
- Siblings are at highest risk in a family study.

CURRENT THERAPY

- Iron overload from hemochromatosis is treated by the weekly removal of 500 mL of blood until the serum ferritin is in the low-normal range of approximately 50 µg/L.
- Some but not all patients require maintenance therapy with three to four phlebotomies per year. In some countries, this can be a voluntary blood donation.
- Excess alcohol, high doses of vitamin C, and iron supplementation should be avoided, but strict dietary restrictions are not recommended.
- Siblings and children of patients should be tested for hemochromatosis with transferrin saturation, ferritin, and genetic testing.

Hemochromatosis is the most common genetic disease in populations of European ancestry. The diagnosis can be elusive because of the nonspecific nature of the symptoms. With the discovery of the hemochromatosis gene (*HFE*) in 1996 came new insights into the pathogenesis of the disease and new diagnostic strategies.

A fundamental issue that arose after the discovery of the *HFE* gene is whether the disease hemochromatosis should be defined strictly on phenotypic criteria such as the degree of iron overload (i.e., transferrin saturation, ferritin, liver biopsy, hepatic iron concentration, iron removed by venesection therapy), or whether the condition should be defined as a familial disease in Europeans most commonly associated with the C282Y mutation of the *HFE* gene and varying degrees of iron overload. Because the genetic test has been increasingly used as a diagnostic tool, most studies now use a combination of phenotypic and genotypic criteria for the diagnosis of hemochromatosis.

Clinical Features

Although hemochromatosis is often classified as a liver disease, it should be emphasized that it is a systemic genetic disease with multisystem involvement. The liver is central in both diagnosis and

prognosis. Hepatomegaly remains one of the more common physical signs in hemochromatosis, but it is not always present in the young, asymptomatic homozygote. In a study of 717 homozygotes from Australia, 8% of men and 1.7% of women had cirrhosis of the liver at the time of diagnosis. The prevalence of cirrhosis in asymptomatic or screened patients is much lower. It is likely that there are factors other than iron overload that contribute to cirrhosis in hemochromatosis. These can include the effects of alcohol or comodifying genes. The effect of iron depletion therapy is usually stabilization of the liver disease, and fibrosis improves with repeat liver biopsy after iron depletion. This accounts for the relatively small number of C282Y homozygotes that require liver transplantation. The other common clinical manifestations are arthralgias, pigmentation, congestive heart failure, impotence, and fatigue. Several large population studies failed to demonstrate an increase in diabetes compared with a control population. A population-based study estimated that only 28% of male and 1% of female C282Y homozygotes will develop symptoms of iron overload.

Diagnosis

A paradox of genetic hemochromatosis is that the disease is underdiagnosed in the general population and overdiagnosed in patients with secondary iron overload.

Preliminary population studies using genetic testing demonstrate a prevalence of homozygotes of approximately 1:227 among whites. The fact that many physicians consider hemochromatosis to be rare implies either a lack of penetrance of the gene (nonexpressing homozygote) or a large number of patients who remain undiagnosed in the community.

Diagnosis

Transferrin Saturation

Previous studies had suggested that transferrin saturation would be a good screening test and diagnostic test for hemochromatosis.

The sensitivity of transferrin saturation in population-screening studies designed to detect C282Y homozygotes (genotypic case definition) was only approximately 75%, and transferrin saturation can be in the normal range in young female homozygotes. A large biologic variation in transferrin saturation within an individual patient has also been reported.

Serum Ferritin

The relationship between serum ferritin and total body iron stores was clearly established by strong correlations with hepatic iron concentration and the amount of iron removed by venesection. However, ferritin can be elevated secondary to chronic inflammation and histiocytic neoplasms. A major diagnostic dilemma in the past was whether the serum ferritin concentration was related to hemochromatosis or to another underlying liver disease, such as alcoholic liver disease, chronic viral hepatitis, or nonalcoholic steatohepatitis. It is likely that most of these difficult cases can now be resolved by genetic testing.

Liver Biopsy

Liver biopsy was previously the gold-standard diagnostic test for hemochromatosis; however, it has shifted from a major diagnostic tool to a method of estimating prognosis and concomitant disease. The need for liver biopsy seems less clear now in the young, asymptomatic C282Y homozygote in whom there is a low clinical suspicion of cirrhosis based on history, physical examination, and liver biochemistry. A large study conducted in France and Canada suggested that C282Y homozygotes with a serum ferritin concentration of less than 1000 µg/L, a normal aspartate transaminase (AST) concentration, and no hepatomegaly have a very low risk of cirrhosis. C282Y homozygotes with a ferritin level greater than 1000 µg/L, an elevated AST, and a platelet count of less than 200,000/mm³ have an 80% chance of having cirrhosis. Hepatic elastography is another noninvasive tool to assess liver fibrosis in hemochromatosis.

Patients with cirrhosis have a 5.5-fold relative risk of death compared with noncirrhotic hemochromatosis patients. Cirrhotic

Hemochromatosis is the most common genetic disease in populations of European ancestry. The diagnosis can be elusive because of the nonspecific nature of the symptoms. With the discovery of the hemochromatosis gene (*HFE*) in 1996 came new insights into the pathogenesis of the disease and new diagnostic strategies.

A fundamental issue that arose after the discovery of the *HFE* gene is whether the disease hemochromatosis should be defined strictly on phenotypic criteria such as the degree of iron overload (i.e., transferrin saturation, ferritin, liver biopsy, hepatic iron concentration, iron removed by venesection therapy), or whether the condition should be defined as a familial disease in Europeans most commonly associated with the C282Y mutation of the *HFE* gene and varying degrees of iron overload. Because the genetic test has been increasingly used as a diagnostic tool, most studies now use a combination of phenotypic and genotypic criteria for the diagnosis of hemochromatosis.

Clinical Features

Although hemochromatosis is often classified as a liver disease, it should be emphasized that it is a systemic genetic disease with multisystem involvement. The liver is central in both diagnosis and

prognosis. Hepatomegaly remains one of the more common physical signs in hemochromatosis, but it is not always present in the young, asymptomatic homozygote. In a study of 717 homozygotes from Australia, 8% of men and 1.7% of women had cirrhosis of the liver at the time of diagnosis. The prevalence of cirrhosis in asymptomatic or screened patients is much lower. It is likely that there are factors other than iron overload that contribute to cirrhosis in hemochromatosis. These can include the effects of alcohol or comodifying genes. The effect of iron depletion therapy is usually stabilization of the liver disease, and fibrosis improves with repeat liver biopsy after iron depletion. This accounts for the relatively small number of C282Y homozygotes that require liver transplantation. The other common clinical manifestations are arthralgias, pigmentation, congestive heart failure, impotence, and fatigue. Several large population studies failed to demonstrate an increase in diabetes compared with a control population. A population-based study estimated that only 28% of male and 1% of female C282Y homozygotes will develop symptoms of iron overload.

Diagnosis

A paradox of genetic hemochromatosis is that the disease is underdiagnosed in the general population and overdiagnosed in patients with secondary iron overload.

Preliminary population studies using genetic testing demonstrate a prevalence of homozygotes of approximately 1:227 among whites. The fact that many physicians consider hemochromatosis to be rare implies either a lack of penetrance of the gene (nonexpressing homozygote) or a large number of patients who remain undiagnosed in the community.

Diagnosis

Transferrin Saturation

Previous studies had suggested that transferrin saturation would be a good screening test and diagnostic test for hemochromatosis.

The sensitivity of transferrin saturation in population-screening studies designed to detect C282Y homozygotes (genotypic case definition) was only approximately 75%, and transferrin saturation can be in the normal range in young female homozygotes. A large biologic variation in transferrin saturation within an individual patient has also been reported.

Serum Ferritin

The relationship between serum ferritin and total body iron stores was clearly established by strong correlations with hepatic iron concentration and the amount of iron removed by venesection. However, ferritin can be elevated secondary to chronic inflammation and histiocytic neoplasms. A major diagnostic dilemma in the past was whether the serum ferritin concentration was related to hemochromatosis or to another underlying liver disease, such as alcoholic liver disease, chronic viral hepatitis, or nonalcoholic steatohepatitis. It is likely that most of these difficult cases can now be resolved by genetic testing.

Liver Biopsy

Liver biopsy was previously the gold-standard diagnostic test for hemochromatosis; however, it has shifted from a major diagnostic tool to a method of estimating prognosis and concomitant disease. The need for liver biopsy seems less clear now in the young, asymptomatic C282Y homozygote in whom there is a low clinical suspicion of cirrhosis based on history, physical examination, and liver biochemistry. A large study conducted in France and Canada suggested that C282Y homozygotes with a serum ferritin concentration of less than 1000 µg/L, a normal aspartate transaminase (AST) concentration, and no hepatomegaly have a very low risk of cirrhosis. C282Y homozygotes with a ferritin level greater than 1000 µg/L, an elevated AST, and a platelet count of less than 200,000/mm³ have an 80% chance of having cirrhosis. Hepatic elastography is another noninvasive tool to assess liver fibrosis in hemochromatosis.

Patients with cirrhosis have a 5.5-fold relative risk of death compared with noncirrhotic hemochromatosis patients. Cirrhotic

patients are also at increased risk of hepatocellular carcinoma. Liver biopsy is considered in typical C282Y homozygotes with liver dysfunction and in potentially iron-overloaded patients without the typical C282Y mutation. Simple C282Y heterozygotes, compound heterozygotes (C282Y/H63D), H63D homozygotes, and patients with other risk factors (e.g., alcohol abuse, chronic viral hepatitis) who have moderate to severe iron overload (ferritin > 1000 µg/L) may be considered for liver biopsy.

Since the introduction of genetic testing, hepatic iron concentration and hepatic iron index have become less useful in the diagnosis of hemochromatosis.

Genetic Testing

A major advance stemming from the discovery of the hemochromatosis gene is the use of a diagnostic genetic test. Most studies report that more than 90% of typical hemochromatosis patients were homozygotes for the C282Y mutation. A second minor mutation, H63D, was also described in the original report. Compound heterozygotes (C282Y/H63D) and, less commonly, H63D homozygotes, resemble C282Y homozygotes with mild to moderate iron overload. Genetic mutations involving ferroportin, hemojuvelin, transferrin receptor 2, ceruloplasmin, and hepcidin are associated with iron overload. It is likely that, as more mutations are found, they will be relevant to only a minority of patients. Commercial tests are rarely available for these rare genetic mutations.

Some patients with clinical pictures indistinguishable from genetic hemochromatosis are negative for the C282Y mutation. Most of these cases appear to be isolated, although a few cases of familial iron overload with negative C282Y testing have been reported. A negative C282Y test should alert the physician to question the diagnosis of genetic hemochromatosis and to reconsider secondary iron overload related to cirrhosis, alcoholism, viral hepatitis, or an iron-loading anemia. If no other risk factors are found, the patient should begin phlebotomy treatment, similar to any other hemochromatosis patient.

The interpretation of the genetic test in several settings is shown in [Box 1](#). Genetic discrimination is a concern, given the widespread use of genetic testing, but discrimination has been rarely reported in screening studies. In the case of hemochromatosis, the advantages of early diagnosis of a treatable disease outweigh the disadvantages of genetic discrimination.

Family Studies

Once the proband case is identified and confirmed with the genetic test for the C282Y mutation, family testing is imperative. Siblings have approximately one in four chance of carrying the gene and should be screened with the genetic test (C282Y and H63D mutation), transferrin saturation, and serum ferritin. A cost-effective strategy now possible with genetic testing is to test the spouse for the C282Y mutation to assess the risk in the children. If the spouse is not a C282Y heterozygote or homozygote, the children will be obligate heterozygotes, assuming paternity and excluding another gene or mutation causing hemochromatosis. This strategy is particularly advantageous if the children are geographically separated or in different health care systems.

Treatment

The treatment of hemochromatosis continues to use the medieval therapy of periodic bleeding. Blood is removed, with the patient in the reclining position over 15 to 30 minutes. Initial treatment consists of the weekly removal of 500 mL of blood. A hemoglobin test is done before each phlebotomy. If the hemoglobin concentration has decreased to less than 10 g/dL, the phlebotomy schedule is modified to 500 mL every 2 weeks. Phlebotomies are continued until the serum ferritin concentration is approximately 50 µg/L. Serum ferritin levels are drawn monthly in patients with significant iron overload and increased to weekly as the ferritin decreases to < 200 µg/L. The concomitant administration of a salt-containing sport beverage (e.g., Gatorade) is a simple method of maintaining plasma volume during the phlebotomy.

Maintenance phlebotomies after iron depletion, consisting of three to four phlebotomies per year, are performed in most patients, although the rate of iron reaccumulation is highly variable. Maintenance therapy is initiated when the serum ferritin rises from 50 µg/L to > 300 µg/L. The transferrin saturation remains elevated in many treated patients and does not normalize unless the patient becomes iron deficient. In some countries, patients with mild iron abnormalities are encouraged to become voluntary blood donors.

Chelation therapy¹ is not recommended for hemochromatosis. Patients are advised to avoid oral iron therapy and alcohol abuse,

¹Not FDA approved for this indication.

BOX 1 Interpretation of Genetic Testing for Hemochromatosis

"C282Y Homozygote"

This is the classic genetic pattern seen in more than 90% of typical cases. Expression of disease ranges from no evidence of iron overload to massive iron overload with organ dysfunction. Siblings have a one in four chance of being affected and should have genetic testing. For children to be affected, the other parent must be at least a heterozygote. If iron studies are normal, false-positive genetic testing or a nonexpressing homozygotic state should be considered

"C282Y/H63D Compound Heterozygote"

This patient carries two copies of the minor mutation. Most patients with this genetic pattern have normal iron studies. A small percentage have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (e.g., alcoholism, viral hepatitis)

"C282Y Heterozygote"

This patient carries one copy of the major mutation. This pattern is seen in approximately 10% of the white population and is usually associated with normal iron studies. In rare cases, the results of iron studies are high, in the range expected in a homozygote rather than a heterozygote. These patients may carry an unknown hemochromatosis mutation, and liver biopsy is helpful to determine the need for phlebotomy therapy

"H63D Homozygote"

Most patients with this genotype will have normal iron studies. A small percentage have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (e.g., alcoholism, viral hepatitis)

"H63D Heterozygote"

This patient carries one copy of the minor mutation. This pattern is seen in approximately 20% of the white population and is usually associated with normal iron studies. This pattern is so common in the general population that the presence of iron overload can be related to another risk factor. Liver biopsy is required to determine the cause of the iron overload and the need for treatment in these cases

"No HFE Mutations"

If iron overload is present without any mutations in the hemochromatosis gene (*HFE*), a careful history for other risk factors must be reviewed, and liver biopsy can be useful to determine the cause of the iron overload and the need for treatment. Most of these are isolated, nonfamilial cases. There are cases described involving genetic mutations in ferroportin, hemojuvelin, transferrin receptor 2, ceruloplasmin, and hepcidin genes. Genetic tests for these mutations are not widely available

but there are no dietary restrictions. Patient support groups have been concerned by the practice of iron fortification of foods, but much of this iron is in an inexpensive form with poor bioavailability.

Hemochromatosis is a common and often underdiagnosed disease. Early diagnosis and treatment result in an excellent long-term prognosis. The development of a diagnostic genetic test has improved the feasibility of the goal of prevention of morbidity and mortality from hemochromatosis.

HEMOLYTIC ANEMIAS

Method of

Thomas G. DeLoughery, MD, MACP FAWM

CURRENT DIAGNOSES

- Suspect hemolysis when anemia is accompanied by signs of red cell breakdown—high low-density lipoprotein and indirect bilirubin with a low haptoglobin.
- The reticulocyte count is often high.
- A positive direct antibody test confirms the diagnosis of autoimmune hemolytic anemia in the presence of hemolysis.
- In patient with non-immune hemolysis, specific testing is required to make the diagnosis.

At the most basic level, hemolytic anemias are caused by red blood cell destruction. This destruction can be due to factors either intrinsic or extrinsic to the red blood cell. The pace of the hemolysis can vary from being only detectable by laboratory abnormalities to fulminant acute severe anemia. A useful way to think about hemolytic anemias is to divide them into hereditary disorders and acquired disorders (Table 1). Defects in any part of the red blood cell lead to inherited disorders, whereas acquired disorders are caused by immune-related processes and other etiologies extrinsic to the red blood cell.

Pathophysiology

Congenital

The major components of the red blood cell are the membrane, hemoglobin, and enzymes; therefore the three major classes of hereditary hemolytic anemias are due to defects in any of these three red blood cell components.

Hereditary spherocytosis is the most common hemolytic anemia caused by membrane defects. This condition is caused by mutations in the proteins that make up the red blood cell skeleton, which leads

to an unstable membrane. The red blood cells in hereditary spherocytosis initially have a normal biconcave disc structure, but after repeated passage through the spleen, they gradually lose portions of the membrane and become more spherical as they age (a process known as *splenic conditioning*). These spherocytes are less deformable and because of that are ultimately trapped and destroyed in the spleen. Less common anemias due to membrane defects are hereditary elliptocytosis and pyropoikilocytosis. In elliptocytosis the skeletal defects are not as profound, so the clinical presentation is usually milder. Most patients with pyropoikilocytosis are homozygous for mutations that cause elliptocytosis and have very unstable red blood cell membranes; often fragments of red blood cells are seen in the circulation.

The most common red blood cell enzyme defect is glucose-6-phosphate dehydrogenase (G6PD) deficiency. An adequate supply of reduced glutathione (GSH) is necessary to protect the erythrocyte from oxidative damage. G6PD catalyzes the conversion of glucose-6-phosphate to 6-phosphogluconate, in the process reducing NADP to NADPH. NADPH is necessary for the conversion of glutathione (GSSG) to reduced GSH. The erythrocyte does not have any other source of NADPH and so is dependent solely on this pathway for reducing power. When G6PD is deficient, this leads to decreased NADPH, which leads to decreased GSH. When the red blood cell undergoes oxidative stress, this lack of reducing power results in damage of red blood cell proteins, especially hemoglobin. These damaged proteins can aggregate, causing membrane damage and red blood cell destruction as the crystalized proteins are removed by the spleen.

Pyruvate kinase deficiency is a hemolytic anemia caused by an enzymatic defect in the glycolytic pathway. Pyruvate kinase catalyzes conversion of phosphoenolpyruvate to pyruvate, generating ATP in the same reaction. Deficiency of pyruvate kinase results in decreased levels of erythrocyte ATP. Lack of ATP results in a leaky cell membrane and loss of water and potassium. This leads to cellular dehydration and rigid, nondeformable cells, which are susceptible to destruction within the spleen.

By far the most common hereditary hemolytic hemoglobin defect is sickle cell anemia. The abnormal hemoglobin protein forms long polymers that disrupt red blood cell integrity. There are also very

but there are no dietary restrictions. Patient support groups have been concerned by the practice of iron fortification of foods, but much of this iron is in an inexpensive form with poor bioavailability.

Hemochromatosis is a common and often underdiagnosed disease. Early diagnosis and treatment result in an excellent long-term prognosis. The development of a diagnostic genetic test has improved the feasibility of the goal of prevention of morbidity and mortality from hemochromatosis.

to an unstable membrane. The red blood cells in hereditary spherocytosis initially have a normal biconcave disc structure, but after repeated passage through the spleen, they gradually lose portions of the membrane and become more spherical as they age (a process known as *splenic conditioning*). These spherocytes are less deformable and because of that are ultimately trapped and destroyed in the spleen. Less common anemias due to membrane defects are hereditary elliptocytosis and pyropoikilocytosis. In elliptocytosis the skeletal defects are not as profound, so the clinical presentation is usually milder. Most patients with pyropoikilocytosis are homozygous for mutations that cause elliptocytosis and have very unstable red blood cell membranes; often fragments of red blood cells are seen in the circulation.

The most common red blood cell enzyme defect is glucose-6-phosphate dehydrogenase (G6PD) deficiency. An adequate supply of reduced glutathione (GSH) is necessary to protect the erythrocyte from oxidative damage. G6PD catalyzes the conversion of glucose-6-phosphate to 6-phosphogluconate, in the process reducing NADP to NADPH. NADPH is necessary for the conversion of glutathione (GSSG) to reduced GSH. The erythrocyte does not have any other source of NADPH and so is dependent solely on this pathway for reducing power. When G6PD is deficient, this leads to decreased NADPH, which leads to decreased GSH. When the red blood cell undergoes oxidative stress, this lack of reducing power results in damage of red blood cell proteins, especially hemoglobin. These damaged proteins can aggregate, causing membrane damage and red blood cell destruction as the crystalized proteins are removed by the spleen.

Pyruvate kinase deficiency is a hemolytic anemia caused by an enzymatic defect in the glycolytic pathway. Pyruvate kinase catalyzes conversion of phosphoenolpyruvate to pyruvate, generating ATP in the same reaction. Deficiency of pyruvate kinase results in decreased levels of erythrocyte ATP. Lack of ATP results in a leaky cell membrane and loss of water and potassium. This leads to cellular dehydration and rigid, nondeformable cells, which are susceptible to destruction within the spleen.

By far the most common hereditary hemolytic hemoglobin defect is sickle cell anemia. The abnormal hemoglobin protein forms long polymers that disrupt red blood cell integrity. There are also very

rare defects in hemoglobin that can cause unstable molecules that can crystallize and lead to hemolysis—most often due to splenic removal of damaged proteins.

Acquired

Autoimmune hemolytic anemias (AIHA) can be mediated by either anti-red blood cell immunoglobulin G (IgG) or immunoglobulin M (IgM) antibodies. In IgG-mediated disease, the antibody binds to red blood cell membrane proteins. The antibody-coated red blood cells are then phagocytized by macrophages found primarily in the spleen, leading to hemolysis.

In IgM-mediated hemolysis (“cold agglutinin disease”), the antibody binds to the red blood cell most often in the periphery of the body. The “cold” appellation comes from the fact that the antibody binds more strongly when below body temperature. Most commonly, complement is fixed only through C3, and then the C3-coated red blood cells are taken up by the macrophages. In rare patients the IgM can fix complement rapidly, leading to intravascular hemolysis by formation of the end product of complement the membrane attack complex.

Rare patients can develop immune hemolysis induced by medication. There have been three mechanisms proposed for drug AIHA. The hapten mechanism is most often associated with the use of high-dose penicillin. High doses of penicillin lead to drug incorporation into the red blood cell membrane by binding to proteins. Another mechanism is the formation of an immune complex of drug, antibody, and red blood cell membrane, which leads to hemolysis. Finally, patients taking certain drugs such as methyl-dopa will develop a positive direct antibody (DAT) after 6 months of therapy and hemolysis, which is indistinguishable from warm antibody AIHA.

In paroxysmal nocturnal hemoglobinuria (PNH), red blood cells lack the regulatory membrane proteins that inhibit activated complement proteins. These proteins include membrane inhibitor of reactive lysis (CD59) and decay-accelerating factor (CD55). The molecular defect in PNH is a mutation of the phosphatidyl inositol glycan complementation group A gene located on the X-chromosome. This enzyme is required for synthesis of glycosyl phosphatidylinositol (GPI)-linked proteins. Cells derived from the PNH stem cells are deficient in all proteins that are linked to the membrane by a GPI-molecule, including those that inactivate complement. Normally there is baseline activation of complement; it is believed that one of the functions of red blood cells is inactivation of these active complement proteins. When activated complement binds PNH red blood cells instead of being destroyed, the resulting membrane attack complex leads to lysis of the red blood cell.

Microangiopathic hemolytic anemias (MAHA) result from destruction of circulating red cells. Although MAHA is commonly associated with thrombotic microangiopathies such as thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS), there are many other possible associated disease states. For example, patients with malignant hypertension can have very severe hemolysis due to increased shearing of red blood cells traversing damaged glomeruli. There may also be associated thrombocytopenia, which can lead to concern that TTP may be present. Hemolysis associated with malignant hypertension resolves rapidly with control of the blood pressure. Scleroderma renal crisis is often accompanied by a MAHA due to both severe hypertension and renal damage.

Cardiac valvular disease can lead to a MAHA. This is seen most commonly after mitral valve repair if there is a small defect at the site where the valve ring is sewn in. Ventricular contraction leads to a small resurgent jet, which results in a high-shear situation in the jet and red blood cell destruction. In some cases, this can result in severe hemolysis and a transfusion-dependent anemia.

Ventricular assist devices (VAD) to support heart failure patients can also lead to hemolysis. This is blood flowing through the device being subjected to high shear rates. Most patients have low levels of hemolysis, but with VAD thrombosis there is an abrupt increase in

hemolysis due to higher shear forces; a rising LDH is an indication to look for VAD thrombosis.

Along with MAHA, there are several other syndromes that may cause mechanical damage to the red blood cells. Clostridium infections can lead to hemolysis by direct damage to red blood cell membranes. The bacteria secrete an alpha-toxin that has phospholipase activity and leads to the red blood cell membrane literally dissolving—which causes the hemoglobin to leak out of the cells. In some cases this can be so severe that the measured hemoglobin may equal the hematocrit. Empty red blood cell “ghosts” may be seen on the smear.

Wilson’s disease may cause episodes of hemolysis along with the neurologic and hepatic disease. This is caused by large amounts of hepatic copper entering the circulation and inducing an oxidative hemolysis. The smear can show spherocytes and “bite cell.” The hemolysis is often transient because it is related to high levels of copper in the serum.

Spur cell anemia is a hemolytic process seen in patients with end-stage liver disease. The lipid metabolism alterations induced by severe liver disease lead to cholesterol crystal formation in the red cell membrane. These crystals are removed by the spleen and can lead to both hemolysis and deformed red cells—“spur cells.”

Prevention

There are a few supportive steps in patients with hemolysis. Although most food is supplemented with folate, high red cell turn over can increase the need for this vitamin. Patients with hemolysis are often supplemented with folic acid 1 mg daily.¹

A key preventive measure for those with G6PD deficiency is avoiding agents that can lead to oxidative stress of red cells. The most complete list of medications found at <https://www.g6pd.org/> and common medications are listed in Table 2. Some rarer red blood cell enzymatic or hemoglobin defects are also sensitive to oxidative stress, so these medications should be avoided in those disease also.

¹Not FDA approved for this indication.

Clinical Manifestations

Inherited

The severity of congenital hemolytic anemia varies tremendously. Some children are very symptomatic right after birth, whereas older patients may only present with mild anemia and subtle laboratory findings. A common presentation is a burst of hemolysis with oxidative or other stressors. Hereditary hemolytic anemias are often more severe right after birth, and severity may decrease with age. Patients with congenital anemia can present with extra-hematologic problems. Given that the serum bilirubin is increased and more bilirubin is excreted in the bile, they may present with pigmented gallstones. Patients can present with gallbladder disease in their teens or twenties, and this should raise the suspicion of hemolytic anemia. These patients may be more prone to skin ulcers around the ankle, which may not heal well.

Classically patients with congenital hemolytic anemias can develop three types of crises. The first is the “hemolytic crisis.” When patients develop fevers or encounter other stresses, the rate of hemolysis may increase, and any inflammation can suppress erythropoiesis, leading to severe anemia. The second type of crisis is the “megaloblastic crisis” where patients become folic acid deficient because of the high folate demand associated with increased red blood cell production. With mass supplementation of folate in the food supply, this incidence has fallen. The final crisis is the “aplastic crisis” where red blood cell production is temporarily compromised and the reticulocyte count plummets. This is most commonly found with infections with parvovirus B-19. The infection clears in most patients within 1 week, but patients often require transfusion support during this time.

Hereditary spherocytosis is most prevalent in northern European populations and occurs with a frequency of approximately 1 in 5000. Most cases (75%) show an autosomal dominant pattern of inheritance. The remainder is due to autosomal recessive inheritance and new mutations. Common clinical features of hereditary spherocytosis include anemia, jaundice, reticulocytosis, splenomegaly, and microspherocytes. Anemia later in life is variable and usually mild. Complications include hemolytic crises, leg ulcers, and gallstones.

With hereditary elliptocytosis, most patients are symptom free, and the frequent finding of elliptocytes on the blood smear is of no clinical consequence. However, approximately 10% to 15% of patients have significant hemolysis and may develop anemia. Mild hereditary elliptocytosis is inherited in an autosomal dominant fashion. The incidence is higher in African and Asian populations because of its beneficial impact on malarial infection. Patients with pyropoikilocytosis have severe hemolysis.

G6PD deficiency is the most common enzyme defect in humans and affects an estimated 600 million people worldwide. G6PD deficiency is transmitted as an X-linked recessive condition. Hundreds of G6PD variants have been identified. Enzymatic activity varies from normal with no clinical consequences to severe deficiency resulting in chronic hemolysis and shortened red blood cell life span, even in the absence of stressors. The two most common variants are the G6PD A variant, which has moderate enzyme deficiency (10%-15% activity), and the G6PD Mediterranean mutation, which has almost no detectable enzyme activity. Despite this, patients with G6PD Mediterranean have a nearly normal erythrocyte life span except under conditions of metabolic or oxidative stress.

The classic presentation of hemolysis with G6PD deficiency is with oxidant stress. For example, certain medications such as sulfonamides can lead to increased oxidative stress. Patients with G6PD deficiency cannot generate enough reducing power to overcome this stress, which leads to oxidative damage to proteins, especially hemoglobin. The patient presents with fulminant hemolysis that can lead to a severe anemia. Because of membrane damage, the blood smear can show spherocytes and “bite cells”—red blood cells with defects caused by splenic conditioning. Treatment is removing the offending agent and is otherwise supportive. A unique presentation is “favism.” After patient eats fava beans, an overwhelming hemolysis develops. This can be idiosyncratic

and occur even in patients who have safely eaten the beans in the past.

Pyruvate kinase deficiency is inherited as an autosomal recessive condition. Anemia is variable and may range from a presentation in early infancy requiring transfusions to fully compensated hemolysis presenting with jaundice alone. Many patients have moderate anemia, jaundice, and splenomegaly. Patients with this disorder are also susceptible to the crises identified above. Splenectomy may be helpful in severe cases, but response is variable.

Acquired

AIHA patients who have IgG as the offending antibody are said to have warm antibody AIHA. The name warm comes from the fact that the antibody reacts best at body temperature. The incidence varies by series but is about 1 in 100,000 patients per year, and women are affected more often than men.

Warm AIHA can complicate several diseases. Lupus patients can develop warm AIHA as part of their disease complex. Of malignancies, that with the strongest association with AIHA is chronic lymphocytic leukemia (CLL). Series show that 5% to 10% of patients with CLL will have warm AIHA. The disease can appear concurrently with CLL or may develop during the course of the disease.

A rare but important variant of warm AIHA is Evan's syndrome. This is the combination of AIHA and immune thrombocytopenia. One to three percent of AIHA is the Evan's variant. The immune thrombocytopenia can precede, occur concurrently, or develop after the AIHA. The diagnosis of Evan's syndrome should raise the concern of underlying disorders. In pediatric and young adult patients, immunodeficiencies such as autoimmune lymphoproliferative disease needs to be considered. In older patients, Evan's syndrome is often associated with T-cell lymphomas.

In rare patients with warm AIHA, IgA or IgM antibodies are implicated. Patients with IgM AIHA often have a severe course with a fatal outcome. Patients' plasma may show spontaneous hemolysis and agglutination. The DAT may not be strongly positive or show C3 reactivity. The clinical clues are C3 reactivity with no cold agglutinins and severe hemolysis, sometimes with intravascular hemolysis.

In cold agglutinin disease, in addition to hemolysis, patients often note symptoms related to agglutination of red blood cells in the peripheral circulation. For example, acrocyanosis will be noted in cold weather. Rare patients will have abdominal pain when eating cold food due to ischemia related to agglutination of red blood cells in the viscera. Some patients with cold agglutinins can have an exacerbation of their hemolysis with cold exposure.

In young patients, cold AIHA is often post-infectious (such as from viral and mycoplasma infections), and the course is self-limited. The hemolysis usually starts 2 to 3 weeks after the illness and will last for 4 to 6 weeks. In older patients, the etiology in more than 90% of cases is a B-cell lymphoproliferative disorder, usually with monoclonal kappa B-cells. The most commonly seen are marginal zone lymphoma, small lymphocytic lymphoma, and lymphoplasmacytic lymphoma.

A unique cold AIHA is paroxysmal cold hemoglobinuria (PCH). This AIHA is most often post-viral affecting children; in the past it complicated any stage of syphilis. The antibody is IgG directed against the P antigen on the RBC. Binding is best in the “cold,” but then complement is activated at body temperature. Because this antibody can fix complement, hemolysis can be rapid and severe, leading to extreme anemia.

Drug-induced AIHA is a rare drug reaction with a lower incidence than drug-related immune thrombocytopenia. The rate of severe drug-related AIHA is estimated at 1 in 1 million, but less severe cases may be missed. Most patients will have positive DAT without signs of hemolysis, although rare patients will have relentless hemolysis resulting in death. With hapten-related AIHA, very few patients will have hemolysis, and in those cases the hemolysis will resolve a few days after discontinuation of the offending drug. With immune complex disease, most often the patient will only have a positive DAT, but rare patients on

exposure or reexposure will have life-threatening hemolysis. The onset of this hemolysis is rapid, with signs of acute illness and intravascular hemolysis. The classic associated drug is quinine, but many other drugs have been implicated.

A virulent form of immune complex hemolysis is associated with both disseminated intravascular coagulation and brisk hemolysis. Patients who receive certain second- and third-generation cephalosporins (especially cefotetan [Cefotan] and ceftriaxone [Rocephin]) have developed this syndrome. The clinical symptoms start 7 to 10 days after receiving the drug—often the patient has only received the antibiotic for surgical prophylaxis. Warm DAT hemolysis with an acute hematocrit drop, hypotension, and disseminated intravascular coagulation develop. The patients are often believed to have sepsis and are then often reexposed to the cephalosporin, resulting in worsening of the clinical status. The outcome is often fatal because of massive hemolysis and thrombosis.

Hemolysis caused by methyldopa is indistinguishable from warm AIHA, which is consistent with the notion that methyldopa induces an autoimmune hemolytic anemia. The hemolysis often resolves rapidly after stopping the methyldopa, although the Coombs test result may remain positive for months. This type of drug-induced hemolytic anemia has been reported with levodopa, procainamide (Pronestyl), and chlorpromazine (Thorazine).

In MAHA, the course of the presentation is dictated by the underlying cause. In valvular hemolysis, the onset of hemolysis is soon after the cardiac procedure and may require transfusion support. With VAD hemolysis, most patients have only mild hemolysis, but with pump thrombosis, the hemolysis can be severe. Patients with spur cell anemia have findings of severe liver disease—high INRs and bilirubin (mean of 9.5 mg/dL). Spur cell hemolysis is associated with an ominous prognosis and average survival of a few months.

PNH is characterized by episodes of hemolysis and a propensity for thrombosis and pancytopenia. Often patients can have PNH for years before the diagnosis is made. The hemolysis can range from being well compensated to transfusion dependence. Patients with PNH often have severe thrombophilia; the leading cause of morbidity and death (before the release of effective therapy) has been thrombosis. The cause of the hypercoagulable state is unknown, but complement-activated platelets have been implicated.

Diagnosis

There are two steps in the diagnosis of hemolytic anemia—first determining the presence of hemolysis, and then finding the cause. Hemolysis is demonstrated by evidence of both red blood cell breakdown as well as the compensatory increase in red blood cell production this stimulates. When red blood cells undergo hemolysis, their contents, mostly hemoglobin and the enzyme LDH, are released. Hemoglobin is by haptoglobin, and the heme moiety is broken down, first to bilirubin and then to urobilinogen, which is excreted in the urine.

The following tests are performed to investigate hemolysis:

LDH: Lactate dehydrogenase is an enzyme found in high concentration in the red blood cell; hemolysis releases this enzyme into the plasma. Most patients with hemolysis will have an elevated LDH level, making this a sensitive test. However, many other processes, including liver disease, pneumonia, and more, will also increase the serum LDH.

Serum bilirubin: Heme is broken down to produce bilirubin. Initially unconjugated, the bilirubin is delivered to the liver where it is conjugated and excreted into the bile. In hemolysis the unconjugated (“indirect bilirubin”) is increased as opposed to liver disease, where the conjugated (“direct bilirubin”) is increased. If a patient has coexisting liver disease with an elevated direct bilirubin, this test is not reliable.

Serum haptoglobin: Haptoglobin binds free serum hemoglobin and is taken up by the liver. Haptoglobin usually falls to very low levels in hemolysis. It’s important to remember that haptoglobin is also an acute-phase reactant that can rise with systemic

disease or inflammation. However, patients with advanced liver disease will have low haptoglobin due to a lack of synthesis, and up to 2% of the population may congenitally lack haptoglobin.

Hemoglobinemia: If the hemolysis is very rapid, the amount of free hemoglobin that is released will overwhelm haptoglobin and lead to the presence of free hemoglobin in the plasma. This can be crudely quantified by examining the plasma. Even minute amounts of free hemoglobin will turn the plasma pink. In fulminant hemolysis, the serum will be cola colored.

Urine hemosiderin: When hemoglobin is excreted by the kidney, the iron is deposited in the tubules. When the tubule cells are sloughed off, they will appear in the urine. The urine can be stained for iron, and, if positive, this is another sign of hemolysis. This is a later sign because it takes a week for enough iron-laden tubule cells to be excreted in detectable quantities.

Mean corpuscular volume (MCV): The MCV may be larger in hemolysis for several reasons. The size of reticulocytes is larger than normal red blood cells, so a brisk reticulocytosis will have a higher MCV. In cold agglutinin disease, the aggregation of red blood cells will falsely increase the MCV. Finally, hemolysis can lead to folate deficiency and a rise in MCV.

Reticulocyte count: With hemolysis the breakdown of red blood cells is accompanied by an increase in the reticulocyte count as marrow tries to compensate. The reticulocyte percentage needs to be adjusted for the hematocrit—a correct value of above 1.5% is considered raised. Recently, automated complete blood count machines have taken advantage of the fact that reticulocytes will absorb certain stains, and these machines can directly measure the reticulocyte count via flow cytometry.

This results in an “absolute” reticulocyte count. This does not have to be corrected for hematocrit, and levels about 90,000/ μ L are considered elevated. However, the reticulocyte count can also be increased in blood loss or in patients who have other causes of anemia (such as treated iron deficiency). In addition, as many of 25% of patients with AIHA will never have elevated reticulocyte counts for reasons such as nutritional deficiency, autoimmune destruction of red blood cell precursors, or lack of erythropoietin.

The blood smear provides vital information (Table 3). The finding of abnormal red blood cell shapes can be a clue to autoimmune hemolysis or red blood cell membrane defects. For example, spherocytes are seen in autoimmune hemolytic anemia, hereditary spherocytosis, Wilson’s disease, clostridial sepsis, and severe burns. Schistocytes are a sign of microangiopathic hemolytic anemia and should prompt concerns for such disease processes as thrombotic thrombocytopenia purpura, valvular hemolysis, VAD, march hemoglobinuria, among many examples.

In hereditary spherocytosis, the blood smear suggests the diagnosis. Confirmation is by demonstrating an increased osmotic fragility, although direct genetic screening for the molecular defects is becoming more common. The blood smear is also critical for

diagnosing hereditary elliptocytosis and hereditary pyropoikilocytosis, although there is an increasing role for genetic diagnosis. Patients with hereditary pyropoikilocytosis are usually homozygous or compound heterozygous for one of the mutations causing mild hereditary elliptocytosis.

Diagnosis of G6PD deficiency is made by measuring enzyme activity. This is best done after the hemolytic episode is over, because reticulocytes have higher G6PD levels and can lead to falsely normal enzyme activity levels.

AIHA demonstrate either IgG or complement on the red blood cell. This is done by the “direct antibody” or “Coombs test.” IgG bound to red blood cells will not agglutinate them. However, if IgM that is directed against IgG or C3 is added, the red blood cells will agglutinate, proving that there is IgG or C3 on the red blood cell membrane. The finding of a positive DAT in the setting of a hemolytic anemia is diagnostic of AIHA.

There are several pitfalls to the DAT. One is that a positive DAT can be found in 1 in 1000 patients in the normal population and up to several percent of ailing patients, especially those with elevated gamma globulin such as patients with liver disease or HIV. Administration of IVIG can also create a false-positive DAT. Conversely, patients can have AIHA with a negative DAT. Some patients have a low amount of IgG binding the red blood cell, which is below the detection limit of the DAT reagents. Other patients can have IgA or “warm” IgM as the cause of the AIHA. Specialty laboratories can test for these possibilities. The diagnosis of DAT-negative AIHA should be made with caution, and other causes of hemolysis-like hereditary spherocytosis or PNH should be excluded.

The DAT in patients with cold AIHA will show cells coated with C3. The blood smear will often show agglutination of the blood, and if the blood cools before being analyzed, the agglutination will interfere with the analysis. Titers of cold agglutinin can range from 1 in 1000 to 1 in >1 million. The autoantibodies are most often directed against the I/i antigen system, with 90% against I. The I specificity is typical with primary cold agglutinin disease and also following mycoplasma infection. The i-specific antigen is most typical of Epstein-Barr and cytomegalovirus infections.

In PCH the DAT is often weakly positive but can be negative. The diagnostic test is the Donath-Landsteiner test. This complex test is performed by incubating samples in three temperature ranges: one at 0°C to 4°C, one set at 37°C, and one incubated first at 0°C to 4°C and then 37°C. The diagnosis of PCH is made if only the third tube shows hemolysis.

For many patients, the first clue to drug-associated AIHA is the finding of a positive DAT in a patient taking a suspect drug (Table 4). Specialty laboratories such as Wisconsin Blood Center or the L.A. Red Cross can perform in vitro studies of drug interactions that can produce a certain diagnosis.

For PNH, the diagnosis had been based on an in vitro demonstration of increased sensitivity of red blood cells to complement lysis. Currently, flow cytometry is performed to examine cells for the absence of GPI-anchored proteins (CD55 or CD59 on red cells, other GPI-anchored proteins on white blood cells). In patients with microangiopathy the smear will show abundant schistocytes with a marked elevated LDH.

Therapy

Splenectomy is curative for most cases of hereditary spherocytosis but is reserved for patients with severe symptoms. For patients with hereditary pyropoikilocytosis, splenectomy can also be useful.

Most patients with G6PD deficiency require no special management beyond the avoidance of provocative medications and food. Highly symptomatic patients with pyruvate kinase deficiency may respond to splenectomy, and in clinical trials a small molecule agent that can increase enzyme activity.

Initial management of warm AIHA is prednisone starting at 1 mg/kg daily. It can take up to 3 weeks to see a response. Once the hematocrit is >30%, the prednisone is slowly tapered. Eighty percent of patients will respond to steroids, but the steroids can be fully tapered off in only 30%. For patients who can be maintained

Tolbutamide (Orinase)
Tricyclic Antidepressants

on 10 mg or less of steroids daily, this maybe the most reasonable long-term therapy.

Current data show that adding rituximab (Rituxan)¹ to steroids for warm AIHA will improve overall response and should be considered early in most patients. These responses appear to be durable, and for relapses, repeating treatment is effective. It is important to remember that, for most patients, the response to rituximab is a gradual one over months; one should not expect a rapid response. Most studies have used the “traditional” 375 mg/m² dosing weekly for 4 weeks, and another option is 1000 mg repeated once 14 days apart.

Splenectomy is now reserved for patients with warm AIHA who do not respond to steroids or rituximab. Reported response rates in the literature range from 50% to 80%, with 50% to 60% remaining in remission. Timing of the procedure is a balance between allowing time for the steroids to work and the risk of toxicity of steroids. A patient who is at low risk for surgery and has either refractory disease or an inability to be weaned from high doses of steroids should have splenectomy considered early.

For patients who do not respond to either splenectomy or rituximab, the therapy is less certain. Although intravenous immune globulin is a standard therapy for immune thrombocytopenia, response rates are low in warm AIHA. Numerous therapies have been reported in small series, but there is no clear approach. Options include the following:

- Azathioprine (Imuran)¹ 75-150 mg/day
- Cyclophosphamide (Cytoxan)¹ 1000 mg monthly bolus IV

¹Not FDA approved for this indication.

- Mycophenolate (CellCept)¹ 500-1000 mg bid
- Cyclosporine (Neoral)¹ 5 mg/kg daily divided in two doses
- Danazol (Danocrine)¹ 200 mg tid

Our approach has been to use mycophenolate for patients who require high doses of steroids or need transfusions. Patients needing lower doses of steroids may be good candidates for danazol to help wean them off steroids.

The sparse literature on Evan's syndrome suggests it can be more refractory to standard therapy, with response rates to splenectomy being in the 50% range. In patients with lymphoma, antineoplastic therapy is crucial. Data are accumulating for patients with autoimmune lymphoproliferative disease: mycophenolate or sirolimus (Rapamune)¹ starting at 2 mg/m² may be effective for splenectomy or rituximab failures.

The importance of diagnosing cold AIHA and differentiating it from warm AIHA is the fact that standard therapy for warm disease steroids is ineffective. Because C3-coated red blood cells are taken up through the reticulo-endothelial system, especially in the liver, as well as the spleen, splenectomy is an ineffective therapy.

Simple measures to help with cold AIHA should be used. Patients should be kept in a warm environment and should try to avoid the cold. If transfusions are needed, they should be infused via blood warmers to prevent hemolysis. In rare patients with severe hemolysis, plasma exchange can be considered. Given the culprit antibody is IgM—mostly intravascular—use of plasma exchange can slow the hemolysis to give time for other therapies to take effect.

Therapy of cold AIHA remains difficult. Currently the drug of choice is rituximab.¹ Response can be seen in 45% to 75% of patients but is almost always a partial response; retreatment is often necessary. As with other autoimmune hematologic diseases, there can be a delay in response. There are data to support adding either fludarabine (Fludara)¹ or bendamustine (Treanda)¹ 90 mg/m² to rituximab. The response rates are higher, but so are the complications of therapy. Although more toxic, this combination can be considered in patients with aggressive disease.

For most patients with drug-induced AIHA, stopping the offending drug is sufficient. It is doubtful that steroids or other autoimmune-directed therapy is effective. For patients with the DIC-hemolysis syndrome, there are anecdotes that plasma exchange may be helpful. Therapy for patients with positive DAT without signs of hemolysis is uncertain. If the drug is essential, then the patient can be observed. If the patient has hemolysis, the drug needs to be discontinued and the patient observed for signs of end-stage organ damage.

Transfusions can be very difficult in AIHA. The presence of the autoantibody can interfere with typing of the blood and almost always interferes with the cross-match, because this final step consists of mixing the patient's serum with donor red blood cells. In most patients with AIHA the autoantibodies will react with any donor cells, rendering a negative cross-match impossible. Without the cross-match the concern is that underlying alloantibodies can be missed, which can lead to transfusion reactions.

Some of these concerns may be allayed by remembering that patients who have never been transfused or pregnant will rarely have alloantibodies. Second, a patient who has undergone transfusion in the remote past may have an amnesic antibody response but not an immediate hemolytic reaction.

When a patient is first suspected of having AIHA, a generous sample of blood should be given to the transfusion service. This will allow for adequate testing of the sample. Second, many centers will test the blood not only for blood groups ABO and D but will also perform full Rh typing and check for Kidd, Duffy, and Kell status. This can allow transfusion of phenotypically matched blood to lessen the risk of alloantibody formation.

One difficult issue is timing of transfusion. Clinicians are often hesitant to transfuse patients with AIHA due to fear of reactions.

But in frail patients with severe anemia—especially elderly patients or those with heart disease—transfusion can be lifesaving. Because in some cases it can take hours to screen for alloantibodies, it is often preferable to transfuse patients with severe anemia while carefully observing for reactions.

The treatment for PNH is the complement inhibitor eculizumab (Soliris), a humanized monoclonal antibody that targets complement protein C5, thereby preventing assembly of the terminal complement complex during complement activation. In studies, treatment with eculizumab has been shown to reduce hemolysis, as well as improve anemia, fatigue, and quality of life in patients with PNH. In addition, eculizumab has demonstrated efficacy in reducing thrombosis.

Management of Complications

The most concerning complication of splenectomy is overwhelming post-splenectomy infection. In adults, the spleen appears to play a minimal role in immunity except for defense from certain encapsulated organisms. Patients will often present with disseminated intravascular coagulation and will rapidly progress to purpura fulminans. Approximately 40% to 50% of patients will die of sepsis even when detected early. The overall lifetime risk may be as high as 1 in 500. The organism most commonly found in these cases is *Streptococcus pneumoniae*, which is reported in more than 50% of cases. *Neisseria meningitidis* and *Haemophilus influenzae* have also been implicated in many cases.

Patients who have undergone splenectomy need to be warned about the risk of overwhelming post-splenectomy infection and instructed to report to the emergency department immediately if they develop a fever greater than 101° or shaking chills. Once in the emergency department, blood cultures should be rapidly obtained and the patient started on antibiotic coverage with agents that cover encapsulated organisms. Patients who are planning to have or are being considered for a splenectomy should be vaccinated for pneumococcal, meningococcal, and H influenza infections. If patients are planning to be treated with rituximab first, they should also be vaccinated because after receiving rituximab, they will not be able to mount an immune response.

The major side effects of rituximab are infusion reactions—often worse with the first dose. These can be controlled with antihistamines, steroids, and, for severe rigors, meperidine (Demerol).¹ Rare patients can develop neutropenia (about 1 in 500) that appears to be autoimmune in nature. Infections appear to be only minimally increased with the use of rituximab. One group at higher risk are patients who are chronic carriers of hepatitis B. These patients may have reactivation of the virus that can be fatal in some cases; patients being considered for rituximab need to be screened for hepatitis B. Progressive multifocal leukoencephalopathy is a very rare risk that is more common in cancer patients and heavily immunosuppressed patients. The overall risk is unknown but is less than 1 in 50,000.

Eculizumab is well tolerated, except for a risk of meningococcal infection estimated at 1 in 500 risk. All patients receiving this agent should be vaccinated and need to report to the emergency department with any sign of infection.

HEMOPHILIA AND RELATED CONDITIONS

Method of

Meera Chitlur, MD; Bulent Ozgonenel, MD; and Roshni Kulkarni, MD

CURRENT DIAGNOSIS

- The hemophilias and von Willebrand disease (VWD) account for 80% to 85% of inherited bleeding disorders. Hemophilia A and B are X-linked, whereas VWD and rare bleeding disorders (RBDs) are autosomal disorders.
- The diagnosis of hemophilia and other inherited bleeding disorders should be confirmed by specific laboratory assays, because screening tests such as prothrombin time (PT) and activated partial thromboplastin time (aPTT) may be normal. Plasma levels of deficient factor determine clinical severity and management.
- Major complications associated with hemophilia are inhibitor development, hemarthrosis, and intracranial hemorrhage. Hemarthrosis is the most common and debilitating complication, and central nervous system bleeding is the most common cause of mortality in hemophilia. Mucosal bleeding and menorrhagia are the most common manifestations of VWD. Bleeding manifestations of RBDs are mild, although homozygotes can present with severe disease.
- Newborns have normal levels of factor VIII; therefore the diagnosis of hemophilia A can be established at birth. Vacuum delivery should be avoided to prevent head bleeds.
- Women and adolescents with menorrhagia and no underlying pathology should be investigated for a bleeding disorder.

CURRENT THERAPY

- Early and effective treatment and prophylaxis can prevent repeated hemarthrosis and joint destruction in persons with hemophilia. Patients should be tested annually for the presence of inhibitors.
- Both plasma-derived and recombinant factor concentrates are effective for the treatment of hemophilia. Cryoprecipitate is not recommended. For mild and moderate hemophilia A and von Willebrand disease, the use of desmopressin (DDAVP) coupled with antifibrinolytics can obviate the use of concentrates. Continued vigilance should be implemented for new and emerging bloodborne pathogens.
- All patients with inherited bleeding disorders should be immunized against hepatitis A and B and followed in close collaboration with the local hemophilia treatment center (<http://www2a.cdc.gov/ncbddd/htcweb/index.asp>). The National Hemophilia Foundation's (www.hemophilia.org) Medical and Scientific Advisory Committee (MASAC) guidelines for updated recommendations and product choice should be followed.

Hemophilia A and Hemophilia B

Hemophilia is an X-linked congenital bleeding disorder caused by a deficiency of factor VIII (hemophilia A) or factor IX (hemophilia

B). Hemophilia A is the most common severe bleeding disorder and affects 1 in 5000 males in the United States; hemophilia B occurs in 1 in 30,000 males.

Pathophysiology

The factor VIII gene is one of the largest genes and spans 186 kb of genomic DNA at Xq28. Inversion mutations account for 40% of severe hemophilia A, and deletions, point mutations, and insertions account for the remainder.

Hepatic and reticuloendothelial cells are presumed sites of factor VIII synthesis. Factor VIII is synthesized as a single chain polypeptide with three A domains (A1, A2, and A3), a large central B domain, and two C domains (Figure 1). The binding sites for von Willebrand's factor (VWF), thrombin, and factor Xa are on the C2 domain, and factor IXa binding sites are on the A2 and A3 domains. The B domain can be deleted without any consequences. VWF protects factor VIII from proteolytic degradation in the plasma and concentrates it at the site of injury.

The factor IX gene is 34kb long and located at Xq26. It is a vitamin K-dependent serine protease composed of 415 amino acids. It is synthesized in the liver and its plasma concentration is about 50 times that of factor VIII. Gene deletions and point mutations result in hemophilia B.

Role of Factors VIII and IX in Coagulation

Factor VIII circulates bound to VWF. It is a cofactor for factor IX and is essential for factor X activation. In the classic coagulation cascade, activation of the intrinsic or extrinsic pathway of coagulation results in sufficient thrombin generation. However, this does not explain bleeding in hemophilia, because the extrinsic pathway is intact. This led to the revised cell-based model of coagulation.

The revised pathway incorporates all coagulation factors into a single pathway initiated by FVII and tissue factor. The contact factors (XI, XII, kallikrein, and high-molecular-weight kininogen) are not essential but serve as a backup. Following injury, encrypted tissue factor is exposed and forms a complex with factor VIIa. The tissue factor–factor VIIa complex activates factor IX to IXa (which moves to the platelet surface) and factor X to Xa. This generates small amounts of thrombin that activates platelets, converts platelet factor V to Va and factor XI to XIa, and releases factor VIII from VWF and activates it. The factor XIa activates plasma factor IX to IXa on the platelet surface, which together with factor VIIIa forms the tenase complex (factor VIIIa/IXa) that converts large amounts of factor X to Xa. Factor Xa forms a prothrombinase complex with FVa and converts large amounts of prothrombin to thrombin, called *thrombin burst*. This results in the conversion of sufficient fibrinogen to fibrin to form a stable clot. (Animations are available at the Foundation of Women and Girls with Blood Disorders (www.fwgbd.org) and www.reddymed.com).

In hemophilia, lack of factor VIII or IX produces a profound abnormality. Factor Xa generated by FVIIa and tissue factor is insufficient because it is soon inhibited by tissue factor pathway inhibitor (negative feedback), and factors VIII and IX, which are required for amplifying the production of Xa, are absent. The primary platelet plug formation and initiation phases of coagulation are normal. Any clot that is formed (from the initiation phase) is friable and porous.

Clinical Features

The diagnosis of hemophilia is often made following a bleeding episode or because of a family history; 30% of cases, however, have no family history. Based on the plasma levels of factor VIII or IX

Figure 1 Factor VIII protein structure.

TABLE 1 Hemophilia Severity and Clinical Manifestations

CHARACTERISTICS	SEVERE (50%–70%)	MODERATE (10%)	MILD (30%–40%)
Factor VIII or IX activity (normal 50%–150%)	<1%	1%–5%	>5%
Age of diagnosis	At birth to 2 y	Childhood or adolescence	Adolescence or adult
Bleeding patterns	2–4/mo	4–6/y	Rare
Clinical manifestations	Hemarthroses, muscle, central nervous system, gastrointestinal bleeding, hematuria	Bleeding into joints or muscle following minor trauma, surgical procedure, dental bleeding Rarely spontaneous	Surgical procedures (including dental) and major trauma

(normal levels are 50%–150%) that correlate with severity and predict bleeding risk, hemophilia is classified as mild (>5%), moderate (1%–5%), and severe (<1%) (Table 1). Approximately 65% of persons with hemophilia have severe disease, 15% have moderate disease, and 20% have mild disease. Most severe disease manifests by 4 years of age; moderate or mild disease is diagnosed later and often following bleeding secondary to trauma or surgery.

Hemophilia can be diagnosed in the first trimester, using chorionic villus sampling and gene analysis. In the second trimester, fetal blood sampling can be performed. Prenatal diagnosis to determine fetal gender can aid in the management of pregnancy and delivery.

The hallmark of severe hemophilia is hemarthrosis, or bleeding into the joint, that can occur spontaneously or with minimal trauma. Although the immediate effects of a joint bleed are excruciating pain, swelling, warmth, and muscle spasm, the long-term effects of recurrent hemarthrosis include hemophilic arthropathy, which is characterized by synovial thickening, chronic inflammation, and repeated hemorrhages resulting in a target joint. Knees, elbows, ankles, hips, and shoulders are commonly affected. Disuse atrophy of surrounding muscles leads to further joint instability. Limitation of joint range of motion due to hemarthrosis often correlates positively with older age, nonwhite race, and increased body mass index, and it affects quality of life.

Muscle hematomas, another characteristic site of bleeding, can lead to compartment syndrome, with eventual fibrosis and peripheral nerve damage. Iliopsoas bleeds manifest with pain and flexion deformity. Gastrointestinal bleeding and hematuria occur less often.

Central nervous system (CNS) hemorrhage is a rare but serious complication with a 10% recurrence rate and is the leading cause of mortality in hemophiliacs. Although most newborns with severe hemophilia experience an uneventful course following vaginal delivery, vacuum extraction is associated with an increased CNS bleeding risk. The incidence of intracranial hemorrhage in newborns with hemophilia is 1% to 4%.

Diagnosis

Hemophilia A and B are clinically indistinguishable, and specific factor assays are the only way to differentiate and confirm the diagnosis. Both should be differentiated from von Willebrand disease (VWD). The prothrombin time (PT), platelet function analyzer (PFA-100), and fibrinogen are normal. (PFA, a platelet-function screening test, is replacing bleeding time, because the bleeding time has low sensitivity and specificity and is operator dependent.) The activated partial thromboplastin time (aPTT) is prolonged when the factor levels are below 30%. Table 2 shows the characteristics and differences between the hemophilias and VWD. Female carriers may be asymptomatic except for those with extreme lyonization resulting in low factor VIII or IX levels. However, some carriers may experience bleeding episodes even with levels of FVIII or IX in the 40% range. Factor VIII levels increase throughout pregnancy and drop to prepregnancy levels following delivery, but factor IX levels remain constant throughout pregnancy.

TABLE 2 Hemophilias and von Willebrand Disease: Key Characteristics and Differences

CHARACTERISTIC	HEMOPHILIA A	HEMOPHILIA B	von WILLEBRAND DISEASE
Incidence	1:5,000	1:30,000	1%–3% of U.S. population
Abnormality	Factor VIII deficiency	Factor IX deficiency	vWF (qualitative and quantitative defect)
Inheritance	X-linked, affects males Gene at the tip of X-chromosome	X-linked, affects males Gene at the tip of X-chromosome	Autosomal dominant (gene: chromosome 12) Some are recessive or compound heterozygotes
Production site	Unknown, liver endothelium	Liver (vitamin K dependent)	Megakaryocytes and endothelial cells
Function	Cofactor; forms tenase complex with factor IX and activates factor X, leading to thrombin burst that results in conversion of large amounts of fibrinogen to fibrin	Serine protease (inactive form: zymogen) activated by factor XI or VIIa; forms a tenase complex with factor VIII and activates factor X	Platelet adhesion to site of injury or damaged endothelium Protects factor VIII from proteolysis
Classification (normal levels 50%–150%)	Mild (>5%) Moderate (1–5%) Severe (<1%)	Mild (>5%) Moderate (1–5%) Severe (<1%)	Type 1 Type 2 (2A, 2B, 2M, 2N) Type 3
Clinical presentation	Positive family history (30% new mutation) Hemarthroses, hematomas, hematuria, intracranial hemorrhage, gastrointestinal hemorrhage, etc.	Positive family history (30% new mutation) Milder disease, although identical hemorrhage sites as hemophilia A	Positive family history Mucocutaneous bleeding (epistaxis, menorrhagia, postdental bleeding) Type 3 can manifest as hemophilia A

TABLE 2 Hemophilias and von Willebrand Disease: Key Characteristics and Differences—cont'd

CHARACTERISTIC	HEMOPHILIA A	HEMOPHILIA B	von WILLEBRAND DISEASE
PFA, bleeding time	Normal	Normal	May be prolonged
PT	Normal	Normal	Normal
aPTT	Prolonged	Prolonged	Prolonged or normal
Factor VIII assay	Decreased or absent	Normal	Decreased or normal (absent type 3)
Factor IX assay	Normal	Decreased or absent	Normal
VWF:Ag	Normal	Normal	Decreased or absent (type 3)
VWF:RCo	Normal	Normal	Decreased or abnormal
VWF multimeres	Normal	Normal	Abnormal in types 1, 2A, 2B; absent in type 3
Specific treatment	Recombinant factor VIII (preferred) Pathogen-safe plasma-derived concentrates DDAVP for mild cases	Recombinant factor IX Pathogen-safe plasma-derived concentrates DDAVP ineffective	DDAVP (intranasal or intravenous) vWF concentrates (pathogen-safe plasma derived)
Inhibitor patients	Immune tolerance, recombinant factor VIIa, APCC	Immune tolerance, recombinant factor VIIa	Inhibitors are rare
Adjunct therapy	Antifibrinolytics	Antifibrinolytics	Oral contraceptives, antifibrinolytics

Abbreviations: APCC = activated prothrombin complex concentrates; aPTT = activated partial thromboplastin time; DDAVP = desmopressin; PFA = platelet function analyzer; PT = prothrombin time; RCo = ristocetin cofactor; VWF = von Willebrand factor; VWF:Ag = von Willebrand factor antigen.

Treatment

The treatment for hemophilia consists of replacement therapy with intravenous factor VIII or factor IX concentrates produced by purification of donor plasma (plasma derived) (e.g., Factor VIII: Hemofil M, Monoclante-P; Factor IX: AlphaNine SD, Mononine) or in cell culture bioreactors (recombinant) (e.g., Factor VIII: Afstyl, Helixate FS; Factor IX: BeneFix, Rixubis). Careful screening of donors combined with heat treatment and viral inactivation methods have made plasma-derived products safer. Plasma-derived and recombinant products appear to have equivalent clinical efficacy. Cryoprecipitate is no longer recommended because of concerns regarding pathogen safety.

Treatment administered only during bleeding symptoms is known as *episodic therapy*, and periodic administration of factor concentrates to prevent bleeding is known as *prophylactic therapy*. Response to treatment is more effective when it is administered early. Although prophylaxis prevents the development of joint disease, the high cost of factor replacement coupled with the need for venous access makes it expensive and difficult and out of reach for patients in the developing world.

The goal of treatment is to raise factor levels to approximately 30% or more for minor bleeds (hematomas or joint bleeds) and 100% for major bleeds (CNS or surgery). Giving 1 U/kg of factor concentrate raises plasma factor VIII levels by 2% and factor IX levels by 1.5% (except with the recombinant factor IX product, where it increases by 0.8%). The half-life of factor VIII is approximately 8 to 12 hours and that of factor IX is up to 24 hours. Factor concentrates can also be given by continuous infusion (3–4 U/kg/hour). The bolus dose varies from 25 to 50 U/kg depending on the severity, site, and type of bleeding and is dosed to the available vial size because of the cost of the products. Table 3 lists the dosing schedule for various types of bleeds.

For short-term therapy (before dental procedures and minor bleeding episodes) in mild hemophilia A and VWD, the synthetic vasopressin analogue desmopressin acetate (DDAVP [Stimate]) is useful. It increases plasma concentrations of coagulation factor VIII and VWF three- to fivefold by releasing the endothelial stores. A DDAVP trial to determine response is helpful in selecting patients who might benefit from such therapy. For hemostatic purposes, intravenous (0.3 µg/kg in 50 mL of normal saline infused over 15–30 min) or intranasal dose (150 µg) can be used. The intranasal dose is 15 times larger than that recommended for diabetes

insipidus. A multidose intranasal spray formulation (Stimate nasal spray) delivers 150 µg per spray. The recommended dosage is one spray for patients who weigh less than 50 kg and two sprays (one in each nostril) for those who weigh more than 50 kg. Desmopressin is ineffective in hemophilia B. Aspirin and aspirin-containing compounds should be avoided in persons with bleeding disorders because they interfere with platelet function and can exacerbate bleeding.

Antifibrinolytics such as ϵ -aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron or Lysteda) are used as adjunct therapies and in mild hemophilia and can decrease the need for factor concentrates. The recommended dosage for ϵ -aminocaproic acid is 75 to 100 mg/kg/dose IV or orally every 4 to 6 hours (maximum 30 g/24 hours). The recommended dosage for tranexamic acid is 10 mg/kg/dose IV or 25 mg/kg body weight orally, three times daily.

For prophylaxis, factor VIII 25 to 40 U/kg administered every other day or factor IX 25 to 40 U/kg twice weekly (because of the longer half-life of factor IX) is aimed at preventing joint disease. Prophylaxis may begin at 1 to 2 years of age and is continued lifelong. Self-infusion before any planned strenuous activity is recommended. Because of the complications of central venous catheters (infections, thrombosis, and mechanical), use of a peripheral vein is encouraged. Over the last 3 years various modified factor products with prolonged half-lives have been developed with an aim to decrease the frequency of infusions and improve quality of life for patients with hemophilia. These include PEGylation, fusion proteins with fusion of the factor protein to the Fc fragment of an immunoglobulin or albumin. In March 2014, the US FDA approved the first long-acting Factor IX Fc fusion protein (Alprolix) for use in patients with hemophilia B after safety and efficacy was established in initial clinical trials in adult patients with hemophilia B. More recently, in June 2014, rFVIII Fc fusion (Eloctate) was approved by the FDA for the treatment and prophylaxis of bleeding episodes in hemophilia A. Clinical trials are still ongoing with other prolonged half-life factor concentrates.

Novel Therapies for the Treatment of Hemophilia

In recent years the field of hemophilia treatment has seen dramatic changes. Treatment options that do not target replacement of the missing factor are now being tested. Factor VIII mimetics such as the bispecific antibody Emicizumab (Hemlibra) (see below), products targeting the endogenous anticoagulants, such as siRNA to AT

TABLE 3 Treatment of Bleeding Episodes and Desired Plasma Levels in Hemophilias A and B

TYPE OF BLEEDING	DESIRED FACTOR LEVEL (%)	FACTOR VIII DOSE (U/kg)	FACTOR IX DOSE (U/kg)	DURATION OF TREATMENT (DAYS)	COMMENTS (DOSE FACTOR TO THE CLOSEST VIAL)
Persistent or profuse epistaxis Oral mucosal bleeding (including tongue and mouth lacerations)	20–30	10–15	20–30	1–2	Local pressure, antifibrinolytics, fibrin glue for local control, nosebleed QR for epistaxis Sedation in small children with tongue laceration
Dental procedures	30–50	15–25	30–50	1 h before procedure	Antifibrinolytics for 7–10 d
Acute hemarthrosis, intramuscular hematomas	30–60	15–50	30–60	1–3	Use lower doses if treated early. Non-weight bearing on affected joint.
Physical therapy	30–50	15–25	30–50	Treat before PT	Consider synovectomy (surgical, radioisotope or chemical) for target joints.
Life-threatening bleeding such as intracranial hemorrhage, major surgery, and trauma	80–100	40–50	80–100	10–14 d	Bolus dose followed by continuous infusion (3–4 U/kg/h); may switch to bolus before discharge
Gastrointestinal bleeding	30–50	15–25	30–50	2–3	May use oral antifibrinolytics
Persistent painless gross hematuria	30–50	15–25	30–50	1–2	Increase PO or IV fluids with low-dose antifibrinolytics; Risk of clotting in the urinary tract with factor replacement

Abbreviation: PT = physical therapy.

III [Fitusiran[®] (Alnylam Pharmaceuticals)]⁵, Anti TFPI antibody [e.g. Concizumab[®] (Novo Nordisk)]⁵ and products targeting the anticoagulant effect of APC are being studied. The advantages are that these products provide the benefits of prophylaxis and do not require frequent injections. More data is needed regarding the safety and efficacy of these medications.

Complications of Treatment

One of the most serious complications of hemophilia treatment is the development of inhibitors or neutralizing antibodies (immunoglobulin [Ig]G) that inhibit the function of substituted factor VIII and factor IX. Approximately 5% to 10% of all hemophiliacs and up to 30% of patients with severe hemophilia A develop inhibitors. The incidence of inhibitors in hemophilia B is lower (1%–3%). Most factor VIII inhibitors arise after a median exposure of 9 to 12 days in patients with severe hemophilia A. They can be transient or permanent and should be suspected if a patient fails to respond to an appropriate dose of clotting factor concentrate. Inhibitors can exacerbate bleeding episodes and hemophilic arthropathy.

Inhibitor levels, measured using Bethesda units (BU), are classified as high titer (>5 BU) or low titer (<5 BU). In patients with low-titer inhibitors, higher than normal doses of factor VIII or IX may be used to treat bleeding. For those with high-titer inhibitors, agents that bypass factor VIII or factor IX are used. These include recombinant activated factor VII and, in the case of hemophilia A, activated prothrombin complex concentrates (APCC) or recombinant porcine factor VIII (currently in prelicensure clinical trials). Immune tolerance induction, a long-term approach designed to eradicate inhibitors, is effective in 70% to 85% of patients with severe hemophilia A; the most important predictor of success of immune tolerance induction is an inhibitor titer of less than 10 BU at the start of immune tolerance induction.

A novel treatment for hemophilia A with inhibitors is emicizumab (also called ACE910, marketed as Hemlibra[®]), a chimeric humanized antibody that triggers and propagates thrombin generation by binding to both factor IX and factor X. By binding to these coagulation factors, the antibody mimics the function of factor VIII. The medication can be given as weekly subcutaneous doses,

and therefore is a preferred regimen in young children. Emicizumab has shown success in preventing bleeding complications in patients with severe hemophilia A with inhibitors. Emicizumab treatment is safe by itself, but thrombotic complications have been observed in individuals receiving concomitant high doses of APCC. Emicizumab was approved by the FDA for the treatment of hemophilia A with inhibitors in 2017.

Although inhibitors are rare in hemophilia B, they can result in anaphylaxis with exposure to factor IX-containing products. Immune tolerance regimens are associated with nephrotic syndrome and are successful in eradicating the inhibitor only in 40% of cases.

Another important complication of treatment is the transmission of bloodborne pathogens such as hepatitis B and C viruses and HIV. In the 1970s, lyophilized plasma factor concentrates of low purity resulted in the transmission of HIV, causing the deaths of many hemophiliacs. Currently, donor screening for pathogens coupled with viral attenuation by heat or solvent detergent technology make these products pathogen safe. However, non-enveloped viruses (parvovirus and hepatitis A) and prions can resist inactivation and can be potentially transmitted.

Patients with bleeding disorders should be encouraged to attend the comprehensive hemophilia treatment centers, where they are educated, trained to self-infuse and calculate dosage, maintain treatment logs, and call for serious bleeding episodes. The mortality rate among patients who receive care at hemophilia treatment centers (HTCs) is lower than among those who do not: 28.1% versus 38.3%, respectively. At the HTCs, hemovigilance for bloodborne and emerging pathogens was maintained through participation in the Centers for Disease Control and Prevention's (CDC) Universal Data Collection (UDC) project. The grant cycle of the UDC was completed in 2012, and a new surveillance instrument is currently in use (Community Counts) that incorporates collecting information on co-morbidities and complications of bleeding disorders in this population.

Routine vaccination against hepatitis A and B is recommended. Gene therapy offers promise of a cure but has not yet become reality. Two gene therapy trials for hemophilia B had shown subtherapeutic or transient expression of factor IX. In December 2011, Nathwani and colleagues reported that a single injection of FIX expressing adenovirus-associated virus (AAV) vector was effective in treating patients with hemophilia B for more than a year. Since

⁵Investigational drug in the United States.

this breakthrough there have been more successful gene therapy trials for the treatment of both hemophilia A and B. This has been a significant breakthrough in the treatment of hemophilia.

von Willebrand Disease

von Willebrand disease (VWD) is an inherited (autosomal dominant) bleeding disorder caused by deficiency or dysfunction of von Willebrand factor (VWF), a plasma protein that mediates platelet adhesion at the site of vascular injury and prevents degradation of factor VIII. A defect in VWF results in bleeding by impairing platelet adhesion or by decreasing factor VIII.

VWF is synthesized in endothelial cells and undergoes dimerization and multimerization, forming low-, intermediate-, and high-molecular-weight (HMW) multimers. The HMW multimers are most effective in promoting platelet aggregation and adhesion. Circulating HMW multimers are cleaved by the protease ADAMTS13, which is deficient in patients with thrombotic thrombocytopenic purpura.

VWD is the most common bleeding disorder, affecting 1% or more of the population. It occurs worldwide and affects all races. VWD is classified into three major categories: partial quantitative deficiency (type 1), qualitative deficiency (type 2), and total deficiency (type 3). There are several different variants of type 2 VWD: 2A, 2B, 2N, and 2M based on the phenotype. About 75% of patients have type 1 VWD.

Clinical Presentation

Mucous membrane-type bleeding (e.g., menorrhagia, epistaxis) and excessive bruising are characteristic clinical features in VWD. Bleeding manifestations vary considerably, and in some cases the diagnosis is not suspected until excessive bleeding occurs with a surgical procedure or trauma. Although excessive menstrual bleeding may be the initial manifestation, it takes 16 years for a diagnosis of bleeding disorder. It is for this reason that the American College of Obstetrics and Gynecology recommended screening for hemostatic disorders in all adolescents and women presenting with menorrhagia and no pathology and before hysterectomy for menorrhagia. In infants or small children with type 3 (severe) VWD, excessive bruising and even joint bleeding (due to very low levels of factor VIII) can mimic hemophilia A.

Diagnosis

Laboratory evaluation for VWD requires several assays to quantify VWF and characterize its structure and function. Many variables affect VWF assay results, including the patient's ABO blood type. Persons of blood group AB have 60% to 70% higher VWF levels than those of blood group O. Thus, some laboratories interpret VWF levels referenced to specific normal ranges for blood types.

Clinical conditions and disorders with elevated VWF levels include pregnancy (third trimester), collagen vascular disorders, following surgery, in liver disease, and in disseminated

intravascular coagulation. Low levels are seen in hypothyroidism and days 1 to 4 of the menstrual cycle.

Symptoms are modified by medications like aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), which can exacerbate the bleeding; oral contraceptives can decrease the bleeding in women with VWD by increasing VWF levels. VWF levels in African American women are 15% higher than in white women. Clinical symptoms and family history are important for establishing the diagnosis of VWD, and a single test is sometimes not sufficient to rule out the diagnosis.

Initial workup should include a complete blood count, aPTT, PT, fibrinogen level, or thrombin time. These tests do not rule out VWD but help rule out thrombocytopenia or factor deficiency as the cause for bleeding. The closure times on the PFA-100, which has replaced the bleeding time as a screening test in some centers, may be prolonged. The aPTT in VWD is only abnormal when factor VIII is sufficiently reduced.

Specific tests for VWD include ristocetin cofactor assay, a factor VIII activity, and VWF antigen (VWF Ag) assay. The Ristocetin cofactor activity measures induced binding of VWF to platelet glycoprotein Ib and is the best functional assay of VWF activity. Multimer analysis is done by agarose gel electrophoresis using anti-VWF polyclonal antibody and is available at reference laboratories. Collagen binding assay and genotyping, especially for Type 2 VWD, are new tests available to assist with the diagnosis.

In type I VWD, the VWF is subnormal in amount, with normal multimer structure. Those with types 2A and 2B VWD lack the HMW multimers. In type 2B, the VWF has a heightened affinity for platelets, often resulting in some degree of thrombocytopenia from platelet aggregation. A useful laboratory test for type 2B is the low-dose ristocetin-induced platelet aggregation (RIPA) assay.

In type 3 (severe) VWD, the affected person has inherited a gene for type I VWD from each parent, resulting in very low levels (3%) of VWF (and low factor VIII, because there is no VWF to protect factor VIII from proteolytic degradation). Less commonly, a person with type 3 is doubly heterozygous. Table 4 provides a quick overview of the laboratory findings in the different variants of VWD.

Treatment

In type 1 VWD (with subnormal levels of normally functioning VWF), the treatment of choice is DDAVP, which causes a rapid release of VWF from storage sites. It can be given intravenously or by the intranasal route. The recommended dose for IV use is 0.3 µg/kg, given in saline over 10 minutes. Most persons with type 1 VWD have a two- to fourfold increase in plasma levels of VWF within 15 to 30 minutes following infusion. The IV route is often used for surgical coverage or for a severe bleeding episode requiring hospitalization. When necessary, repeat doses may be given at 12- to 24-hour intervals. Tachyphylaxis is less commonly seen in VWD patients than in hemophilia patients. It is important to monitor free water intake following DDAVP administration because it can cause hyponatremia and seizures.

TABLE 4 Clinical Variants of von Willebrand Disease

TYPE	FACTOR VIII	VWF AG	RISTOCETIN COFACTOR	RIPA	MULTIMER
1	↓	↓	↓	↓ or normal	Normal
2A	↓ or normal	↓↓	↓	↓↓	Large and intermediate multimers absent
2B	↓ or normal	↓↓	↓ or normal	↓ to low dose	Large multimers absent
2M	Variably ↓	Variably ↓	↓	Variably ↓	Normal
2N	↓↓	Normal	Normal	Normal	Normal
3	↓↓↓↓	↓↓↓↓	↓↓↓↓	None	Absent
Platelet type	↓ or normal	↓ or normal	↓	↓ to low dose	Large multimers absent

Abbreviations: Ag = antigen; RIPA = ristocetin-induced platelet aggregation; vWF = von Willebrand factor.

The concentrated form of desmopressin for intranasal use (Stimate Nasal Spray) may be used. The recommended dosage is one 150- μ g spray for patients who weigh less than 50 kg and two sprays (one in each nostril) for those who weigh more than 50 kg. Some young women with menorrhagia have benefited from its use at the onset of menses, with a second dose after 24 hours. Others have used it approximately 45 minutes before invasive dentistry, with good results.

In the type 2 variants (VWF produced is abnormal), desmopressin can cause an increase in abnormal VWF. Although some persons with type 2A might respond, desmopressin is seldom useful in type 2 and might even be contraindicated (as in type 2B, where it can exacerbate the thrombocytopenia).

In type 3 VWD, desmopressin is ineffective because there is no VWF to be released from storage sites. For type 3 patients and in persons with type 1 VWD who do not respond adequately to desmopressin, an intermediate-purity plasma-derived concentrate rich in the hemostatically effective HMW multimers of VWF (such as Humate P) should be used to treat moderately severe or severe bleeding episodes and for before surgery. There is also a new recombinant VWF concentrate (Vonvendi[®]) currently approved for use only in adults.

As in hemophilia, antifibrinolytics are an effective adjunctive treatment for invasive dental procedures or other bleeding in the oropharyngeal cavity. These may be effective even when used alone in some VWD women with menorrhagia. For epistaxis, Nosebleed QR, a hydrophilic powder, can help.

Special Situations

Pregnancy

VWF (and factor VIII) levels increase during the third trimester of pregnancy, and women with type 1 VWD have a decrease in bruising or other bleeding symptoms. However, those with type 2 VWD (abnormal vWF) and type 3 (no VWF) have no change in the bleeding tendency. Even in type 1 VWD, VWF levels fall following delivery, so treatment (with IV desmopressin or Humate P) may be needed.

Acquired von Willebrand Disease

Acquired VWD occurs in persons who do not have a lifelong bleeding disorder. Conditions associated with acquired VWD include underlying autoimmune disease (lymphoproliferative disorders, myeloproliferative disorders, or plasma cell dyscrasias), valvular and congenital heart disease, Wilms' tumor, chronic renal failure, and hypothyroidism. The mechanism of acquired VWD is unknown. Medications such as valproic acid can also cause VWD. Removal of the underlying condition often corrects the VWF. Desmopressin, Humate P, recombinant factor VIIa, or plasma exchange may be tried, if necessary, to treat bleeding.

Rare Bleeding Disorders

The rare bleeding disorders account for 3% to 5% of inherited coagulation deficiencies, other than factor VIII, factor IX, or VWF deficiencies. They are autosomal recessive and affect both sexes. The prevalence of rare bleeding disorders ranges from 1:500,000 to 1:2,000,000. Bleeding manifestations are restricted to persons who are homozygotes or compound heterozygotes. Rare bleeding disorders are common in countries such as Iran, where consanguineous marriages are customary. Ashkenazi Jews are particularly affected by factor XI deficiency. Deficiency of factor XII is a risk factor for thrombosis but not for bleeding. Most cases of rare bleeding disorders are identified by abnormal screening tests coupled with specific factor assays.

Factor concentrates (recombinant or plasma derived) are available for some of the deficiencies (mostly in Europe, but not in the United States). Fibrogammin P, a plasma-derived virally purified FXIII concentrate, is now licensed and commercially available in the United States under the trade name of Corifact. In addition, a novel Recombinant FXIII concentrate (Tretten[®]) has been approved for the treatment of congenital FXIII subunit A deficiency. The advantages of concentrates are pathogen safety and small volume. The use of antifibrinolytics and fibrin glue as adjunct therapy for bleeding manifestations is encouraged. Table 5 lists the inheritance, frequency, manifestations, and treatments of the rare bleeding disorders.

TABLE 5 Rare Bleeding Disorders: Inheritance, Clinical Features, and Treatment

FACTOR	PREVALENCE	TYPE	INHERITANCE	MANIFESTATION AND DIAGNOSIS	TREATMENT	HEMOSTATIC LEVELS	HALF-LIFE

HODGKIN LYMPHOMA

Method of
James O. Armitage, MD

CURRENT DIAGNOSIS

- Hodgkin lymphoma typically presents as painless lymphadenopathy in young people.
- Systemic symptoms are often absent but may include “B” symptoms (fevers, drenching night sweats, or weight loss) or diffuse pruritus.
- Definitive diagnosis is by tissue biopsy, ideally by excisional lymph node biopsy. Fine-needle aspiration (FNA) is insensitive for the diagnosis of Hodgkin lymphoma and should be avoided.

CURRENT THERAPY

- Treatment is guided by clinical stage using the Ann Arbor staging system.
- Limited-stage disease (stages I–IIA) without adverse risk factors (also called “early favorable”) may be treated with combined-modality therapy (ABVD × 2 cycles followed by 20 Gy involved-field radiation), or 4 to 6 cycles of ABVD alone. Stanford V is an alternative option.
- Limited-stage disease (I–IIA) with adverse risk factors (also called “early unfavorable”) may be treated with combined-modality therapy (4 cycles of ABVD followed by 30 Gy involved-field radiotherapy), or with 6 cycles of ABVD alone. Patients with bulky disease at presentation should receive combined-modality therapy.
- Advanced-stage disease (Ann Arbor stage IIB–IV) should be treated with ABVD for 6 cycles. Radiation should be included for bulky stage II disease, and may be considered for consolidation of bulky presenting sites in stage III–IV disease. Escalated BEACOPP is an alternative treatment option.
- Selection of treatment should be informed by the toxicity profiles of available therapies, as well as the location of disease and the age and comorbidities of the patient.

Epidemiology

Hodgkin lymphoma is cancer of lymphoid tissue accounting for approximately 9000 new cases every year in the United States, and 1200 deaths. The median age of diagnosis is 35 years, but there is a bimodal distribution with the highest peak in the early 20s and then a rising incidence after the age of 60.

Pathology

Pathologically, Hodgkin lymphoma is broadly categorized as either classical Hodgkin lymphoma (CHL) or nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) (Table 1). CHL

TABLE 1 Classification of Hodgkin Lymphoma	
Classic Hodgkin lymphoma	95%
Nodular sclerosis	75%
Mixed cellularity	15%
Lymphocyte rich	5%
Lymphocyte depleted	5%
Nodular lymphocyte-predominant Hodgkin lymphoma	5%

includes four histologic subtypes, which are grouped together because of a common malignant cell—the Hodgkin Reed-Sternberg (HRS) cell—and shared natural history, prognosis, and approach to therapy. These subtypes, in order of frequency, are Nodular Sclerosis (NSHL), Mixed Cellularity (MCHL), Lymphocyte Rich (LRHL), and Lymphocyte depleted (LD).

NSHL accounts for approximately 70% of new cases of HL in the United States, and occurs with a female predominance. All other subtypes of CHL occur more frequently in men. NLPHL accounts for only about 5% of new cases of HL each year, and occurs more commonly in men than in women.

Risk Factors

Most cases of Hodgkin lymphoma are sporadic, although a few risk factors have been identified. An increased risk of CHL among first-degree family members points to a heritable genetic susceptibility. Identical twins of CHL patients have a markedly increased risk of developing CHL, whereas other first-degree relatives are four times likelier to develop CHL than the general population. Given the low overall incidence in the population, the absolute risk of CHL among first-degree relatives remains quite low.

NSHL occurs more frequently in the Western world and is associated with a favorable socioeconomic status. MCHL, on the other hand, is the most common subtype in developing countries, and is often associated with underlying Epstein-Barr virus (EBV) infection, but the absolute risk of developing CHL after infectious mononucleosis remains low at approximately 1 in 1000. The median time to CHL diagnosis after infectious mononucleosis is 4 years. HIV infection is associated with a tenfold increased risk of developing CHL, related to the immune suppression and increased rate EBV transformation. Risk is similarly increased in other immunosuppressive states such as congenital immunodeficiency and after solid organ or hematopoietic stem cell transplantation.

Clinical Manifestations

CHL most commonly presents with painless lymphadenopathy. The most common locations are in the neck (75%) and mediastinum (60%), followed by the axillae, retroperitoneal, and inguinal lymph nodes. Nodes are generally mobile and firm or rubbery on examination. The spleen is involved in approximately 20% of cases. Extranodal sites are uncommonly involved, including bone marrow, lungs, liver, bone, and other sites. Patients with bulky mediastinal disease may present with dyspnea, chest pressure, or cough, though even large mediastinal masses may be asymptomatic. Superior vena cava syndrome is uncommon. Systemic “B” symptoms (fever >38°C, unintentional weight loss of >10% of body weight over 6 months, and drenching night sweats) occur in approximately one third of patients at diagnosis. Generalized pruritus is not considered a “B” symptom but is present in a minority of patients, in whom it may presage the diagnosis by many months. Pain at involved nodal or bony sites with alcohol ingestion is rarely present, but is unique and the mechanism is not understood. Notable laboratory findings at diagnosis are typically mediated by cytokine production associated with the lymphoma, and may include anemia, thrombocytosis, leukocytosis, eosinophilia, lymphopenia, and hypoalbuminemia. The degree of these

Epidemiology

Hodgkin lymphoma is cancer of lymphoid tissue accounting for approximately 9000 new cases every year in the United States, and 1200 deaths. The median age of diagnosis is 35 years, but there is a bimodal distribution with the highest peak in the early 20s and then a rising incidence after the age of 60.

Pathology

Pathologically, Hodgkin lymphoma is broadly categorized as either classical Hodgkin lymphoma (CHL) or nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) (Table 1). CHL

TABLE 1 Classification of Hodgkin Lymphoma	
Classic Hodgkin lymphoma	95%
Nodular sclerosis	75%
Mixed cellularity	15%
Lymphocyte rich	5%
Lymphocyte depleted	5%
Nodular lymphocyte-predominant Hodgkin lymphoma	5%

includes four histologic subtypes, which are grouped together because of a common malignant cell—the Hodgkin Reed-Sternberg (HRS) cell—and shared natural history, prognosis, and approach to therapy. These subtypes, in order of frequency, are Nodular Sclerosis (NSHL), Mixed Cellularity (MCHL), Lymphocyte Rich (LRHL), and Lymphocyte depleted (LD).

NSHL accounts for approximately 70% of new cases of HL in the United States, and occurs with a female predominance. All other subtypes of CHL occur more frequently in men. NLPHL accounts for only about 5% of new cases of HL each year, and occurs more commonly in men than in women.

Risk Factors

Most cases of Hodgkin lymphoma are sporadic, although a few risk factors have been identified. An increased risk of CHL among first-degree family members points to a heritable genetic susceptibility. Identical twins of CHL patients have a markedly increased risk of developing CHL, whereas other first-degree relatives are four times likelier to develop CHL than the general population. Given the low overall incidence in the population, the absolute risk of CHL among first-degree relatives remains quite low.

NSHL occurs more frequently in the Western world and is associated with a favorable socioeconomic status. MCHL, on the other hand, is the most common subtype in developing countries, and is often associated with underlying Epstein-Barr virus (EBV) infection, but the absolute risk of developing CHL after infectious mononucleosis remains low at approximately 1 in 1000. The median time to CHL diagnosis after infectious mononucleosis is 4 years. HIV infection is associated with a tenfold increased risk of developing CHL, related to the immune suppression and increased rate EBV transformation. Risk is similarly increased in other immunosuppressive states such as congenital immunodeficiency and after solid organ or hematopoietic stem cell transplantation.

Clinical Manifestations

CHL most commonly presents with painless lymphadenopathy. The most common locations are in the neck (75%) and mediastinum (60%), followed by the axillae, retroperitoneal, and inguinal lymph nodes. Nodes are generally mobile and firm or rubbery on examination. The spleen is involved in approximately 20% of cases. Extranodal sites are uncommonly involved, including bone marrow, lungs, liver, bone, and other sites. Patients with bulky mediastinal disease may present with dyspnea, chest pressure, or cough, though even large mediastinal masses may be asymptomatic. Superior vena cava syndrome is uncommon. Systemic “B” symptoms (fever >38°C, unintentional weight loss of >10% of body weight over 6 months, and drenching night sweats) occur in approximately one third of patients at diagnosis. Generalized pruritus is not considered a “B” symptom but is present in a minority of patients, in whom it may presage the diagnosis by many months. Pain at involved nodal or bony sites with alcohol ingestion is rarely present, but is unique and the mechanism is not understood. Notable laboratory findings at diagnosis are typically mediated by cytokine production associated with the lymphoma, and may include anemia, thrombocytosis, leukocytosis, eosinophilia, lymphopenia, and hypoalbuminemia. The degree of these

laboratory abnormalities typically tracks with increased disease burden. Hypercalcemia is an uncommon presenting feature, and is most commonly caused by increased production of calcitriol. Rarely, CHL can present with paraneoplastic cholestatic liver disease characterized by fevers and high conjugated bilirubin levels, but usually without frank infiltration by Hodgkin lymphoma on liver biopsy.

NLPHL presents in the majority of cases with localized painless peripheral adenopathy. Most patients are men between the ages of 30 and 50. The systemic “B” symptoms and laboratory abnormalities occasionally seen at presentation in CHL are rare in NLPHL.

Diagnosis

Diagnosis of HL requires pathologic examination, ideally performed by excisional biopsy, which obtains the largest amount of tissue for analysis and preserves tissue architecture. Hodgkin lymphoma may be difficult to diagnose on small biopsies because the malignant cells represent only about 1% of the overall tumor cellularity, whereas the majority is comprised of polyclonal reactive lymphocytes, neutrophils, and eosinophils. Inadequate tissue sampling may therefore falsely suggest a reactive inflammatory process as opposed to the underlying malignancy. Core needle or mediastinoscopic biopsies may be used for deep nonpalpable lesions where excisional surgical biopsies are not possible. Fine-needle aspiration (FNA) should not be used for diagnosis when lymphoma is suspected in the differential diagnosis because of the high rate of false-negative results. On histologic examination of CHL, the involved tissue is effaced by an infiltration of malignant Hodgkin Reed-Sternberg (HRS) cells amidst a rich inflammatory background. The classic HRS cell is typically large with abundant cytoplasm and a bilobed nucleolus, each with a single large eosinophilic nucleolus giving it the classic “owl’s eye” appearance (Figure 1). Mononuclear variants also occur. By immunohistochemistry, the HRS cells usually stain positively for surface markers CD30 and CD15, and are usually negative for the pan-lymphoid marker CD45 and the B-cell marker CD20. The inflammatory microenvironment in NSHL is further characterized by dense bands of fibrosis from which its name is derived.

NLPHL is similarly characterized pathologically by infrequent atypical malignant cells amidst a polyclonal inflammatory microenvironment composed primarily of small lymphocytes in large nodular meshworks of follicular dendritic cells. The malignant lymphocyte-predominant (LP) cell is quite different from the HRS cells of CHL, in that it expresses CD45 and CD20, and does not express CD30 or CD15.

Differential Diagnosis

The differential diagnosis of lymphadenopathy is quite broad, and includes a wide range of malignancies, including lymphomas and solid tumors, infections, autoimmune diseases, hypersensitivity

Figure 1 Classic Reed-Sternberg cell demonstrating large size, multinucleated nucleus, and prominent eosinophilic nucleolus.

syndromes, and others. Diagnostic evaluation is guided by the clinical presentation as well as the size, location, and examination characteristics of the adenopathy.

Staging and Risk Stratification

Following confirmation of a pathologic diagnosis, patients with Hodgkin lymphoma undergo staging studies to determine the extent of disease involvement. Unlike many other cancers, Hodgkin lymphoma is highly curable regardless of stage, but the staging does assist in treatment selection and risk stratification. Staging is based on the Cotswold modification of the Ann Arbor Staging system (Table 2). This system was developed for Hodgkin lymphoma based on the tendency for HL to spread predictably via lymphatic spread to adjacent nodal regions. Limited-stage disease is therefore confined to either a single lymph-node region (stage I) or multiple lymph-node regions on a single side of the body (stages II), whereas advanced-stage disease involves nodal regions on both sides of the diaphragm (stage III) or with extensive involvement of an extranodal site (stage IV) such as the lungs, liver, bone, or bone marrow. Additional letters may be added to the numeric stage to denote the absence or presence of “B” symptoms (“A” or “B”), bulky disease measuring greater than 10 cm (“X”) or splenic involvement (“S”). Stage IIB disease is typically categorized as advanced stage.

Staging begins with a physical examination with careful attention paid to all palpable lymph node regions, the spleen, and Waldenstrom’s ring. Radiographic staging is performed with whole-body computed tomographic (CT) scans, ideally in conjunction with a Positron Emission Tomography (PET) scan as a combined PET/CT scan, which enhances the sensitivity over CT scans alone. Bone-marrow biopsy is often not performed in modern staging because of the enhanced sensitivity of PET scans in detecting bone marrow involvement in HL, which is often patchy in nature, and because of the incorporation of systemic therapy into the treatment plans of virtually all patients with either limited-stage or advanced-stage disease, ensuring that any sites of subclinical disease are still exposed to lymphoma-directed therapy. Similarly, staging laparotomy is never performed for modern staging given the sensitivity of modern radiographic techniques.

Additional pretreatment studies include routine laboratory testing with a complete blood count and differential; erythrocyte sedimentation rate; and complete metabolic panel including liver function, renal function, calcium, and albumin. Given the

TABLE 2 Ann Arbor Staging System (Cotswold Modification)

STAGE	DEFINITION
I	Confined to single lymph node region or limited involvement of a single extranodal site (IE)
II	Confined to two or more lymph node regions on the same side of the diaphragm
III	Lymph node regions involved on both sides of the diaphragm
IV	Extensive involvement of one or more extranodal sites
MODIFIERS	
E	Localized focus of extranodal disease or localized extension of nodal disease into an extranodal site (e.g., hilar lymph node invading the lung)
A	Absence of “B” symptoms: fever ($>38^{\circ}\text{C}$), drenching night sweats, or unintentional loss of greater than 10% body weight over the previous 6 months.
B	Presence of “B” symptoms
S	Splenic involvement (the spleen is considered a nodal site)
X	Bulky disease (greater than 10 cm or greater than 1/3 the width of the maximal intrathoracic diameter)

association of HIV infection in a minority of cases, HIV antibody testing at baseline is recommended. Assessment of left ventricular function with an echocardiogram or MUGA scan, as well as pulmonary evaluation with pulmonary function testing, should be checked in anticipation of doxorubicin and bleomycin containing therapy, respectively. Although most chemotherapy for Hodgkin lymphoma carries only minimal risk of sterility, fertility counseling for patients in their childbearing years is recommended before initiation of therapy.

Risk Stratification

Although Hodgkin lymphoma is a highly curable disease, clinical and laboratory variables can stratify patients into lower and higher risk groups. The cure rate for limited-stage CHL with modern therapy is greater than 85%. Identified risk factors can place patients into an “early favorable” or “early unfavorable” category, though, importantly, the vast majority of patients in both groups will be cured of their disease with initial therapy. Adverse risk factors denoting early unfavorable disease include age greater than 50 years, bulky mediastinal mass, involvement of more than three nodal areas, extranodal disease, presence of systemic “B” symptoms, and an elevated erythrocyte sedimentation rate.

Within advanced-stage CHL, multivariable analysis identified seven adverse risk factors that are summed to generate the International Prognostic Score (IPS). These adverse risk factors at the time of diagnosis are male sex, age greater than 45 years, stage IV disease, serum albumin <4.0 g/dL, hemoglobin concentration less than 10.5 g/dL, white blood cell count greater than 15,000/mm³, and lymphopenia (<600 cells/mL or <8% of white blood cells). Data in the modern era with ABVD (doxorubicin [Adriamycin], bleomycin [Bleoxane], vinblastine [Velban] and dacarbazine [DTIC-Dome]) show 5-year freedom from progression ranging from 62% in the highest risk patients to 88% in the lowest risk patients, and 5-year overall survival ranging from 67% to 98%.

Prognosis in NLPHL is generally more favorable than that in classical HL, owing to a significantly more indolent natural history and higher likelihood of presenting as localized disease. Although late relapses may occur, very few patients die of NLPHL.

Treatment

Limited-Stage Classical Hodgkin Lymphoma

Standard therapy for limited-stage (stage I-IIA) CHL has most commonly included combined-modality therapy with systemic chemotherapy followed by involved-field radiation. This standard evolved over many years, during which time randomized clinical trials demonstrated improved overall survival favoring combined-modality therapy compared to radiation alone, and showed no benefit to extended-field radiation over narrower radiation fields.

Patients with nonbulky limited-stage disease and absence of adverse risk factors (“early favorable”) may receive only 2 cycles of chemotherapy with ABVD followed by 20 Gy of radiation therapy to all involved fields. Bulk is defined as greater than one third of the maximum thoracic diameter greater than or equal to 10 cm in maximal diameter. Among patients with limited-stage disease with presenting bulk or presence of adverse risk factors (“early unfavorable”), combined-modality therapy is intensified to consist of 4 cycles of ABVD followed by 30 Gy of involved-field radiotherapy. Similar excellent results have been obtained with the Stanford V regimen, which is an 8- to 12-week chemotherapy program including mechlorethamine (Mustargen), doxorubicin, vinblastine, prednisone, vincristine (Oncovin, Vincasar PFS), bleomycin, and etoposide (Toposar),¹ along with involved-field radiation therapy. Treatment intensification with the escalated BEACOPP regimen (bleomycin, etoposide,¹ doxorubicin [Adriamycin], cyclophosphamide (Cytoxan), vincristine [Oncovin], procarbazine [Matulane] and prednisone) has been compared to ABVD in early unfavorable disease, each followed by involved-field radiation therapy, and

found no difference in overall survival to favor the intensified approach. ABVD remains the most commonly employed chemotherapy backbone for limited-stage Hodgkin lymphoma given the tolerability of the regimen and reduced reliance on alkylating agents.

Radiation therapy in young patients with Hodgkin lymphoma has prompted safety concerns given the increased incidence of late toxicities from mediastinal radiotherapy, including increased risk of secondary malignancies such as breast cancer, thyroid cancer, and lung cancer, as well as heart disease and lung disease. A large randomized trial comparing chemotherapy alone to combined-modality therapy showed a small increased risk of recurrence in patients who receive chemotherapy alone, but an improved overall survival 10 years after completion of therapy favoring chemotherapy alone, due to an excess of nonlymphoma deaths in the irradiated patients. Notably, the radiation used in this trial was more extensive than modern involved-field radiotherapy, which may have overestimated the rate of late radiation events, but 94% of patients receiving ABVD alone remained alive and well 12 years later, demonstrating outstanding results from the radiation-sparing approach. These data support consideration of ABVD chemotherapy alone for 4 to 6 cycles in patients with nonbulky limited-stage Hodgkin lymphoma. Patients with bulky disease have not been included in a randomized trial sparing radiation, and so combined-modality therapy remains the standard of care for such patients. Ongoing clinical trials in limited-stage disease are evaluating the role of early interim PET scanning in guiding intensity of chemotherapy and inclusion of radiation therapy.

Advanced-Stage Classical Hodgkin Lymphoma

Advanced-stage CHL (Ann Arbor stages IIB-IV) had been a nearly uniformly fatal disease before the development of effective combination chemotherapy with the introduction of MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) at the National Cancer Institute in 1964. ABVD subsequently emerged as an alternative to MOPP and was confirmed to have improved efficacy and reduced toxicity in a randomized trial that defined it as the standard of care. Modern outcomes with ABVD for advanced-stage disease produce 5-year freedom from progression and overall survival of 78% and 90%, respectively. ABVD is administered on days 1 and 15 of a 28-day cycle for 6 total cycles. Consolidative radiation therapy is not routinely administered in advanced-stage disease, except in the setting of an incomplete response to chemotherapy alone, or to bulky sites of disease at presentation.

The escalated BEACOPP regimen has been extensively explored as an alternative to ABVD, and does modestly decrease the rate of recurrence, but without a clear impact on overall survival. Stanford V has also been evaluated in several randomized trials of advanced-stage disease without evidence of superiority over ABVD. In the absence of an overall survival benefit favoring escalated BEACOPP or Stanford V, and the increased treatment-associated toxicity associated with intensified therapy, most practitioners in North America continue to favor ABVD as the standard of care for advanced-stage disease, although this remains a subject of worldwide debate.

Treatment of Relapsed Hodgkin Lymphoma

Although the majority of patients with CHL will be cured with initial treatment, approximately 15% of patients will relapse and require additional therapy. Patients who relapse with localized disease greater than 1 year after completion of initial therapy and without systemic “B” symptoms may be treated with conventional-dose second-line chemotherapy followed by involved-field radiation. The majority of patients, however, will relapse in less than 12 months or with more advanced disease, for which conventional-dose chemotherapy offers a disappointingly low chance of cure. In such patients, second-line chemotherapy followed by high-dose chemotherapy with autologous stem cell support offers a cure rate approaching 50% and is the modern treatment of choice. Patients who relapse after high-dose

¹Not FDA approved for this indication.

chemotherapy may be candidates for allogeneic stem cell transplantation with curative intent, but success rates are low, and risks of treatment-associated morbidity and mortality are significant.

For patients who are not candidates for intensive therapy, or who relapse after stem cell transplantation, multiple chemotherapy options are available that may offer palliative disease control. An appealing option at relapse is the antibody drug conjugate brentuximab vedotin (Adcetris), which is a monoclonal antibody against CD30 bound to the microtubule toxin monomethyl auristatin E (MMAE). This targeted therapy is FDA approved for relapsed Hodgkin lymphoma based on an overall response rate of 75% and complete response rate of 34% in patients relapsing after high-dose chemotherapy and autologous stem cell transplantation. Current efforts are evaluating earlier use of brentuximab vedotin. The phase III double blind placebo-controlled AETHERA trial studied brentuximab consolidation therapy for patients in remission immediately after autologous stem cell transplantation for high risk relapsed Hodgkin lymphoma. Patients randomized to receive brentuximab consolidation had a significantly improved progression-free survival of 43 months, compared with 24 months in placebo-treated patients. No difference in overall survival has yet been observed in this trial, but patients progressing on the placebo arm did cross over and receive brentuximab at that time. These results led to FDA-approval of brentuximab vedotin in this setting. Clinical trials incorporating brentuximab vedotin into upfront therapy in both limited- and advanced-stage Hodgkin lymphoma are ongoing. Most recently, immune checkpoint inhibitors have emerged as highly active agents in relapsed classical Hodgkin lymphoma. Hodgkin Reed-Sternberg cells carry frequent genomic amplifications of chromosome 9p24.1, leading to constitutive expression of programmed death 1 (PD-1) ligands, which interact with PD-1 on the surface of T-cells in the microenvironment promoting immune evasion. This led to a phase I study of the PD-1 inhibitor nivolumab (Opdivo)¹ in relapsed/refractory Hodgkin lymphoma, and found an overall response rate of 87%, some of which were durable. Similarly encouraging activity has been observed with an additional PD-1 inhibitor, pembrolizumab (Keytruda).¹ Further investigation of these agents as monotherapy and in combination is ongoing.

Treatment of Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) follows a unique natural history from CHL, and is typically treated with less-intensive therapy. Limited-stage NLPHL usually presents at peripheral locations rather than the mediastinum, and may be treated with involved-field radiation alone (without chemotherapy), which produces a 10-year overall survival in excess of 95%. Advanced-stage NLPHL is uncommon, but may be treated with rituximab (Rituxan)¹ because of the CD20 positivity of the malignant LP cells, with encouraging single-agent activity. Combination chemotherapy with either ABVD or with alkylator-based regimens is also effective.

Monitoring

Patients on therapy for Hodgkin lymphoma are evaluated for response using PET and CT scans, ideally as a combined-modality PET/CT scan. A complete response on PET/CT following 2 cycles of chemotherapy predicts for an extremely favorable prognosis, while a persistent positive PET scan is associated with a high rate of treatment failure. Clinical trials evaluating treatment intensification for patients with positive PET scans after 2 cycles of chemotherapy are ongoing, but presently there is no evidence that intensified therapy overcomes the negative prognostic effect of interim PET positivity, and so treatment modification based on interim PET results is not recommended outside of a clinical trial. Patients undergoing therapy for Hodgkin lymphoma are also evaluated with routine blood counts and chemistries to assess for

treatment-associated marrow and organ toxicity. Patients receiving bleomycin are typically evaluated every 2 cycles with repeat pulmonary function tests to detect early evidence of bleomycin lung injury, though the predictive value of pulmonary function testing is controversial. After completion of therapy, PET/CT scans should also be used for end-of-treatment restaging, where it increases sensitivity over CT scans alone, particularly in the assessment of residual masses, which often represent residual scar tissue and debris of successfully treated disease.

Once patients achieve remission, they are followed by their oncologist in cooperation with their primary care physician to assess for relapse, as well as late treatment-associated toxicities. Patients are monitored with periodic history and physical examination. CT scans are typically performed every 6 months for 2 to 3 years after completion of therapy, and thereafter only if prompted by concerning signs, symptoms, or physical findings. There is no role for PET scans in the routine follow-up of Hodgkin lymphoma after remission has been achieved. After completion of radiographic surveillance, periodic history and physical examination continue, as does laboratory evaluation, to monitor for the development of uncommon late toxicities, including secondary malignancies, heart disease, and lung disease. Specific monitoring is dependent in part on the precise treatment the patient received.

Complications

Combination chemotherapy may be associated with fatigue, bone marrow suppression, increased susceptibility to infection, gastrointestinal upset, constipation, peripheral neuropathy, and mouth sores, among other complications. Doxorubicin carries a low risk of myocardial injury and congestive heart failure, and bleomycin carries a risk of lung injury, which may be life threatening. The risk of bleomycin lung injury persists lifelong, and may be precipitated by exposure to high inspired fractions of oxygen or other pulmonary insults. Risks of myelodysplasia and secondary leukemia, as well as impaired fertility, are rare after ABVD, but occur with increased frequency after MOPP, escalated BEACOPP, and high-dose chemotherapy.

Radiation-associated toxicities may occur decades after completion of therapy and are a function of dose and volume of tissue exposure. Secondary malignancies steadily increase beginning approximately a decade after completion of therapy, and include breast cancer, lung cancer, thyroid cancer, gastrointestinal cancers, urogenital cancers, melanoma, and non-Hodgkin lymphomas, among others. Age-appropriate cancer screening is recommended, as well as consideration of breast MRI for women who received mediastinal radiation as children or young adults.

Mediastinal radiation, particularly in combination with doxorubicin-containing chemotherapy, confers multiple cardiac risks to be aware of in long-term follow-up, including premature coronary artery disease, cardiomyopathy, valvular heart disease, and restrictive pericarditis. Lung exposure to radiation, particularly in concert with bleomycin, also confers a risk of radiation pneumonitis or late radiation fibrosis. Radiation to the neck may be associated with dental caries, dry mouth, thyroid dysfunction, and cerebrovascular disease. Long-term care of the Hodgkin lymphoma patient requires attention to risk not only of relapse, but of the many late complications of therapy that may have substantial impact on long-term morbidity and mortality in Hodgkin lymphoma survivors.

IRON DEFICIENCY ANEMIA

Method of

Paul Paulman, MD

CURRENT DIAGNOSIS

Symptoms

- Fatigue
- Poor exercise tolerance
- Weakness
- Irritability
- Poor concentration
- Dry mouth
- Headache
- Pica

Signs

- Pallor
- Systolic heart murmur if anemia is present
- Atrophy of lingual papillae
- Koilonychia
- Chlorosis

Laboratory Findings

- Decreased iron seen on bone marrow aspirate (gold standard)
- Low serum ferritin (diagnostic)
- Low serum iron level
- High serum iron-binding capacity
- Low serum hemoglobin
- Low mean corpuscular hemoglobin
- Low mean corpuscular volume
- Variations in size and shape of red blood cells

CURRENT THERAPY

Oral Replacement

- Ferrous sulfate (or other equivalent iron preparation) 325 mg three times daily.
- Add ascorbic acid tablet 500 mg with each iron tablet to increase iron absorption.
- Consider enteric-coated tablets to decrease gastrointestinal problems associated with oral iron therapy.

Parenteral Replacement

- If oral therapy is not tolerated, parental preparations including iron dextran, iron sucrose, or ferric gluconate may be used.

Unstable Patient

- If the patient is hemodynamically unstable due to anemia, consider blood transfusion.

Treatment Endpoint

- Iron deficiency has been corrected if the serum ferritin is 50 ng/mL or more.

Epidemiology

Iron is necessary for production of erythrocytes and the normal functioning of several iron-containing cellular enzymes. Iron deficiency is defined as the decrease of total iron stores in the body. Iron deficiency anemia results when iron deficiency is severe enough to decrease erythropoiesis. The most common cause of iron deficiency in the US adult population is blood loss. The most common sources of blood loss are menstrual and gastrointestinal. Other causes of iron deficiency include inadequate intake during high-demand states such as pregnancy, early childhood, or erythropoietin therapy. A diet low in iron-rich foods (vegetarian or vegan) can lead to iron deficiency.

Gastrointestinal diseases including Crohn's disease, sprue, and postgastrectomy states can decrease iron absorption from the gastrointestinal tract, resulting in iron deficiency. Chronic inflammatory states can lead to decreased use of available iron stores, leading to symptoms of iron deficiency.

Iron deficiency is the most common micronutrient deficiency in the world. Iron deficiency affects approximately 2% to 5% of children and adolescents in the United States and 4% of the US adult population, including 20% of women of childbearing age, 50% of pregnant women, and 2% of men.

Risk Factors

Risk factors for iron deficiency include age, socioeconomic status, sex, diet, disease, and medical treatment. Infants, children, and adolescents are at risk, especially during periods of rapid growth. Low socioeconomic status, including minority population group and low income, increase the risk for iron deficiency. Risk is increased in women during the childbearing years and during pregnancy and breastfeeding. Diets low in iron-rich foods, including vegan and vegetarian diets, increase the risk.

Any illness or therapy that leads to decreased absorption of iron or loss of blood also increases the risk. Gastrointestinal diseases causing blood loss or decreased iron absorption can lead to iron deficiency. Antacids cause decreased iron absorption and nonsteroidal antiinflammatory drugs (NSAIDs) cause gastrointestinal blood loss. Erythropoietin therapy depletes iron stores because of increased hematopoiesis. Frequent phlebotomy, including repetitive blood donation or treatment for polycythemia or hemochromatosis, decreases iron stores.

Pathophysiology

Total body iron stores for men are approximately 3.5 g and for women are about 2.5 g. More than 70% of body iron is found in hemoglobin, and the remainder is contained in myoglobin, tissue enzymes, and storage or transport proteins. Iron absorption takes place almost exclusively in the duodenum and upper jejunum. In a

IRON DEFICIENCY ANEMIA

Method of

Paul Paulman, MD

CURRENT DIAGNOSIS

Symptoms

- Fatigue
- Poor exercise tolerance
- Weakness
- Irritability
- Poor concentration
- Dry mouth
- Headache
- Pica

Signs

- Pallor
- Systolic heart murmur if anemia is present
- Atrophy of lingual papillae
- Koilonychia
- Chlorosis

Laboratory Findings

- Decreased iron seen on bone marrow aspirate (gold standard)
- Low serum ferritin (diagnostic)
- Low serum iron level
- High serum iron-binding capacity
- Low serum hemoglobin
- Low mean corpuscular hemoglobin
- Low mean corpuscular volume
- Variations in size and shape of red blood cells

CURRENT THERAPY

Oral Replacement

- Ferrous sulfate (or other equivalent iron preparation) 325 mg three times daily.
- Add ascorbic acid tablet 500 mg with each iron tablet to increase iron absorption.
- Consider enteric-coated tablets to decrease gastrointestinal problems associated with oral iron therapy.

Parenteral Replacement

- If oral therapy is not tolerated, parental preparations including iron dextran, iron sucrose, or ferric gluconate may be used.

Unstable Patient

- If the patient is hemodynamically unstable due to anemia, consider blood transfusion.

Treatment Endpoint

- Iron deficiency has been corrected if the serum ferritin is 50 ng/mL or more.

Epidemiology

Iron is necessary for production of erythrocytes and the normal functioning of several iron-containing cellular enzymes. Iron deficiency is defined as the decrease of total iron stores in the body. Iron deficiency anemia results when iron deficiency is severe enough to decrease erythropoiesis. The most common cause of iron deficiency in the US adult population is blood loss. The most common sources of blood loss are menstrual and gastrointestinal. Other causes of iron deficiency include inadequate intake during high-demand states such as pregnancy, early childhood, or erythropoietin therapy. A diet low in iron-rich foods (vegetarian or vegan) can lead to iron deficiency.

Gastrointestinal diseases including Crohn's disease, sprue, and postgastrectomy states can decrease iron absorption from the gastrointestinal tract, resulting in iron deficiency. Chronic inflammatory states can lead to decreased use of available iron stores, leading to symptoms of iron deficiency.

Iron deficiency is the most common micronutrient deficiency in the world. Iron deficiency affects approximately 2% to 5% of children and adolescents in the United States and 4% of the US adult population, including 20% of women of childbearing age, 50% of pregnant women, and 2% of men.

Risk Factors

Risk factors for iron deficiency include age, socioeconomic status, sex, diet, disease, and medical treatment. Infants, children, and adolescents are at risk, especially during periods of rapid growth. Low socioeconomic status, including minority population group and low income, increase the risk for iron deficiency. Risk is increased in women during the childbearing years and during pregnancy and breastfeeding. Diets low in iron-rich foods, including vegan and vegetarian diets, increase the risk.

Any illness or therapy that leads to decreased absorption of iron or loss of blood also increases the risk. Gastrointestinal diseases causing blood loss or decreased iron absorption can lead to iron deficiency. Antacids cause decreased iron absorption and nonsteroidal antiinflammatory drugs (NSAIDs) cause gastrointestinal blood loss. Erythropoietin therapy depletes iron stores because of increased hematopoiesis. Frequent phlebotomy, including repetitive blood donation or treatment for polycythemia or hemochromatosis, decreases iron stores.

Pathophysiology

Total body iron stores for men are approximately 3.5 g and for women are about 2.5 g. More than 70% of body iron is found in hemoglobin, and the remainder is contained in myoglobin, tissue enzymes, and storage or transport proteins. Iron absorption takes place almost exclusively in the duodenum and upper jejunum. In a

non-iron-deficient state, only about 6% to 10% of iron from food is absorbed (1 mg of 15 mg/day of dietary iron). Factors that increase iron absorption from the gut include ingestion of heme (meat) iron, iron-deficient states, and coadministration of vitamin C (ascorbic acid). Factors that decrease iron absorption include ingestion of certain foods including vegetable fiber phytates, tea tannates, bran, and medications including tetracyclines and antacids.

Iron deficiency develops in stages. During the early stage, iron needs exceed iron intake and body iron stores are depleted, causing an increase in absorption of dietary iron. As this process continues, erythropoiesis is impaired, leading to iron deficiency anemia, and dysfunction of iron-containing cellular enzymes can occur. This enzyme dysfunction can contribute to the fatigue and loss of stamina seen in patients with iron deficiency anemia. Iron deficiency during childhood can result in deficiencies in growth and cognitive function.

Prevention

Prevention of iron deficiency is focused on providing supplemental dietary iron to populations at risk for iron deficiency. Current recommendations include elemental iron supplementation (1 mg/kg/d) for breast-fed infants after 6 months of age and iron supplementation of infant formula (12 mg/L elemental iron) for formula-fed infants. Iron-enriched cereals should be among the first solid foods offered to infants. Whole cow's milk should be avoided during the first year of life to decrease the possibility of occult gastrointestinal bleeding. Supplemental iron should be taken during pregnancy and breast-feeding.

Clinical Manifestations

Patients with iron deficiency may be asymptomatic. The presence of symptoms and signs of iron deficiency depend on the degree of deficiency, the time course of the development of iron deficiency, and the overall physiologic state of the patient. Common symptoms of iron deficiency include fatigue, weakness, irritability, poor concentration, exercise intolerance, dry mouth, and headache. Severe iron deficiency can cause pica, a craving to eat substances such as ice, dirt, clay, or paint. Signs of iron deficiency include pallor and a systolic heart murmur if anemia is present, alopecia, atrophy of lingual papillae, koilonychia, and chlorosis.

Diagnosis

The gold standard for diagnosis of iron deficiency is the demonstration of decreased iron available for erythropoiesis on a bone marrow aspiration sample. The wide availability of reliable serum iron markers makes bone marrow sampling for diagnosis of iron deficiency unnecessary in most cases. A low serum iron is characteristic of both iron deficiency and anemia of chronic disease. Serum total iron binding capacity is decreased in iron deficiency and elevated in anemia of chronic disease. Serum iron and total iron binding capacity are often ordered together. Many authorities think serum ferritin determination is the most useful laboratory test for iron deficiency. Ferritin levels reflect the quantity of iron stored in the reticuloendothelial system. A low serum ferritin level is diagnostic of iron deficiency. Serum ferritin levels can be falsely elevated in the presence of inflammation.

The diagnosis of iron deficiency anemia requires a decline in serum hemoglobin to less than 13 g/dL in men or 12 g/dL in women along with a decreased mean corpuscular volume and mean corpuscular hemoglobin and the presence of iron deficiency. Other findings in iron deficiency anemia include variation in erythrocyte shape and size (poikilocytosis and anisocytosis) and elevation in the coefficient of red blood cell distribution width (RDW).

Because gastrointestinal blood loss is a common cause of iron deficiency anemia, patients who present with iron deficiency anemia should be considered for appropriate screening for gastrointestinal conditions, including malignancies.

TABLE 1 Difference Between Iron Deficiency Anemia and Anemia of Chronic Illness

TEST	IRON DEFICIENCY ANEMIA	ANEMIA OF CHRONIC ILLNESS
Serum iron	Low	Low
Ferritin	Low	Increased
Red cell morphology	Variable	Normal
C-reactive protein	Normal	Increased

Differential Diagnosis

The differential diagnosis of iron deficiency includes causes of fatigue and exercise intolerance such as hypothyroidism, electrolyte disturbances due to diuretic therapy, left ventricular dysfunction, chronic lung disease, malignancies, or liver disease.

Anemia of chronic disease can mimic iron deficiency anemia. Differentiating characteristics of the two types of anemia can be found in Table 1.

Treatment

Iron may be replaced via oral or intravenous routes. The most cost-effective oral iron preparation is a non-enteric-coated ferrous sulfate tablet. The most common oral iron replacement regimen consists of one 325 mg ferrous sulfate tablet (Feosol) by mouth three times daily. Each 325 mg ferrous sulfate tablet contains 65 mg of elemental iron.

Other iron salts, ferrous gluconate (Fergon) and ferrous fumarate (Ferro-Sequels) are available for oral replacement. The absorption of oral iron is enhanced by taking the pills on an empty stomach or with an ascorbic acid tablet (500 mg). Because of the gastric distress often caused by oral iron replacement, most practitioners prescribe enteric-coated iron tablets.

Patients who cannot take or cannot tolerate oral iron can be treated with intravenous iron preparations, iron dextran (InFeD), ferric carboxymaltose, iron sucrose (Venofer),¹ ferric gluconate (Ferrlecit), or ferumoxytol (Feraheme). Because of the pain associated with the injection and other problems, intramuscular iron is seldom used.

Patients who are severely anemic and hemodynamically unstable may be candidates for blood transfusion. To determine the total dose of iron needed to correct the deficiency, the total iron deficit (depleted stores plus the deficit in red cell hemoglobin iron) should be calculated before beginning therapy. Because the most common cause of iron deficiency is blood loss, the management of iron deficiency should include identification of the source and cause of blood loss.

Monitoring

The earliest marker for successful iron replacement is an increase in the reticulocyte count, which occurs within 5 to 10 days of initiation of iron replacement. A hemoglobin increase of 2 g/dL is considered an appropriate response to oral iron replacement. Complete blood counts should be obtained at 1 month and 2 months after beginning replacement therapy. Iron deficiency should be corrected after 2 months of replacement therapy. Treatment of iron deficiency should continue until the serum ferritin reaches a level of 50 ng/mL. Darkening of stools after 2 or 3 days of starting oral iron replacement is a reliable marker of compliance.

Complications

If properly treated, iron deficiency has few complications in adults. Untreated iron deficiency in infants and small children can lead to cognitive development and growth deficits. Treating iron deficiency without identifying the source and cause of blood loss could result in delay or failure to diagnose gastrointestinal malignancies or other serious clinical problems.

MULTIPLE MYELOMA

Method of

S. Vincent Rajkumar, MD; and Robert A. Kyle, MD

CURRENT DIAGNOSIS

- Malignant clonal plasma cell disorder
- Characterized by presence of a monoclonal immunoglobulin in the serum or urine in most patients
- Typical manifestations include anemia, osteolytic bone lesions, and renal failure
- Initial workup should include a bone marrow aspiration and biopsy with fluorescent in situ hybridization studies to determine molecular cytogenetic type
- Standard risk: trisomies (hyperdiploidy), t(11;14), and t(6;14)
- Intermediate risk: t(4;14)
- High risk: 17p-, (t14;16) or t(14;20)

CURRENT THERAPY

- Do not begin treatment until symptomatic multiple myeloma develops (CRAB: calcium elevated, renal failure, anemia, bone lesions) or other myeloma defining events are present.
- Decide whether an autologous stem cell transplant is feasible. If it is, one must avoid melphalan (Alkeran) therapy as initial treatment.
- Initial therapy is typically consists of a triplet regimen such as lenalidomide (Revlimid), bortezomib (Velcade), and dexamethasone¹ (VRd)
- Patients who are candidates for autologous stem cell transplantation should collect stem cells after 3–4 cycles of induction. After collection, patients proceed to either early transplantation, or resume initial therapy and postpone transplant until relapse.
- Patients who are not stem cell transplant candidates receive initial therapy for a duration of approximately 12 months. Frail patients can be treated with the doublet regimen of Rd, in which case therapy is continued until progression if tolerated.
- Relapsed or refractory myeloma should be treated with one of the active drugs given alone or in combination. Active agents include thalidomide, lenalidomide, bortezomib, carfilzomib (Kyprolis), pomalidomide (Pomalyst), daratumumab (Darzalex), ixazomib (Ninlaro), elotuzumab (Empliciti), panobinostat (Farydak), corticosteroids, anthracyclines, and alkylators.

¹Not FDA approved for this indication.

Epidemiology

In the United States, multiple myeloma constitutes 1% of all malignant diseases and slightly more than 10% of hematologic malignancies. The annual incidence is 4 to 5 per 100,000; the incidence in African Americans is twice that in whites. The apparent recent increase in rates is probably caused by increased availability and use of medical facilities and improved diagnostic techniques, particularly in the older population. The median age at diagnosis is approximately 70 years.

Risk Factors

The cause of multiple myeloma is unclear. Exposure to radiation might play a role. Persons in agricultural occupations who are exposed to pesticides, herbicides, or fungicides have an increased risk of multiple myeloma. Benzene and petroleum products, hair dyes, engine exhaust, furniture worker products, obesity, and chronic immune stimulation have also been reported as risk factors. The risk of developing multiple myeloma is higher for patients with a first-degree relative with the disease. Clusters of two or more first-degree relatives or identical twins have been recognized.

Clinical Manifestations

Weakness, fatigue, bone pain, recurrent infections, and symptoms of hypercalcemia or renal insufficiency should alert the physician to the possibility of multiple myeloma. Anemia is present in 70% of patients at the time of diagnosis. An M protein is found in the serum or urine in more than 97% of patients with multiple myeloma by immunofixation studies and the serum-free light chain assay. Lytic lesions, osteoporosis, or fractures are present at diagnosis in 80% of patients and can be detected by conventional radiography or whole body low dose computed tomography. Magnetic resonance imaging (MRI) and positron emission tomography/computed tomography (PET/CT) are also helpful in patients who have skeletal pain but no abnormality on radiographs or when there are other clinical concerns about the extent of the disease. Hypercalcemia is present in 15% of patients, and the serum creatinine value is 2 mg/dL or greater in almost 20% of patients at diagnosis.

Diagnosis

If multiple myeloma is suspected, the patient should have, in addition to a complete history and physical examination:

- Determination of values for hemoglobin, leukocytes with differential count, platelets, serum creatinine, calcium, and uric acid
- A radiographic survey of bones, including humeri and femurs, preferably utilizing low-dose whole body computed tomography or positron emission tomography-computed tomography (PET-CT).
- Serum protein electrophoresis with immunofixation
- Quantitation of immunoglobulins, serum free light chain (FLC) assay
- Bone marrow aspirate and biopsy
- Routine urinalysis
- Electrophoresis and immunofixation of an adequately concentrated aliquot from a 24-hour urine specimen
- Fluorescence in situ hybridization (FISH)
- Measurement of β_2 -microglobulin, C-reactive protein, and lactate dehydrogenase

Box 1 lists the International Myeloma Working Group updated criteria for diagnosis of myeloma and related disorders. Metastatic carcinoma, lymphoma, leukemia, and connective tissue disorders can resemble multiple myeloma and must be considered in the differential diagnosis. Patients with multiple myeloma must be differentiated from those with monoclonal gammopathy of undetermined significance (MGUS) and smoldering (asymptomatic) multiple myeloma (SMM). Patients with MGUS and SMM may remain stable for long periods and not require treatment (see Box 1). The patient's symptoms, physical findings, and all laboratory and radiographic data must be considered in the decision to begin therapy. If there are doubts about whether to begin

Multiple myeloma is characterized by the neoplastic proliferation of clonal plasma cells. It is typically associated with a monoclonal (M) protein in the serum and/or urine.

Multiple myeloma is characterized by the neoplastic proliferation of clonal plasma cells. It is typically associated with a monoclonal (M) protein in the serum and/or urine.

Monoclonal Gammopathy of Undetermined Significance

- Serum M protein < 3 g/dL
- Clonal bone marrow–plasma cells < 10%
- Absence of end-organ damage (CRAB) attributable to a plasma cell proliferative disorder

Smoldering Multiple Myeloma

- Serum M protein \geq 3 g/dL and/or clonal bone marrow–plasma cells 10–60%
- Absence of myeloma defining events or amyloidosis

Multiple Myeloma

- Presence of clonal bone marrow plasma cells 10% or greater or biopsy proven plasmacytoma
- Presence of end-organ damage (CRAB) thought to be related to a plasma cell proliferative disorder or other myeloma defining event (clonal bone marrow plasma cells 60% or higher, serum free light chain ratio 100 or more provided involved free light chain level is 100 mg/L or more, more than one focal lesion on magnetic resonance imaging)

Abbreviations: CRAB = calcium elevated, renal failure, anemia, bone lesions; M = monoclonal.

Derived from Rajkumar SV, Dimopoulos MA, Palumbo A, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. *Lancet Oncol* 2014;15:e538-e548.

treatment, therapy should be withheld and the patient should be reevaluated in 2 to 3 months. No evidence indicates that early treatment of multiple myeloma is advantageous.

Treatment

Patients with symptomatic multiple myeloma may be classified as having high-risk, intermediate-risk, or standard-risk disease. High-risk disease is defined as the presence of del(17p), t(14;16), or t(14;20) with FISH. The presence of t(4;14) or gain of 1q is considered intermediate-risk disease. Lactate dehydrogenase, circulating plasma cells, and β_2 -microglobulin levels are additional important risk factors. Approximately 15% to 20% of patients with symptomatic multiple myeloma have high-risk disease.

If clinical trials are not available, one may separate patients into those eligible for an autologous stem cell transplant (SCT) versus those not eligible. An autologous SCT adds about 1 year of survival on average when compared with patients treated with conventional-dose chemotherapy alone.

Eligibility for autologous SCT in multiple myeloma varies from country to country. In the United States, decisions are made on a patient-by-patient basis depending on the physiologic age rather than the chronologic age. In most institutions, patients older than 70 years or with serum creatinine greater than 2.5 mg/dL, Eastern Cooperative Oncology Group (ECOG) performance status of 3 or 4, or New York Heart Association (NYHA) functional status class III or IV are considered ineligible for autologous SCT. Although patients with kidney failure may have an autologous SCT, the morbidity and mortality are higher.

Initial Therapy for Transplant-Eligible Patients

The approach to treatment of newly diagnosed myeloma in patients eligible for stem cell transplantation is summarized in Figure 1A. Bortezomib (Velcade), lenalidomide (Revlimid), dexamethasone (Decadon)¹ (VRD) is the preferred standard initial therapy for multiple myeloma. In a randomized trial conducted by the Southwest Oncology Group, VRD was superior to lenalidomide plus dexamethasone (Rd) in terms of progression free survival (PFS) and overall survival (OS). Bortezomib and dexamethasone are typically administered once weekly. In the VRD regimen lenalidomide is given at a dose of 25 mg daily on days 1–14 of a 21 day cycle. Bortezomib plus cyclophosphamide (Cytoxan) 300 mg/m² orally once weekly plus dexamethasone 40 mg once weekly (VCD) is an option for patients presenting with acute renal failure. Bortezomib should be given at weekly intervals because it is equally efficacious and is associated with less peripheral neuropathy. It is also preferable to administer bortezomib subcutaneously to diminish the risk of neuropathy. An alternative to VRD if lenalidomide is not available is bortezomib, thalidomide (Thalomid), and dexamethasone (VTD). An alternative to VRD in high-risk patients less than 65 years of age is carfilzomib (Kyprolis), lenalidomide, dexamethasone (KRD). In all regimens, it is preferable to administer dexamethasone at a dose no greater than 40 mg per week unless there is need for urgent cytoreduction as in patients with acute renal failure and cast nephropathy.

Autologous Stem Cell Transplantation

Following 3 to 4 months of induction therapy with one of the initial regimens, one must collect the stem cells in patients eligible for transplantation. The stem cells must be collected before the patient is exposed to prolonged therapy, especially melphalan (Alkeran). Granulocyte colony-stimulating factor (G-CSF, Neupogen) with or without cyclophosphamide (Cytoxan) is used for mobilizing

¹Not FDA approved for this indication.

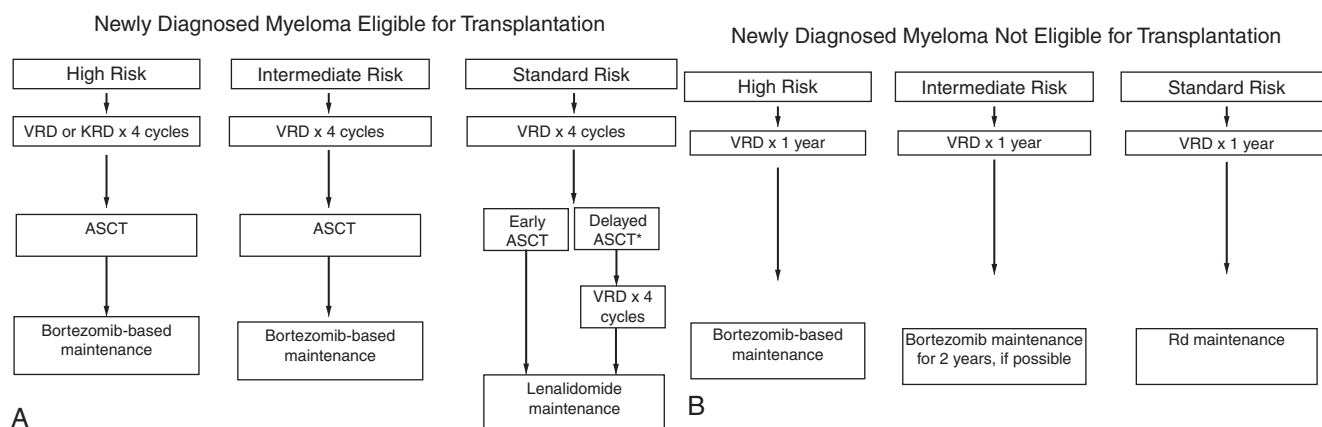

Figure 1 Approach to the treatment of newly diagnosed myeloma in patients eligible for stem cell transplantation (A) and Approach to the treatment of newly diagnosed myeloma in patients not eligible for stem cell transplantation (B). Abbreviations: KRd, carfilzomib, lenalidomide, dexamethasone; VRD, bortezomib, lenalidomide, dexamethasone; ASCT, autologous stem cell transplantation; Rd, lenalidomide plus dexamethasone. Modified from Rajkumar SV, Multiple myeloma: 2016 update on diagnosis, risk-stratification, and management. *Am J Hematol* 2016;91:720-734.

stem cells. G-CSF plus cyclophosphamide is preferred in patients who are treated with lenalidomide plus dexamethasone induction, who are older than 65 years, or who have received such therapy for over 4 months. Plerixafor (Mozobil) may also be used for mobilization of hematopoietic stem cells. It is advisable to collect 6×10^6 CD34⁺ cells/kg, which is sufficient for two transplants in patients less than 65 years of age.

The timing of autologous SCT takes into account the patient's wishes, and it may be done early (when the patient recovers from stem cell collection) or delayed until relapse. There is no difference in overall survival among patients who receive an autologous SCT immediately following collection of stem cells and those who receive it at first relapse. In general, we prefer an early transplant because this provides a better quality of life and time without therapy.

Melphalan 200 mg/m² is the preferred conditioning regimen³ for autologous SCT. Tandem transplantation is not recommended for most patients. An exception would be young patients (less than 65 years of age) with high-risk multiple myeloma, in whom such an approach can be considered on a case-by-case basis.

The mortality rate with autologous SCT is approximately 1%. Unfortunately, multiple myeloma is not eradicated, and the autologous peripheral stem cells are contaminated by myeloma cells or their precursors.

Bone marrow transplantation from an identical twin donor (syngeneic) is the treatment of choice if such a donor is available. Results are superior to allogeneic transplantation.

Maintenance Therapy Following Autologous Stem Cell Transplantation

In a large prospective study, multiple myeloma patients were given a tandem transplant and then randomized to no maintenance, pamidronate (Aredia)¹ maintenance, or pamidronate plus thalidomide maintenance. Although thalidomide improved the response rate and overall survival, it often resulted in peripheral neuropathy. Moreover, the overall survival benefit was lost with longer follow-up.

Three randomized trials have tested the value of lenalidomide as maintenance therapy following stem cell transplantation. An overall survival benefit has been observed in a meta-analysis of the three trials. This benefit appears to be mainly restricted to standard-risk patients. An increased risk of second cancers has been noted with lenalidomide maintenance and further follow-up is needed. In another randomized trial improved overall survival with bortezomib maintenance has been reported, but it is not clear whether the benefit is due to the maintenance therapy or differences in induction therapy between the two groups. We recommend lenalidomide maintenance for standard-risk patients following autologous SCT. In intermediate- and high-risk patients, we recommend bortezomib-based maintenance.

Allogeneic Transplantation

Allogeneic bone marrow transplantation (myeloablative and non-myeloablative) has been tested in myeloma, but treatment-related mortality is high and graft-versus-host disease is a troublesome problem. Further, only a small proportion of patients with multiple myeloma are eligible. Allogeneic transplantation is currently not recommended for routine use outside of a clinical trial. An exception to this are young patients with high-risk disease in first relapse after autologous transplantation who are willing to assume the high treatment-related mortality associated with allogeneic SCT.

Initial Therapy for Patients Who Are Ineligible for Autologous Stem Cell Transplantation

From the 1960s to the early 1990s, alkylating agent-based chemotherapy with oral administration of melphalan and prednisone¹ (MP) was used as initial therapy in patients who were not candidates for SCT. Subsequently, the addition of thalidomide to MP (MPT regimen) was found to produce overall survival improvement compared with MP.

Another option for patients who are not candidates for transplantation was bortezomib (Velcade) plus MP (the VMP regimen).

However, melphalan-based regimens have several adverse effects, and have fallen out of favor. In a recent randomized trial, Rd was found to be superior to MPT. Thus, the initial therapy for patients not eligible for transplantation now resembles that of transplant eligible patients. The current approach to treatment of newly diagnosed myeloma in patients not eligible for stem cell transplantation is summarized in Figure 1B. Currently, we prefer VRD as initial therapy. Other options include VCD and VTD. For frail patients, the doublet regimen of Rd can be used.

We continue the initial chemotherapy regimen for approximately 12 months followed usually by Rd maintenance in standard risk patients and bortezomib-based maintenance in intermediate and high risk patients. The addition of daratumumab (Darzalex) to VMP has shown better response rates and progression free survival compared with VMP, but benefit in terms of overall survival is needed before this approach can be recommended. Further data from randomized trials on the addition of daratumumab to the current standard of VRD is also needed.

Relapsed or Refractory Multiple Myeloma

Almost all patients with multiple myeloma who survive eventually relapse. If relapse occurs more than 6 months after treatment is discontinued, the initial chemotherapy regimen should be reinstituted. Most patients respond again, but the duration and quality of response are usually inferior to the initial response. Recently, several new drugs have been approved for the treatment of multiple myeloma including pomalidomide (Pomalyst), carfilzomib (Kyprolis), daratumumab (Darzalex), elotuzumab (Empliciti), panobinostat (Farydak), and ixazomib (Ninlaro).

Thalidomide

Thalidomide (Thalomid) is usually instituted in a dose of 50 to 100 mg daily and, if necessary, escalated to 200 mg daily if tolerated. It is most often used in combinations such as VTD. Side effects include sedation, fatigue, constipation, rash, deep venous thrombosis, edema, bradycardia, and hypothyroidism. Virtually all patients develop a sensorimotor peripheral neuropathy. The use of thalidomide in pregnancy is contraindicated, and the STEPS program (System for Thalidomide Education and Prescribing Safety) must be followed to prevent teratogenic effects.

Bortezomib

Bortezomib (Velcade) is a proteasome inhibitor that produces a response rate of approximately 35% in patients with relapsed or refractory myeloma. It is most often used in combinations such as VRD, VCD, or VTD to maximize response rates. The most troublesome side effect is peripheral neuropathy, which can occur in 35% to 40% of patients. The neuropathy is often painful but does improve in most patients after discontinuing bortezomib. The risk of neuropathy can be greatly reduced by using bortezomib in a once weekly subcutaneous schedule.

Lenalidomide

Lenalidomide (Revlimid) as a single-agent produces an objective response in approximately 30% of patients with relapsed or refractory multiple myeloma. The major side effects are cytopenias, and the dose needs to be modified accordingly. The combination of lenalidomide plus low-dose dexamethasone (Rd) is the backbone of several myeloma treatment regimens.

Carfilzomib

Carfilzomib (Kyprolis) is a new proteasome inhibitor approved for the therapy of patients with multiple myeloma who have received at least two prior therapies, including both an immunomodulatory agent and bortezomib, and have disease progression on or within 60 days of the completion of the last therapy. Carfilzomib needs to be administered intravenously twice weekly. In a recent randomized trial, the combination of carfilzomib, lenalidomide, and dexamethasone (KRd) was found to have superior response rate, progression free survival, and overall survival compared with Rd.

¹Not FDA approved for this indication.

³Exceeds dosage recommended by the manufacturer.

Pomalidomide

Pomalidomide (Pomalyst) is an analog of lenalidomide and thalidomide. It has shown significant clinical activity in patients who are refractory to both bortezomib and lenalidomide (dual refractory). It is approved for patients with multiple myeloma who received at least two prior therapies, including both lenalidomide and bortezomib, and have disease progression on or within 60 days of the completion of the last therapy. It is administered orally at a dose of 2–4 mg daily for 21 days every 28 days. The major side effects are cytopenias and fatigue.

Panobinostat

Panobinostat (Farydak) is a pan-deacetylase inhibitor that is approved for the treatment of multiple myeloma in patients who have received at least two prior therapies, including both an immunomodulatory agent and bortezomib. It is administered orally at a starting dose of 20 mg three times a week for 2 weeks every 3 weeks. It is given in combination with bortezomib and dexamethasone.¹ It is associated with severe diarrhea in approximately 25% of patients, so use must be restricted to younger patients in good performance status who have failed other treatments but are not yet refractory to bortezomib. If the drug is used, the dose must preferably be lower than the approved label dose, and the dose of bortezomib and dexamethasone must also be reduced to a once-weekly schedule. The drug approval carries a black-box warning concerning cardiac arrhythmias and severe diarrhea.

Elotuzumab

Elotuzumab (Empliciti) is a monoclonal antibody that is approved for the treatment of relapsed myeloma. It targets the signaling lymphocytic activation molecule F7 (SLAMF7). In a randomized trial of 646 patients, elotuzumab plus Rd was superior to Rd, median PFS 19.4 months versus 14.9 months, respectively, $P < 0.001$.

Daratumumab

Daratumumab (Darzalex) is a monoclonal antibody that is approved for the treatment of relapsed myeloma. It targets CD38, a molecule universally expressed on myeloma cells. Daratumumab has a response rate of approximately 30% in heavily pre-treated patients. Two randomized trials have found improvement in PFS with the addition of daratumumab to Rd and bortezomib-dexamethasone, respectively.

Ixazomib

Ixazomib (Ninlaro) is an oral proteasome inhibitor approved for the treatment of relapsed myeloma. It is a boronic acid derivative similar to bortezomib. It is administered once weekly orally. Compared with bortezomib it has a lower risk of peripheral neuropathy.

Other New Drugs

New drugs that are in clinical trials include new proteasome inhibitors (marizomib⁵, oprozomib⁵, and dinaciclib⁵). Chimeric antigen receptor (CAR) T cell therapy targeting B cell maturation antigen (BCMA) and anti-BCMA monoclonal antibody therapy have also shown significant progress in clinical trials.

Supportive Therapy

Radiotherapy

Palliative radiation in a dose of 20 to 30 Gy should be limited to patients who have disabling pain and a well-defined focal process that has not responded to chemotherapy. Analgesics in combination with chemotherapy usually can control the pain. This approach is preferred to local radiation because pain often occurs at another site, and local radiation does not benefit the patient with systemic disease. In addition, the myelosuppressive effects of radiotherapy and chemotherapy are cumulative and can restrict future therapy. Radiation is required for spinal cord compression from

plasmacytoma. Postsurgical radiation after stabilization of fractures or impending fractures is rarely needed.

Hypercalcemia

Hypercalcemia must be suspected if the patient has anorexia, nausea, vomiting, polyuria, increased constipation, weakness, confusion, stupor, or coma. If it is untreated, renal insufficiency usually develops. Hydration, preferably with isotonic saline and prednisone (25 mg orally four times daily), is effective in many patients with mild to moderate hypercalcemia (calcium < 13 mg/dL). If more-severe hypercalcemia occurs, zoledronic acid (Zometa) at a dose of 4 mg intravenously over 15 minutes or pamidronate (Aredia) 90 mg given intravenously over at least 2 hours is indicated. Calcitonin (Miacalcin) may be used if rapid reduction of calcium levels is needed. Hemodialysis may be necessary for extremely severe hypercalcemia. The dosage of prednisone must be reduced and discontinued as soon as possible.

Renal Insufficiency

Approximately 20% of patients with multiple myeloma have a serum creatinine level of 2.0 mg/dL or more at diagnosis. Myeloma kidney (cast nephropathy) and hypercalcemia are the two major causes. Myeloma kidney is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. Some light chains are very nephrotoxic, but no specific amino acid sequence of the nephrotoxic light chain has been identified.

Dehydration, infection, nonsteroidal antiinflammatory agents, and radiographic contrast media can contribute to acute kidney failure. Hyperuricemia or amyloid deposition can produce renal insufficiency. Nephrotic syndrome rarely occurs in multiple myeloma unless amyloidosis is present.

Maintenance of a high fluid intake producing 3 L of urine per 24 hours is important for preventing kidney failure in patients with Bence Jones proteinuria. If hyperuricemia occurs, allopurinol (Zyloprim) in doses of 300 mg daily provides effective therapy.

Acute kidney failure should be treated promptly with appropriate fluid and electrolyte replacement. Patients with kidney failure should be treated with either VCD or VTD to reduce the tumor mass as quickly as possible. A trial of plasmapheresis is reasonable in an attempt to prevent chronic dialysis. Hemodialysis and peritoneal dialysis are equally effective and are necessary for patients with symptomatic azotemia.

Anemia

Almost every patient with multiple myeloma eventually becomes anemic. Increased plasma volume from the osmotic effect of the M protein can produce hypervolemia and can spuriously lower the hemoglobin and hematocrit values. Patients with significant symptoms should be considered for red blood cell transfusion. If a transfusion is indicated, irradiated leukocyte-reduced red cells are preferred.

In patients with newly diagnosed myeloma, induction chemotherapy is often associated with a prompt improvement in hemoglobin levels, so it is better to avoid the use of erythropoietin. Erythropoietin (Eprex) should be seriously considered in relapsed patients receiving chemotherapy who have a persistent, symptomatic hemoglobin level of 10 g/dL or less.

Erythropoietin reduces the transfusion requirement and increases hemoglobin concentration in more than half of patients. Those with low serum erythropoietin values are more likely to respond. Most physicians proceed with a trial of erythropoietin 150 U/kg three times weekly, or 40,000 U once a week. Darbepoetin, a long-lasting erythropoietin (Aranesp), may be given weekly or biweekly. Erythropoietin should be discontinued when the hemoglobin reaches 11 g/dL.

Skeletal Lesions

Bone lesions manifested by pain and fractures are a major problem. A skeletal radiographic survey should be repeated at 6-month intervals, or sooner if pain develops. Patients should be encouraged to be as active as possible because confinement to bed increases

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

demineralization of the skeleton. Trauma must be avoided because even mild stress can result in a fracture. Fixation of long bone fractures or impending fractures with an intramedullary rod and methyl methacrylate gives excellent results.

All patients with multiple myeloma who have lytic lesions, pathologic fractures, or severe osteopenia should receive an IV bisphosphonate. Pamidronate (Aredia) 90 mg intravenously over 2 hours every 4 weeks or zoledronic acid (Zometa) 4 mg intravenously over 15 minutes every 4 weeks are equally efficacious. The dosage of bisphosphonates should be reduced with renal insufficiency. Because renal insufficiency or nephrotic-range proteinuria can occur, serum creatinine and 24-hour urine protein monitoring is necessary. One should seriously consider stopping the IV bisphosphonate in patients who have responsive or stable disease after 2 years of therapy. In other patients we recommend reducing the dose to once every 3 months. A recent randomized trial has found that denosumab (Xgeva), a monoclonal antibody targeting RANKL may be as effective in reducing skeletal events as zoledronic acid, and may be an option for selected patients with significant renal impairment.

Bisphosphonates should be resumed upon relapse with new-onset skeletal-related events. Osteonecrosis of the jaw can occur in patients receiving bisphosphonates. Although the relationship is unclear, it is essential to obtain a complete dental evaluation and perform preventive dental treatment before beginning bisphosphonates. The patient should practice good oral hygiene during therapy. Invasive procedures (especially dental extractions) should be avoided during bisphosphonate therapy. Osteonecrosis of the jaw should be managed conservatively.

Vertebroplasty or kyphoplasty may be helpful for patients with an acute compression fracture of the spine. Both have been associated with pain relief. Results appear to be better when the procedure is performed shortly after the compression fracture. Leakage of the methyl methacrylate is a potential adverse event. A choice between vertebroplasty and kyphoplasty depends on the expertise of the physician performing the procedure.

Infections

Bacterial infections are more common in patients with myeloma than in the general population. All patients should receive pneumococcal and influenza immunizations despite their suboptimal antibody response. Substantial fever is an indication for appropriate cultures, chest radiography, and consideration of antibiotic therapy. The greatest risk for infection is during the first 3 months after chemotherapy is initiated and prophylactic antibiotics (levofloxacin [Levaquin] or co-trimoxazole [Bactrim]) should be considered during this period. Antiviral prophylaxis (acyclovir [Zovirax] 400 mg twice daily or valacyclovir [Valtrex] 500 mg once daily) should be given to all patients receiving bortezomib because of the increased risk of herpes zoster. Intravenous immunoglobulin (IVIg, Gammagard)¹ may be helpful in selected patients who have recurrent serious infections despite the use of prophylactic antibiotics. It is inconvenient, associated with side effects, and very expensive. Consequently, few of our patients receive IVIg.

Hyperviscosity Syndrome

Symptoms of hyperviscosity can include oronasal bleeding, gastrointestinal bleeding, blurred vision, neurologic symptoms, or congestive heart failure. Most patients have symptoms when the serum viscosity measurement is more than 4 cP, but the relationship between serum viscosity and clinical manifestations is not precise. The decision to perform plasmapheresis, which promptly relieves the symptoms of hyperviscosity, should be made on clinical grounds rather than serum viscosity levels. Hyperviscosity is more common in immunoglobulin (IgA) myeloma than in IgG myeloma.

Extradural Myeloma (Cord Compression)

The possibility of cord compression must be considered if weakness of the legs or difficulty in voiding or defecating occurs. The sudden onset of severe radicular pain or severe back pain with neurologic symptoms suggests compression of the spinal cord. MRI or CT of the entire spine must be performed immediately. Radiation therapy in a dose of approximately 30 Gy is beneficial in about one half of patients. Dexamethasone (Decadron)¹ should be administered in addition to radiation therapy. Surgical decompression is necessary only if the neurologic deficit does not improve.

Venous Thromboembolism

Patients with multiple myeloma have an increased risk of venous thromboembolism. This is due to the malignancy itself as well as therapy with lenalidomide, thalidomide, or pomalidomide. All patients receiving lenalidomide (or thalidomide or pomalidomide) need deep vein thrombosis (DVT) prophylaxis with aspirin¹ (81 mg or 325 mg daily) or full-dose warfarin (Coumadin)¹ or low-molecular-weight heparin¹.

Emotional Support

All patients with multiple myeloma need substantial and continuing emotional support. The physician's approach must be positive in emphasizing the potential benefits of therapy. It is reassuring for patients to know that some survive for 10 years or more. It is vital that the physician caring for patients with multiple myeloma has the interest and capacity for dealing with incurable disease over the span of years with assurance, sympathy, and resourcefulness.

MYELODYSPLASTIC SYNDROMES

Method of

Jamile M. Shammo, MD

CURRENT DIAGNOSIS

- Myelodysplastic syndromes are diseases of the elderly.
- Chronic unexplained cytopenias should be evaluated to rule out myelodysplastic syndromes.
- Bone marrow biopsy with cytogenetic testing is necessary to make the diagnosis.
- The international prognostic scoring system (IPSS) is an important tool for risk stratification and choice of therapy.

CURRENT THERAPY

- Myelodysplastic syndromes are broadly divided into two therapeutic categories per the IPSS: low-risk disease (encompassing low and intermediate-1 risk groups), and high-risk disease (encompassing Intermediate-2 and high risk groups).
- The IPSS-R defines 5 prognostic groups (very low, low, intermediate, high, and very high risk). Treatment options are also dependent on risk category.
- Patients with low-risk disease should receive supportive care and hematopoietic growth factors; those with deletion 5q abnormality should be treated with lenalidomide (Revlimid).
- Patients with high-risk disease should be treated with a hypomethylating agent and should be considered for allogeneic stem cell transplantation.

Epidemiology

The myelodysplastic syndromes (MDS) represent a group of heterogeneous clonal stem cell disorders that affect the elderly. The reported annual incidence of approximately 4.4 per 100,000 of the general United States population is highest among whites and non-Hispanics. The onset of MDS before the age of 50 years is rare; the incidence rises with age such that in patients older than 70 years, the incidence exceeds 45 per 100,000 persons. Men are nearly twice as likely to be affected as women (5.8 vs 3.3 per 100,000 per year).

Risk Factors

De novo or primary MDS refers to cases in which no prior toxic exposure can be documented. Therapy-related MDS, on the other hand, occurs in patients who have been previously treated with either chemotherapy, radiotherapy or both. Median onset of therapy-related MDS varies with the agents used and is usually 2 to 5 years after initial exposure or chemotherapy.

Tobacco use and occupational exposure to solvents and agricultural chemicals have also been associated with the development of MDS. A minority of MDS cases might have evolved from an antecedent hematologic disorder such as aplastic anemia or paroxysmal nocturnal hemoglobinuria. Several rare and inherited genetic disorders have been associated with a higher risk of developing MDS, such as Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan syndrome, and Shwachman-Diamond syndrome.

Pathophysiology

A variety of pathophysiological processes has been described in association with MDS, resulting in ineffective hematopoiesis and peripheral cytopenias. These processes include excessive apoptosis of myeloid progenitors, abnormal responses to cytokines and growth factors, epigenetic aberrations resulting in gene silencing, chromosomal abnormalities, and a defective bone marrow micro-environment. Recently, several somatic point mutations affecting multiple genes have been identified in up to 50% of MDS patients. However, the initiating event remains is unknown.

Clinical Manifestations

Some patients with MDS are symptom free, but the majority present with peripheral blood cytopenias, of which anemia is the most common. Patients might complain of fatigue, weakness, and exercise intolerance. Those with significant neutropenia and thrombocytopenia can present with infections or bleeding. Systemic symptoms are less common but, when present, can herald disease progression. Similarly, the presence of Sweet's syndrome (acute febrile neutrophilic dermatosis) can herald transformation to acute leukemia. Organomegaly and lymphadenopathy are uncommon. Infection is the cause of death in approximately 20% to 35% of cases. Transformation to acute leukemia occurs in about 30% of all patients.

Diagnosis

The diagnosis of MDS can be challenging, because its clinical and pathologic characteristics can overlap with other disorders such as aplastic anemia, myeloproliferative neoplasms, and acute leukemia.

A thorough history and physical examination should be performed on every patient with one or more peripheral blood cytopenias, along with basic laboratory tests such as iron studies, vitamin B₁₂, and folic acid levels. However, many disorders can cause pancytopenia; therefore consideration for a hematology referral should be entertained for the evaluation of pancytopenia or persistent otherwise-unexplained cytopenias, in which case a bone marrow biopsy may be necessary.

The diagnosis of MDS requires an evaluation of the peripheral blood smear, a bone marrow biopsy and aspirate to ascertain the presence of myeloid dysplasia; iron stains, which are necessary for the detection of ring sideroblasts; and cytogenetic studies to detect abnormal clones. Bone marrow dysplasia involving at least 10% of the cells of a specific myeloid lineage is the hallmark of MDS. Conventional karyotyping can detect cytogenetic abnormalities in 50% of patients with de novo MDS and in 95% of patients with therapy-related MDS. The presence of certain cytogenetic abnormalities can aid in making the diagnosis of MDS, particularly when dysplastic features are not prominent. It should be noted that the presence of +8, -Y, or del(20q) is not considered to be MDS-defining in that setting.

Recently, next-generation sequencing (NGS) has allowed for the identification of point mutations in the majority of patients with MDS. These mutations involve genes encoding for splicing factors, epigenetic modifiers, and transcription factors among others. NGS is increasingly utilized in this patient population to assist in making the diagnosis (.SF3B1 in MDS-RS), or to provide important prognostic information (TP53 in del 5 MDS).

Differential Diagnosis

MDS should be distinguished from a broad number of disorders including megaloblastic anemia, aplastic anemia, large granular lymphocyte leukemia, myelofibrosis, copper deficiency, and HIV infection, which can cause anemia and dysplastic features in the bone marrow. Exposure to certain drugs and toxins can result in marrow dysplasia. These include mycophenolate mofetil (Cellcept), ganciclovir (Cytovene), lead, and excess zinc. Such changes are reversible once the offending agent is discontinued. The diagnosis of MDS can be made by performing a bone marrow biopsy to detect dysplasia and rule out other disorders that can also cause pancytopenia. Every effort should be made to rule out other reactive causes of dysplasia prior to making a diagnosis of MDS.

MYELODYSPLASTIC SYNDROMES

Method of

Jamile M. Shammo, MD

CURRENT DIAGNOSIS

- Myelodysplastic syndromes are diseases of the elderly.
- Chronic unexplained cytopenias should be evaluated to rule out myelodysplastic syndromes.
- Bone marrow biopsy with cytogenetic testing is necessary to make the diagnosis.
- The international prognostic scoring system (IPSS) is an important tool for risk stratification and choice of therapy.

CURRENT THERAPY

- Myelodysplastic syndromes are broadly divided into two therapeutic categories per the IPSS: low-risk disease (encompassing low and intermediate-1 risk groups), and high-risk disease (encompassing Intermediate-2 and high risk groups).
- The IPSS-R defines 5 prognostic groups (very low, low, intermediate, high, and very high risk). Treatment options are also dependent on risk category.
- Patients with low-risk disease should receive supportive care and hematopoietic growth factors; those with deletion 5q abnormality should be treated with lenalidomide (Revlimid).
- Patients with high-risk disease should be treated with a hypomethylating agent and should be considered for allogeneic stem cell transplantation.

Epidemiology

The myelodysplastic syndromes (MDS) represent a group of heterogeneous clonal stem cell disorders that affect the elderly. The reported annual incidence of approximately 4.4 per 100,000 of the general United States population is highest among whites and non-Hispanics. The onset of MDS before the age of 50 years is rare; the incidence rises with age such that in patients older than 70 years, the incidence exceeds 45 per 100,000 persons. Men are nearly twice as likely to be affected as women (5.8 vs 3.3 per 100,000 per year).

Risk Factors

De novo or primary MDS refers to cases in which no prior toxic exposure can be documented. Therapy-related MDS, on the other hand, occurs in patients who have been previously treated with either chemotherapy, radiotherapy or both. Median onset of therapy-related MDS varies with the agents used and is usually 2 to 5 years after initial exposure or chemotherapy.

Tobacco use and occupational exposure to solvents and agricultural chemicals have also been associated with the development of MDS. A minority of MDS cases might have evolved from an antecedent hematologic disorder such as aplastic anemia or paroxysmal nocturnal hemoglobinuria. Several rare and inherited genetic disorders have been associated with a higher risk of developing MDS, such as Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan syndrome, and Shwachman-Diamond syndrome.

Pathophysiology

A variety of pathophysiological processes has been described in association with MDS, resulting in ineffective hematopoiesis and peripheral cytopenias. These processes include excessive apoptosis of myeloid progenitors, abnormal responses to cytokines and growth factors, epigenetic aberrations resulting in gene silencing, chromosomal abnormalities, and a defective bone marrow micro-environment. Recently, several somatic point mutations affecting multiple genes have been identified in up to 50% of MDS patients. However, the initiating event remains is unknown.

Clinical Manifestations

Some patients with MDS are symptom free, but the majority present with peripheral blood cytopenias, of which anemia is the most common. Patients might complain of fatigue, weakness, and exercise intolerance. Those with significant neutropenia and thrombocytopenia can present with infections or bleeding. Systemic symptoms are less common but, when present, can herald disease progression. Similarly, the presence of Sweet's syndrome (acute febrile neutrophilic dermatosis) can herald transformation to acute leukemia. Organomegaly and lymphadenopathy are uncommon. Infection is the cause of death in approximately 20% to 35% of cases. Transformation to acute leukemia occurs in about 30% of all patients.

Diagnosis

The diagnosis of MDS can be challenging, because its clinical and pathologic characteristics can overlap with other disorders such as aplastic anemia, myeloproliferative neoplasms, and acute leukemia.

A thorough history and physical examination should be performed on every patient with one or more peripheral blood cytopenias, along with basic laboratory tests such as iron studies, vitamin B₁₂, and folic acid levels. However, many disorders can cause pancytopenia; therefore consideration for a hematology referral should be entertained for the evaluation of pancytopenia or persistent otherwise-unexplained cytopenias, in which case a bone marrow biopsy may be necessary.

The diagnosis of MDS requires an evaluation of the peripheral blood smear, a bone marrow biopsy and aspirate to ascertain the presence of myeloid dysplasia; iron stains, which are necessary for the detection of ring sideroblasts; and cytogenetic studies to detect abnormal clones. Bone marrow dysplasia involving at least 10% of the cells of a specific myeloid lineage is the hallmark of MDS. Conventional karyotyping can detect cytogenetic abnormalities in 50% of patients with de novo MDS and in 95% of patients with therapy-related MDS. The presence of certain cytogenetic abnormalities can aid in making the diagnosis of MDS, particularly when dysplastic features are not prominent. It should be noted that the presence of +8, -Y, or del(20q) is not considered to be MDS-defining in that setting.

Recently, next-generation sequencing (NGS) has allowed for the identification of point mutations in the majority of patients with MDS. These mutations involve genes encoding for splicing factors, epigenetic modifiers, and transcription factors among others. NGS is increasingly utilized in this patient population to assist in making the diagnosis (.SF3B1 in MDS-RS), or to provide important prognostic information (TP53 in del 5 MDS).

Differential Diagnosis

MDS should be distinguished from a broad number of disorders including megaloblastic anemia, aplastic anemia, large granular lymphocyte leukemia, myelofibrosis, copper deficiency, and HIV infection, which can cause anemia and dysplastic features in the bone marrow. Exposure to certain drugs and toxins can result in marrow dysplasia. These include mycophenolate mofetil (Cellcept), ganciclovir (Cytovene), lead, and excess zinc. Such changes are reversible once the offending agent is discontinued. The diagnosis of MDS can be made by performing a bone marrow biopsy to detect dysplasia and rule out other disorders that can also cause pancytopenia. Every effort should be made to rule out other reactive causes of dysplasia prior to making a diagnosis of MDS.

Classification and Risk Stratification

Since 1982, there have been various proposals for the classification and risk stratification of MDS. The French-American-British (FAB) classification scheme was the first attempt developed to address the broad range of morphologic features and clinical outcomes in MDS. It identified five subtypes based on morphology and percentage of marrow blasts: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). This classification allowed MDS to be separated into distinct subsets relative to survival and acute leukemia evolution.

The World Health Organization (WHO) revised the FAB system to further refine MDS subsets by adding a category of refractory cytopenia with multilineage dysplasia, recognizing 5q-deletion syndrome as a separate clinical and pathologic entity, and lowering the blast percentage from 30% to 20% to diagnose acute myelogenous leukemia (AML). The WHO system was revised in 2008 and again in 2016. The most recent revision eliminated reference to refractory anemia and modified the terminology to identify 6 general MDS categories based on presence of single or multilineage dysplasia, ring sideroblasts, blast percentage and del(5q) (Table 1).

The International Prognostic Scoring System (IPSS) was introduced in 1997 to address the variability in prognosis within FAB subtypes. It predicts survival and risk of evolution to acute leukemia. The IPSS is calculated by adding scores assigned to three variables: blast cell count, cytogenetics, and number of cytopenias (Table 2). The IPSS was revised in 2012 (IPSS-R) to incorporate 5 cytogenetic categories and to account for the depth of cytopenias in MDS (Table 3). The IPSS/IPSS-R are widely used to predict the prognosis and clinical behavior of patients with various forms of MDS and to guide choice of therapy.

Treatment

A variety of therapeutic options exist for the treatment of MDS patients spanning the spectrum from supportive care to allogeneic stem cell transplantation. Choice of therapy should take into account the patient's age, comorbidities, and the IPSS/IPSS-R score.

The treating physician should consider the ultimate goal of therapy and whether it is intended to cure, extend survival, or merely palliate symptoms. In the first decade of the 21st century, several novel therapeutic options for MDS have emerged. Clinical trials evaluating novel agents are being conducted to help identify effective agents for patients who have relapsed or failed to respond to standard therapies.

Supportive Care

Supportive care has been the cornerstone of MDS therapy for decades; it includes red blood cell transfusion for symptomatic anemia, platelet transfusion to reduce the risk of or to treat bleeding, and use of hematopoietic growth factors such as erythropoiesis stimulating agents (ESA) and colony-stimulating factors such as granulocyte colony-stimulating factor (G-CSF) (Filgrastim [Neupogen]) and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Sargramostim [Leukine]).¹

There are two currently available ESAs: a recombinant human erythropoietin (rhu-EPO; epoetin alfa [Epogen, Procrit]) and a super-sialylated form of EPO (darbepoetin alfa [Aranesp]). These are considered the standard of care for the treatment of anemia in patients with low-risk MDS. A predictive model for response to such treatment has been developed by the Nordic MDS study group to guide patient selection. In general, patients with a serum

¹Not FDA approved for this indication.

TABLE 1 WHO 2008 Classification of Myelodysplastic Syndromes

DISEASE	BLOOD FINDINGS	BONE MARROW FINDINGS
Refractory cytopenias with unilineage dysplasia (RCUD) Refractory anemia (RA) Refractory neutropenia (RN) Refractory thrombocytopenia (RT)	Unicytopenia or bicytopenia* No or rare blasts (<1%) [†]	Unilineage dysplasia: ≥10% of the cells in one myeloid lineage <5% blasts <15% of erythroid precursors are ring sideroblasts
Refractory anemia with ring sideroblasts (RARS)	Anemia No blasts	>15% of erythroid precursors are ring sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenia(s) No or rare blasts (<1%) [†] No Auer rods <10 ⁹ /L monocytes	Dysplasia in ≥10% of the cells in ≥2 myeloid lineages (neutrophils, erythroid precursors, megakaryocytes) <5% blasts in marrow No Auer rods ±15% ring sideroblasts
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenia(s) <5% blasts [†] No Auer rods <10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 5 5%–9% blasts No Auer rods
Refractory anemia with excess blasts-2 (RAEB-2)	Cytopenia(s) 5%–19% blasts ±Auer rods [‡] <10 ⁹ /L monocytes	Unilineage or multilineage dysplasia 10%–19% blasts ±Auer rods [‡]
Myelodysplastic syndrome, unclassified (MDS-U)	Cytopenias ≤1% blasts [†]	Unequivocal dysplasia in <10% of cells in one or more myeloid cell lines when accompanied by a cytogenetic abnormality considered as presumptive evidence for a diagnosis of MDS <5% blasts
MDS associated with isolated del(5q)	Anemia Usually normal or increased platelet count No or rare blasts (<1%)	Normal to increased megakaryocytes with hypolobated nuclei <5% blasts Isolated del(5q) cytogenetic abnormality No Auer rods

*Bicytopenia is occasionally observed. Cases with pancytopenia should be classified as MDS-U.

[†]If the marrow myeloblast percentage is <5% but there are 2%–4% myeloblasts in the blood, the diagnostic classification is RAEB-1. Cases of RCUD and RCMD with 1% myeloblasts in the blood should be classified as MDS-U.

[‡]Cases with Auer rods and <5% myeloblasts in the blood and <10% in the marrow should be classified as RAEB-2.

TABLE 2 International Prognostic Scoring System (IPSS) for MDS

PROGNOSTIC VARIABLE	SCORE VALUE				
	0	0.5	1.0	1.5	2.0
Marrow blasts (%)	<5	5–10	11–20	—	21–30
Karyotype*	Good	Intermediate		Poor	
Cytopenia [†]	0/1	2/3			

*Cytogenetics: Good = normal, -Y alone, del(5q) alone, del(20q) alone; Poor = complex (≥ 3 abnormalities) or chromosome 7 anomalies; Intermediate = other abnormalities.

This excludes karyotypes t(8;21), inv16 and t(15;17), which are considered to be AML, not MDS.

[†]Cytopenias: neutrophil count <1800/ μ L, platelets <100,000/ μ L, Hb <10 g/dL.

TABLE 3 Survival and Progression by IPSS Risk Category

RISK CATEGORY	% IPSS POP.	OVERALL SCORE	MEDIAN SURVIVAL (Y) IN THE ABSENCE OF THERAPY	25% AML PROGRESSION (Y) IN THE ABSENCE OF THERAPY
Low	33	0	5.7	9.4
Intermediate 1	38	0.5–1.0	3.5	3.3
Intermediate 2	22	1.5–2.0	1.2	1.1
High	7	≥ 2.5	0.4	0.2

Abbreviation: IPSS = International Prognostic Scoring System.

EPO level less than 500 mU/mL and low transfusion burden are likely to respond by improving their hemoglobin level and reducing their need for transfusions.

Immunomodulatory Drugs

The novel class of immunomodulatory drugs includes thalidomide (Thalomid)¹ and lenalidomide (Revlimid). Thalidomide was investigated initially with some success in patients with low-risk disease. However, its use was compromised because of poor tolerability. Lenalidomide has been approved for the treatment of patients with low-risk MDS who harbor deletion 5q abnormality, because it was shown in clinical trials to result in transfusion independence in about two thirds of such patients.

Hypomethylating Agents

Currently, two hypomethylating agents are approved for the treatment of MDS: 5-azacitidine (Vidaza) and decitabine (Dacogen). These agents are cytosine analogues known to inhibit and deplete DNA methyltransferase, which adds a methyl group to cytosine residues in newly formed DNA, resulting in the formation of a hypomethylated DNA in vitro. The exact mechanism of action in vivo has not yet been identified.

Results of randomized clinical trials comparing these agents to best supportive care in patients with MDS have demonstrated a statistically significant improvement in response rate and hematologic improvement. It has been shown for the first time that treatment with 5-azacitidine was reported to result in prolongation of survival in patients with Int-2 and high-risk. Both drugs have myelosuppressive properties and comparable response rates.

Immunosuppressive Therapy

Immunosuppressive therapy with antithymocyte globulin (Thymoglobulin)¹ or cyclosporine (Neoral)¹ (or both) was evaluated in several clinical trials and was shown to result in durable hematological responses in a subset of MDS patients, specifically, younger patients with low-risk disease, hypocellular marrows, PNH clone, human leukocyte antigen (HLA)-DR 15 phenotype, and low transfusion need.

Hematopoietic Stem Cell Transplantation

Allogeneic stem cell transplantation is the only curative therapy for MDS patients; this option is feasible for a small subset: typically, younger patients with good performance status and an available HLA-matched donor. Approximately 40% of patients can be cured with this modality. The recent introduction of reduced-intensity conditioning regimens and nonmyeloablative transplants has resulted in expanding the age limit for performing the procedure, reducing transplant-related complications and mortality. However it has been associated with a higher risk of relapse. Because stem cell transplantation is associated with a high rate of treatment-related death—estimated at 39% at 1 year—and the development of acute and chronic graft versus host disease, such treatment is recommended to patients with high-risk disease. Patients with low-risk MDS may be considered for transplant at disease progression.

Conclusion and Future Direction

MDS is a chronic disease characterized by features reminiscent of bone marrow failure states with a variable propensity for leukemic evolution. It is curable only by allogeneic stem cell transplantation, which is feasible in only a small subset of patients. For all others, the treatment goal is aimed at improving quality of life and prolonging survival. A variety of ongoing clinical trials are evaluating novel agents and combinations of drugs to further optimize the outcome of patients with this disease. Meanwhile, a great deal of research is focused on understanding the molecular underpinning of this disease to enhance our understanding of the biology of this heterogeneous disorder.

NEUTROPENIA

Method of

Natalie S. Callandar, MD

CURRENT DIAGNOSIS

- Neutropenia is typically defined as an absolute neutrophil count in peripheral blood of less than 1500 cells/mm³.
- Neutropenia may result from congenital or acquired causes.
- Most neutropenia results from decreased production of neutrophil precursors but can be due to increased destruction.
- Neutropenia can be isolated or encountered with pancytopenia.
- Neutropenia occurring with fever can be a medical emergency requiring urgent intervention.
- Severe chronic neutropenia can be a result of medications, inherited disorders, or disease.

CURRENT THERAPY

- Symptomatic neutropenia can be treated with granulocyte-colony stimulating factors. Antibiotic prophylaxis is appropriate in certain situations. Benign neutropenia should be monitored without any specific intervention. Patients with symptomatic neutropenia secondary to myelodysplasia, aplastic anemia, and

inherited disorders (Schwachman-Diamond, dyskeratosis congenita) may be candidates for hematopoietic cell transplantation. Steroids may have a role in some patients with autoimmune neutropenia.

Neutropenia is defined as an absolute neutrophil count (in turn, the sums of neutrophils [polymorphonuclear cells] and bands) of less than 1500/mm³. Neutrophils are short-lived, under constant production (estimated 10¹¹ manufactured daily), and, along with monocytes, form a key part of the innate immune system. It is estimated that only about 3–5% of the total neutrophils are in circulation at any one time, given their life span of around 5–7 hours, and their numbers are constantly replenished. These cells migrate rapidly to sites of injury and inflammation, under the influence of chemotactic cytokines, such as C5a, interleukin 8, and monocyte chemotactic factor, and quickly infiltrate tissues. Neutrophils utilize integrins, primarily CD11b/CD18 expressed on the cell surfaces, to accomplish this.

Neutrophils possess surface receptors that enable them to bind to and ingest foreign particles and microbes by a process known as phagocytosis. This function is enhanced if the microbes are “opsonized,” i.e., “tagged” with various opsonic proteins such as immunoglobulins, complement fragment C3b, and mannan binding lectin, for which neutrophils express multiple specific receptors. Phagocytosis is followed by degranulation and respiratory burst activity, and this leads to killing of the target as well as inflammatory changes in the tissues. The respiratory burst is an important pathway for microbial killing and involves the generation of superoxide, hydrogen peroxide, hydroxyl radical, and subsequently hypochlorous acid and chloramines, all of which can be directly toxic to microbes.

Normal neutrophil counts vary by age and ethnicity. For example, newborns tend to have high neutrophil count for several days, which then falls into the normal adult range by the first weeks of life. Premature infants, i.e., those born under 32 weeks’ gestation, appear to have slightly lower neutrophil counts. Some persons of African or Middle Eastern descent may typically have a neutrophil count <1000/mm³ with no apparent increased risk of infection. Genetic studies have suggested that this finding is associated with a polymorphism of a red cell membrane antigen, the Duffy-Ag receptor for chemokines (DARC). Absence of this receptor appears to confer resistance to invasion by *Vivax* malarial merozoites, which may account for its persistence in the population. As a rule, women appear to have a slightly higher neutrophil count than men do at all stages of life.

Determining the depth and chronicity of neutropenia is critical. The degree of neutropenia is important to appropriately assess for the risk of pyogenic infections. Severe neutropenia is defined as an ANC <500/mm³, with moderate neutropenia defined as an ANC between 500 and 1000/mm³. Chronic neutropenia has been defined as the persistence of ANC less than 1000/mm³ for more than 3 months; cyclic neutropenia is typically characterized by 3-week cycles, with relatively normal neutrophil counts between nadirs. The age of the patient with neutropenia may also offer clues as to etiology. The most common cause of neutropenia in pediatric patients is viral infection; however, neutropenia in infants less than 6 months of age is often caused by autoimmune mechanisms. Persistent neutropenia found in children 1 year of age or more is often idiopathic but could represent an underlying genetic disorder. If a patient is otherwise asymptomatic, observation over a period of weeks with intermittent interrogation of neutrophil count is the preferred management, prior to embarking on a more extensive evaluation.

Pathophysiology

Neutropenia is a common but transient finding in patients with viral illnesses, particularly children, and is thought to be due to decreased production or increased peripheral destruction. Infections with HIV, Epstein-Barr virus, Hepatitis A and B, and measles are well known to cause neutropenia in patients of all ages. Severe

NEUTROPENIA

Method of

Natalie S. Callandar, MD

CURRENT DIAGNOSIS

- Neutropenia is typically defined as an absolute neutrophil count in peripheral blood of less than 1500 cells/mm³.
- Neutropenia may result from congenital or acquired causes.
- Most neutropenia results from decreased production of neutrophil precursors but can be due to increased destruction.
- Neutropenia can be isolated or encountered with pancytopenia.
- Neutropenia occurring with fever can be a medical emergency requiring urgent intervention.
- Severe chronic neutropenia can be a result of medications, inherited disorders, or disease.

CURRENT THERAPY

- Symptomatic neutropenia can be treated with granulocyte-colony stimulating factors. Antibiotic prophylaxis is appropriate in certain situations. Benign neutropenia should be monitored without any specific intervention. Patients with symptomatic neutropenia secondary to myelodysplasia, aplastic anemia, and

inherited disorders (Schwachman-Diamond, dyskeratosis congenita) may be candidates for hematopoietic cell transplantation. Steroids may have a role in some patients with autoimmune neutropenia.

Neutropenia is defined as an absolute neutrophil count (in turn, the sums of neutrophils [polymorphonuclear cells] and bands) of less than 1500/mm³. Neutrophils are short-lived, under constant production (estimated 10¹¹ manufactured daily), and, along with monocytes, form a key part of the innate immune system. It is estimated that only about 3–5% of the total neutrophils are in circulation at any one time, given their life span of around 5–7 hours, and their numbers are constantly replenished. These cells migrate rapidly to sites of injury and inflammation, under the influence of chemotactic cytokines, such as C5a, interleukin 8, and monocyte chemotactic factor, and quickly infiltrate tissues. Neutrophils utilize integrins, primarily CD11b/CD18 expressed on the cell surfaces, to accomplish this.

Neutrophils possess surface receptors that enable them to bind to and ingest foreign particles and microbes by a process known as phagocytosis. This function is enhanced if the microbes are “opsonized,” i.e., “tagged” with various opsonic proteins such as immunoglobulins, complement fragment C3b, and mannan binding lectin, for which neutrophils express multiple specific receptors. Phagocytosis is followed by degranulation and respiratory burst activity, and this leads to killing of the target as well as inflammatory changes in the tissues. The respiratory burst is an important pathway for microbial killing and involves the generation of superoxide, hydrogen peroxide, hydroxyl radical, and subsequently hypochlorous acid and chloramines, all of which can be directly toxic to microbes.

Normal neutrophil counts vary by age and ethnicity. For example, newborns tend to have high neutrophil count for several days, which then falls into the normal adult range by the first weeks of life. Premature infants, i.e., those born under 32 weeks’ gestation, appear to have slightly lower neutrophil counts. Some persons of African or Middle Eastern descent may typically have a neutrophil count <1000/mm³ with no apparent increased risk of infection. Genetic studies have suggested that this finding is associated with a polymorphism of a red cell membrane antigen, the Duffy-Ag receptor for chemokines (DARC). Absence of this receptor appears to confer resistance to invasion by *Vivax* malarial merozoites, which may account for its persistence in the population. As a rule, women appear to have a slightly higher neutrophil count than men do at all stages of life.

Determining the depth and chronicity of neutropenia is critical. The degree of neutropenia is important to appropriately assess for the risk of pyogenic infections. Severe neutropenia is defined as an ANC <500/mm³, with moderate neutropenia defined as an ANC between 500 and 1000/mm³. Chronic neutropenia has been defined as the persistence of ANC less than 1000/mm³ for more than 3 months; cyclic neutropenia is typically characterized by 3-week cycles, with relatively normal neutrophil counts between nadirs. The age of the patient with neutropenia may also offer clues as to etiology. The most common cause of neutropenia in pediatric patients is viral infection; however, neutropenia in infants less than 6 months of age is often caused by autoimmune mechanisms. Persistent neutropenia found in children 1 year of age or more is often idiopathic but could represent an underlying genetic disorder. If a patient is otherwise asymptomatic, observation over a period of weeks with intermittent interrogation of neutrophil count is the preferred management, prior to embarking on a more extensive evaluation.

Pathophysiology

Neutropenia is a common but transient finding in patients with viral illnesses, particularly children, and is thought to be due to decreased production or increased peripheral destruction. Infections with HIV, Epstein-Barr virus, Hepatitis A and B, and measles are well known to cause neutropenia in patients of all ages. Severe

bacterial infections may also produce profound neutropenia, particularly in more debilitated or elderly patients; this finding is associated with a higher likelihood of mortality. Many drugs, particularly chemotherapy drugs, can cause myelosuppression, leading to neutropenia of variable severity and duration. Radiation exposure, either therapeutic or accidental, can also cause delayed reactions, but neutropenia and reversibility is related to dose and surface area exposed. A number of pharmaceutical agents are associated with idiopathic neutropenia, presumably immune related. Rare congenital disorders can be associated with long-term neutropenia, and most of these are identifiable at an early age. Neutropenia can also be caused by primary hematologic disorders such as leukemia, lymphoma, and myelodysplasia, where the etiology of neutropenia is caused either by ineffective myelopoiesis or infiltration by a malignant clone. Widely metastatic cancer, such as prostate or breast, can occasionally present with neutropenia due to extensive marrow replacement. Several collagen vascular diseases such as rheumatoid arthritis, lupus, and Wegener's granulomatosis also may be associated with neutropenia. Finally, splenomegaly from variable causes can produce neutropenia through sequestration.

History

The evaluation of a patient with neutropenia starts with a thorough personal and family history. Important items include general questions regarding age and recent health including fevers, weight loss, and night sweats. The duration of these symptoms is critical, as neutropenia persisting over several months is likely to be pathological. Lightheadedness or dizziness or decreased exercise tolerance may indicate associated anemia. It is also valuable to ask about the existence of relatives with neutropenia or other blood disorder. Interrogation regarding exposure to recent or remote infectious agents, various drugs, including both over-the-counter and prescription, and supplements is essential, as is inquiring about any previous history of neutropenia. Patients should be asked about any past medical history of cancer, or cancer chemotherapy and radiation therapy and previous surgery, particularly involving the gastrointestinal tract. Patients should be asked about their acute and chronic alcohol consumption.

Physical Examination

Most patients with neutropenia will have a normal physical exam at the time their low counts are documented. However, certain patients may present with fever and weight loss, or other constitutional symptoms. The presence of pallor, bruising, and petechiae likely indicates a patient with pancytopenia. Patients should be asked about bowel habits and any rectal pain, discomfort, or discharge that could be related to perirectal abscess. Patients should be asked about any past similar or recurrent episodes and family history of any blood disorders. A detailed history of any drug exposures, including any chemotherapy agents, should be elicited. For patients on systemic anticancer therapy, it is useful to inquire if they have had similar problems and the severity of previous infections, including hospitalizations. Localized or systemic rash may suggest a viral exanthem, drug-mediated rash, or collagen vascular disease. The finding of adenopathy and splenomegaly may suggest an underlying hematologic disorder. Chronic buccal or skin ulcerations or necrotic ulcerations should be noted. It is important to recognize that neutropenic patients may be unable to form abscesses due to the fact that pus is composed of neutrophils. Therefore small areas of induration or erythema may be significant. Similarly, interpretation of fluid analysis, e.g., urinalysis, should be tempered by this knowledge.

Laboratory examinations should include a complete blood count with a blood smear, the latter preferably reviewed by a hematologist or pathologist. Serum chemistries, including LDH, liver and renal studies, may be warranted. For patients with suspected cyclical neutropenia, blood testing twice weekly for 4–6 weeks may be necessary to document the fluctuations. Additional testing may be appropriate, including flow cytometry to look for abnormal lymphocytes, mutational analysis, and even bone marrow biopsy and aspirate.

Management

Patients expected to have long (i.e., greater than 7 days) and severe neutropenia may be candidates for prophylactic interventions (Table 1). Over a decade ago, a large randomized study validated the practice of quinolone-based prophylaxis for patients receiving intensive chemotherapy with a high likelihood of causing

TABLE 1 Drugs Associated With Neutropenia or Agranulocytosis[†]

CLASS	DRUG	FREQUENCY REPORTED	NATURE OF REACTION
Antibiotics	Semisynthetic penicillins (amoxicillin, ampicillin*)	Intermediate	Both
	Cephalosporins	Intermediate	Both
	Vancomycin	High	Both
	Macrolides	Low	Neutropenia

	Cimetidine, Ranitidine	Low	Neutropenia

*Denotes drug for which specific attributable risk has been reported in either casecontrolled studies or studies normalized to the prescription rate.

[†]Excludes drugs for which neutropenia is an expected side effect (e.g., chemotherapy).

"Frequency reported" refers to the number of case reports in recent systematic reviews for each drug, but is not always normalized to the frequency with which each drug is prescribed and thus may not accurately represent the true risk associated with these drugs.³⁷

"Nature of Reaction:" All of the drugs in this table have been reported to be associated with agranulocytosis, but some more frequently cause dose-related neutropenia in clinical practice.

neutropenia in order to prevent clinically significant infections. Antibiotic prophylaxis may also be considered in some of the congenital syndromes associated with prolonged neutropenia (see below). Similarly, prophylactic use of granulocyte-colony stimulating factors, e.g., filgrastim (Neupogen) and tbo-filgrastim (Granix), may be considered for these same patients, with the exception of those with underlying myeloid malignancies, where the use of such agents is controversial. PEGylated filgrastim (Neulasta), with an extended half-life, can also be considered. Because the simultaneous use of steroids in patients who are profoundly neutropenic significantly increases the risk of invasive fungal infections, any prolonged exposure to systemic corticosteroids should be avoided. Alternatively, patients with chronic neutropenia who must receive steroids are candidates for fungal prophylaxis.

Patients presenting with signs of impending or current sepsis, such as fever, unexplained hypotension, and/or tachycardia, should be immediately evaluated, and appropriate interventions including blood and urine cultures and the institution of broad-spectrum antibiotics must commence quickly to avoid serious complications. Studies have consistently shown that in this group of patients delay of institution of antibiotics is associated with an increased risk of mortality. The utility of tests such as procalcitonin in neutropenic patients to rule out infection is debatable. Aggressive management of the unstable neutropenic patient can truly be lifesaving. The routine use of growth factors for treatment of neutropenia with infection or sepsis is controversial and is not recommended. However, the prophylactic use of filgrastim or sargramostim (Leukine)¹ in high-risk populations to maintain an adequate neutrophil count should be considered for some patients with chemotherapy- and other drug-induced neutropenia, as well as with high-risk cyclic neutropenia patients.

¹Not FDA approved for this indication.

Etiology

Acquired Causes of Neutropenia

Infectious Agents

Infections are a common cause of transient neutropenia, particularly in children. Agents such as varicella, measles, rubella, influenza, adenovirus, hepatitis B and C, EBV, or HIV infection have been associated with neutropenia. EBV and HIV in particular can cause prolonged neutropenia. In children, acute parvovirus B19 infection may cause neutropenia, although the classic presentation in adults is that of red cell aplasia. Bacterial pathogens are less likely to be associated with significant neutropenia, with the exception of mycobacteria, Rickettsia, and Brucella infections. Overwhelming bacterial sepsis can be associated with profound neutropenia, particularly in children and the elderly, and this is associated with a poor prognosis. The routine introduction of colony-stimulating factors while a patient is acutely ill is of unclear benefit.

Drug-Induced Neutropenia

One of the most common causes of neutropenia, particularly in adults, is drugs. Drug associated neutropenia seems to increase in incidence with aging, with most reported cases in patients over 65 years, and with a slight female predominance. The mechanism by which drugs cause neutropenia varies, and includes myelosuppression, hypersensitivity or autoimmune reactions, and specific suppression of neutrophil production. Some drugs such as penicillins or cephalosporins can cause neutropenia by acting as haptens. Others, such as fludarabine (Fludara), propylthiouracil (PTU), methimazole (Tapazole), and rituximab (Rituxan), appear to trigger the production of antineutrophil antibodies resulting in increased clearance of neutrophils. Neutropenia related to rituximab can be quite delayed and long lasting, persisting for weeks to months. Newer chemotherapeutic antibodies can also produce neutropenia, e.g., blinatumomab (Blinicyto), an agent used to treat

acute lymphoblastic leukemia; and obinutuzumab (Gazyva) and ofatumumab (Arzerra), two different anti-CD 20 antibodies used to treat B-cell malignancies. Although assays to detect anti-neutrophil antibodies associated with drug exposure exist, their variable specificity and turnaround time limit their utility in making treatment decisions, and they are often expensive. Furthermore, there is a lack of consensus as to the appropriate assay that should be used. Patients with drug-related neutropenia can present with lymphadenopathy, mucocutaneous rash, and fever. The optimal management of such patients includes cessation of the suspecting agent, watching for recovery over days to weeks, and at times rechallenging to verify the association.

Neutropenia related to anthracyclines or alkylating agents is caused by bone marrow suppression and therefore is often accompanied by anemia and thrombocytopenia. Among the many oral chemotherapy agents in common use that can be associated with neutropenia are capecitabine (Xeloda), sunitinib (Sutent), sorafenib (Nexavar), and lenalidomide (Revlimid). Several antiviral agents routinely cause neutropenia, including ganciclovir (Cytovene) and valganciclovir (Valcyte). Antipsychotic and anticonvulsant drugs rarely produce neutropenia, but patients receiving these agents should be periodically monitored. Clozapine (Clozaril) is one drug most often cited with neutropenia or agranulocytosis and therefore carries a black box warning. Neutropenia associated with fever has been seen in patients receiving valproic acid (Depakene). Immunosuppressive agents such as methotrexate (Trexall), cyclosporine (Neoral), tacrolimus (Prograf), and sirolimus (Rapamune) can cause neutropenia. Newer biologic agents used to treat rheumatological disorders, including leflunomide (Arava) and those targeting tumor necrosis factor (e.g. etanercept [Enbrel] or adalimumab [Humira]), also may be associated with neutropenia. The development of severe neutropenia in patients receiving these agents is more likely in patients with lower baseline neutrophil counts.

Nutritional Deficiencies

Ineffective myelopoiesis can result from congenital or acquired vitamin B12 or folic acid, and rarely copper deficiency. B12 and folate are essential components in DNA synthesis, necessary for the constant production of neutrophils. Severe B12 deficiency can present as pancytopenia. Typically affected individuals display macrocytosis, may have the characteristic hypersegmented neutrophils, as well as high levels of lactate dehydrogenase. Patients with severe folate deficiency will manifest the same hematologic findings but lack other symptoms, such as posterior column findings. Severe copper deficiency can result in peripheral blood and bone marrow findings that mimic myelodysplastic syndromes; in addition, patients with long-standing deficiency may also exhibit peripheral neuropathy, fatigue, and arthritis. Of note, patients who have undergone bariatric surgery are at risk for severe B12 and copper deficiencies, and therefore should be screened for this if they present with persistent and unexplained cytopenias. Protein calorie malnutrition, related to starvation or perhaps more commonly in the United States with anorexia nervosa, can lead to neutropenia. Other causes of myelosuppression include prolonged exposure to folate antagonists, such as trimethoprim/sulfamethoxazole (Bactrim), and chronic excessive alcohol use.

Primary and Secondary Disorders of Bone Marrow

Several hematologic malignancies can present with neutropenia, including myelodysplastic syndromes, acute myeloid and lymphoblastic leukemia and idiopathic aplastic anemia, myeloproliferative disorders, plasma cell dyscrasias, and lymphoma. In these disorders either through myelosuppression or infiltration, orderly hematopoiesis is disrupted. Hairy cell leukemia is associated with both neutropenia and monocytopenia, and affected patients often present with splenomegaly. Such patients may have a well-documented history of mild neutropenia for many years before a definitive diagnosis is made. Metastatic cancer, in particular prostate, breast, and non-small cell lung cancer, can be associated

with neutropenia as well as other cytopenias due to infiltration of the marrow cavity.

Large granular lymphocytosis, sometimes referred to as LGL leukemia, can be associated with neutropenia. In this rare disorder, patients are typically over the age of 60 years and often present with profound neutropenia. Less commonly affected patients will have constitutional symptoms and hepatosplenomegaly. The abnormal lymphocytes aberrantly express NK- and T-cell markers such as CD52 and CD57. Examination of a peripheral blood smear reveals lymphocytes with abnormal granules, but definitive diagnosis usually rests on flow cytometric analysis of peripheral blood. Treatment typically consists of low dose cyclosporine¹, methotrexate¹ or cyclophosphamide (Cytoxan)¹. Rheumatologic disorders associated with neutropenia include systemic lupus, in which patients with anti-Ro or SSA antibodies appear more likely to display neutropenia. There is also evidence that such patients have T-cell or monocyte-mediated myelosuppression, possibly through the elaboration of various cytokines.

Felty's syndrome is a clinical triad that refers to the presence of rheumatoid arthritis, splenomegaly, and neutropenia. Affected patients have often had deforming phenotype of RA for years; due to the development of more effective treatments for RA, this syndrome is encountered less often. Such patients can develop severe and life-threatening infections. Flow cytometry of peripheral blood reveals a predominance of lymphocytes, but typically, these are polyclonal. There is a strong association with the development of this disorder with the presence of HLA DR4. Autoimmune neutropenia in the absence of a defined rheumatologic disorders can also occur, and is often mild. Indications for treatment include an absolute neutrophil count less than 500/mm³ as well as constitutional symptoms such as fever or infection. Such patients typically respond to corticosteroids or intravenous gamma globulin (Gamunex)¹.

Autoimmune neutropenia is almost exclusively seen in children between the ages of 6 and 12 months. The etiology remains obscure, but affected children generate antibodies against human neutrophil antigens 1 and 1, as well as the FcReceptor CyRbIIIb and CD 11b, an integrin expressed on many leukocytes, including neutrophils, monocytes, and NK cells. The condition is typically self-limiting, with most patients recovering after several years. Affected children may have very low neutrophil counts, ranging between 0–150/mm³, and with many of the patients are under 2 years of age. The diagnosis is often one of exclusion, although testing for antineutrophil antibodies can be performed looking for antibodies against the above epitopes, noting the previously mentioned caveats. Treatment consists of supportive care with prophylactic antibiotics as appropriate.

Paroxysmal nocturnal hemoglobinuria is a rare, acquired disorder, best grouped under bone marrow failure syndromes, in which affected individuals display a variety of symptoms, including cytopenias, abnormal blood clotting, and hemoglobinuria. Patients may experience periods of relatively normal health and blood counts, but a substantial percentage of patients go on to develop aplasia or myelodysplasia. The disease is caused by mutations in the PIG-A gene, which then results in loss of GPI-anchored proteins. Diagnosis is typically made by flow cytometry, looking for cells that lack CD56 and CD 59. Treatments included supportive care, anticoagulation for patients with thrombosis, and the complement inhibitor Eculizumab (Soliris). Bone marrow transplantation offers the only curative therapy.

Chronic Idiopathic Neutropenia

Rarely adult patients present with chronic neutropenia with no specific etiology found. This is termed *chronic idiopathic neutropenia* (CIN) and should only be applied to a patient who has undergone a thorough evaluation for other etiologies. Patients tend to have quite low neutrophil counts but otherwise appear healthy, and there is a female predominance. The label CIN is typically applied

¹Not FDA approved for this indication.

to patients whose neutropenia lasts more than 3 months. As part of the presentation, other cell line numbers, such as red cells and platelets, should be normal. In addition, absolute numbers of other white blood cell count components, e.g., monocytes, eosinophils, and basophils, should also be within normal limits. There is no known associated genetic alteration to explain this presentation at this time. A majority of these patients trace their heredity to the Greek Islands.

Splenic Enlargement/Sequestration

Splenic enlargement results from intrinsic splenic disease such as glycogen.

Storage diseases (e.g., Gaucher's disease) or systemic causes of splenic hyperplasia arising from portal hypertension, cirrhosis, chronic inflammation, neoplasia (such as marginal zone lymphoma or hairy cell leukemia), or chronic hemolytic anemias can lead to secondary neutropenia due to presumed sequestration. Usually the neutropenia is mild to moderate, and often patients have accompanying mild anemia and thrombocytopenia. The cytopenias may improve with treatment of any underlying infiltrative disease. Splenectomy should be reserved for very select cases, due to its associated subsequent prolonged increased risk of infection and thrombosis.

Genetic Disorders Associated With Neutropenia

Neutropenia discovered in an infant or child is often benign and self-limited. However, several genetic disorders, commonly grouped as severe congenital neutropenia (SGN), are associated with profound neutropenia. Collectively these disorders have a very low incidence of around 6/1,000,000 children. Table 2 outlines the most frequently seen genetic disorders. The etiology of these disorders remained obscure until most cases were linked to mutations in ELANE, formerly known as ELA2. ELANE encodes for a serine protease that cleaves elastin and other proteins. This enzyme is inhibited by alpha-1-antitrypsin. Mutations in the mitochondrial gene, HAX1, also frequently encountered in this scenario. Some patients with SGN appear to have very mild or no symptoms, whereas others experience recurrent ulcerations and febrile episodes. Patients can be treated intermittently with G-CSF in the form of filgrastim¹ or other analogues. The diagnosis is typically made by having a patient undergo serial blood counts over several weeks to months. Many of these disorders can progress over many years to acute leukemia; however, there is no convincing data that the use of growth factors promotes this transformation. On the other hand, cyclic neutropenia is defined as neutropenia recurring roughly every 2 to 5 weeks and lasting 3 to 6 days. Although patterns vary from patient to patient, they tend to be internally consistent for a given patient. As opposed to children with SCN, patients with cyclic neutropenia are often not diagnosed until adulthood, and their associated infections are often quite mild. These patients can also benefit from intermittent G-CSF, and there is a very low risk of progression to AML. Over 70 different mutations leading to SCN or cyclic neutropenia have been described, and mutations in ELANE have been implicated in both disorders. However, additional factors modifying the genotype are not known.

Kostmann syndrome, first identified in 1950, is an autosomal recessive disorder characterized by profound neutropenia, neurological manifestations, and a strong propensity to develop life threatening bacterial and fungal infections. Patients are typically identified in infancy. Recently, mutations in the HAX1 gene have been identified, which is important for maintaining mitochondrial integrity and appears integral in regulating neutrophil apoptosis. These patients can be supported with G-CSF. Unfortunately, affected children have an increased risk of developing acute myelogenous leukemia and myeloma dysplastic syndromes.

WHIM syndrome, which stands for Warts, Hypogammaglobulinemia, Immunodeficiency, and Myelokathexis, is an autosomal dominant disorder caused by mutations that affect the function of chemokine receptor type 4 (CXCR4), expressed in various cells.

TABLE 2 Acquired Disorders Associated With Neutropenia

CAUSE	ETIOLOGIC FACTORS AND AGENTS	ASSOCIATED FINDINGS
Aplastic anemia	Stem cell destruction and depletion	Pancytopenia
Vitamin B ₁₂ or folate deficiency Copper deficiency Chronic alcohol ingestion	Malnutrition; congenital deficiency of B ₁₂ absorption, transport, and storage; vitamin avoidance Bariatric surgery; excessive zinc supplementation Maturation arrest; impaired chemotaxis	Megaloblastic anemia, hypersegmented neutrophils Anemia, neuropathy Increased infections, thrombocytopenia
Acute leukemia, chronic myelogenous leukemia	Bone marrow replacement with malignant cells	Pancytopenia, leukocytosis
Myelodysplasia	Dysplastic maturation of stem cells	Bone marrow hypoplasia/hyperplasia with megaloblastoid red cell precursors, thrombocytopenia
Prematurity with birth weight <2 kg	Impaired regulation of myeloid proliferation and reduced size of postmitotic pool	Maternal preeclampsia
Chronic idiopathic neutropenia	Impaired myeloid proliferation and/or maturation	None
Paroxysmal nocturnal hemoglobinuria	Acquired stem cell defect secondary to mutation of PIG-A gene	Pancytopenia, thrombosis, venothromboembolism; iron deficiency

Adapted from Newburger PE, Boxer LA. Leukopenia. In Kliegman RM, Stanton BF, St. Gene III JW, et al. (eds). *Nelson Textbook of Pediatrics*, 19th ed. Philadelphia: Saunders, 2011, p. 748.

Affected patients present with profound neutropenia, and the etiology appears to be the impaired release of neutrophils from the bone marrow compartment. Patients also show reduced numbers of B cells and a propensity for infections with human papilloma virus, which may be refractory to therapy. Studies are under way to evaluate if the stem cell-mobilizing agent plerixafor (Mozobil)¹ may be of benefit in these patients.

Chediak-Higashi syndrome, another rare autosomal dominant disorder, is characterized by oculocutaneous albinism, bleeding diathesis, neuropathy, and recurrent infections. A hallmark of this disorder are abnormally large azurophilic granules in neutrophils that tend to be reduced in number. This rare syndrome derives from mutations in the lysosomal-trafficking regulator gene LYST. The only treatment to cure this disorder is hematopoietic stem cell transplantation.

Griscelli syndrome type II is a rare autosomal disorder characterized by hypopigmentation of the skin, presence of large clumps of pigment in the hair shafts, and abnormal accumulation of end-stage melanosomes in melanocytes. Unlike Che'diak-Higashi

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

syndrome, peripheral granulocytes do not exhibit giant granules. Patients have mild neutropenia, which is caused by a mutation in RAB27a; the mutation leads to a predisposition to the hemophagocytic syndrome. The only curative to treatment is hematopoietic stem cell transplantation.

Schwachmann-Diamond is a rare autosomal recessive disorder, resulting from mutations in the SBDS gene located on chromosome 7. The disorder is characterized by pancreatic exocrine deficiency, skeletal abnormalities, delayed neurologic development, and bone marrow dysfunction including increased risk of myelodysplasia and AML. Affected individuals present with neutrophils counts $<1000/\text{mm}^3$ and typically are diagnosed in infancy.

Dyskeratosis congenita typically results from mutations in the DKC1 gene, inherited in an X-linked fashion, although autosomal dominant inheritance is seen in about 10% of cases. Patients present in early adolescence with nail dystrophy, abnormal skin pigmentation and leukoplakia, as well as pulmonary and hepatic findings. There is a high rate of progression to aplastic anemia. The treatment of choice is allogeneic bone marrow transplantation, but patients appear to have excess chemotherapy-related morbidity with this procedure.

Glycogen Storage Diseases Associated With Neutropenia

Glycogen storage disease type 1b features neutropenia and recurrent infections, along with the more common manifestations of glycogen storage diseases, e.g., glycogen accumulation in the liver, and hypoglycemic events. This rare, autosomal recessive disorder results from a deficiency in glucose-6-phosphate transporter (G6PT). Severe neutropenia can also be seen in patients with G6PC3 mutations. These individuals also tend to have genitourinary malformations and cardiac abnormalities.

Infants and children with persistent neutropenia, particularly if there are other noteworthy physical signs and symptoms, should be referred to a pediatric hematologist or academic center with expertise in managing these disorders.

Miscellaneous Genetic Disorders

Familial hemophagocytic lymphohistiocytosis (FLH) is a rare autosomal recessive disorder caused by mutations in a number of genes, including *PRF1* (FHL2), *UNC13D* (FHL3), *STX11* (FHL4), and *STXBP2* (FHL5). Affected individuals present early in life with a variety of symptoms, including fever, hepatosplenomegaly, and variable cytopenias. Patients also manifest hyperferritinemia, which is a distinctive feature of FLH, along with other liver function abnormalities. The disorder is uniformly fatal without treatment, which typically consists of the agent etoposide (Toposar)¹ and maintenance therapy with cyclosporine (Neoral)¹.

NON-HODGKIN LYMPHOMA

Method of

Andrew M. Evens, DO, MSc

CURRENT DIAGNOSIS

- The etiology of non-Hodgkin lymphoma (NHL) is not known, although several risk factors and conditions are associated with an increased risk of developing lymphoma, including congenital immunosuppression conditions (ataxia-telangiectasia, Wiskott-Aldrich syndrome, and X-linked lymphoproliferative syndrome), acquired immunodeficiency states (e.g., HIV and after solid organ transplantation), viruses (e.g., human T-lymphotrophic virus (HTLV)-1 and hepatitis C virus), and autoimmune disorders (e.g., Sjögren's syndrome, celiac sprue, and systemic lupus erythematosus).
- Patients most commonly present clinically with enlarged lymph nodes, splenomegaly, and bone marrow involvement, but they may also present with other extranodal disease sites (e.g., stomach, skin, liver, bone, brain).
- NHL has many different clinicopathologic subtypes—more than 70 types are included in the World Health Organization's classification of lymphoid neoplasms. The natural history and prognosis of these vary greatly from indolent and slow-growing types (over many years) to highly aggressive (within weeks) types.
- Excisional lymph node resection is the gold standard procedure in establishing the precise NHL histology. Expert hematopathology review incorporating morphologic, immunophenotypic, and genetic features is essential for an accurate diagnosis.

CURRENT THERAPY

- Indolent lymphomas are low-grade and represent slow-growing non-Hodgkin lymphoma (NHL) that may remain stable with low tumor burden not warranting therapy for several years. The disease is highly responsive to treatment with a variety of treatment options (remission rates exceeding 90% with combined rituximab/chemotherapy), although the clinical course is characterized by repetitive relapses. Outside of early-stage disease and therapy with allogeneic stem cell transplantation, low-grade NHLs are not curable.
- Transformation of follicular lymphoma to a high-grade NHL occurs in 30% to 40%, or 3% to 4% of patients each year; it is less common in other indolent subtypes. Transformation is typically heralded by an aggressive change in the patient's clinical condition.
- Diffuse large B-cell lymphoma (DLBCL), the most common aggressive NHL, is curable in all stages in the majority of patients with rituximab (Rituxan)-based chemotherapy. A variety of primary extranodal DLBCL clinical subtypes warrant specialized therapy, such as primary central nervous system lymphoma.
- Long-term survivors are at increased risk for second cancers. The highest relative risk of developing a secondary malignancy occurs more than 21 to 30 years after original diagnosis. Patients who received an anthracycline (e.g., doxorubicin [Adriamycin]) as part of therapy are at a long-term increased risk for cardiovascular disease.

syndrome, peripheral granulocytes do not exhibit giant granules. Patients have mild neutropenia, which is caused by a mutation in RAB27a; the mutation leads to a predisposition to the hemophagocytic syndrome. The only curative to treatment is hematopoietic stem cell transplantation.

Schwachmann-Diamond is a rare autosomal recessive disorder, resulting from mutations in the SBDS gene located on chromosome 7. The disorder is characterized by pancreatic exocrine deficiency, skeletal abnormalities, delayed neurologic development, and bone marrow dysfunction including increased risk of myelodysplasia and AML. Affected individuals present with neutrophils counts $<1000/\text{mm}^3$ and typically are diagnosed in infancy.

Dyskeratosis congenita typically results from mutations in the DKC1 gene, inherited in an X-linked fashion, although autosomal dominant inheritance is seen in about 10% of cases. Patients present in early adolescence with nail dystrophy, abnormal skin pigmentation and leukoplakia, as well as pulmonary and hepatic findings. There is a high rate of progression to aplastic anemia. The treatment of choice is allogeneic bone marrow transplantation, but patients appear to have excess chemotherapy-related morbidity with this procedure.

Glycogen Storage Diseases Associated With Neutropenia

NON-HODGKIN LYMPHOMA

Method of

Andrew M. Evens, DO, MSc

CURRENT DIAGNOSIS

- The etiology of non-Hodgkin lymphoma (NHL) is not known, although several risk factors and conditions are associated with an increased risk of developing lymphoma, including congenital immunosuppression conditions (ataxia-telangiectasia, Wiskott-Aldrich syndrome, and X-linked lymphoproliferative syndrome), acquired immunodeficiency states (e.g., HIV and after solid organ transplantation), viruses (e.g., human T-lymphotrophic virus (HTLV)-1 and hepatitis C virus), and autoimmune disorders (e.g., Sjögren's syndrome, celiac sprue, and systemic lupus erythematosus).
- Patients most commonly present clinically with enlarged lymph nodes, splenomegaly, and bone marrow involvement, but they may also present with other extranodal disease sites (e.g., stomach, skin, liver, bone, brain).
- NHL has many different clinicopathologic subtypes—more than 70 types are included in the World Health Organization's classification of lymphoid neoplasms. The natural history and prognosis of these vary greatly from indolent and slow-growing types (over many years) to highly aggressive (within weeks) types.
- Excisional lymph node resection is the gold standard procedure in establishing the precise NHL histology. Expert hematopathology review incorporating morphologic, immunophenotypic, and genetic features is essential for an accurate diagnosis.

CURRENT THERAPY

- Indolent lymphomas are low-grade and represent slow-growing non-Hodgkin lymphoma (NHL) that may remain stable with low tumor burden not warranting therapy for several years. The disease is highly responsive to treatment with a variety of treatment options (remission rates exceeding 90% with combined rituximab/chemotherapy), although the clinical course is characterized by repetitive relapses. Outside of early-stage disease and therapy with allogeneic stem cell transplantation, low-grade NHLs are not curable.
- Transformation of follicular lymphoma to a high-grade NHL occurs in 30% to 40%, or 3% to 4% of patients each year; it is less common in other indolent subtypes. Transformation is typically heralded by an aggressive change in the patient's clinical condition.
- Diffuse large B-cell lymphoma (DLBCL), the most common aggressive NHL, is curable in all stages in the majority of patients with rituximab (Rituxan)-based chemotherapy. A variety of primary extranodal DLBCL clinical subtypes warrant specialized therapy, such as primary central nervous system lymphoma.
- Long-term survivors are at increased risk for second cancers. The highest relative risk of developing a secondary malignancy occurs more than 21 to 30 years after original diagnosis. Patients who received an anthracycline (e.g., doxorubicin [Adriamycin]) as part of therapy are at a long-term increased risk for cardiovascular disease.

The term *malignant lymphoma* was originally introduced by Billroth in 1871 to describe neoplasms of lymphoid tissue. Generally speaking, lymphomas are neoplasms of the immune system. Traditionally, lymphomas are divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).

There are many different clinicopathologic subtypes of NHL (>60). By cell of origin, the majority of NHLs are of B-cell origin (85%–90%); T-cell NHLs account for 10% to 15% of lymphomas in the United States, whereas natural killer cell or histiocytic lymphomas are rare (<1%).

NHLs manifest most commonly clinically with involvement of lymph nodes, spleen, and bone marrow, but they can involve other extranodal sites (stomach, skin, liver, bone, brain, etc.). Peripheral blood involvement uncommonly occurs (leukemic phase of lymphoma). The natural history and prognosis vary greatly among the different subtypes of NHL from indolent subtypes that are often slow-growing (i.e., therapy not warranted for years) to very aggressive and rapidly fatal types (within weeks) if not treated. Most NHL subtypes are highly treatable with initial remission rates over 90% to 95% using combined rituximab/chemotherapy; however, indolent NHLs are generally incurable, whereas the goal of treating most aggressive NHLs is cure.

Epidemiology

Currently, NHL represents approximately 5% of all cancer diagnoses, being the seventh-most common cancer in women and the seventh in men. Estimates from the American Cancer Society indicate that in 2017 approximately 72,240 new cases of NHL will be diagnosed in the United States and approximately 20,140 people

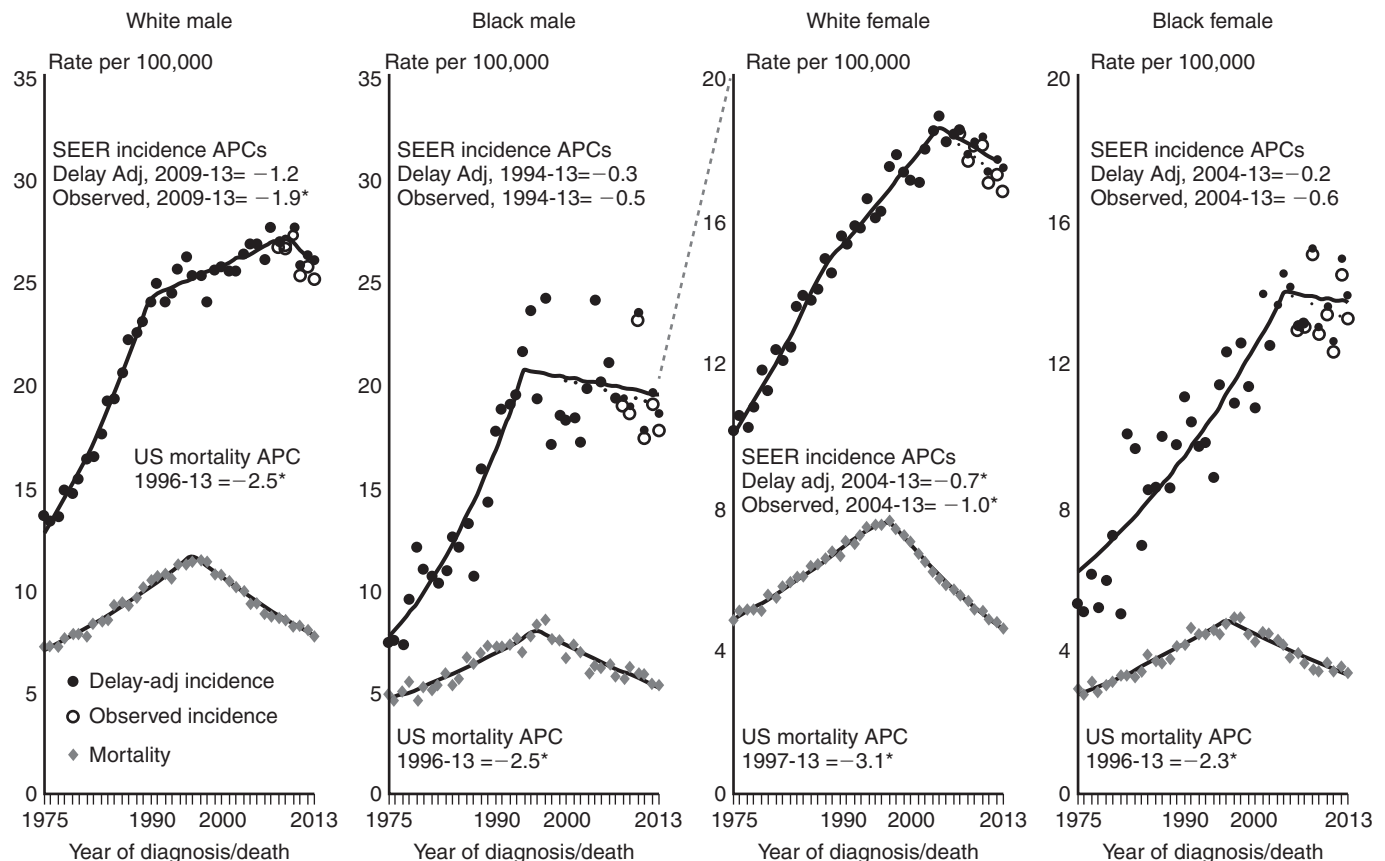

will die of the disease. In addition, there are approximately 600,000 people living with NHL in the United States.

Geographic Distribution

The incidence of NHL varies throughout the world, in general being more common in developed countries, with rates in the United States of more than 15 per 100,000 compared with 1.2 per 100,000 in China. In the United States, the incidence rates of NHL more than doubled between 1975 and 1995, representing one of the largest increases of any cancer. The increases have been more pronounced in whites, males, the elderly, and those with NHL diagnosed at extranodal sites. Similar findings have been reported in other developed countries. The incidence rates of NHL began to stabilize in the late 1990s, although the temporal trends vary by histologic subtype, as well as by race and sex (Figure 1). Some of the increase may be related to improved diagnostic techniques and access to medical care and the increased risk of NHL attributable to HIV infection. However, additional factors are likely responsible for this unexpected increase in incidence.

Age

Overall, NHL incidence rises exponentially with increasing age. In persons older than 65 years, the incidence is 90.9 per 100,000 population compared with 7.1 per 100,000 population for persons aged 20 to 49 years. Except for high-grade lymphoblastic and Burkitt lymphomas (the most common types of NHL seen in children and young adults), the median age at presentation for most subtypes of NHL exceeds 60 years.

Source: SEER 9 areas and US mortality files (national center for health statistics, CDC).

*Rates are age-adjusted to the 2000 US Std population (19 age groups - census P25-1103).

Regression lines and APCs are calculated using the joinpoint regression program version 4.3.0.0. April 2016, National cancer institute.

The APC is the annual percent change for the regression line segments. The APC shown on the graph is for the most recent trend.

*The APC is significantly different from zero ($p < 0.05$).

Figure 1 SEER observed incidence, SEER delay adjusted incidence, and US death rates for non-Hodgkin lymphoma, by race and sex.

Race and Ethnicity

Incidence varies by race and ethnicity, with whites overall having a higher risk than African Americans and Asian Americans (incidence rates increased 50% to 60% in whites compared with blacks). Most NHL subtypes are more common in whites than in blacks; however, peripheral T-cell lymphoma, mycosis fungoides, and Sézary syndrome occur more often in blacks than in whites.

Etiology and Risk Factors

Chromosomal Translocations and Molecular

Rearrangements

Nonrandom chromosomal and molecular rearrangements play an important role in the pathogenesis of many lymphomas and often correlate with histology and immunophenotype. These chromosomal changes often result in oncogenic gene products; for example, t(11;14)(q13;q32) translocation results in overexpression of *bcl-1* (cyclin D1) in mantle-cell lymphoma, while translocation with 8q24 leads to *c-myc* overexpression in nearly all Burkitt lymphomas and in 10%–15% of patients with diffuse large B-cell lymphoma. Research to discover more information regarding the prognostic and pathogenic importance of these oncogenes continues, although they are currently used primarily in clinical practice for diagnostic purposes. Additionally, these genes serve as potential targets for novel therapeutics.

Environmental Factors

Environmental factors may also play a role in the development of NHL, including particular occupations (e.g., chemists, painters, mechanics, machinists) and chemicals (solvents and pesticides). Patients who receive chemotherapy or radiation therapy for any indication are also at increased risk for developing NHL as a secondary cancer as discussed later.

Viruses

Several viruses have been implicated in the pathogenesis of NHL, including Epstein-Barr virus, human T-cell lymphotropic virus 1 (HTLV-1), Kaposi sarcoma–associated herpesvirus (KSHV, also known as human herpesvirus 8 [HHV-8]), and hepatitis C virus (HCV). Meta-analyses have shown 13% to 15% seroprevalence of HCV in certain geographic regions among persons with B-cell NHL. Further, HCV infection is associated with the development of clonal B-cell expansions and certain subtypes of NHL, particularly in the setting of essential (type II) mixed cryoglobulinemia. HTLV-1 is a human retrovirus that establishes a latent infection through reverse transcription in activated T-helper cells. A minority (5%) of carriers will develop adult T-cell leukemia lymphoma. KSHV-like DNA sequences are often detected in primary effusion lymphomas in patients with HIV infection and in those with multicentric (plasma cell variant) Castleman's disease.

Bacterial Infections

Gastric mucosa-associated lymphoid tissue (MALT) lymphoma is seen most often, but not exclusively, in association with *Helicobacter pylori* infection. Infection with *Borrelia burgdorferi* has been detected in about 35% of patients with primary cutaneous B-cell lymphoma in Scotland. Studies indicate that *Campylobacter jejuni* and immunoproliferative small intestinal disease are related. European reports have noted an association between infection with *Chlamydia psittaci* and ocular adnexal lymphoma. The infection was found to be highly specific and does not reflect a subclinical infection among the general population. Furthermore, remission of NHL to antibiotics has been reported. Attempts to confirm this association in the Western hemisphere have been unsuccessful.

Immunodeficiency

Patients with congenital conditions of immunosuppression are at increased risk of NHL. These conditions include ataxia-telangiectasia; Wiskott-Aldrich syndrome; X-linked lymphoproliferative syndrome; severe combined immunodeficiency;

acquired immunodeficiency states, such as HIV infection; and iatrogenic immunosuppression. Relative risk of NHL is increased 150- to 250-fold among patients with AIDS; patients usually develop high grade NHLs, such as Burkitt's lymphoma or diffuse large B-cell lymphoma. The incidence of posttransplantation lymphoproliferative disorders (PTLD) after solid organ transplantation ranges from 1% to 3% in kidney transplant recipients to 10% to 12% in heart and multiorgan transplant recipients, the latter who require more potent immunosuppressive therapy.

Autoimmunity

An increased incidence of gastrointestinal lymphomas is seen in patients with celiac (nontropical) sprue and inflammatory bowel disease, particularly Crohn's disease. An aberrant clonal intraepithelial T-cell population can be found in up to 75% of patients with refractory celiac sprue before overt T-cell lymphoma develops. Sjögren's disease is associated with a 6-fold increased risk of NHL overall with risk varying in part on severity of disease (5 to 200 times); moreover, the risk specifically of parotid marginal zone lymphoma is increased 1000-fold. Additionally, systemic lupus erythematosus and rheumatoid arthritis have been associated with a slightly increased risk of B-cell lymphoma.

Genetic Susceptibility

Several studies have implicated a role for genetic variants in the risk of NHL, including genes that influence DNA integrity and methylation, genes that alter B-cell survival and growth, and genes that involve innate immunity, oxidative stress, and xenobiotic metabolism.

Signs and Symptoms

Fever, weight loss, and night sweats, referred to as B symptoms, are more common in advanced and aggressive subtype NHLs, but they may be present at all stages and in any histologic subtype.

Low-Grade or Indolent Lymphomas

Painless, slowly progressive peripheral adenopathy is the most common clinical presentation in patients with low-grade lymphomas. Patients sometimes report a history of waxing and waning adenopathy before seeking medical attention. Spontaneous regression of enlarged lymph nodes can occur, which may cause a low-grade lymphoma to be confused with an infectious condition. Primary extranodal involvement and B symptoms are uncommon at presentation; however, both are more common in advanced or end-stage disease and in particular indolent NHL subtypes (e.g., gastric MALT and nongastric extranodal MALT). Bone marrow is frequently involved, sometimes in association with cytopenias. Splenomegaly is seen in about 40% of patients, but the spleen is rarely the only involved site besides the specific subtype of splenic marginal zone lymphoma.

High-Grade or Aggressive Lymphomas

The clinical presentation of high-grade lymphomas is more varied. Although the majority of patients present with adenopathy, more than one third present with extranodal involvement alone or with adenopathy, the most common sites being the gastrointestinal tract (including Waldeyer's ring), skin, bone marrow, sinuses, genitourinary tract, bone, and central nervous system. B symptoms are more common, occurring in about 30% to 40% of patients. Lymphoblastic lymphoma often manifests with an anterior superior mediastinal mass, superior vena cava syndrome, and leptomeningeal disease. American patients with Burkitt lymphoma often present with a large abdominal mass and symptoms of bowel obstruction. In addition, certain histologic NHL subtypes manifest with symptoms unique to that particular lymphoma subtype; for example, angioimmunoblastic T-cell lymphoma (AITL) in addition to lymphadenopathy presents with disease features including organomegaly, skin rash, pleural effusions, arthritis, eosinophilia, and varied immunologic abnormalities such as positive Coombs' test, cold agglutinins, hemolytic anemia, antinuclear antibodies, and polyclonal hypergammaglobulinemia.

Screening

No effective methods are currently available for screening patients or populations for NHL.

Diagnosis

A definitive diagnosis can be made only by biopsy of pathologic lymph nodes or tumor tissue. It is critical in most cases to perform an *excisional* lymph node resection to avoid false-negative results and inaccurate histologic classification; fine-needle aspirations or core biopsies are often insufficient for diagnostic purposes. When clinical circumstances make surgical biopsy of involved lymph nodes or extranodal sites prohibitive, a core biopsy obtained under CT or ultrasonographic guidance may suffice, but it often requires the integration of histologic examination and immunophenotypic and molecular studies for accurate diagnosis. A formal review by an expert hematopathologist is mandatory. In addition to morphologic review and immunostaining of tissue, other studies such as detailed cellular immunophenotyping and genotyping for relevant oncogenes are often needed to complete the diagnosis.

In addition to a detailed history and physical examination, baseline staging studies are warranted. These consist of blood tests (complete blood count with differential, complete metabolic panel including liver function tests, and lactate dehydrogenase), CT of chest, abdomen, and pelvis, and bilateral bone marrow biopsy and aspirate (Box 1). For aggressive NHL histologies, functional imaging is advocated (i.e., FDG-PET [fluorodeoxyglucose (¹⁸F) positron emission tomography]), as is assessment of ejection fraction in anticipation of anthracycline-based chemotherapy. Testing for history of hepatitis B virus (HBV) is recommended, especially before starting anti-CD20 antibody therapy; evidence suggests that anti-CD20 antibody therapy (e.g., rituximab) increases the risk of HBV reactivation above the known rate of chemotherapy-associated reactivation. HIV serology should be obtained in patients with relevant risk factors, especially for diffuse large B-cell lymphoma (DLBCL) and Burkitt lymphoma. HTLV-1 serology is recommended in patients who present with cutaneous T-cell lymphoma lesions, especially if they have hypercalcemia.

BOX 1

Initial Assessment and Workup for Non-Hodgkin Lymphoma

- Excisional tissue resection
- Detailed history and physical examination
- CBC with differential, metabolic panel (including liver function), and LDH
- CT scans (chest, abdomen, pelvis)
- Nuclear functional imaging (i.e., FDG-PET)*
- Bone marrow biopsy and aspirate
- Heart function (e.g., MUGA) if anthracycline therapy anticipated
- EGD, colonoscopy, or both†
- HIV and HBV testing (with risk factors and/or if monoclonal antibody therapy planned)
- Consider TB testing (i.e., PPD with anergy panel) with history of exposure
- Assessment of CSF (when applicable or with risk factors)‡
- Consider early institution of TLS prophylaxis (e.g., intravenous fluids, allopurinol [Zyloprim])*

*Primarily for aggressive NHL subtypes.

†With clinical suspicion of involvement; EGD for NHL head and neck involvement (e.g., tonsil, base of tongue, nasopharynx), and consider colonoscopy for MCL (if symptomatic).

‡Consider for aggressive histologies with <1 extranodal site and elevated LDH and for particular unique lymphoma locations (e.g., testicular, sinus, breast, paraspinal).

Abbreviations: CBC = complete blood count; CSF = cerebrospinal fluid; CT = computed tomography; EGD = esophagogastroduodenoscopy; FDG-PET = fluorodeoxyglucose (¹⁸F) positron emission tomography; HBV = hepatitis B virus; LDH = lactate dehydrogenase; MCL = mantle-cell lymphoma; MUGA = multigated acquisition [scan]; NHL = non-Hodgkin's lymphoma; PPD = purified protein derivative [tuberculosis test]; TB = tuberculosis; TLS = tumor lysis syndrome.

Examination of cerebrospinal fluid and consideration of intrathecal chemotherapy prophylaxis is applicable for patients with DLBCL with bone marrow, epidural, testicular, paranasal sinus, breast, or multiple extranodal sites (especially when in conjunction with elevated lactate dehydrogenase). Testing is mandatory for high-grade lymphoblastic lymphoma and Burkitt lymphoma and its variants and primary central nervous system lymphoma if there is no evidence of increased intracranial pressure. Upper gastrointestinal endoscopy or gastrointestinal series with small bowel follow-through is recommended in patients with head and neck involvement (tonsil, base of tongue, nasopharynx) and those with primary gastrointestinal disease. Mantle cell lymphoma is associated with a high incidence of occult gastrointestinal involvement. In addition, MRI of the complete craniospinal axis and ocular examination is advocated with any brain or leptomeningeal disease involvement to rule out multifocal disease.

Classification

The 1965 Rappaport's Classification of malignant lymphomas was based solely on architecture and cytology. Since then, with the help of advanced cellular and genetic technologies, numerous new unique NHL entities have emerged. The World Health Organization (WHO) classification was revised in 2016, which continues to emphasize immunophenotyping, genotyping, and clinical features (Table 1). Another way to group the many different lymphoma histologies is by clinical presentation and prognosis (Table 2).

TABLE 1 2016 WHO Classification of Mature Lymphoid, Histiocytic, and Dendritic Neoplasms

Mature B-cell neoplasms

Score ≥6: 30%

*Disease in bone marrow, CNS, liver/GI tract, or lung.

Prognosis**International Prognostic Index**

The International Prognostic Index was developed as a prognostic factor model for aggressive NHLs treated with doxorubicin-containing regimens (Box 2). In the pre-rituximab era, persons with no risk factors or one risk factor had a predicted 5-year overall survival rate of 73%, compared with 26% for high-risk patients with four or five risk factors. In the post-rituximab era, the survival rates have improved (see Box 2). A variant of the International Prognostic Index (IPI) is also useful in predicting outcome in patients with follicular low-grade lymphoma (FLIPI) or mantle cell lymphoma (MIPI) and in patients who have relapsed or refractory large B-cell lymphoma.

Molecular Profiling

DNA microarray technology for gene expression profiling has identified distinct prognostic subgroups in many NHL subtypes including DLBCL and follicular NHL. Patients with germinal center B-like DLBCL have an improved overall survival compared with other molecular profiles. Recent studies in follicular NHL have identified gene expression signatures that also predicted survival. Interestingly, the genes that defined the prognostic signatures were not expressed in the tumor cells, but were expressed by the nonmalignant tumor-infiltrating cells—primarily T cells, macrophages, and dendritic cells.

Treatment

The therapeutic approach for NHL differs for each clinicopathologic subtype. Chemotherapy remains the most important modality. However, in some instances, radiation therapy or, rarely, surgical resection plays a role. Biologic approaches, including monoclonal antibodies and antibody-drug conjugates have shown significant activity and are now incorporated into most treatment paradigms. Autologous and allogeneic stem-cell transplantation are mostly reserved for patients with recurrent or refractory disease.

Indolent B-Cell Non-Hodgkin Lymphomas

Indolent lymphomas are low-grade and represent slow-growing NHLs that may be stable with low tumor burden that may not warrant therapy for several years. The disease is responsive to treatment (remission rates above 90% with combined rituximab/chemotherapy), although the clinical course is characterized by repetitive relapses. Outside of early-stage disease and therapy with an allogeneic stem cell transplant, low-grade NHLs are not curable. The median survival of patients with advanced-stage follicular lymphoma in the pre-rituximab era was 9 to 10 years, although that is significantly longer now (approximately 15–17 years). Transformation to a high-grade NHL occurs in 30% to 40% (3%–4% of patients each year) of follicular lymphoma patients (less common in other indolent subtypes) and is typically heralded by an aggressive change in the patient's clinical condition (e.g., B symptoms, rapidly rising LDH).

General Principles

Only a minority of patients present with early-stage disease (i.e., stage I or II). Low-dose involved field radiotherapy is a valid treatment option for these patients (especially stage I and not central sites of disease), and associated 15- to 20-year disease-free survival rates are greater than 50%. Treatment for patients with advanced-stage disease ranges from observation (i.e., watchful waiting) to anti-CD20 monoclonal antibody therapy (rituximab [Rituxan]) with or without chemotherapy. Treatment choice depends in part on tumor burden and the patient's individual disease characteristics and baseline functional status. Treatment with frontline rituximab chemotherapy (outpatient therapy given once every 3–4 weeks typically for 6–8 cycles) for patients with high tumor burden is associated with median progression-free survival rates of approximately 4 to 5 years.

Treatment options for relapsed indolent lymphoma include repeating rituximab with or without a different chemotherapy regimen, radioimmunotherapy, or stem-cell transplantation. Autologous stem-cell transplantation is an option for patients with relapsed disease, although an improvement in overall survival is debated. Allogeneic stem cell transplantation is a potential curative modality for patients with relapsed or refractory disease, although patient selection is critical owing to potential morbidity and mortality related to this therapeutic option.

Special Considerations

Localized gastric MALT lymphoma cases often may be managed with therapy for *H pylori* infection; radiation is typically reserved for failure to eradicate *H pylori*. Patients with lymphoplasmacytic lymphoma (Waldenström's macroglobulinemia) can present clinically with hyperviscosity or cryoglobulinemia, which may be

managed acutely with plasmapheresis, but ultimately systemic therapy similar to that for other indolent NHLs is warranted.

Aggressive or High-Grade Non-Hodgkin Lymphomas

High-grade B- and T-cell NHLs are typically aggressive lymphomas that are fatal in weeks to a few months if not treated. However, many of these NHLs are curable with multiagent chemotherapy.

General Principles

DLBCL, the most common aggressive NHL, is curable in all stages in the majority of patients (60%–70%). A key to treatment is anti-CD20 monoclonal antibody combined with anthracycline-based chemotherapy: rituximab-CHOP (R-CHOP) (cyclophosphamide, doxorubicin, vincristine, prednisone). The number of treatment cycles depends on stage of disease and response to treatment. Standard therapy for advanced-stage disease is 6 R-CHOP cycles, whereas patients with early-stage disease may receive 3 or 4 cycles followed by involved field radiation. There are emerging data regarding the prognostic importance of *MYC* rearrangement (from tumor testing) as a single finding and especially in conjunction with *BCL-2* and/or *BCL6* (i.e., double or triple hit) by molecular studies as well as with immunohistochemical staining. Outcomes with R-CHOP for DLBCL patients with a molecular double hit (e.g., presence of *MYC* and *BCL-2*) are modest; more intensive and novel therapeutic options should be considered. Therapy for relapsed DLBCL typically includes abbreviated salvage non-cross-resistant chemotherapy followed by autologous stem-cell transplantation (autoSCT) for patients who have chemotherapy-sensitive disease, which is curative in approximately 35% to 45% of patients.

Mantle cell lymphoma is a B-cell NHL with initial high remission rates (>90–95%), but it has more modest long-term outcomes, and it is difficult to cure. With standard chemotherapy regimens (e.g., R-CHOP), the median progression-free survival rates are only 18 to 20 months. With more-intensive chemotherapy regimens (e.g., R-hyperCVAD/R-MA [rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone/rituximab, methotrexate]), 5-year progression-free survival rates are near 70%. Some groups induction therapy with aggressive high-dose cytarabine¹ (Cytosar-U)-based chemotherapy followed by consolidative autologous stem-cell transplantation in first remission. As noted later, there has been the integration of several novel therapeutic agents into the treatment paradigm of mantle-cell lymphoma.

Burkitt's lymphoma and related high-grade NHLs (e.g., lymphoblastic lymphomas) are often rapidly growing malignancies with a doubling time of 24 hours. Prompt initiation of therapy, including aggressive supportive care measures, is often warranted. With aggressive chemotherapy regimens, including prophylactic intrathecal chemotherapy, the majority of Burkitt's patients younger than age 50 years are cured (>70%–80%). In addition, there are data showing high efficacy using lower-intensity treatment consisting of infused etoposide (Toposar¹), doxorubicin, and cyclophosphamide with vincristine, prednisone, and rituximab (EPOCH-R) for patients with untreated Burkitt's lymphoma.

Systemic (i.e., non-cutaneous) peripheral T-cell NHLs are mostly aggressive malignancies; they are treatable, however, cure rates are significantly lower compared with most aggressive B-cell NHLs. Standard therapy consists typically of CHOP-based chemotherapy with or without autologous SCT in first remission as consolidation. Associated five-year disease-free survival rates are approximately 20% to 30%. Several novel targeted agents have also been FDA approved over the last several years for the treatment of T-cell NHL (see below).

Special Considerations

There are several clinical subtypes of DLBCL that present as primary extranodal manifestations such as primary testicular DLBCL and primary gastric DLBCL. If these lymphomas are localized,

treatment typically consists of abbreviated cycles (3–4) of R-CHOP followed by involved field radiation. In addition, intrathecal chemotherapy prophylaxis is warranted for testicular DLBCL given the predilection of CNS involvement.

Primary central nervous system lymphoma is typically DLBCL; high-dose methotrexate chemotherapy is a key component of therapy.

A long-standing therapeutic maneuver for solid organ transplant-related PTLDs has been reduction of immunosuppression, although, using this approach alone, mortality rates have ranged from 50% to 60% in most series. Recent evidence with use of initial rituximab-based therapy suggests significantly improved outcomes in the modern era.

The majority of AIDS-related NHLs are aggressive or high-grade types: DLBCL or Burkitt lymphoma. Similar therapy as immunocompetent NHL is often recommended. Response to therapy, including cure rate, has improved significantly with better control of opportunistic infections and highly active antiretroviral therapy (HAART).

Mycosis fungoides and Sézary syndrome are cutaneous T-cell lymphomas that initially might show eczematous lesions. It is often difficult to establish diagnosis, but eventually the lesions develop into plaques and tumors. Lymph nodes, spleen, and visceral organs may be involved. Sézary syndrome is a variant of mycosis fungoides and shows peripheral blood involvement; patients usually have diffuse erythroderma. Skin-targeted modalities for treatment of early-stage mycosis fungoides include psoralens with ultraviolet A light (PUVA), narrowband-ultraviolet light, skin electron-beam radiation, and topical steroids, retinoids, carmustine (BiCNU), and nitrogen mustard (Mustargen).¹ Treatment goals in advanced stages are to reduce tumor burden and to relieve symptoms. Treatment options also include mono- or polychemotherapy including CHOP, extracorporeal photopheresis, interferons, retinoids, monoclonal antibodies, and recombinant toxins.

During therapy for aggressive/high-grade NHLs, attention should be paid to preventing tumor lysis syndrome. Measures to prevent this complication include aggressive hydration, allopurinol (Zyloprim), alkalinization of the urine, and frequent monitoring of electrolytes, uric acid, and creatinine. Rasburicase (Elitek), a recombinant urate oxidase enzyme, is an expensive but potent agent for treating hyperuricemia.

Novel Treatment Options and Modalities

Many new agents targeting specific molecular targets have become available for the treatment of lymphoma. Novel agents in lymphoma include bortezomib (Velcade) and lenalidomide (Revlimid), which are FDA approved for relapsed or refractory mantle-cell lymphoma, and histone deacetylase inhibitors, which are approved for cutaneous T-cell lymphoma and peripheral T-cell NHLs as well. In addition, bortezomib was recently FDA approved for untreated mantle-cell lymphoma patients (in combination with immunochemotherapy). Other new agents which are FDA approved for the treatment of patients with chronic lymphocytic leukemia (CLL), including in higher risk patient populations (e.g., p53 mutated), are idelalisib (Zydeliq), an inhibitor of PI3K delta; an inhibitor of Bruton's tyrosine kinase (BTK), ibrutinib (Imbruvica), which is also FDA approved for patients with CLL Mantle cell lymphoma (MCL); and venetoclax (Venclexta), a BCL2 mimetic acting as an inhibitor of BCL2. New anti-CD20 antibodies have also been approved for the treatment of CLL (e.g., obinutuzumab (Gazyva) and antibody drug conjugates, such as brentuximab vedotin (Adcetris), which is FDA approved for relapsed anaplastic (T-cell) large-cell lymphoma. These novel therapeutic agents are mostly FDA approved for patients with relapsed or refractory disease, however, there are a multitude of ongoing studies in the frontline/untreated setting and in varied sequences and combinations. There also remains great excitement in the continued application of new immunotherapy approaches in NHL such as via checkpoint inhibitors (e.g., programmed death-1 (PD-1) inhibitors) as well as chimeric antigen receptor (CAR) T-cell

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

therapy, which involve removal of T-cells from patients followed by bioengineered CARs (e.g., CD19) that facilitate antigen/tumor recognition when re-infused into the patient.

Follow-Up of Long-Term Survivors Relapse

Among patients with aggressive lymphomas, such as DLBCL, most recurrences are seen within the first 2 years after the completion of therapy, although later relapses occur uncommonly. Physical examination and laboratory testing at 2- to 3-month intervals and follow-up CT scans at 6-month intervals for the first 2 years after diagnosis are recommended; however, there is ongoing debate regarding the impact that post-surveillance scans have on disease outcomes. Detection of recurrent disease is important in part because these patients may be candidates for potentially curative therapy (e.g., stem-cell transplantation). Patients with advanced low-grade NHL are at a constant risk for relapse, as discussed before.

Secondary Malignancies

Long-term NHL survivors are at an increased risk for second cancers. Generally, the risk is increased with history of radiation use, but it is also seen with chemotherapy. In a survey of 28,131 Dutch registry patients with NHL who survived 2 years or longer, significant excesses of second cancers were seen for nearly all solid tumors as well as acute myelogenous leukemia (AML) and Hodgkin's lymphoma. The standardized incidence ratio (SIR) for solid tumors after NHL was 1.65. The SIRs for solid tumors are increased for up to 30 years after NHL diagnosis, with the highest relative risk of developing a secondary malignancy occurring more than 21 to 30 years after original diagnosis.

Late Treatment Complications

There has been more selective use of radiation as part of therapy for NHL. Thus the risk of certain radiation-induced complications has been reduced in patients treated more recently. Nevertheless, the risk still exists. Transplant recipients are at increased risk for secondary myelodysplasia and AML, regardless of whether they received radiation. All chemotherapy agents may cause long-term morbidity; in particular, patients who received an anthracycline (e.g., doxorubicin [Adriamycin]) are at a long-term increased risk of cardiovascular disease. Among Dutch and Belgian NHL patients treated with at least six cycles of doxorubicin-based chemotherapy, cumulative incidence of cardiovascular disease was 12% at 5 years and 22% at 10 years. Risk of coronary artery disease matched that of the general population; however, risk of chronic heart failure was significantly increased (SIR, 5.4) as was stroke (SIR, 1.8). Risk factors associated with excess risk included younger age at start of NHL treatment (<55 years), preexisting hypertension, any salvage treatment, and use of radiotherapy; risk relating to radiotherapy was dose-dependent. Continued studies are needed to develop optimal secondary prevention strategies.

PERNICIOUS ANEMIA AND OTHER MEGALOBlastic ANEMIAS

Method of

Emmanuel Andr s, MD, PhD

CURRENT DIAGNOSIS

- Megaloblastic anemia is a macrocytic anemia characterized by macroovalocytes and hypersegmented neutrophils on the peripheral smear.
- In adults, many underlying conditions lead to megaloblastic anemia, but the most common ones are folate (folic acid, vitamin B₉) deficiency, vitamin B₁₂ (cobalamin) deficiency, and pernicious anemia.
- In the adult population, folate deficiency usually develops as a result of inadequate dietary intake or as an adverse effect of several drugs (methotrexate [Trexal], cotrimoxazole [Bactrim], sulfasalazine [Azulfidine], anticonvulsants) or alcohol intake.
- In adults and the elderly, vitamin B₁₂ deficiency is mainly due to cobalamin malabsorption from food and to pernicious anemia.

CURRENT THERAPY

- Recognition of the condition causing megaloblastic anemia is a prerequisite of successful therapy.
- Treatment of nutrient-deficiency megaloblastic anemia is easy with nutrient replacement.
- Vitamin B₁₂ deficiency can be treated with both oral and parenteral therapy.
- If vitamin B₁₂ deficiency is untreated, folate repletion will correct the megaloblastic anemia but not the associated neuro-pathic changes that occur with B₁₂ deficiency.

Anemia is a common condition, especially in adults, and its prevalence increases with age. It affects quality of life, physical function, and even cognitive function in elderly patients. Anemia is a comorbid condition that affects other diseases (e.g., heart disease, cerebrovascular insufficiency) and is associated with a risk of death. Thus, anemia should not be accepted as a benign condition or a consequence of aging. In adults, many underlying conditions lead to megaloblastic anemia, but the most common ones are nutrient deficiencies, especially folate (folic acid, vitamin B₉) deficiency, vitamin B₁₂ (cobalamin) deficiency, and pernicious anemia. Recognition of these conditions is a prerequisite of successful therapy.

Although low hemoglobin levels are often seen with advancing age, anemia should not be assumed to be a normal consequence of aging. Age may be associated with compromised hematopoietic reserve, and the elderly can be more susceptible to anemia in the

therapy, which involve removal of T-cells from patients followed by bioengineered CARs (e.g., CD19) that facilitate antigen/tumor recognition when re-infused into the patient.

Follow-Up of Long-Term Survivors Relapse

Among patients with aggressive lymphomas, such as DLBCL, most recurrences are seen within the first 2 years after the completion of therapy, although later relapses occur uncommonly. - In adults and the elderly, vitamin B₁₂ deficiency is mainly due to cobalamin malabsorption from food and to pernicious anemia.

CURRENT THERAPY

- Recognition of the condition causing megaloblastic anemia is a prerequisite of successful therapy.
- Treatment of nutrient-deficiency megaloblastic anemia is easy with nutrient replacement.
- Vitamin B₁₂ deficiency can be treated with both oral and parenteral therapy.
- If vitamin B₁₂ deficiency is untreated, folate repletion will correct the megaloblastic anemia but not the associated neuro-pathic changes that occur with B₁₂ deficiency.

Anemia is a common condition, especially in adults, and its prevalence increases with age. It affects quality of life, physical function, and even cognitive function in elderly patients. Anemia is a comorbid condition that affects other diseases (e.g., heart disease, cerebrovascular insufficiency) and is associated with a risk of death. Thus, anemia should not be accepted as a benign condition or a consequence of aging. In adults, many underlying conditions lead to megaloblastic anemia, but the most common ones are nutrient deficiencies, especially folate (folic acid, vitamin B₉) deficiency, vitamin B₁₂ (cobalamin) deficiency, and pernicious anemia. Recognition of these conditions is a prerequisite of successful therapy.

Although low hemoglobin levels are often seen with advancing age, anemia should not be assumed to be a normal consequence of aging. Age may be associated with compromised hematopoietic reserve, and the elderly can be more susceptible to anemia in the

presence of hematopoietic stress induced by an underlying disorder. Consequently, it is important to identify the underlying disorder. In practice, a hemoglobin (Hb) level less than 10 g/dL is considered a trigger for the investigation of the cause of anemia.

Definition

The World Health Organization (WHO) defines anemia as a hemoglobin concentration less than 12 g/dL for nonpregnant women and less than 13 g/dL for men. Megaloblastic anemia is characterized by many large immature and dysfunctional red blood cells (megaloblasts) in the bone marrow and by hypersegmented or multisegmented neutrophils. Megaloblastic anemia includes nutrient deficiencies related to folate and vitamin B₁₂ and pernicious anemia. Megaloblastic anemia is included in the group of macrocytic anemias (mean corpuscular volume [MCV] >100 fL). Macrocytic anemia also includes anemia related to chronic alcohol use (with or without liver disease), thyroid failure, and myelodysplastic syndromes.

Epidemiology

In adults, the prevalence of anemia varies by country, ethnic group, and the health status of the patients. Living conditions can also influence this prevalence. Nevertheless, the prevalence of anemia increases with advancing age, especially after age 60 to 65 years, and rises sharply after the age of 80 years. Results from the third National Health and Nutrition Examination Survey (NHANES III) carried out in the United States indicates that the prevalence of anemia was 11% in community-dwelling men and 10.2% among women 65 years or older. Survey findings also indicate that most anemia among the elderly is mild; only 2.8% of women and 1.6% of men have a hemoglobin less than 11 g/dL.

Results from the Framingham cohort indicate a slightly lower prevalence of anemia among older people living in the United States compared to the NHANES III survey. In the Framingham group of 1016 subjects 67 to 96 years of age, the prevalence of anemia in men and women is 6.1% and 10.5%, respectively.

In adults, causes of anemia are divided into three broad groups: nutrient-deficiency anemia, including iron deficiency, folate deficiency, and B₁₂ deficiency anemia; anemia of chronic disease, perhaps better termed anemia of chronic inflammation; and unexplained anemia. Table 1 presents the cause of anemia in 300 consecutive patients hospitalized in an internal medicine department.

In the NHANES III study, 34% of all anemia in elderly patients is caused by deficiencies of nutrients including folate, vitamin B₁₂,

and iron, alone or in combination. About 60% of nutrient-deficiency anemia is associated with iron deficiency, and most of those cases are the result of chronic blood loss from gastrointestinal lesions. The remaining cases of nutrient-deficiency anemia are usually associated with vitamin B₁₂ or folate deficiency (or both) and are easily treated. Twelve percent of anemias were associated with renal insufficiency, 20% were due to chronic diseases, and in 34% the cause remained unexplained.

Etiology

Folate Deficiency Anemia in Adults

A balanced diet contains 500 to 700 µg of folate. On average, 50% to 60% of dietary folate is absorbed in the duodenum and jejunum. Folate deficiency usually develops as a result of inadequate dietary intake. The body stores very little folate, only enough to last 4 to 6 months. Patients usually have a history of weight loss, poor weight gain, and weakness. In addition, several drugs (methotrexate [Trexall], cotrimoxazole [Bactrim], sulfasalazine [Azulfidine], and anticonvulsants) and alcohol can cause deficiency of folate by inhibiting absorption or by affecting folate metabolism.

Vitamin B₁₂ Deficiency Anemia in Adults

Deficiency of vitamin B₁₂ and folate are common, especially among the elderly, each occurring in at least 5% of patients. In these patients, the etiologies of cobalamin deficiency are represented primarily by food-cobalamin malabsorption, other causes of malabsorption such as surgical resection of the stomach or ileum, pernicious anemia, and, more rarely, by intake deficiency. In our work, in which we followed more than 200 elderly patients with a proven deficiency, food-cobalamin malabsorption accounted for about 60% to 70% of the etiologies of cobalamin deficiency, and pernicious anemia accounted for 15% to 25%. Figure 1 presents the principal causes of cobalamin deficiency in 172 patients hospitalized in an internal medicine department.

Food-Cobalamin Malabsorption

Initially described by Carmel in the 1990s, food-cobalamin malabsorption is characterized by the inability to release bound cobalamin from food or intestinal transport proteins, particularly in the setting of hypochlorhydria, where the absorption of unbound cobalamin is normal. This syndrome is defined by cobalamin deficiency despite sufficient food-cobalamin intake and a normal

BOX 1 Food-Cobalamin Malabsorption Syndrome

Criteria for Food-Cobalamin Malabsorption

Low serum cobalamin (vitamin B₁₂) levels

Normal results of Schilling test using free cyanocobalamin labeled with cobalt-58, or abnormal results of derived Schilling test*

No anti-intrinsic factor antibodies

No dietary cobalamin deficiency

Associated Conditions or Agents

Gastric disease

- Atrophic gastritis
- Type A atrophic gastritis
- Gastric disease associated with *Helicobacter pylori* infection
- Partial gastrectomy
- Gastric bypass
- Vagotomy

Pancreatic insufficiency

- Alcohol abuse
- Gastric or intestinal bacterial overgrowth
- Achlorhydria
- Tropical sprue
- Ogylvie's syndrome
- HIV

Drugs

- Antacids (H₂-receptor antagonists and proton-pump inhibitors)
- Biguanides (metformin [Glucophage])

Alcohol abuse

Sjögren's syndrome, systemic sclerosis

Haptocorrin deficiency

Aging or idiopathic

*Derived Schilling tests use food-bound cobalamin (e.g., egg yolk, chicken, and fish proteins).

Schilling test. The normal Schilling test rules out pernicious anemia and other causes of malabsorption. The principal characteristics of this syndrome are listed in [Box 1](#).

Food-cobalamin malabsorption is caused primarily by atrophic gastritis. More than 40% of patients older than 80 years have

gastric atrophy. Factors that commonly contribute to food-cobalamin malabsorption include *Helicobacter pylori* infection, chronic carriage of *H. pylori*, intestinal microbial proliferation (in which case, cobalamin deficiency can be corrected by antibiotic treatment); long-term ingestion of antacids, H₂-receptor antagonists and proton-pump inhibitors, and biguanides (metformin [Glucophage]); chronic alcoholism; surgery or gastric reconstruction (e.g., bypass surgery for obesity); and complete or partial pancreatic exocrine failure.

Pernicious Anemia

Pernicious anemia, also known as Biermer's anemia or Addison's anemia, is caused by impaired absorption of vitamin B₁₂ owing to the neutralization of intrinsic factor action in the setting of immune atrophic gastritis. In elderly patients, this form of megaloblastic anemia is one of the leading causes of cobalamin deficiency. Pernicious anemia has a genetic component. In practice, the diagnosis of pernicious anemia is based on the presence of intrinsic factor antibodies in serum (specificity, >98%; sensitivity, around 50%) or biopsy-proven autoimmune atrophic gastritis. The presence of *H. pylori* infection in gastric biopsies is an exclusion factor. Pernicious anemia is associated with other immunologic diseases such as Sj  gren's syndrome, Hashimoto's disease, type 1 diabetes mellitus, and celiac disease.

Other Causes of Cobalamin Deficiency

Cobalamin deficiency caused by dietary deficiency or malabsorption is rare. Dietary causes of deficiency are limited to elderly people who are already malnourished. This mainly concerns elderly patients living in institutions or in psychiatric hospitals. Since the 1980s, the malabsorption of cobalamin has become rare, owing mainly to the decreasing frequency of gastrectomy and surgical resection of the terminal small intestine. Other disorders associated with cobalamin malabsorption include deficiency in the exocrine function of the pancreas after chronic pancreatitis (usually alcoholic), lymphomas or tuberculosis of the intestine, Crohn's disease, Whipple's disease, and celiac disease. Uncommon etiology also includes nitrous oxide anesthesia and abuse.

Clinical Features

[Box 2](#) presents features related to vitamin B₁₂ deficiency. It should be noted that vitamin B₁₂ deficiency may be present in the absence of anemia. The symptoms of folate deficiency are nearly

BOX 2 Nonhematologic Manifestations of Vitamin B₁₂ Deficiency

Neuropsychiatric

Common

Polyneuritis (especially sensitive ones)

Ataxia

Babinski's phenomenon

Classic

Combined sclerosis of the spinal cord

Rare

Cerebellar syndromes affecting the cranial nerves including optic neuritis, optic atrophy

Urinary incontinence

Fecal incontinence

Under Study

Changes in higher cognitive functions, including dementia

Stroke and atherosclerosis (hyperhomocysteinemia)

Parkinsonian syndromes

Depression

Multiple sclerosis

Digestive

Classic

Hunter's glossitis

Jaundice

Lactate dehydrogenase and bilirubin elevation (intramedullary destruction)

Debatable

Abdominal pain

Dyspepsia

Nausea, vomiting

Diarrhea

Disturbances in intestinal functioning

Rare

Resistant and recurring mucocutaneous ulcers

Other

Under Study

Atrophy of the vaginal mucosa

Chronic vaginal and urinary infections (especially mycosis)

Venous thromboembolic disease

Angina (hyperhomocysteinemia)

indistinguishable from those of cobalamin deficiency. Box 3 presents the other hematologic manifestations of cobalamin deficiency.

Diagnosis

Patients with nutrient-deficiency anemia often have mild to moderate anemia with hemoglobin levels between 8 and 10 g/dL. In anemia of exclusive folate and/or vitamin B₁₂ deficiency, the erythrocytes are usually macrocytic (MCV >100 fL). Megaloblastic processes are characterized on the peripheral smear by macro-ovalocytes and hypersegmented neutrophils. Bone marrow aspiration, which is rarely required for diagnosis, demonstrates large immature and dysfunctional red blood cells (megaloblasts) and hypersegmented or multisegmented neutrophils. In cobalamin deficiency (<150 pmol/L), serum vitamin B₁₂ level is low (<200 pg/mL), serum methylmalonic acid is increased, and homocysteine levels are increased. In folate deficiency, testing the red cell folate concentration is more reliable than the serum level.

Prevention

Providing food sources of nutrients is best for preventing megaloblastic anemia. Food source supplementation may be necessary, especially for the very old. The National Academy of Sciences recommends that folate and vitamin B₁₂ be supplemented for the elderly in the form of fortified cereal.

Treatment

Treatment of megaloblastic anemia requires particular attention to discerning the cause. In adult patients, vitamin B₁₂ deficiency anemia may be treated by vitamin B₁₂ supplementation, parenterally or orally. Our working group has developed an effective oral treatment regimen for food-cobalamin malabsorption and pernicious anemia using crystalline cobalamin (cyanocobalamin)¹ (Figure 2). The effect of oral cobalamin treatment in patients presenting with severe neurologic manifestations has not yet been adequately documented.

For folate deficiency anemia, therapeutic doses of folic acid vary between 1 and 5 mg/day. Usually, these various therapies are continued for at least 3 to 6 months, provided that the underlying causes of the deficiency have been corrected.

If vitamin B₁₂ deficiency is present but undiagnosed, folate repletion will correct the megaloblastic anemia, but not the possible neuropathic changes that occur with B₁₂ deficiency.

¹Not FDA approved for this indication.

Parenteral administration

(Regardless of the etiology of the vitamin deficiency)

Intensification treatment:

Cyanocobalamin: 1000 µg per day for one week, then 1000 µg per week for 1 month

Maintenance treatment:

Cyanocobalamin: 1000 µg per month until the cause is corrected, or for life in the case of pernicious anemia

Oral administration

(for intake deficiency, food-cobalamin malabsorption, and pernicious anemia)

Intensification treatment:

Cyanocobalamin: 1000 µg per day for 1 month

Maintenance treatment:

Cyanocobalamin 125 to 500 µg per day for intake deficiency and food-cobalamin malabsorption and
Cyanocobalamin: 1000 µg per day for pernicious anemia

PLATELET-MEDIATED BLEEDING DISORDERS

Method of

Eric H. Kraut, MD

**CURRENT DIAGNOSIS**

- Platelet-mediated bleeding disorders commonly present with bleeding from mucosal surfaces or skin. Bleeding caused by reduced platelet counts may present with petechiae or purpura, whereas abnormalities of function are more likely to present with bleeding after injury or menstruation.
- Evaluation of platelet function used to be measured by the bleeding time. However, it is now more commonly evaluated by the PFA-100 or platelet aggregation studies.
- Thrombocytopenia is most commonly caused by deficient production of platelets from the bone marrow, decreased platelet

survival in the circulation, or sequestration of platelets by an enlarged spleen.

- Patients may bleed after trauma at platelet counts under 50,000/ μ L and develop petechiae or purpura at platelet counts under 20,000/ μ L, but they usually do not have severe bleeding unless platelet counts drop below 10,000/ μ L.
- The most common causes of new thrombocytopenia in the hospitalized patient are drugs or infection, whereas the usual cause of new platelet function abnormalities are medications.
- Patients in the hospital and placed on heparin should have their platelet counts monitored, and a reduction of 50% should be evaluated for heparin-induced thrombocytopenia.
- Immune thrombocytopenic purpura (ITP) usually presents in outpatients as new-onset mucocutaneous bleeding associated with only a reduced platelet count or unexplained asymptomatic isolated thrombocytopenia.
- Drugs that inhibit platelet activation and aggregation, such as aspirin, clopidogrel (Plavix), and dipyridamole (Persantine) can lead to significant bleeding, especially after surgery or procedures. This effect may last for 7 to 10 days.
- Patients presenting with a lifetime history of easy bruising and/or heavy menses should have careful evaluation of their bleeding history and family history of bleeding. If positive, studies to rule out Von Willebrand disease or hereditary disorders of platelet granules such as storage pool disorder should be done.

CURRENT THERAPY

- Patients with severe thrombocytopenia (platelet counts <10,000/ μ L) that is due to impaired production are at risk of severe bleeding and should be considered for platelet transfusions. The benefit of transfusing platelets when the platelet count reaches this level and the patient is not bleeding has been demonstrated as reducing bleeding in some patients in a recent study.
- Standard practice for platelet transfusions is to maintain platelet counts above 50,000/ μ L for patients with gastrointestinal bleeding and 75,000-100,000/ μ L for neurosurgical procedures. Platelet transfusions should be considered for certain other invasive procedures.
- Patients with immune thrombocytopenia should not receive platelet transfusions unless they are having significant bleeding since response to platelet transfusion occurs in less than 10% of patients and is short lasting.
- Patients with ITP who have no bleeding and platelet counts > 30,000/ μ L can be followed without treatment since the risk of bleeding is low.
- In patients with ITP and thrombocytopenia less than 10,000/ μ L, initial treatment with high doses of corticosteroids in combination with IVIG (Gamunex) induces a rapid rise in platelets, usually within 24 hours.
- Current treatment for patients with ITP who fail prednisone treatment include splenectomy, rituximab (Rituxan),¹ or thrombopoietin agonists (romiplostim [Nplate] or eltrombopag [Promacta]).
- Patients with chronic renal failure can develop severe bleeding diathesis, which appears to be multifactorial including platelet dysfunction. Dialysis can reduce bleeding but not completely correct it. Other treatment that may help include desmopressin (DDAVP),¹ tranexamic acid (Lysteda),¹ and synthetic erythropoietin (Epogen).¹
- Patients with drug induced platelet dysfunction who may need to undergo surgery or who are bleeding may require platelet transfusions.
- Patients with inherited platelet disorders and mild bleeding can be treated with desmopressin (DDAVP) but if severe may require platelet transfusions.

¹Not FDA approved for this indication.

Platelets Role in Hemostasis

Platelets are small non-nucleated blood cells that are derived from bone marrow megakaryocytes. Their production is controlled by the hormone thrombopoietin produced in the liver, and they survive in the circulation for 8 to 10 days. On blood vessel injury, they form a seal or plug at the site of injury to limit bleeding. This initial event, termed *primary hemostasis*, occurs after endothelial injury when the subendothelial surface is exposed to circulating blood. Platelets are drawn to the site via von Willebrand factor (vWF), which, in combination with other proteins including fibrillar collagen, fibronectin and laminin, leads to platelet adhesion. After platelets adhere to the vessel wall, they are activated, undergo a shape change and release products from their granules. These platelet granule products, including ADP and thromboxane A₂, further potentiate this process. Fibrinogen then binds to platelets via GPIIb/IIIa on the platelet surface causing firm platelet aggregation. The platelet secretory release reaction and aggregation recruits other platelets forming a firm hemostatic plug. Platelets also support the coagulation phase by interacting with circulating clotting factors and providing a surface for generation of thrombin. Secondary hemostasis occurs and thrombin-mediated fibrin mesh stabilizes the platelet plug.

Clinical Manifestations

The hallmark of platelet-mediated bleeding disorders is mucocutaneous bleeding such as nose bleeds, prolonged bleeding after tooth extractions, and heavy menstrual bleeding. When the platelet count drops below 30,000/ μ L, one may also see petechiae or purpuric lesions, especially on lower extremities.

Quantitative Platelet Disorders (Thrombocytopenia)

Primary hemostasis depends on an adequate number of platelets to prevent bleeding. A significant reduction in platelets or thrombocytopenia is usually defined as <100,000/ μ L. However, bleeding usually does not occur until the platelet count drops much lower. For example, spontaneous bleeding may only occur only when the platelet count is <20,000/ μ L and severe life-threatening bleeding occurs only <10,000/ μ L. Thrombocytopenia can develop due to inadequate platelet production from the bone marrow, reduced platelet survival in the circulation, or sequestration of platelets in the spleen. Differentiating the cause requires evaluation of the patients associated medical problems, physical findings, drug history, blood chemistry analysis, and possibly bone-marrow sampling.

Decreased platelet production is often the result of chemotherapeutic drugs for cancer, some antibiotics and antivirals (Table 1), or radiation therapy. These drugs may cause bone-marrow injury including damage to the megakaryocytes. Complete recovery may occur after stopping the offending agent. One common agent that can induce thrombocytopenia is alcohol. Thrombocytopenia associated with reduction in the white blood cell count and/or red blood cell count should alert physicians to the possibility of a bone marrow disorder such as forms of leukemia or aplastic anemia. In cases where the cause is not evident, a bone marrow biopsy may be necessary to demonstrate whether there is a malignancy that may require urgent treatment.

Patients with reduced platelet production can often be observed without intervention depending on the severity of the thrombocytopenia, presence of bleeding, or the need to perform invasive procedures. Guidelines for transfusion of platelets to prevent bleeding (prophylactic transfusion) have changed in the last few years. With evidence that severe bleeding may not occur in most patients until the platelet count is below 10,000/ μ L, limited platelet resources, and potential for development of alloimmunization to platelets, transfusions are not usually given unless sustained platelet counts are below 10,000/ μ L. When platelets are transfused it is appropriate to measure the response with a platelet count 1 hour post-transfusion. The platelet count should rise 30,000 to 40,000/ μ L for the usual four-pack of platelet transfusion. Patients requiring frequent transfusions may require single-donor apheresis or HLA-matched platelets to obtain a good response.

TABLE 1 Drugs Commonly Implicated as Causes of Drug-Induced Thrombocytopenia

CATEGORY	IMPLICATED IN SEVERAL REPORTS
Heparin	Unfractionated and LMWH
Cinchona alkaloids	Quinidine, quinine
Platelet inhibitors	Abciximab (RepPro), eptifibatide (Integrilin), tirofiban (Aggrastat)
Antirheumatic agents	Gold salts
Antimicrobial agents	Linezolid (Zyvox), rifampin, sulfonamides, vancomycin
Sedative and anticonvulsants	Valproic acid, phenytoin, carbamazepine
Histamine receptor antagonists	Cimetidine
Diuretic agents	Chlorothiazide
Analgesic agents	Acetaminophen, naproxen, diclofenac
Chemotherapy agents	Oxaliplatin (Eloxatin), fludarabine (Fludara), and others

Thrombocytopenia Resulting from Increased Platelet Destruction

Normally, platelets live in the circulation for 10 days, and the bone marrow replenishes them at the same rate that they are destroyed. Platelet survival may be altered by both nonimmune and immune processes. Severe infections will often lead to increased platelet destruction, and the platelet count returns to normal when the infection is adequately treated. Consumption of platelets also can occur in association with microangiopathic hemolytic anemia, as seen in disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP/HUS). It is important to review the blood smear to document fragmented red blood cells and evaluate coagulation parameters to help differentiate DIC from TTP/HUS and other causes of consumption. TTP/HUS may require specific and urgent treatment to prevent life-threatening complications. Platelet transfusions are not usually given for TTP because there are reports of patients deteriorating after transfusions.

Immune-mediated platelet destruction is seen in response to several common drugs, including the sulfonamides and vancomycin. The characteristic pattern of immune-mediated platelet destruction is a sharp drop in the platelet count 7 to 10 days after starting the drug. The platelet count may drop to $\leq 5000/\mu\text{L}$. Recognition is important because significant bleeding may occur, and the platelet count will only improve after discontinuation of the drug. Glycoprotein IIa/IIIb inhibitors, which are often used after cardiac stent placement, may cause a dramatic drop in the platelet count to as low as $1000/\mu\text{L}$ within hours of administration. This is important to recognize because this is one case where platelet transfusions may be necessary to prevent severe bleeding and it can be easily confused with other causes of low platelet counts.

Heparin-induced thrombocytopenia (HIT) is a unique drug reaction for several reasons. First, although thrombocytopenia is the initial sign of this entity, the major and feared complication is arterial and venous thromboses. It appears to affect 4% to 5% of patients exposed to unfractionated heparin and about 0.5% of patients exposed to low-molecular-weight heparin. Those at highest risk are female surgical patients who receive a minimum of 4 days of either type of heparin. The classic pattern is exposure to heparin at any dose with development of antibodies to heparin at day 4 and a 50% reduction in platelet count by day 6. The antibodies responsible are to the heparin-platelet factor 4 complex (IgG-PF4). A suspicious clinical pattern and a high antibody titer measured by an enzyme-linked immunosorbent assay are often

diagnostic. Patients suspected of having HIT are at a high risk of thromboembolic disease within the first 24 hours of the drop in platelet count, and the heparin should be immediately stopped. However, despite the reduced platelet count, bleeding is unusual. Patients should be placed on an alternative anticoagulant, usually a direct thrombin inhibitor. The platelet count takes about 2 weeks to return to normal, and warfarin (Coumadin) should not be started until the platelet count returns to normal to avoid warfarin-associated necrosis. By reducing protein C and protein S, warfarin creates a temporary hypercoagulable state and places the patient at risk for warfarin-associated necrosis during the time when patients are most susceptible to thrombosis from HIT.

Immune thrombocytopenic purpura (ITP), previously termed *idiopathic thrombocytopenic purpura* affects 1 to 3 people per 100,000, but is probably the most common cause of severe isolated thrombocytopenia seen in the outpatient setting. It affects all ages, although ITP in childhood has a unique natural history. Childhood ITP is often associated with viral illness, is commonly transient, and may not need treatment. In adults, 40% of patients may have protracted or recurrent episodes of ITP, and the majority of patients need treatment. It was demonstrated in the 1950s that ITP is caused by circulating antiplatelet antibodies, and, like many autoimmune diseases, it is more common in women. When ITP presents in association with other diseases such as systemic lupus erythematosus or chronic lymphatic leukemia, or in patients with HIV, management of the underlying disease is important. The clinical presentation of ITP depends on the degree of thrombocytopenia. Mild thrombocytopenia of 20,000 to 80,000/ μL is often asymptomatic, whereas platelet counts under 20,000/ μL may present with mucocutaneous bleeding and diffuse petechiae and purpura. Thrombocytopenia, an otherwise normal blood count and peripheral blood smear without evidence of splenomegaly in a patient with no other illness helps make a tentative diagnosis. A bone marrow biopsy is no longer considered necessary to confirm the diagnosis.

Treatment of ITP has changed over the last several years, and initial treatment after the diagnosis requires evaluation of the platelet count, whether it is increasing or decreasing, and the presence or absence of bleeding. Patients who have counts above 20,000/ μL without bleeding and who are not in need of an invasive procedure can be observed without intervention. Patients with counts between 10,000 and 20,000/ μL may be started on oral prednisone at 1 mg/kg. Patients with severe thrombocytopenia less than 10,000/ μL and those who are bleeding can receive high-dose dexamethasone (Decadron) at 40 mg daily for 4 days and IVIG (Gamunex). There is usually a response to treatment within 24 hours. Although usually not helpful or required, about 10% of patients will have a response to platelet transfusion, and this can be considered for patients presenting with low platelet counts and bleeding. Refractory or recurrent ITP is a common problem in these patients, and recommendations for treatment include splenectomy, rituximab (Rituxan), or thrombopoietin agonists. The choice of which to use depends on the patient and his or her clinical condition.

Thrombocytopenia Due to Hypersplenism

The platelet mass is distributed 70% in the circulation and 30% in the spleen. Enlargement of the spleen and/or alteration of blood flow in portal hypertension may increase platelet sequestration in the spleen and reduce the platelet count in the peripheral blood circulation. Patients' counts rarely drop below 20,000/ μL . Thus, thrombocytopenia caused by hypersplenism does not usually need any intervention. Patients with hepatitis C and cirrhosis may present with low platelet counts, and this may represent both hypersplenism and secondary immune thrombocytopenia. A trial of steroids may be used if these patients' clinical situation requires therapy.

Qualitative Platelet Function Disorders

Acquired Qualitative Platelet Function Disorders

Acquired disorders of platelet function are commonly seen, because platelets are the target of medications used to prevent arterial and cardiac stent thrombosis. Spontaneous bleeding is not common, but bleeding resulting from trauma or surgery can be a

significant clinical problem. Because many patients may be on multiple antiplatelet agents or anticoagulants at the same time, the risk of bleeding needs to be recognized. Acquired qualitative disorders of platelet function may be due to drugs, hematologic diseases, or medical illnesses.

Drugs are the most common cause of acquired platelet dysfunction with differing risks of bleeding due to different targets. Aspirin causes irreversible acetylation of cyclooxygenase I (COX-1) and inhibits generation of prostaglandin A₂. Although it is considered a weak antiplatelet agent with up to 25% resistance, aspirin increases the risk of bleeding in otherwise normal patients. Major bleeding was seen in up to 3.7% of patients and, when aspirin is used in combination with other antiplatelet agents or in patients with underlying bleeding disorders, the bleeding risk is higher. Clopidogrel (Plavix) is a thienopyridine prodrug, and the active metabolite irreversibly inhibits the surface receptor P2Y₁₂ on platelets. In clinical trials the risk of major bleeding in patients taking clopidogrel was similar to what is described with aspirin. Clopidogrel may significantly increase bleeding after surgery. GPIIb/IIIa receptor antagonists used after cardiac stent placement inhibit platelet aggregation and can induce severe thrombocytopenia.

Malignancies of the bone marrow may produce abnormally functioning platelets or alter platelet function by affecting vWF. The myeloproliferative and myelodysplastic disorders may produce platelets with reduced numbers of granules and may have associated increased risk of gastrointestinal bleeding and bleeding after invasive procedures. Acquired von Willebrand disease an infrequent cause of abnormal bleeding, can be seen in patients with lymphoproliferative disease, multiple myeloma, and Waldenström macroglobulinemia.

Systemic illness can alter platelets and increase the bleeding risk. Acute and chronic renal failure are common causes of platelet-function abnormalities. In uremia, hemorrhagic complications include upper gastrointestinal bleeding, pericardial bleeding, and intracranial bleeding. Bleeding in renal failure is believed to be multifactorial and includes impaired release of platelet granules, decreased prostaglandin formation, vWF dysfunction, and presence of severe anemia. Effective treatment includes improvement of the anemia with erythropoietin (Epogen)¹ or desmopressin (DDAVP)¹ or conjugated estrogens (Premarin).¹

Hereditary Qualitative Platelet Function Disorders

Inherited abnormalities of platelet function are infrequent disorders that give rise to bleeding of varying severity. Inherited abnormalities of platelet function are often classified according to the type of genetic defect. Bernard-Soulier syndrome (BSS) is a severe bleeding disorder with autosomal recessive inheritance characterized by thrombocytopenia, decreased platelet adhesion, reduced platelet survival, and giant platelets on blood smear. Patients with BSS have defects in the GPIb-IX-V complex leading to reduced binding to vWF. Glanzmann thrombasthenia is an autosomal recessive disorder with defects of integrin α IIb β 3, a receptor on activated platelets that normally binds platelets during aggregation. Platelet aggregation to ADP and thrombin is abnormal. Patients with BSS and Glanzmann thrombasthenia who need treatment require platelet transfusions.

Hereditary disorders of platelet secretion are common reasons patients present to clinicians for evaluation of mucocutaneous bleeding. Defects in platelet dense granules (δ storage pool disease) are suspected in patients with bleeding and a negative workup for von Willebrand disease. Diagnosis is made by platelet electron microscopy and or platelet aggregation studies. Granule deficiency associated with abnormalities of other lysosome-related organelles may lead to specific phenotypes such as Hermansky-Pudlak and Chediak-Higashi disease. Gray platelet syndrome (GPS), or alpha granule deficiency, is an autosomal recessive disorder with mild bleeding. GPS patients may also be thrombocytopenic. Treatment for bleeding or in preparation for surgery includes desmopressin (DDAVP)¹ or platelet transfusions.

¹Not FDA approved for this indication.

POLYCYTHEMIA VERA

Method of

Peter R. Duggan, MD; and Sonia Cerquozzi, MD

CURRENT DIAGNOSIS

- Polycythemia vera (PV) should be considered when there is persistent elevation of hemoglobin (> 165 g/L in men and > 160 g/L in women) or hematocrit (> 49% in men and > 48% in women).
- *JAK2V617F* mutation testing and erythropoietin levels should be performed when PV is suspected.
- Bone marrow biopsy and aspiration may be necessary in some cases to confirm the diagnosis of PV and to distinguish PV from other myeloproliferative neoplasms (MPNs).
- PV is highly likely when *JAK2V617F* mutation is present and erythropoietin level is subnormal. When *JAK2V617F* mutation is seen with normal erythropoietin level, PV is possible; bone marrow biopsy is recommended to differentiate PV from other MPNs. When *JAK2V617F* is normal and erythropoietin is low, consider *JAK2* exon 12 mutational analysis or alternative diagnosis of congenital polycythemia. Wildtype *JAK2V617F* with normal or high erythropoietin level makes PV very unlikely, and patients should be investigated for secondary causes of polycythemia.
- Investigations for secondary polycythemia that may be indicated include:
 - Chest x-ray
 - Pulse oximetry
 - Arterial blood gas including carboxyhemoglobin and methemoglobin levels
 - Kidney and liver function tests
 - Abdominal imaging studies (ultrasound or computed tomography [CT] scan)
 - Oxyhemoglobin dissociation curve
 - Sleep studies

significant clinical problem. Because many patients may be on multiple antiplatelet agents or anticoagulants at the same time, the risk of bleeding needs to be recognized. Acquired qualitative disorders of platelet function may be due to drugs, hematologic diseases, or medical illnesses.

Drugs are the most common cause of acquired platelet dysfunction with differing risks of bleeding due to different targets. Aspirin causes irreversible acetylation of cyclooxygenase I (COX-1) and inhibits generation of prostaglandin A₂. Although it is considered a weak antiplatelet agent with up to 25% resistance, aspirin increases the risk of bleeding in otherwise normal patients. Major bleeding was seen in up to 3.7% of patients and, when aspirin is used in combination with other antiplatelet agents or in patients with underlying bleeding disorders, the bleeding risk is higher. Clopidogrel (Plavix) is a thienopyridine prodrug, and the active metabolite irreversibly inhibits the surface receptor P2Y₁₂ on platelets. In clinical trials the risk of major bleeding in patients taking clopidogrel was similar to what is described with aspirin. Clopidogrel may significantly increase bleeding after surgery. GPIIb/IIIa receptor antagonists used after cardiac stent placement inhibit platelet aggregation and can induce severe thrombocytopenia.

Malignancies of the bone marrow may produce abnormally functioning platelets or alter platelet function by affecting vWF. The myeloproliferative and myelodysplastic disorders may produce platelets with reduced numbers of granules and may have associated increased risk of gastrointestinal bleeding and bleeding after invasive procedures. Acquired von Willebrand disease an infrequent cause of abnormal bleeding, can be seen in patients with lymphoproliferative disease, multiple myeloma, and Waldenström macroglobulinemia.

Systemic illness can alter platelets and increase the bleeding risk. Acute and chronic renal failure are common causes of platelet-function abnormalities. In uremia, hemorrhagic complications include upper gastrointestinal bleeding, pericardial bleeding, and intracranial bleeding. Bleeding in renal failure is believed to be multifactorial and includes impaired release of platelet granules, decreased prostaglandin formation, vWF dysfunction, and presence of severe anemia. Effective treatment includes improvement of the anemia with erythropoietin (Epogen)¹ or desmopressin (DDAVP)¹ or conjugated estrogens (Premarin).¹

Hereditary Qualitative Platelet Function Disorders

Inherited abnormalities of platelet function are infrequent disorders that give rise to bleeding of varying severity. Inherited abnormalities of platelet function are often classified according to the type of genetic defect. Bernard-Soulier syndrome (BSS) is a severe bleeding disorder with autosomal recessive inheritance characterized by thrombocytopenia, decreased platelet adhesion, reduced platelet survival, and giant platelets on blood smear. Patients with BSS have defects in the GPIb-IX-V complex leading to reduced binding to vWF. Glanzmann thrombasthenia is an autosomal recessive disorder with defects of integrin α IIb β 3, a receptor on activated platelets that normally binds platelets during aggregation. Platelet aggregation to ADP and thrombin is abnormal. Patients with BSS and Glanzmann thrombasthenia who need treatment require platelet transfusions.

Hereditary disorders of platelet secretion are common reasons patients present to clinicians for evaluation of mucocutaneous bleeding. Defects in platelet dense granules (δ storage pool disease) are suspected in patients with bleeding and a negative workup for von Willebrand disease. Diagnosis is made by platelet electron microscopy and or platelet aggregation studies. Granule deficiency associated with abnormalities of other lysosome-related organelles may lead to specific phenotypes such as Hermansky-Pudlak and Chediak-Higashi disease. Gray platelet syndrome (GPS), or alpha granule deficiency, is an autosomal recessive disorder with mild bleeding. GPS patients may also be thrombocytopenic. Treatment for bleeding or in preparation for surgery includes desmopressin (DDAVP)¹ or platelet transfusions.

 - Pulse oximetry
 - Arterial blood gas including carboxyhemoglobin and methemoglobin levels
 - Kidney and liver function tests
 - Abdominal imaging studies (ultrasound or computed tomography [CT] scan)
 - Oxyhemoglobin dissociation curve
 - Sleep studies

- All patients should be treated with phlebotomy and/or cytoreductive therapy to target hematocrit less than 45%.
- Low-dose aspirin¹ (acetylsalicylic acid [ASA]) should be used in *all patients* without a contraindication.
- In *high-risk* patients with PV (age > 60 years and/or history of thrombosis), cytoreductive therapy should be used in combination with ASA.
- Alkylating agents should be avoided as cytoreductive therapy owing to the risk of acute leukemia.
- Conventional cardiovascular risk factors (diabetes, hypertension, hyperlipidemia) should be aggressively managed, and cigarette smoking should be discouraged.
- Thromboembolic events should be managed according to accepted management guidelines. Thromboprophylaxis should be used after surgery and in other high-risk situations.

¹Not US Food and Drug Administration (FDA) approved for this indication.

Polycythemia vera is a clonal stem cell disorder characterized by an increase in red cell production independent of the stimulation by erythropoietin. PV is the most common of the chronic myeloproliferative neoplasms (MPNs), occurring in approximately 2 to 3 people per 100,000 annually. The median age at diagnosis is 70 years, and it is rare in patients younger than 40 years.

A mutation of the tyrosine kinase Janus kinase 2 (*JAK2*) is consistently found in PV. This sheds some light on the pathogenesis of the disease and is useful in the diagnosis of PV and other MPNs. A single acquired mutation (*V617F*) of the gene for the JH-2 domain of *JAK2* can be found in 90% to 95% of patients with PV. The JH-2 domain functions to inhibit *JAK2* activity. In normal erythropoiesis, binding of erythropoietin to its receptor lifts this inhibition and allows *JAK2* stimulation of cell division and differentiation. In mutated *JAK2*, this inhibitory function is absent, leading to constitutive activity of the tyrosine kinase. This mutation is also present in about half of patients with essential thrombocythosis and primary myelofibrosis. The small number of patients with PV who are negative for the common *JAK2V617F* mutation have another functionally similar mutation within *exon 12*.

Presentation

Many patients with PV are asymptomatic, and PV is diagnosed after the incidental finding of an elevated hemoglobin or hematocrit on routine complete blood count. Splenomegaly is present in 30% to 40% of patients. Up to half of patients experience nonspecific symptoms such as weight loss, sweating, headache, fatigue, epigastric discomfort, visual disturbances, and dizziness. Many of these symptoms are likely caused by decreased blood flow due to an increased blood viscosity from polycythemia.

Generalized pruritus is often described, often after a warm bath or shower (aquagenic pruritus). Although the cause of this is unknown, it is thought to be due to the degranulation of increased numbers of mast cells in the skin of patients, releasing histamine and other inflammatory mediators. However, the symptom responds poorly to antihistamines, and it does not always resolve with treatment of PV.

Venous and arterial thromboembolic events are a major cause of morbidity and mortality in PV. Thrombosis at presentation occurs in up to 40% of patients. Ischemic stroke, transient ischemic attack, and myocardial infarction are common, especially among elderly patients. These, along with deep venous thrombosis and pulmonary embolus, are the most common thrombotic events and often result in serious morbidity, disability, and even death. Thrombotic events that are considered unusual in the general population, such as Budd-Chiari syndrome; portal, mesenteric, and other abdominal vein thrombosis; and cerebral venous thrombosis, occur more commonly among patients with PV. The possibility of an underlying MPN should be considered when a patient presents with such an event.

PV can manifest with symptoms of peripheral vascular disease. Patients with erythromelalgia describe a painful burning sensation of the hands and feet; pallor, erythema, or cyanosis of the extremities; and sometimes cutaneous ulceration. Erythromelalgia results from microvascular thrombosis and ischemia due to platelet activation and aggregation and responds well to platelet reduction and antiplatelet agents such as aspirin (ASA).¹

Almost all patients with PV are iron deficient at diagnosis, even before the onset of therapeutic phlebotomy. Other manifestations of PV include acute gouty arthritis, peptic ulcer disease, erosive gastritis, and hypertension.

Diagnosis and Differential Diagnosis

The 2016 World Health Organization (WHO) diagnostic criteria for PV are shown in [Box 1](#). The *JAK2V617F* mutation is present in about 95% of cases of PV. Erythropoietin level is decreased in more than 90% and is rarely elevated. Few patients with PV carry a mutation of *exon 12* (~4%) of the *JAK2* gene instead of the more common *JAK2V617F* mutation. A *JAK2* mutation can also be found in about half of patients with essential thrombocythosis and primary myelofibrosis.

Leukocytosis and thrombocytosis are present in the majority of cases of PV. Red cell mass is increased. A nuclear medicine study measuring red cell mass and plasma volume is rarely required with the availability of *JAK2* testing, but it may be useful when relative polycythemia is suspected. Bone marrow biopsy and aspiration are not often needed for a diagnosis of PV but have been included as a major criterion within the revised WHO classification. Bone marrow examination can be important for diagnosing PV in the rare cases where *JAK2* is negative and to differentiate PV from other *JAK2*-positive MPNs when the distinction cannot be made based on peripheral blood counts.

Erythrocytosis can occur as a result of a number of other conditions in the absence of PV ([Box 2](#)). A careful history and physical examination with selected investigations can usually distinguish PV from secondary polycythemia and relative polycythemia (see Current Diagnosis). In relative (apparent, spurious) polycythemia, there is usually only a modest increase in the hematocrit, because of a decrease in plasma volume rather than a true increase in red cell mass. Thrombocytosis, leukocytosis, and splenomegaly should be absent. Causes include smoking, dehydration, and use of diuretics, and it is also described in middle-aged, obese, hypertensive men (Gaisböck syndrome).

¹Not FDA approved for this indication.

BOX 1

2016 World Health Organization Diagnostic Criteria for Polycythemia Vera

Diagnosis requires three major criteria or first two major criteria and minor criterion.*

Major Criteria

1. Hemoglobin > 165 g/L in men, 160 g/L in women, or Hematocrit > 49% in men, > 48% in women, or Other evidence of increased red cell volume[†]
2. Bone marrow biopsy: hypercellular for age with trilineage growth (panmyelosis)
3. Presence of *JAK2V617F* or *JAK2* exon 12 mutation

Minor Criterion

1. Subnormal serum erythropoietin level

*Bone marrow biopsy may not be required in sustained erythrocytosis—hemoglobin > 185 g/L (hematocrit > 55.5%) in men or > 165 g/L (hematocrit > 49.5%) in women—if major criterion 3 and minor criterion are present.

[†]> 25% above mean normal predicted value.

BOX 2 Differential Diagnosis of Polycythemia

Normal Red Cell Mass

Relative polycythemia
Gaisböck syndrome

Elevated Red Cell Mass

Primary Polycythemia
Polycythemia vera

Secondary Polycythemia

- Congenital EPO receptor mutations
- Chuvash polycythemia
- High-affinity hemoglobin
- Appropriately elevated EPO (hypoxia driven)
- Chronic hypoxic lung disease
- Cardiac shunts or cyanotic heart disease
- Sleep apnea
- Methemoglobinemia
- High altitude
- Chronic carbon monoxide poisoning
- Cigarette smoking
- Renal artery stenosis
- Inappropriately elevated EPO
- Renal cell carcinoma
- Hepatocellular carcinoma
- Hemangioblastoma
- Uterine fibroids
- Other causes:
- EPO (Epogen) administration
- Androgens (testosterone)
- Kidney transplant

Abbreviation: EPO = erythropoietin.

Red cell mass can be elevated owing to increased stimulation of erythropoiesis by high levels of erythropoietin. Erythropoietin can be increased as an appropriate response to chronic hypoxia (sleep apnea, right-to-left cardiac shunts, chronic lung disease, high altitude, smoking, methemoglobinemia), and it can be inappropriately elevated owing to erythropoietin-secreting tumors (renal cell carcinoma, hepatocellular carcinoma, cerebellar hemangioma, uterine fibroids) or decreased kidney perfusion (renal artery stenosis). Familial causes of polycythemia include high-affinity hemoglobins, erythropoietin receptor mutations, and Chuvash polycythemia. Polycythemia occurs in 10% to 15% of patients following kidney transplantation, and this may be due to erythropoietin secretion by the native kidneys or increased sensitivity to erythropoietin. Polycythemia can be drug induced, such as with the use of performance-enhancing drugs (erythropoietin [Epogen], androgens) in athletes and testosterone replacement in men.

Prognosis

Patients with PV have a reduced life expectancy compared with the general population, with a median survival of approximately 14 years, or 24 years if younger than age 60 at diagnosis.

Despite therapy, thrombosis remains an important cause of mortality. Cardiac disease, ischemic stroke, pulmonary embolus, and other thrombotic events account for 40% of deaths among patients with PV. Nonfatal thrombosis is common, occurring in almost 4% of patients annually. Age and a history of prior thromboembolic events

are independent risk factors for thrombosis and can be used to predict a patient's risk of future events (Box 3). Low-risk patients are younger than 60 years and have no history of thrombosis. They experience new events at a rate of 2% per year. For patients older than 60 years or with a past history of thrombosis, this rate is 5% annually, but it can be as high as 11% when both risk factors are present.

The contribution of other cardiovascular risk factors (smoking, diabetes, hypertension, hyperlipidemia) to thrombotic risk in PV has been studied, with inconclusive results. However, because these are major contributors to the development of cardiovascular disease in the general population, they should also be considered when assessing risk in patients with PV. Leukocytosis (white blood cell count $> 15 \times 10^9/L$) has been associated with a higher risk of arterial thrombosis.

Conversely, the risk of major hemorrhage is low, with fatal bleeding responsible for less than 5% of all deaths. However, there is considerable excess mortality from malignancy, in particular transformation to a myelodysplastic syndrome, myelofibrosis, or acute leukemia. The rate of leukemic transformation is less than 10% at 20 years. Risk factors for leukemic transformation include advanced age, leukocytosis, and abnormal karyotype. Approximately 10% of patients transform to myelofibrosis (post-PV myelofibrosis). Risk factors for post-PV myelofibrosis include leukocytosis and *JAK2V617F* allele burden of greater than 50%.

Treatment

The goals of treatment in PV are to lower the risk of thrombosis while minimizing toxicity. This is achieved by a combination of phlebotomy, aspirin,¹ and hydroxyurea (Hydrea)¹ or other cytoreductive agents. The use of these therapies can be individualized based on a patient's risk of developing future thromboembolic events. Risk stratification (Box 3) aims at identifying patients with PV at higher risk of thrombotic events who require cytoreductive therapy. Because cerebrovascular and cardiovascular disease are among the main causes of morbidity and mortality for these patients, careful attention should be paid to the management of conventional cardiovascular risk factors. Hypertension, diabetes, and hyperlipidemia should be controlled with standard measures based on current guidelines, and patients should be encouraged to stop smoking. As the hematocrit increases in PV, there is a dramatic increase in blood viscosity. Phlebotomy is the fastest, most effective way to normalize a patient's hematocrit, and it should be initiated immediately in those with newly diagnosed PV. Blood volume should be reduced as rapidly as possible. Usually, 500 mL of blood is removed every 1 or 2 days until the hematocrit is less than 45%. The frequency of phlebotomy or volume of blood removed can be decreased in elderly patients, those with cardiovascular disease, or others who do not tolerate this schedule. The optimal target in patients with PV is to maintain a hematocrit less than 45% to lower the risk of major thrombotic events and death from cardiovascular causes. Regular phlebotomy eventually results in iron deficiency, at which point most patients' phlebotomy needs decrease dramatically. Iron replacement should be avoided.

Aspirin

Previous studies did not support the routine use of aspirin to prevent thrombosis in PV. However, high doses of aspirin were used in these early studies, resulting in excess bleeding in the treatment arm. The results of a recent large randomized trial show that low-dose aspirin (100 mg/day) reduces major thrombotic events (nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis). This was accomplished without an increase in bleeding risk. Although there was a trend suggesting more minor bleeding events in those receiving aspirin, the rates of major bleeding were identical for those receiving aspirin or placebo. The benefit from aspirin was seen, even though this study included many low-risk patients without a prior history of thromboembolism. Low-dose aspirin (75–100 mg daily)¹ should be started in all patients without

BOX 3 Thrombotic Risk in Polycythemia Vera

Low Risk

Age < 60 years and no history of thrombosis

High Risk

Age ≥ 60 years and/or history of thrombosis

¹Not FDA approved for this indication.

a contraindication to the drug (history of bleeding or intolerance). Because of the risk of bleeding from acquired von Willebrand disease that can occur with extreme thrombocytosis, aspirin should be held when platelets are more than $1500 \times 10^9/L$ until the count can be lowered by cytoreduction.

Cytoreductive Therapy

Cytoreductive therapy is recommended for high-risk patients with PV (Box 3). Hydroxyurea (HU)¹ is the cytoreductive agent most commonly used to treat PV. Hydroxyurea can safely control blood counts and decreases spleen size in PV and other MPNs. Randomized data are limited, but hydroxyurea also appears to reduce thrombotic complications. A starting dosage of 15 to 20 mg/kg daily (1000–1500 mg daily) is used. Occasional phlebotomy is still required to maintain hematocrit less than 45%, but the frequency usually decreases. Myelosuppression is the main toxicity. The lowest dosage that provides therapeutic effect should be used, and excess myelosuppression should be avoided. The dosage can be titrated to ensure that the white cell count remains higher than $3.0 \times 10^9/L$, neutrophils are higher than $2.0 \times 10^9/L$, and platelets are in the normal range.

Hydroxyurea has been associated with leg ulcers and other skin changes, especially after long-term use. There is growing evidence that hydroxyurea does not contribute to the excess rates of acute leukemia seen in PV; rates are no different than in those treated with phlebotomy alone. However, transformation is clearly associated with the use of other chemotherapeutic agents such as chlorambucil (Leukeran)¹, busulfan (Myleran)¹, and pipobroman (Vercyte),² accounting for one-third of the deaths among patients with PV treated with these agents. The use of these agents should be avoided. Hydroxyurea resistance can occur in up to 11% of patients and is associated with increased risk of death. Both hydroxyurea resistance and intolerance are defined according to the European Leukemia Net (ELN) criteria.

Interferon- $\alpha 2b$ (IFN- $\alpha 2$) (Intron A)¹ is an alternative treatment option in the setting of hydroxyurea resistance and/or intolerance and often is considered in young patients with PV. IFN- αb is available in both short-acting and controlled-release (pegylated) formulations. IFN- α is commonly administered subcutaneously with a starting dose of 3 million units daily, or pegylated IFN- α (Peg-Intron)¹ is given at 45 to 90 μg weekly. Studies have shown its efficacy in controlling blood counts in addition to achieving complete hematologic and molecular responses. The inconvenience of its administration and its side effects including mood disturbances and flulike illness make it a less desirable therapy. Controlled studies are comparing hydroxyurea with pegylated forms of IFN- α . At present, both are first-line cytoreductive treatment options with recommendations that IFN- α be used in females with childbearing potential.

JAK Inhibitors

Ruxolitinib (Jakafi), a *JAK1/2* inhibitor, was originally approved in patients with myelofibrosis, including myelofibrosis evolving¹ from PV. There was a significant reduction in spleen size and constitutional symptoms in almost half of these patients. In the phase III RESPONSE trial, ruxolitinib illustrated its effectiveness in controlling hematocrit ($< 45\%$), reducing spleen size ($\geq 35\%$), and improving symptoms in patients with PV who had hydroxyurea intolerance or resistance, resulting in its approval as a second-line cytoreductive agent in PV. The most common side effects are anemia and thrombocytopenia.

Other Treatment Issues

Hyperuricemia is common in myeloproliferative neoplasms and occasionally results in kidney stones or gout. Allopurinol (Zyloprim) 300 mg daily can be used to reduce uric acid levels in patients with

these complications. For those with intractable pruritus, several agents have been used with variable success. Some patients respond to aspirin,¹ hydroxyurea¹, cimetidine (Tagamet)¹, cyproheptadine (Periactin)¹, and paroxetine (Paxil)¹ 20 mg daily. Both IFN- α ¹ and ruxolitinib have been successful in the majority of cases.

Less than 60% of pregnancies occurring in patients with PV are successful. First-trimester fetal loss is the most common complication, and third-trimester fetal loss, preterm birth, and intrauterine growth restriction are also common. Phlebotomy should be used to keep the hematocrit at less than 45%. Interferon- $\alpha 2b$ ¹ is recommended for those requiring cytoreductive therapy during pregnancy; other cytoreductive agents are contraindicated owing to possible teratogenic effects. There is some evidence that the use of low-dose aspirin¹ throughout pregnancy improves live birth rate. It is recommended that prophylactic low-molecular-weight heparin (LMWH) be used for 6 weeks postpartum.

Surgery in patients with PV has a high risk of both operative bleeding and postoperative thromboembolism. Elective surgeries should be delayed until cytoreductive measures and phlebotomy can be used to achieve good control of blood counts. Aspirin should be held for 1 week before surgery to reduce the risk of hemorrhage. LMWH should be given after surgery to prevent deep venous thrombosis. Mechanical compression stockings are an option for patients with bleeding that prevents the use of anticoagulation. When thromboembolic events do occur, treatment should be according to current management guidelines. Venous thromboembolism is treated with LMWH and warfarin (Coumadin). Indefinite anticoagulation should be considered because of the high risk of recurrent events. Low-dose aspirin is indicated in those with a history of arterial events such as stroke and myocardial infarction.

¹Not FDA approved for this indication.

PORPHYRIAS

Method of

Claus A. Pierach, MD

CURRENT DIAGNOSIS

- There is not just one porphyria; there are at least six types (and a few very rare ones because of homozygosity and dual porphyrias).
- There is not one single test covering all porphyrias. For suspected acute porphyria, screening for excessive porphobilinogen in the urine is the test of choice.
- If cutaneous porphyria is in the differential diagnosis, quantitative measurements of porphyrins in urine and stool are recommended.
- Family studies and genetic counseling are always indicated in these hereditary diseases.

CURRENT THERAPY

- Prophylaxis is mandatory and depends on the type of porphyria.
- Abstinence from alcohol is always indicated.
- The drug list should be respected in the acute porphyrias.
- Glucose therapy for the acute attack has been superseded by the more effective, definitive treatment with hematin (hemin, Panhematin), to be instituted as soon as possible once the diagnosis has been ascertained.

The *porphyrias* present a group of mostly inherited diseases where disturbances along the biosynthetic pathway to heme lead to accumulations of metabolic intermediaries. Porphyria cutanea tarda usually occurs without discernible inheritance; it can also be induced by chemicals. All steps of heme synthesis are enzymatically regulated, and all porphyrias are a result of specific impasses along these transitions. Not all enzymatic defects result in clinically relevant or recognizable disease manifestations in every patient. On the one hand, the severity of the enzymatic defect plays a role. On the other, some poorly understood revealing or unveiling cofactors are operational; enzyme cofactors are likely contributing as well. The prevalence of the porphyrias is not known and fluctuates in different parts of the world; for example, variegate porphyria is most common in South Africa, whereas porphyria cutanea tarda is the most common porphyria in the United States.

The porphyrias can be divided between neurovisceral (acute) and cutaneous manifestations. Two types, the very rare delta-aminolevulinic acid-dehydratase deficiency porphyria and acute intermittent porphyria (AIP), have only neurologic symptoms (acute attacks and possibly chronic manifestations). Hereditary coproporphyria and variegate porphyria can have both neurologic and dermatologic signs and symptoms. Congenital erythropoietic porphyria, porphyria cutanea tarda, and erythropoietic protoporphyria exhibit only skin lesions but can be complicated by other problems, such as anemia or hepatic insufficiency.

Heme Synthesis

Succinyl coenzyme-A and glycine are the initial building blocks, subsequently transformed through eight enzymatic steps to the end product, heme, in itself essential not only for hemoglobin but also for other hemoproteins such as cytochromes, myoglobin, and other enzymes including catalase, nitric oxide synthase, and tryptophan pyrrolase. Heme synthesis happens in all cells but mostly in the liver and in the bone marrow. It is controlled by heme through feedback inhibition of the first step, delta-aminolevulinic acid synthase. Figure 1 shows the various steps, intermediaries, and resulting porphyrias. Porphyrins and their precursors, delta-

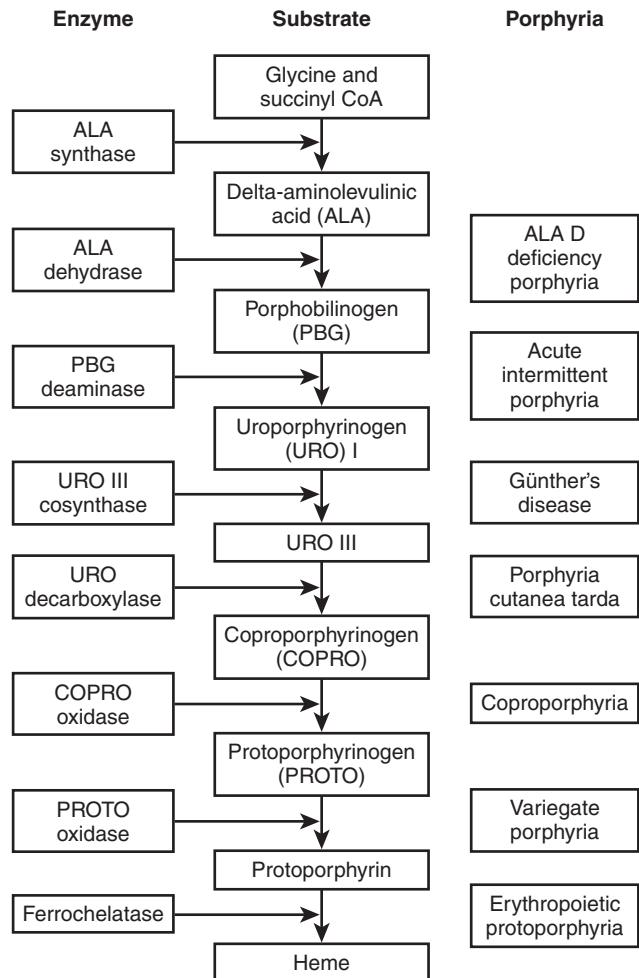

Figure 1 Heme biosynthetic pathway. Enzymes that have defects or deficiencies that cause the various porphyrias are listed on the left side, heme and precursors are in the middle, and the resulting² porphyrias are on the right side. Abbreviation: CoA = coenzyme A.

aminolevulinic acid (ALA) and porphobilinogen (PBG), are only generated during heme synthesis and not during heme catabolism toward bilirubin.

Specific enzymatic defects result in specific patterns of heme precursors and are of high diagnostic value when determining the type of porphyria. The ultimate step in ruling in or out if a person has the genetic defect for a specific porphyria is DNA testing, currently offered by the Mount Sinai Genetic Testing Laboratory (porphyria@mssm.edu). However, these specific tests are not necessary in the clinical evaluation of a patient in whom porphyria is suspected. Here, quick and simple tests are sufficient. The excretory pattern of heme precursors is influenced by their water solubility, which decreases toward heme; ALA and PBG are highly water soluble and measured in urine, whereas protoporphyrin is so hydrophobic that it is only excreted in stool and not in urine.

There is no single test that can reveal all types of porphyrias. The porphyric symptomatology can differ from type to type, and there is considerable overlap among the various porphyrias. For this reason, highly specific and sensitive laboratory tests are necessary. All porphyrias with acute manifestations manifest with similar attacks and respond to similar treatment, but they exhibit different biochemical patterns according to their specific enzyme defect. A clinically useful grouping splits the porphyrias between acute (neurovisceral) and cutaneous.

The Acute Porphyrias

There are four types of acute porphyria to consider:

- The very rare ALA-dehydratase deficiency porphyria is inherited in an autosomal recessive fashion.

- AIP, an autosomal dominant disorder, is the most common of the acute porphyrias (except in South Africa where variegate porphyria is more common).
- Hereditary coproporphyria, an autosomal dominant disease, is commonly misdiagnosed because coproporphyrin is often moderately and nonspecifically increased in many disorders.
- Variegate porphyria is autosomal dominant and probably the mildest of the acute porphyrias.

All acute porphyrias are sensitive to a multitude of drugs and circumstances (a short list is included in [Box 1](#)). Hereditary coproporphyria and variegate porphyria can also have skin lesions resembling porphyria cutanea tarda. Skin lesions and acute attacks can happen at the same time or one after the other, or only one manifestation may ever be present in a given patient.

BOX 1

Short List of Safe and Unsafe Drugs in the Acute Porphyrias*

Safe

- Acetaminophen (Tylenol)
- Aspirin
- Atropine
- Bromides
- Cimetidine (Tagamet)
- Erythropoietin (Epogen, Procrit)
- Gabapentin (Neurontin)
- Glucocorticoids
- Insulin
- Narcotic analgesics
- Penicillins
- Phenothiazine
- Ranitidine (Zantac)
- Streptomycin
- Digoxin (Lanoxin)
- Labetalol (Trandate), propranolol (Inderal)
- Paraldehyde²
- Bupivacaine (Marcaine)
- Chloral hydrate
- Tetracycline
- Vitamins

Unsafe

- Alcohol
- Barbiturates
- Carbamazepine (Tegretol)
- Carisoprodol (Soma)
- Clonazepam (Klonopin)
- Danazol (Danocrine)
- Diclofenac (Voltaren)
- Ergotamines
- Estrogens, progesterones
- Ethchlorvynol (Placidyl)²
- Glutethimide (Doriden)
- Griseofulvin (Grifulvin)
- Mephenytoin (Mesantoin), phenytoin (Dilantin)
- Meprobamate (Equanil)
- Methypyrion (Noludar)²
- Metoclopramide (Reglan)
- Primidone (Mysoline)
- Pyrazinamide
- Pyrazolone
- Rifampin (Rifadin)
- Sulfonamides
- Valproic acid (Depakene)

²Not available in the United States.

*Drug not listed cannot be considered safe or unsafe.

Diagnosis

Diagnosis of the porphyric attack hinges mainly on a keen sense of suspicion. Any inexplicable symptom complex involving abdominal pain, tachycardia, and psychological findings should be suspect for porphyria. However, no clinical presentation can be called *porphyric* without biochemical support. Small deviations from the narrow normal range for heme precursors are fairly common and nonspecific. PBG or ALA must be markedly elevated, at least fivefold above the normal range, and, if not, porphyria is an unlikely explanation for a patient's acute symptoms.

Older screening mechanisms such as the Watson-Schwartz test and the Hoesch test have been replaced by easier, more specific, semiquantitative tests such as the Trace PBG kit (Thermo Fisher Scientific), but they still rely on the color reaction with Ehrlich's aldehyde. This or a similar test must be available in all emergency departments and in all acute care hospitals. A *random* urine sample is sufficient for the initial diagnostic evaluation, and if it is positive it must be later followed up by more-detailed tests such as quantitative measurements of porphyrins and precursors in a 24-hour urine collection. Fecal porphyrin measurements may also be called for. Enzyme measurements and genetic testing are rarely indicated, but they are used when more routine tests fail. Because the porphyrias are almost always hereditary, family studies are highly appropriate. The proper interpretation of any test result is best done in the context of available clinical information.

Clinical Presentation

Clinical presentations of porphyric attacks vary so much that the term *the little imitator* has been used. Not all signs or symptoms are always present, but severe and poorly localized abdominal pain and unexplained tachycardia are so prevalent that their absence further complicates the diagnosis of an acute porphyric attack. The genesis of the attack is not well understood, but acutely increased demand for heme and production of toxic intermediary products are considered to be the culprit. Increased demand for heme and increased production of intermediary products can be due to a wide variety of circumstances, from drugs through hormones (premenstrual phase) to stress, infection, fasting, and starvation. However, most carriers of the genetic defect for an acute porphyria remain symptom free all their lives. Some have only one or two attacks, and only a few suffer from many attacks.

The clinical picture with pain, fast heart rate, and neurovisceral symptoms can be complicated by, at times, severe hyponatremia, heralding seizures with therapeutic dilemmas (see [Box 1](#)) and respiratory paralysis necessitating ventilatory support. Death is rare nowadays, especially when the diagnosis is made early. The recovery is usually complete, but at times it is prolonged, up to 1 year after a severe attack.

Superb nursing care, initially preferable in an intensive care unit, is necessary, and meticulous attention has to be paid to *all* problems. Dehydration from vomiting is common, and ileus and urinary retention are not infrequent; hyponatremia occurs in approximately half of the porphyric attacks. Muscle strength must be tested frequently. Twice-daily measurement of vital capacity helps to assess the necessity for respiratory assistance. High blood pressure and tachycardia deserve careful attention and, if appropriate, cautious treatment with a β -blocker. A negative caloric balance must be avoided, and, if present initially, it is best treated with carbohydrates (if necessary, intravenously with glucose, up to 300 g/day), and then later with a balanced diet.

Treatment

Therapy must always start with a careful look at the drugs recently taken by the patient. It is best to discontinue as many drugs as possible, especially those deemed unsafe (see [Box 1](#)). Appropriate lists of safe and unsafe drugs in porphyria are readily available from websites (www.porphyriafoundation.com and www.porphyria-europe.com). An infection must be diligently searched for and treated at once. Seizure precautions are especially indicated if hyponatremia is found. Analgesics should be adequately dispensed; opiates are often necessary in fairly large doses.

Specific therapy was introduced a generation ago in the form of hematin (hemin, Panhematin), available from Lundbeck Inc. (847-282-1000 or www.lundbeckinc.com). This has largely replaced glucose (300 g/day), which had the main advantages of availability, relatively low cost, and the possibility of curbing an early or mild attack.

But one must not wait for quick improvement in a patient's condition and should at once take steps to obtain the definitive medication, hematin. This represents the equivalent to the end product, heme, and exerts its beneficial effect through repression of the deranged, and in the porphyric attack, markedly activated pathway to heme. It is still unclear whether the quick suppression of potentially toxic heme precursors (in 1–2 days) or a postulated replenishment of an assumed heme deficiency is the effective mechanism. *Early* administration of hematin is strongly advocated because the course of a porphyric attack is unpredictable, and a point of no return can unfortunately be reached quickly. Thus the infusion of hematin must start as soon as possible.

A daily dose of 2 to 4 mg/kg body weight is recommended for up to 4 days. Longer treatment periods are of questionable value but may be tried in severe cases for up to 2 weeks. The infusion must be strictly intravenous and with ample flushing because hematin can cause thrombosis and phlebitis. Because it is a procoagulant and anticoagulant, frequent measurements of coagulation parameters are advisable. Anticoagulants such as warfarin (Coumadin) should if possible be avoided. Admixture of 5% human serum albumin (Albuminar-5) has been advocated to stabilize the final hematin solution and to lessen side effects. Hematin is available in many countries as heme arginate (Normosang).²

A beneficial clinical effect can be expected in 1 to 2 days, accompanied by a decrease in all heme precursors, most notably ALA and PBG. Many patients have received many treatment courses with hematin without apparent loss of effectiveness. Prophylactic use of hematin can be helpful in the treatment of women with frequent premenstrual exacerbations of their acute porphyria. Hematin should never be given as a diagnostic test to see if unexplained symptoms reminiscent of porphyria lessen. The diagnosis of a porphyric attack must be as quick, precise, and certain as possible, especially in new cases.

Partial liver transplantation has been successfully undertaken and found to be curative in patients with unrelenting porphyric attacks.

Prophylaxis of porphyric attacks is of great importance and can be accomplished to a large extent by avoidance of unsafe drugs, by stable caloric intake, and by prompt attention to intercurrent illnesses. It is a difficult decision if unsafe drugs have to be administered for a vital indication such as seizures. Here, consultation with an expert in porphyria is strongly advised.

The Cutaneous Porphyrias

The symptomatology of cutaneous porphyrias is mainly photosensitivity, often combined with skin fragility and blisters. All of these findings occur because of porphyrin toxicity, resulting in cutaneous light absorption at the wavelength of 400 to 410 nm and subsequent formation of damaging reactive oxygen species. Thus two therapeutic approaches are plausible: decrease of porphyrins and protection of the skin from sunlight. The usual sunscreens are, however, ineffective, and reflective agents containing zinc or titanium, although better, are less popular because of their appearance.

In three porphyrias—porphyria cutanea tarda, hereditary coproporphyria, and variegate porphyria—the skin lesions are rather similar, but erythropoietic protoporphyria and congenital erythropoietic porphyria can lead to very painful nonblistering skin lesions, and, in congenital erythropoietic porphyria, even to mutilations.

Porphyria Cutanea Tarda

Porphyria cutanea tarda is the most common porphyria and occurs because of uroporphyrinogen-decarboxylase deficiency and accumulation of mostly uroporphyrin. It can be inherited autosomal dominantly but more often occurs sporadically. It can also be due to toxins such as halogenated aromatic hydrocarbons.

The most prominent skin manifestations are seen on the dorsa of the hands and on the face, consisting of blisters filled with mostly clear fluid; shallow, slow-healing ulcers; whitish plaques; and tiny inclusion bodies, *milia*. Hypertrichosis and hyperpigmentation are often seen.

Unveiling factors promote the manifestation of the disease and consist mainly of liver disease, often due to alcohol. Hepatitis, often type C, and HIV infections are also common revealers. The drug list (see [Box 1](#)) is *not* applicable to the cutaneous porphyrias. The diagnosis is easily suspected at inspection and confirmed by measurement of urinary uroporphyrin excretion, typically manifold increased above the normal range.

There are two treatment options with different principles but rather similar effectiveness. Repeat phlebotomies of 350 to 450 mL at 1- to 2-week intervals are performed and followed by hemoglobin and ferritin measurements. Overt anemia should be avoided. Ferritin usually reaches the lower end of the normal range after approximately 8 to 10 phlebotomies, and clinical remission can be expected after approximately half a year. Remission can be long lasting, especially when unveiling factors are avoided; total abstinence from alcohol is advocated. Patients should not take iron-enriched vitamins because iron plays a critical role in porphyria cutanea tarda.

If phlebotomies are contraindicated (due to anemia or pulmonary or cardiac disease) or are very inconvenient, low-dose chloroquine (Aralen)¹ (125 mg twice weekly) can be given orally. This flushes porphyrins from the liver and can be continued until remission is reached. In such low doses, the drug is virtually free from side effects.

Patients on chronic dialysis can develop porphyria cutanea tarda and also *pseudoporphyria*. Here, plasma porphyrin measurements establish the correct diagnosis. Patients with porphyria cutanea tarda and end-stage renal disease respond well to erythropoietin (Epogen, Procrit)¹, probably via iron depletion through incorporation of iron into hemoglobin. Pseudoporphyria is also seen as a side effect of many drugs, mostly nonsteroidal antiinflammatory drugs and diuretics. Although it is phenotypically identical to porphyria cutanea tarda, pseudoporphyria does not respond to phlebotomies or chloroquine.

Patients with porphyria cutanea tarda have a much higher incidence of hepatocellular carcinoma and should be checked twice annually with hepatic imaging and measurement of alpha fetoprotein.

Congenital Erythropoietic Porphyria (Günther Disease)

Congenital erythropoietic porphyria (Günther disease), a rare autosomal recessive disorder, is usually apparent shortly after birth when brick-colored urine in diapers is observed because of excessive amounts of uroporphyrin (even more impressive under UV light). This porphyria and the rare homozygous porphyria cutanea tarda, hepatoerythropoietic porphyria, can be progressive and severely mutilating. Therapy is limited to sun protection and blood transfusion if hemolytic anemia is present.

Erythropoietic Protoporphyria

Erythropoietic protoporphyria is an autosomal dominant disorder due to a deficiency of ferrochelatase, the last enzyme in heme biosynthesis. Urinary porphyrins are normal, but protoporphyrin is markedly elevated in red cells and in stool. These patients suffer from instantly painful sun sensitivity, followed by edema and wrinkles in the thickened, light-exposed skin. In contrast to porphyria cutanea tarda, blisters are not seen here. Approximately one fifth of

²Not available in the United States.

¹Not FDA approved for this indication.

these patients develop progressive liver disease secondary to hepatic accumulation of protoporphyrin. Liver transplantation can become necessary.

Therapy is often beneficial with oral β -carotene¹ (up to 400 mg/day for adults). This leads to a harmless slight orange-yellow discoloration of the skin and often effective sun protection. Ideally, the β -carotene dose should be adjusted to a plasma level between 11 and 15 mmol/L.

¹Not FDA approved for this indication.

SICKLE CELL DISEASE

Method of

Enrico M. Novelli, MD; Mark T. Gladwin, MD; and Lakshmanan Krishnamurti, MD

CURRENT DIAGNOSIS

- Sickle cell disease (SCD) is diagnosed by neonatal screening in the United States.
- Persons with congenital hemolytic anemia should be tested for SCD by hemoglobin electrophoresis regardless of their ethnic background.
- Infection with parvovirus B19 should be suspected in children presenting with acute anemia and reticulocytopenia.
- Human leukocyte antigen (HLA) class I and II testing should be performed in all patients with SCD and unaffected siblings to identify candidates for hematopoietic stem cell transplant.
- Transcranial Doppler screening for primary prevention of stroke is indicated in children with homozygous SCD.
- Acute chest syndrome is diagnosed in patients presenting with fever, hypoxemia, and a radiographic pulmonary infiltrate.
- Screening for iron overload by ferritin, quantitative liver magnetic resonance imaging (MRI), cardiac MRI, or liver biopsy is indicated in all patients who have received more than 10 lifetime transfusions.
- Pulmonary hypertension screening by transthoracic echocardiogram is indicated in all patients with homozygous SCD.

CURRENT THERAPY

- All children with SCD should receive penicillin prophylaxis.
- High fever should be treated empirically with coverage for *Streptococcus pneumoniae* pending results of blood cultures.
- Children with high transcranial Doppler velocity need to be placed on a chronic transfusion regimen to keep the hemoglobin (Hb) S less than 30%.
- Painful vaso-occlusive episodes warrant prompt treatment with an individualized intravenous opiate regimen, as well as supportive care and incentive spirometry.
- Preoperative transfusion should aim at a target hemoglobin level of 10 g/dL regardless of the HbS percentage and is indicated in all patients with SCD undergoing major surgery.
- Therapy with hydroxyurea is indicated in all patients at all ages with HbSS disease and HbS β -thalassemia, and in patients with HbSC with a severe phenotype on a case-by-case basis.
- Erythropoietin-stimulating agents can be used in conjunction with hydroxyurea to prevent or ameliorate reticulocytopenia and in patients with underlying renal insufficiency.
- Iron chelation is indicated in all patients with findings of iron overload.
- Treatment of acute chest syndrome includes parenteral antibiotics to cover atypical microorganisms and transfusion, with exchange transfusion reserved for the most severe cases.
- Patients with pulmonary hypertension should receive optimal hematologic care (maximal hydroxyurea and/or chronic transfusion therapy) and specific therapy for pulmonary hypertension in severe cases, with coordination and referral to a pulmonary hypertension specialist.
- Stem cell transplantation should be offered to all patients who have a matched donor and display a severe phenotype.

Epidemiology

SCD affects 70,000 to 100,000 persons in the United States and millions worldwide. The hemoglobin (Hb) S mutation arose in West-Central Africa approximately 7300 years ago and then propagated to vast tropical and subtropical areas due to the selective pressure of malaria infection. It is predominantly found in persons of African, Mediterranean, Arab, or Indian ancestry. In the United States, approximately 1 in 15 African Americans harbors the HbS (sickle hemoglobin) mutation and 1 in 400 is affected by the disease. Most patients with SCD in the United States are homozygous for HbS (SS), with heterozygous HbSC being the second most common abnormality. Conversely, in Mediterranean countries, HbS/ β -thalassemia is the most common SCD syndrome, and in the Arab peninsula HbSS in combination with hereditary persistence of fetal hemoglobin (HPFH) is particularly prevalent.

Pathophysiology

SCD consists of a group of inherited hemoglobinopathies characterized by a qualitatively abnormal hemoglobin molecule that affects the structure and integrity of the red blood cells (RBCs). SCD is an autosomal recessive disease due to homozygosity for HbS, characterized by a single base substitution in the β -globin gene of the hemoglobin tetramer, leading to an amino acid substitution (valine to glutamic acid), or coinheritance of HbS with other abnormal hemoglobins such as hemoglobin C, D, E, and O or β -thalassemia.

HbS is less soluble than normal hemoglobin (HbA) in the deoxygenated state and polymerizes when sickle RBCs are exposed to hypoxic conditions in the microcirculation. In the classic pathophysiologic explanation of SCD, sickled RBCs containing HbS polymers are less deformable and remain trapped in the microcirculation, causing end-organ ischemia and necrosis. Compounding this mechanism, more recent literature has emphasized the role of cellular adhesion, abnormal cytokine levels, ischemia-reperfusion injury, oxidative damage, sterile inflammation, and an abnormal

these patients develop progressive liver disease secondary to hepatic accumulation of protoporphyrin. Liver transplantation can become necessary.

Therapy is often beneficial with oral β -carotene¹ (up to 400 mg/day for adults). This leads to a harmless slight orange-yellow discoloration of the skin and often effective sun protection. Ideally, the β -carotene dose should be adjusted to a plasma level between 11 and 15 mmol/L.

- Erythropoietin-stimulating agents can be used in conjunction with hydroxyurea to prevent or ameliorate reticulocytopenia and in patients with underlying renal insufficiency.
- Iron chelation is indicated in all patients with findings of iron overload.
- Treatment of acute chest syndrome includes parenteral antibiotics to cover atypical microorganisms and transfusion, with exchange transfusion reserved for the most severe cases.
- Patients with pulmonary hypertension should receive optimal hematologic care (maximal hydroxyurea and/or chronic transfusion therapy) and specific therapy for pulmonary hypertension in severe cases, with coordination and referral to a pulmonary hypertension specialist.
- Stem cell transplantation should be offered to all patients who have a matched donor and display a severe phenotype.

Epidemiology

SCD affects 70,000 to 100,000 persons in the United States and millions worldwide. The hemoglobin (Hb) S mutation arose in West-Central Africa approximately 7300 years ago and then propagated to vast tropical and subtropical areas due to the selective pressure of malaria infection. It is predominantly found in persons of African, Mediterranean, Arab, or Indian ancestry. In the United States, approximately 1 in 15 African Americans harbors the HbS (sickle hemoglobin) mutation and 1 in 400 is affected by the disease. Most patients with SCD in the United States are homozygous for HbS (SS), with heterozygous HbSC being the second most common abnormality. Conversely, in Mediterranean countries, HbS/ β -thalassemia is the most common SCD syndrome, and in the Arab peninsula HbSS in combination with hereditary persistence of fetal hemoglobin (HPFH) is particularly prevalent.

Pathophysiology

SCD consists of a group of inherited hemoglobinopathies characterized by a qualitatively abnormal hemoglobin molecule that affects the structure and integrity of the red blood cells (RBCs). SCD is an autosomal recessive disease due to homozygosity for HbS, characterized by a single base substitution in the β -globin gene of the hemoglobin tetramer, leading to an amino acid substitution (valine to glutamic acid), or coinheritance of HbS with other abnormal hemoglobins such as hemoglobin C, D, E, and O or β -thalassemia.

HbS is less soluble than normal hemoglobin (HbA) in the deoxygenated state and polymerizes when sickle RBCs are exposed to hypoxic conditions in the microcirculation. In the classic pathophysiologic explanation of SCD, sickled RBCs containing HbS polymers are less deformable and remain trapped in the microcirculation, causing end-organ ischemia and necrosis. Compounding this mechanism, more recent literature has emphasized the role of cellular adhesion, abnormal cytokine levels, ischemia-reperfusion injury, oxidative damage, sterile inflammation, and an abnormal

endothelial milieu. HbS polymers also lead to deformity and fragility of the RBC membrane, with resulting intra- and extravascular hemolysis.

Patients with SCD suffer from severe chronic hemolytic anemia and acute episodes of RBC trapping and destruction in the microvasculature (vaso-occlusive episodes). Vaso-occlusive episodes are the hallmark of SCD and are characterized by more intense episodic vaso-occlusion, often with increasing hemolysis, and are due to exogenous or endogenous factors that acutely alter the rheologic properties of the RBCs. The main determinants of RBC sickling and vaso-occlusion are hypoxemia, RBC dehydration, RBC concentration, high HbS relative to fetal hemoglobin (HbF), and blood viscosity; these can occur in a multitude of clinical settings. Most common clinical inciting events leading to vaso-occlusive episodes are dehydration due to inadequate replacement of fluid losses, thermal changes, surgical stress, exposure to low oxygen tension, infections, and psychological stressors.

Epidemiologic studies indicate that the risk of vaso-occlusive episodes and acute chest syndrome is related to high steady-state hemoglobin levels, leukocytosis, and low HbF levels. These findings are consistent with pathogenic mechanisms of altered red cell rheology, higher viscosity, HbS polymerization, and inflammatory cellular adhesion. Interestingly, the epidemiologic risk factors associated with chronic vascular complications such as pulmonary hypertension, cutaneous leg ulceration, priapism, systemic systolic hypertension, renal failure with proteinuria, and possibly stroke are different and include a low steady-state hemoglobin level, increased hemolytic intensity, iron overload, and markers of low nitric oxide bioavailability. One hypothesis is that SCD is driven by two overlapping but different mechanisms of disease: on one hand, vaso-occlusion causes vaso-occlusive episodes and acute chest syndrome, and on the other hand, hemolytic anemia leads to endothelial dysfunction and chronic vasculopathy. Both are caused fundamentally by HbS polymerization.

Prevention

See “Evidence-Based Management of Sickle Cell Disease: Expert Panel Report, 2014” at <http://www.nhlbi.nih.gov/health-pro/guidelines/sickle-cell-disease-guidelines> for detailed, consensus guidelines on prevention and treatment.

Bacterial Infections

Before the antibiotic era, most patients with SCD succumbed to bacterial sepsis from encapsulated organisms. A landmark multicenter, randomized, double-blind, placebo-controlled clinical trial of prophylaxis with oral penicillin in children with sickle cell anemia published in 1986 showed that bacterial prophylaxis started at birth reduced by about 80% the incidence of infection in the penicillin group, as compared with the group given placebo. This study became the foundation for universal screening of SCD. Results of the Penicillin Prophylaxis in Sickle Cell Study II (PROPS 2) trial show that prophylaxis can be safely discontinued at age 5 years as long as there is no history of prior serious pneumococcal infection or surgical splenectomy and in the setting of appropriate comprehensive care. All children should also receive both the 13-valent pneumococcal conjugate (Prevnar 13) and 23-valent pneumococcal polysaccharide (Pneumovax) vaccines, and adults should receive Pneumovax. Vaccinations for *H. influenzae* and *N. meningitidis* are also indicated.

Neurologic Events

Stroke is a devastating complication of SCD and affects predominantly children with HbSS and abnormal transcranial Doppler (TCD) results. Silent cerebral infarcts are MRI-detectable abnormalities that also carry a high risk of morbidity, including overt stroke and cognitive impairment. There is conclusive evidence that chronic transfusions are effective in the primary and secondary prevention of both overt and silent strokes in SCD. The first landmark trial (STOP) published in 1995 showed that the first stroke can be prevented by placing children with abnormal TCD on prophylactic monthly transfusions with a target HbS of less than 30%.

Transfusions were later found to also have a beneficial effect on reducing the incidence of the recurrence of silent cerebral infarcts, as shown by the SIT trial. The importance of continuing transfusions for more than 30 months was underscored by the STOP 2 trial, where TCD abnormalities recurred and the incidence of silent cerebral infarctions on MRI was higher in the transfusion-halted group. The enthusiasm over the beneficial effects of transfusions was tempered by the concerns about the side effects of long-term, possibly indefinite use of this therapeutic strategy. There has been, therefore, an interest in exploring whether hydroxyurea (Droxia, Siklos) could represent an alternative to transfusion in high-risk children. Specifically, the SWiTCH trial explored the hypothesis that hydroxyurea and phlebotomy could maintain an acceptable stroke recurrence rate and significantly reduce the hepatic iron burden as compared to a prophylactic chronic transfusion regimen. Unfortunately, the trial was terminated early because of a significantly higher stroke recurrence rate in the hydroxyurea arm compared to the transfusion arm, with equivalent hepatic iron burden in both groups. Thus the issue of when, if ever, it is safe to discontinue transfusions for the secondary prevention of stroke is still unknown. Conversely, as shown by the results of the TWiTCH trial, another study halted prematurely by the National Institutes of Health, hydroxyurea is not inferior to chronic transfusions in lowering TCD velocities in children at high risk but without a history of stroke, thereby suggesting that this drug may be equally effective in the primary prevention of neurologic complications.

Clinical Manifestations

Multiple genetic and epigenetic factors affect the SCD phenotype. Patients homozygous for HbS (SS) or compound heterozygous for HbS and a nonfunctional β^0 -thalassemia allele tend to display the most severe manifestations. On the other end of the spectrum, hereditary persistence of HbF (HPFH), particularly common in Saudi Arabia, or coinheritance of β -thalassemia mitigates the phenotype. While the net effect of high HbF levels on the phenotype of SCD is beneficial, coinheritance of one or two α -thalassemia alleles has a more complex effect. α -thalassemia is present in approximately 30% of patients with SCD and is associated with higher hemoglobin, lower mean corpuscular volume (MCV), and decreased rate of hemolysis. These effects are protective toward stroke and leg ulcers, but lead to increased rates of vaso-occlusive episodes, osteonecrosis, and acute chest syndrome because of increased blood viscosity related to the higher hemoglobin level. Patients with HbSC and HbS/ β^+ -thalassemia have an intermediate severity phenotype (Table 1). Haplotypes of polymorphic sites in the β -globin gene cluster in chromosome 11 have been associated with different disease severity and rates of complications. Other yet unidentified genetic factors predispose certain patients to develop a particularly severe hemolysis with brisk reticulocytosis and a high rate of specific complications that include leg ulcers, priapism, and pulmonary hypertension.

Hematology

This section describes the main clinical manifestations of SCD in each organ system (Figure 1 and Table 2).

TABLE 1 Severity of the Main Sickle Cell Syndromes

GENOTYPE	CLINICAL SEVERITY	HEMOGLOBIN (g/dL)
HbSS	Usually marked	6–10
HbS- β^0 -thalassemia	Moderate to marked	6–10
HbS- β^+ -thalassemia	Mild to moderate	9–12
HbSC	Mild to moderate	10–15
HbSS-HPFH	Mild	

Abbreviations: HbSC = heterozygous phenotype; HbSS = homozygous phenotype; HPFH = hereditary persistence of fetal hemoglobin.

Figure 1 Acute and chronic complications of sickle cell disease.

TABLE 2 Landmark Randomized Clinical Trials in Sickle Cell Disease

YEAR OF PUBLICATION	TITLE	MAIN FINDINGS
1986	Prophylaxis with oral penicillin in children with sickle cell anemia: A randomized trial	84% reduction in incidence of infection and no deaths from pneumococcal septicemia in the penicillin group
1995	Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH)	Reduced incidence of painful crises, ACS, and transfusion in the hydroxyurea group Survival benefit in follow-up study
1995	Preoperative Transfusion in Sickle Cell Disease Study	A conservative transfusion regimen was as effective as an aggressive regimen in preventing perioperative complications in patients with sickle cell anemia
1996	Multicenter investigation of bone marrow transplantation for sickle cell disease	HCT is safe in SCD with survival and event-free survival at 4 y of 91% and 73% and can lead to cure
1998	Stroke Prevention Trial in Sickle Cell Anemia (STOP)	Transfusion reduces the risk of a first stroke by 92% in children with sickle cell anemia who have abnormal results on transcranial Doppler ultrasonography
2005	Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP 2)	Discontinuation of transfusion for the prevention of stroke in children with sickle cell disease results in a high rate of reversion to abnormal blood-flow velocities on Doppler studies and stroke
2009	Improving the Results of Bone Marrow Transplantation for Patients with Severe Congenital Anemias	Nine of 10 adults who received nonmyeloablative allogeneic hematopoietic stem cell transplantation for severe sickle cell disease achieved stable, mixed donor–recipient chimerism and reversal of the sickle cell phenotype, without acute or chronic GVHD.
2011	Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG)	Children ages 9–18 mo randomized to receive hydroxyurea irrespective of disease severity for 2 y had decreased pain episodes, dactylitis, ACS, hospitalization, leukocyte count, and transfusion and increased hemoglobin as compared to children receiving placebo.
2014	Silent Infarct Trial (SIT)	Children with silent cerebral infarcts and normal TCD velocity who were randomized to chronic transfusion therapy had a 58% relative risk reduction in the recurrence of silent cerebral infarct or stroke as compared to those in the observation arm.

Abbreviations: ACS = acute chest syndrome; GVHD = graft-versus-host disease; HCT = hematopoietic cell transplantation; SCD = sickle cell disease; VOE = vaso-occlusive crisis.

Baseline or Steady-State Hematologic Abnormalities

Chronic intravascular and extravascular hemolysis causes a chronic anemia of moderate to severe intensity in HbSS and HbS/ β^0 -thalassemia, with a hemoglobin range of 6 to 9 g/dL. In HbSC and HbS/ β^+ -thalassemia, the anemia may be mild or absent. The anemia of SCD is usually normocytic in HbSS, with anisocytosis and poikilocytosis and a population of small dehydrated dense cells, irreversibly sickled cells, numerous reticulocytes, and schistocytes. Reticulocytosis is common but not compensatory, and nucleated RBCs are seen in acute exacerbations of the anemia

such as in splenic or hepatic sequestration. Baseline leukocytosis with neutrophilia is also common and is a poor prognostic sign associated with acute chest syndrome in adults and frequent vaso-occlusive episodes in children. Preclinical studies have shown that leukocytes are not simply a marker of disease activity and acute phase but also have a direct pathogenic role in cellular adhesion and vaso-occlusion. The platelet count is commonly elevated in SCD, particularly in patients who are autosplenectomized as a result of repeated splenic infarction, and platelet activation is increased. In the subset of patients with HbSC and

HbS/ β^+ -thalassemia who retain a functional spleen and develop splenomegaly, features of hypersplenism may instead be observed with resulting mild pancytopenia.

Hematologic Indices During Vaso-Occlusive Episodes

In acute vaso-occlusive episodes the total Hb decreases as a result of hemolysis (by 1.6 g/dL in acute chest syndrome). The lactate dehydrogenase (LDH), reticulocyte count, and other markers of hemolysis such as aspartate transaminase (AST) and indirect bilirubin are elevated in steady state, and in many—but not all—patients are further increased during vaso-occlusive episodes. Haptoglobin levels are chronically depressed in SCD and typically not measurable, even in steady state, in patients with HbS homozygosity. In patients with HbSC, vaso-occlusive episodes may be due to increased blood viscosity and RBC sickling, and worsening hemolysis might not be readily appreciated.

Splenic sequestration crises occur mostly in childhood and are characterized by anemia disproportionate to the degree of hemolysis, reticulocytosis, and acute splenomegaly. Splenic sequestration and repeated episodes of splenic infarction eventually lead to autosplenectomy, although some patients develop splenomegaly. Splenic infarction usually manifests with left upper-quadrant pain and may be massive, involving more than 50% of the splenic tissue.

In severe vaso-occlusive episodes, massive bone marrow infarction can also occur. In these instances, the peripheral blood smear reveals a leukoerythroblastic picture with immature neutrophilic forms, nucleated RBCs, and teardrop cells. Fat emboli syndrome, a life-threatening complication of vaso-occlusive episodes, can then develop as bone marrow fat embolizes to peripheral capillary beds, leading to multiorgan failure.

Red Blood Cell Alloimmunization

RBC alloimmunization is a common complication of transfusional therapy in SCD and occurs in approximately 30% of patients. It is primarily due to the disparate expression of RBC antigens in African Americans as compared to the donor pool, which is mostly composed of Caucasians. Alloimmunization complicates RBC matching and leads to delayed hemolytic transfusion reactions. Alloantigens that become undetectable by indirect Coombs test 2 months after exposure to mismatched blood have the potential to result in future false-negative cross-matching results. A subset of heavily alloimmunized patients with SCD undergoes life-threatening hemolytic reactions upon exposure to mismatched RBC units. In these hyperhemolytic crises, there is intense hemolysis of transfused and nontransfused RBCs and acute anemia. Treatment of hyperhemolytic crises is empirical and includes erythropoietin-stimulating agents (ESA), parenteral steroids, and intravenous immunoglobulins (Gammagard).¹

Iron Overload

Hemosiderosis is the other major complication of transfusional therapy in SCD and is characterized by iron deposition in the heart, liver, and endocrine glands, leading to organ failure and significant morbidity and mortality. It commonly occurs in patients who have received more than 10 lifetime transfusions or more than 20 packed RBC units. Liver biopsy is the gold standard for diagnosis but it is an invasive and uncomfortable procedure. Hepatic and myocardial iron quantitation by MRI is supplanting liver biopsy as the preferred test to diagnose iron overload and monitor therapy with iron chelators, although when this is not available diagnosis often rests on the finding of an elevated ferritin and transferrin saturation in the appropriate clinical setting.

Hemostatic Activation and Thrombosis

Numerous studies have shown that arterial and venous thrombosis are common in SCD and include pulmonary embolism, in situ pulmonary thrombosis, and stroke. In SCD, alterations at all levels of the hemostatic system have been described: patients with sickle cell

disease exhibit increased basal and stimulated platelet activation, increased markers of thrombin generation and fibrinolysis, increased tissue factor activity, and increased von Willebrand factor (vWF) antigen and thrombogenic ultralarge vWF multimers with depressed ADAMTS13 activity. Interestingly, hemostatic activation is amplified during vaso-occlusive episodes, as shown by increases in multiple markers of thrombosis as compared to steady state, suggesting a link between hemolysis and thrombosis.

Neurology

Ischemic stroke is common in SCD, with the highest incidence between 2 and 5 years of age. Patients may develop overt stroke from large vessel occlusion (5%–8% of patients with HbSS) or silent infarcts from focal ischemia detectable by MRI without symptoms of acute stroke (20%–35% of patients with HbSS). The pathophysiology of stroke in SCD is unclear, although genetic factors and an unbalance between oxygen demand and supply have been postulated. Multiple epidemiologic studies have shown that the risk factors for ischemic stroke in adult patients include HbSS genotype, severity of anemia, systolic hypertension, male gender, and increasing age. Patients with repeated strokes are at risk for development of anatomic abnormalities and Moyamoya pattern of vascularization, which predisposes to both ischemic and hemorrhagic stroke later in life. The highest incidence of intracerebral hemorrhages occurs in patients older than 20 years.

Both overt and silent strokes have a negative impact on IQ and cause cognitive impairment measurable by psychometric testing. Children and adults with SCD can develop cognitive impairment and subtle signs of accelerated brain aging and vascular dementia even in the absence of focal ischemia by MRI, with a low hematocrit being a predictor of neuropsychological dysfunction. These abnormalities are probably due to chronic and diffuse, as opposed to focal, cerebral anoxia and may be unmasked by psychometric testing.

Ophthalmology

Retinal abnormalities are common in SCD and are often asymptomatic until the occurrence of ophthalmologic emergencies. Retinal disease is due to arteriolar occlusion, with subsequent vascular proliferation, neovascularization, retinal hemorrhage (stage IV), and detachment (stage V). Patients with HbSC are more prone to retinal complications, possibly as a result of increased blood viscosity.

Nephrology

Renal abnormalities are common in SCD and manifest primarily as hematuria, proteinuria, and renal tubular acidosis. Hematuria is usually due to papillary necrosis and is an acute finding that requires supportive care and carries a good prognosis. Rarely, gross hematuria requires urologic consultation. Tubular functional defects include an inability to concentrate the urine (hyposthenuria) and renal tubular acidosis. Hyposthenuria often manifests with enuresis in childhood, and it is clinically relevant because it predisposes patients to an increased risk of dehydration. Renal tubular acidosis similar to type IV renal tubular acidosis is a common finding in SCD and may lead to hyperkalemia, an important consideration in patients already predisposed to hyperkalemia with intravascular hemolysis and whenever therapy with angiotensin-converting enzyme inhibitors is entertained.

Hyperphosphatemia and hyperuricemia are also often observed in SCD. Microalbuminuria may be detected in early adulthood and tends to progress to nephrotic range proteinuria. Focal segmental glomerulosclerosis is the most common glomerular abnormality and it is probably due to glomerular sickling and infarction. There are currently no approved therapies to prevent progression to end-stage renal disease, which occurs in up to 20% of patients and at a median age of 37 years. Renal replacement therapy is often needed in older adults with SCD. Serum creatinine and 24-hour creatinine clearance are not adequate for screening and monitoring of progression of kidney disease, because tubular secretion of creatinine is preserved and glomerular hyperfiltration is common in SCD,

¹Not FDA approved for this indication.

leading to a relatively low creatinine and a high glomerular filtration rate even in patients with underlying kidney impairment. Testing for microalbuminuria, plasma cystatin C levels and hemoglobinuria may instead be used as screening tools for chronic kidney disease.

Leg Ulcers

Leg ulcers occur in 10% to 20% of patients with HbSS and have been associated with a chronically high hemolytic rate. They are usually located over the malleolar areas and are exquisitely painful, debilitating, disfiguring, and nonhealing. Vascular and plastic surgery consultation are recommended and aim at excluding local vascular problems that can complicate management of the ulcers and at providing prompt débridement and skin grafting. Although hydroxyurea is associated with development of leg ulcers in patients with myeloproliferative disorders, there is no such link with leg ulcers in SCD. Whereas wound healing may be impaired with hydroxyurea use, patients who develop an increase in fetal hemoglobin and have reduced sickling as a result of hydroxyurea therapy might have a net benefit in terms of tissue oxygenation and perfusion. Transfusional therapy, including exchange transfusional therapy, topical nitrates,¹ and nutritional zinc⁷ or L-arginine⁷ supplementation, have shown benefit in anecdotal reports, but the evidence is inconclusive.

Gastroenterology

Nausea, vomiting, and dyspepsia in SCD are related to delayed gastric emptying and gastrointestinal motility disorders, autonomic neuropathy, or medical therapy. Opiates are often responsible for acute nausea and vomiting, whereas other medications such as hydroxyurea and deferasirox (Exjade) are occasionally responsible for chronic symptoms. Gastroparesis may be due to damage of the microvasculature of autonomic nerves (vasa vasorum) from repeated episodes of sickling.

The liver may be episodically affected by hepatic sequestration crises, heralded by direct hyperbilirubinemia, right upper quadrant pain from distention of the hepatic capsule, acute anemia, and reticulocytosis or by sinusoidal vaso-occlusion leading to severe episodes of intrahepatic cholestasis. Supportive therapy and transfusions are indicated for hepatic vaso-occlusive complications. Exchange transfusion may be the preferred modality for hepatic sequestration with the goal of preventing rethrombosis once the pooled RBCs are released back into the circulation. Elevation of liver injury tests may be drug-induced (hydroxyurea, deferasirox), but also related to hepatic sickling, particularly if it occurs during a vaso-occlusive episode.

Infectious Disease

Patients homozygous for HbSS develop functional asplenia during childhood. This is due to repeated episodes of splenic infarction leading to fibrosis and autosplenectomy. As a result, children are susceptible to overwhelming bacterial sepsis from encapsulated organisms such as *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*. High pediatric mortality from sepsis was therefore common before a landmark study published in 1986 demonstrated the benefit of penicillin prophylaxis instituted at birth. Vaccination for encapsulated organisms is also standard of care in children and adults. In spite of preventive measures, the incidence of life-threatening bacterial infections is increased in SCD, and high fever should be treated empirically as in splenectomized patients, with coverage for penicillin-resistant *S. pneumoniae* pending blood culture results. Patients with indwelling venous catheters are at risk of catheter-related bacteremia.

Viral infections with bone marrow-tropic viruses such as Epstein-Barr virus, cytomegalovirus, and predominantly parvovirus B19 place patients at risk for myelosuppression, which can further worsen chronic anemia. In children, infections with parvovirus

B19 are responsible for transient red cell aplasia and severe aplastic crises, characterized by acute anemia and reticulocytopenia due to intra marrow destruction of erythroid precursors. Treatment of these episodes includes transfusion and intravenous immunoglobulins,¹ besides supportive measures.

Pulmonology

A subset of patients with vaso-occlusive episodes develop acute chest syndrome, the major pulmonary complication of SCD. Acute chest syndrome is a lung injury syndrome defined by fever, pleuritic chest pain, oxygen desaturation, and multilobar radiographic infiltrates associated with severe vaso-occlusive episodes, infection, and bone marrow fat embolization (Figure 2). It usually develops 2 to 3 days after hospitalization for vaso-occlusive episodes and is often misdiagnosed as nosocomial pneumonia or aspiration pneumonia, particularly because it displays a predilection for the lower lobe of the lungs. Although pneumonia often accompanies acute chest syndrome, proper diagnosis is important because acute chest syndrome warrants simple or exchange transfusion in addition to antibiotic therapy and supportive measures. Common infectious pathogens identified in cases of acute chest syndrome include *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella pneumophyla*, thus dictating inclusion of a macrolide in the antibiotic cocktail. Pulmonary embolism with resulting infarct is also in the differential diagnosis of acute chest syndrome and may occur concurrently in 17% of patients. If not recognized and treated promptly, acute chest syndrome leads to pulmonary failure and carries a high mortality.

Airway hyperreactivity is common in children with SCD and needs to be actively diagnosed and aggressively treated because it is associated with worse SCD outcomes. Children with chronic respiratory symptoms should be tested for bronchial hyperresponsiveness.

Chronic complications of SCD include pulmonary fibrosis and pulmonary hypertension. Pulmonary hypertension (PH) is an emergent complication of SCD and is associated with a high morbidity and mortality. Multiple epidemiologic studies have shown that a high baseline hemolysis rate, low hemoglobin, increasing age, a history of leg ulcers, liver dysfunction, iron overload, and kidney failure are risk factors for the development of pulmonary hypertension. Three epidemiologic studies and a randomized clinical trial have shown that an elevated tricuspid regurgitant jet velocity (TRV) measured by Doppler echocardiography is a common occurrence in SCD with 30% of the patients having a TRV of 2.5 m/sec (2 standard deviations [SDs] above the normal mean) or higher, and 10% of the patients having a TRV of 3.0 m/sec (3 SDs above the normal mean) or higher. These have proved to be valuable cutoff values, as a TRV of less than 2.5 m/sec, when combined with an N-terminal pro B-type natriuretic peptide (NT-proBNP) value less than 160 has a high negative predictive value for PH. A TRV of 3.0 m/sec or higher confers a positive predictive value for having PH by RHC of 60% to 75% and a relative risk for death of 10.6. Controversy exists on the significance of an intermediate TRV value of 2.5 to 2.9 m/sec, as it is unclear how accurately it predicts RHC-diagnosed PH. In three subsequent studies, patients with intermediate or high TRV values had a prevalence of PH by RHC ranging from 25% to 65% depending on what specific cutoff value was used as the criteria to perform a RHC (2.5 vs. 2.8) and on whether patients with evidence of end-organ damage were included or excluded. It is, however, worrisome that regardless of the prevalence of PH, patients with an intermediate TRV are as a whole at increased risk of death (relative risk 4.4). One screening approach is to consider RHC in all patients with TRV of 3.0 or higher and in patients with intermediate TRV values of 2.5 to 2.9 m/sec if the NT-proBNP is greater than 160 pg/mL or the 6-minute walk is less than 333 meters or there is a high clinical pretest probability of having PH (mosaic perfusion pattern on CT scan, low DLCO, significant dyspnea on exertion, etc.). It is likely that

¹Not FDA approved for this indication.

⁷Available as dietary supplement.

¹Not FDA approved for this indication.

Figure 2 Vicious cycle of acute chest syndrome (ACS). Vaso-occlusive crises are characterized by increased intraerythrocytic polymerization of deoxygenated hemoglobin S, leading to red blood cell sickling, cellular hyperadhesion, hemolysis, and vaso-occlusion in the microvasculature. These processes are responsible for acute pain (pain crisis) and bone marrow necrosis. ACS typically occurs in a subset of patients 2 to 3 days after hospitalization for a vaso-occlusive episode, and radiographically may present as new multilobar, basilar infiltrates on a chest x-ray. Fat embolization from the necrotic marrow is a recognized cause of ACS and is diagnosed by identifying lipid-laden macrophages in the bronchoalveolar lavage. Pulmonary infection is, however, the most common trigger of ACS and may be superimposed over existing pulmonary infarction. Hypoventilation and molecular pathogens such as reactive oxygen species from ischemia-reperfusion injury and by-products of hemolysis may also play a role in inducing or exacerbating lung injury. Finally, in situ pulmonary thrombosis has been frequently identified as a co-morbid condition in patients with ACS and may be caused by endothelial and hemostatic activation. As a result of lung injury, ventilation-perfusion mismatches and shunting ensues, with subsequent hemoglobin desaturation and hypoxemia. Tissue hypoxia in turn triggers further hemoglobin S polymerization and sickling in a vicious cycle.

intermediate TRV values will need to be combined with other measures of right ventricular function and functional capacity such as NT-proBNP, and 6-minute walk to derive a highly predictive composite biomarker of PH. All studies have been concordant on the high risk of death conferred by PH in SCD whether measured by echocardiography, NT-proBNP, or RHC. Noninvasive transthoracic Doppler echocardiography is recommended by the American Thoracic Society as a screening test in homozygous SCD due to its safety, low cost, and availability. The definitive diagnosis of PH, however, requires a confirmatory right heart catheterization (RHC).

Right heart catheterization studies of patients with SCD and pulmonary hypertension reveal a hyperdynamic state similar to the hemodynamics characteristic of portopulmonary hypertension. It is increasingly clear that pulmonary pressures rise acutely in vaso-occlusive episodes and even more during acute chest syndrome. This suggests that acute pulmonary hypertension and right heart dysfunction represent a major comorbidity during acute chest syndrome, and right heart failure should be considered in patients presenting with acute chest syndrome.

Cardiology

Similar to other conditions with chronic anemia, SCD is associated with a hyperdynamic state, low peripheral vascular resistance, and normal blood pressure or hypotension. In this setting, even mild elevation of the blood pressure can indicate relative hypertension and represent a risk factor for stroke. Because there are no studies

on the treatment of hypertension in SCD, general guidelines on antihypertensive therapy are applied.

Coronary artery disease is rarely observed in SCD, although many patients complain of chest pain during vaso-occlusive episodes. In these instances, the usual workup for acute coronary syndrome is recommended. It is possible that myocardial microvascular occlusions are the predominant ischemic event in SCD.

Left-sided heart disease in SCD is primarily due to diastolic dysfunction (present in approximately 13% of patients), although systolic dysfunction and mitral or aortic valvular disease (2% of patients) can also occur. The presence of diastolic dysfunction alone in SCD patients is an independent risk factor for mortality. Patients with both pulmonary vascular disease and echocardiographic evidence of diastolic dysfunction are at a particularly high risk for death (odds ratio, 12.0; 95% confidence interval [CI], 3.8–38.1; $P < 0.001$).

Cardiac dysfunction is a late complication and the major cause of death in patients with iron overload. Heart failure and conduction defects are the most common abnormalities and warrant emergent iron chelation treatment. Deferoxamine (Desferal), deferasirox (Exjade), and deferiprone (Ferroprox) reduce cardiac iron content and may be used in combination in severe cases.

Methadone (Dolophine) is associated with a risk of QTc prolongation, which carries a risk of arrhythmias and sudden death, particularly in the setting of pulmonary hypertension and iron overload. Frequent electrocardiographic (ECG) monitoring, as well as dosage reduction or discontinuation, are warranted in this group, particularly if the QTc is greater than 500 msec.

Endocrinology

Iron overload is a common cause of endocrinopathy in SCD and thalassemia, with the hypophysis, gonads, and thyroid glands being particularly affected. Patients with iron overload should therefore undergo screening for endocrine dysfunction as it is mandated in thalassemia.

Patients with SCD are, however, at risk for specific endocrine problems regardless of their iron status. Delayed growth and puberty are relatively common, presenting in females with delayed age of menarche by 2 to 3 years and in males with small testicular size and hypospermia. Likely pathogenic factors include increased catabolism, chronic hypoxemia, hospitalizations with prolonged immobility, ischemic insults during vasoocclusive episodes, and chronic use of opiates.

Priapism

Priapism is the most common urogenital complication in patients with the HbSS genotype. It is a sustained, painful erection in the absence of sexual stimulation from occlusion of the penile blood return. It is defined as stuttering if it lasts from minutes to less than 3 hours, and as prolonged if it lasts more than 3 hours. The latter is considered a urologic emergency because of the risk of permanent fibrosis and impotence, and requires a urologic consultation. Pseudoephedrine (Sudafed)¹ may lead to detumescence in nonemergency settings, whereas aspiration of the corpus cavernosum is required in the emergency setting and is performed under conscious sedation and local anesthesia. This is usually accompanied by installation of epinephrine.¹ Other supportive measures, such as intravenous fluids and parenteral opiates, are usually indicated.

Penile shunts are employed as a last resort to prevent further episodes of priapism by increasing the cavernous blood flow using native vessels or by creating an arteriovenous shunt. They invariably result in impotence, which can be ameliorated by implantation of an inflatable penile prosthesis. There are data showing that sildenafil (Viagra)¹ therapy can prevent priapism by altering vascular smooth muscle tone through inhibition of phosphodiesterase 2 activity.

Diagnosis

The diagnosis of SCD rests on the hemoglobin electrophoresis or high-performance liquid chromatography (HPLC), which allows detection of most hemoglobin variants. In patients with microcytosis α -globin gene sequencing may reveal coinheritance of an α -thalassemia trait.

Neonatal Screening

Children with SCD have an increased susceptibility to bacteremia due to *S. pneumoniae*, which can occur as early as 4 months of age and carries a case fatality rate as high as 30%. Acute splenic sequestration crises also contribute to mortality in infancy. Diagnosis by newborn screening and immediate entry into programs of comprehensive care, including the provision of effective pneumococcal prophylaxis, can reach infants who might otherwise be lost to the health care system and has been demonstrated to decrease morbidity and improve survival. Currently, newborn screening and follow-up of SCD are carried out in all 50 states in the United States as well as in most developed countries and initiatives are under way to introduce universal newborn screening in most sub-Saharan African countries.

Late Diagnoses and Misdiagnoses

Rarely, patients who were born before the adoption of universal screening or who were lost at the time of follow-up of positive neonatal screening results are only diagnosed late in life. This occasionally occurs in patients with HbSC who might have normal hemoglobin and hematocrit and a mild disease phenotype. Alternatively, the disease may be misdiagnosed as iron deficiency in patients with HbS/ β^+ -thalassemia on account of their microcytosis,

which places them at risk of futile and potentially harmful prolonged trials of iron supplementation. Patients who have a low HbS level (<40%) due to recent transfusion or who have only mildly decreased hemoglobin (HbSC or HbS/ β^+ -thalassemia) may receive an erroneous diagnosis of sickle cell trait (carrier state).

Treatment

From the original description of SCD in 1910 to the 1970s, there was no efficacious therapy for SCD, and most patients died within the first 2 decades of life, with infectious complications being responsible for the majority of pediatric fatalities. Several preventive and pharmacologic milestones since then, and the realization that care has to occur in a multidisciplinary setting, have profoundly affected the natural history of the disease (Table 3). Median age at death in resource-rich countries was 42 years in male patients and 48 years in female patients with HbSS, according to data from the Cooperative Study of Sickle Cell Disease in the 1980s (a pre-hydroxyurea setting), thereby still lagging approximately 2 to 3 decades behind that of the general African American population. The following sections summarize the therapeutic approach to the most important complications of SCD.

Vaso-Occlusive Episodes

Acute pain from vaso-occlusive episodes in SCD is extremely intense, affects both children and adults, and is due to ischemia or necrosis of the vascular beds. Most patients report severe pain in the bones and joints of the extremities, as well as lower back, although acute ischemia and pain can affect unusual sites such as the mandibular area. Occasionally, an affected limb displays the typical signs of inflammation, such as edema, warmth, and erythema, but a paucity of signs is the norm. Imaging studies such as MRI and bone scan can reveal signs of acute bone marrow infarction in a painful bony area, but they are not routinely employed in the workup of a pain episode.

Intravenous opiates, as well as nonsteroidal antiinflammatory drugs (NSAIDs), are the mainstay of treatment of a pain episode. Even in opiate-naïve patients with SCD, opioid dosages often exceed those required for other indications. For instance, doses of intravenous hydromorphone (Dilaudid) of 1 to 2 mg are typical in adult patients. Most patients, however, are on an oral pain regimen at home and have a history of multiple admissions for vaso-occlusive episodes. In these cases, individualized care based on prior effective regimens and the patient's own perception of the intensity of pain are recommended. After an attempt at controlling the pain with three or four closely spaced opiate boluses is made, patients who are in persistent discomfort or have evidence of underlying complications triggering the vaso-occlusive episode should be admitted and ideally placed on patient-controlled analgesia. The American Pain Society has published guidelines for the treatment of acute and chronic pain in SCD, followed by other institutions in the past decade.

Common obstacles to prompt and effective care in SCD are the health professional's fear of overdosing the patient, as well as misconceptions about addiction and pseudoaddiction. In general, health care professionals tend to overestimate the prevalence of opioid use disorder in SCD and tend to undertreat patients significantly, leading to patients' frustration and anger when their pain demands are not met (pseudoaddiction).

Nonpharmacologic therapies such as biofeedback, relaxation, and localized heat may be effective and should be incorporated into the management of pain episodes whenever possible. Care for vaso-occlusive episodes should also include management of possible precipitating factors: dehydration and hypovolemia should be corrected with hypotonic crystalloids, and an infection workup should be initiated in patients with fever, hypoxemia, or leukocytosis above baseline. Antiemetics and antipruritus therapy are also usually required.

Prior experiences in multiple institutions have shown that a dedicated facility for effective and rapid management of uncomplicated vaso-occlusive episodes reduces hospitalizations and length of stay and facilitates integration of care—psychological, socioeconomic, and nutritional—in a multidisciplinary approach. This experience

TABLE 3 Manifestations of Sickle Cell Disease with Key Prevention and Treatment Strategies

MANIFESTATION	PREVENTION	TREATMENT
Pneumococcal sepsis	Penicillin, Prevnar/Pneumovax vaccination	Antibiotic therapy for penicillin-resistant <i>Streptococcus pneumoniae</i>
Splenic or liver sequestration	—	Exchange transfusion
Painful vaso-occlusive episode	Hydroxyurea (Droxia), prevention of exposure to triggers	Intravenous fluids, parenteral opiates, supplemental oxygen
Acute chest syndrome	Incentive spirometry during VOE, hydroxyurea	Transfusion, broad-spectrum antibiotics with atypical coverage
Iron overload	Optimization of transfusion therapy	Iron chelation with deferasirox (Exjade) or deferoxamine (Desferal)
RBC alloimmunization	Transfusion with leukoreduced RBCs	—
CVA	Chronic transfusion in children with high transcranial Doppler velocity	Exchange transfusion and thrombolytics in selected cases
Pulmonary hypertension	Hydroxyurea?, treatment of predisposing conditions such as obstructive sleep apnea, hypoxemia, thromboembolism	Hydroxyurea, chronic transfusion therapy, specific therapy
Kidney disease	Antihypertensive therapy?, hydroxyurea?, ACE inhibitors?	ACE inhibitors?, renal replacement therapy, kidney transplant
Priapism	Hydroxyurea?	Pseudoephedrine (Sudafed), ¹ aspiration of corpus cavernosum, sildenafil (Viagra) ¹
Leg ulcers	Hydroxyurea?, chronic transfusion?	Surgical débridement, surgical grafting

Abbreviations: ACE = angiotensin-converting enzyme; CVA = cerebrovascular accident; RBC = red blood cells; TCD = transcranial Doppler; VOE = vaso-occlusive crisis.
¹Not FDA approved for this indication.

is the basis of the concept of the day hospital in SCD and relies on the need to provide prompt assessment and treatment of pain, safe dose titration to relief, monitoring of adverse effects, and adequate disposition (emergency department, inpatient admission, home) in a clinical environment familiar with SCD and the individual patient.

Chronic Pain

Chronic pain is common, and a study employing pain diaries compiled by patients shows that most patients with SCD experience pain on an almost daily basis (PiSCES study). Patients who have successfully transitioned from pediatric to adult care, have a good support system, and are distracted by their work or school schedules tend to cope better and require less pharmacologic support. In many cases, though, short-acting and long-acting opiates are required to empower the patient to manage pain at home and minimize use of the emergency department. Drugs for neuropathic pain, such as gabapentin (Neurontin),¹ may also be used in combination with opiates. Recently, several US states have identified SCD as one of the severe medical conditions for which medical marijuana use is approved. While large, controlled studies of medical marijuana in SCD are missing, the potential benefit of cannabinoids on the neuropathic pain of SCD, opiate sparing, and the management of other complications makes them an attractive therapeutic strategy.

Because analgesic care is life-long, consultation with pain specialists is often valuable, particularly in patients for whom more sophisticated pain regimens are needed. For instance, the mu-opioid receptor partial agonist buprenorphine (Buprenex, Butrans), opioid rotation, and methadone used as analgesic can help reduce the total opiate requirements. Urine toxicology screens are indicated and should be scheduled at regular intervals both to document adherence with the therapy and to screen for use of illicit substances.

Transfusional Therapy

In SCD, the benefits of transfusion in terms of improved hemodynamics and oxygenation need to be balanced with the risks of iron

overload, alloimmunization, transfusion reactions, and viral transmission of infectious agents. Leuko-reduced, sickle-negative RBCs with extended phenotypic matching for Rh Cc, Ee, and Kell, which account for 80% of detected antibodies, are required. By employing extended phenotypic matching, the rate of alloimmunization decreased from 3% to 0.5% per unit, and the rate of delayed hemolytic transfusion reactions decreased by 90% in the STOP study. In previously immunized patients, a full RBC match also inclusive of matching for the Duffy, Kidd, and S antigens is recommended. Indications for transfusion include hemoglobin less than 5 g/dL or less than 6 g/dL with symptoms and any severe complication such as stroke, aplastic anemia, splenic or hepatic sequestration, or acute chest syndrome.

Prophylactic transfusions have been considered standard of care before surgery (with the exclusion of minor procedures such as intravenous port placement); the benefit of preoperative transfusions in preventing SCD-related complications in HbSS patients has also been confirmed in a small randomized clinical trial (the TAPS study). As to the type of transfusion strategy to be used, a clinical trial published in 1995 showed that a conservative prophylactic transfusion regimen to achieve a target hemoglobin of 10 g/dL and any HbS value was as effective as an aggressive regimen to achieve a hemoglobin of 10 g/dL and a target HbS value of less than 30% in preventing postsurgical complications such as acute chest syndrome.

Exchange transfusion (erythrocytapheresis with RBC exchange) is usually reserved for the most severe complications, which include acute chest syndrome with impending pulmonary failure, acute stroke and its prevention in children, multiorgan failure, and sepsis. **Box 1** summarizes the main indications for simple and exchange transfusion in SCD as well as the areas of uncertainty.

Iron Chelation

Patients who have received more than 10 transfusions or 20 units of packed RBCs should be screened for iron overload. Most authorities recommend initiation of iron chelation based on a ferritin level consistently greater than 1000 ng/mL, based on data from the thalassemia literature, although liver iron quantitation by MRI or biopsy should be obtained, when available, prior to therapy and to monitor its effectiveness. In the United States, the

¹Not FDA approved for this indication.

BOX 1 Indications for Transfusion**No Indication**

Chronic steady-state anemia
 Uncomplicated painful episode
 Infections
 Minor surgery without general anesthesia
 Aseptic necrosis of hip or shoulder
 Uncomplicated pregnancy

Unclear Indication

Intractable or frequent painful episodes
 Leg ulcers
 Before receiving IV contrast dye
 Complicated pregnancy
 Cerebrovascular accident in adults
 Chronic organ failure

Simple Transfusion

Symptomatic anemia

- High output cardiac failure
- Dyspnea
- Angina
- Central nervous system dysfunction

Sudden decrease in hemoglobin

- Aplastic crisis
- Acute splenic sequestration

Severe anemia (Hb ~5 g/dL) with fatigue or dyspnea
 Preparation for surgery with general anesthesia

Exchange Transfusion

Acute cerebrovascular accident
 Multiple organ system failure
 Acute chest syndrome
 Hepatic sequestration
 Retinal surgery

oral chelating agents deferasirox (Exjade) and deferiprone (Ferriprox) and the parenteral deferoxamine (Desferal) are available and should be administered until the ferritin level is less than 500 ng/mL for three consecutive measurements. Patients on iron chelation with deferasirox and deferoxamine require monitoring of hepatic, renal, auditory, and visual toxicity, and particular caution has to be exercised in the setting of renal disease, because transient, reversible increases in serum creatinine as well as rare instances of irreversible acute kidney injury have been reported in patients with underlying renal insufficiency. Deferiprone has been associated with agranulocytosis and neutropenia, mandating close monitoring of the absolute neutrophil count during therapy.

Erythropoietic Stimulating Agents

Whereas a brisk reticulocytic response is common in SCD, patients who develop renal failure or aplastic crises or who receive therapy with hydroxyurea may experience a relative or absolute reticulocytopenia (<100,000 reticulocytes/mL) and a worsening of their baseline anemia. In these situations, therapy with erythropoietic stimulating agents (ESAs) may be beneficial.

Because of bone marrow expansion in patients with HbSS, higher starting doses of erythropoietin (Epogen, Procrit)¹ than in patients without SCD and on the order of 300 U/kg three times per week (or alternatively as a single dose of 900 U/kg once weekly) may be considered. For darbepoetin (Aranesp),¹ a reasonable starting dose is 100 to 200 µg/weekly or every 2 weeks. ESAs can be titrated by 20% to 25% increases in dose per week in patients who do not respond adequately. Weekly monitoring of hematocrit is essential to avoid overdosage and relative erythrocytosis, which can lead to hyperviscosity and vaso-occlusive episodes.

Nutritional Considerations

Malnutrition, growth retardation, and stunting with findings of low lean and fat body mass are highly prevalent in children and adolescents with SCD due to their increased caloric demands and a hypermetabolic state. Macronutrient and micronutrient deficiencies are common, and nutritional counseling is warranted. Hypovitaminosis D and low bone mineral density are also prevalent in children and adults. Folic acid¹ is indicated at the dose of 1 mg daily as in other hemolytic diseases, particularly where folate nutritional supplementation programs are absent. Strategies aimed at decreasing iron intake and absorption should be implemented early. There is also growing interest in antioxidant nutraceuticals, although there are no clear guidelines in these areas at present. The small subset of patients who are overweight or obese is at risk for exacerbating or precipitating common orthopedic problems in SCD such as avascular necrosis of the femoral head and its resulting disability. These patients should also receive targeted nutritional counseling.

Hydroxyurea

Since the pediatric hematologist Janet Watson suggested in 1948 that the paucity of sickle cells in the peripheral blood of newborns was due to the presence of increased HbF, there has been interest in developing therapies to modulate the hemoglobin switch from fetal to newborn life and prolong HbF production. Several antineoplastic agents, including 5-azacytidine (Vidaza)¹ and hydroxyurea, became the focus of attention after they were found to increase HbF levels in nonhuman primates and individuals with SCD.

The landmark Multicenter Study of Hydroxyurea in Sickle Cell Disease (MSH) showed that the incidence of painful crises was reduced from a median of 4.5 per year to 2.5 per year in hydroxyurea-treated patients with SCD. The rates of acute chest syndrome and blood transfusion were also reduced significantly. A follow-up for up to 9 years of 233 of the original 299 subjects showed a 40% reduction in mortality among those who received hydroxyurea. This study led to the approval of hydroxyurea (Droxia, Siklos) as the first disease-modifying therapy in adults with SCD. More recent studies showed that hydroxyurea is safe and effective in children and adults with SCD. The recently concluded BABY HUG study showed that children 9 to 18 months with HbSS disease randomized to receive 2 years of hydroxyurea therapy, irrespective of the disease severity, had less dactylitis and fewer pain episodes, hospitalizations, and transfusions than children receiving placebo.

On the molecular and cellular levels, the benefits of hydroxyurea are mostly related to increased intracellular HbF, which prevents the formation of HbS polymers and sickling. In addition to this mechanism, some patients on hydroxyurea who do not adequately increase their HbF levels also display clinical benefits, suggesting that hydroxyurea might have other beneficial rheologic properties.

Although the MSH study only included patients with HbSS, its findings traditionally have been extrapolated to other sickle cell syndromes such as HbSC and HbS/β-thalassemia. A report from Greece, where S/β-thalassemia is highly prevalent, has confirmed that hydroxyurea similarly reduces complications and mortality in patients with HbS/β⁰-thalassemia, with a nonsignificant benefit also observed in HbS/β⁺-thalassemia. Existing guidelines also recommend hydroxyurea in patients with HbSC disease, but there is still no high level evidence to support this practice.

Hydroxyurea has been indicated at a dosage of 15 mg/kg (7.5 mg/kg in patients with renal disease) in patients with frequent pain episodes, history of acute chest syndrome, other severe vaso-occlusive episodes, or severe symptomatic anemia, although another sensible approach is to prescribe it to all patients with HbSS regardless of their phenotype. Endpoints are less pain, increase in HbF to 15% to 20%, increased hemoglobin level to 7 to 9 g/dL in severely anemic patients, improved well-being, and acceptable myelotoxicity. The dosage can be increased by

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

Start therapy if one or more of the following conditions are present:

- frequent pain episodes
- history of acute chest syndrome
- other severe VOE
- severe symptomatic anemia

Starting dose: 15 mg/kg or 7.5 mg/kg if the patient has kidney disease

Endpoints:

- less pain
- increase in HbF to 15%–20%
- increased hemoglobin level to 7–9 g/dL
- improved well-being
- acceptable myelotoxicity

Dose escalation: increase dose by 500 mg every other day every 8 weeks if no toxicity encountered to a maximum of 35 mg/kg

Lab monitoring:

- At time of initiation or escalation: check CBC/differential/reticulocyte count every 2 weeks; serum chemistries every 2–4 weeks, percent HbF every 6–8 weeks
- During maintenance: check CBC/differential/reticulocyte count chemistries monthly, percent HbF every 3 months

Criteria to hold:

- ANC <2000
- Hb <9.0 g/dL and reticulocyte count <80,000 (alternatively start Epo)
- Platelet count <80,000
- Raising creatinine
- 2-fold elevation of AST or ALT over baseline
- 2 months prior to planned conception/pregnancy

Figure 3 Protocol for hydroxyurea treatment.

500 mg every other day every 8 weeks to a maximum of 35 mg/kg if no toxicity is encountered. Considering the potential myelotoxicity, hepatotoxicity, and nephrotoxicity of this medication, laboratory monitoring needs to be performed every 2 weeks at the time of initiation or escalation and monthly during maintenance therapy. Laboratory studies should include a complete blood cell (CBC) count, differential and reticulocyte count, and serum chemistries. Measurements of HbF can be performed every 3 months. An elevated MCV is a marker of adherence to the therapy.

Criteria for holding hydroxyurea are listed in [Figure 3](#). Patients need to be counseled on the teratogenic potential, as demonstrated in animal studies, as well as the risks of infertility and leukemogenesis, although a growing body of evidence shows that these risks may have been overestimated in patients with SCD.

Other side effects that can affect compliance include, but are not limited to, weight gain, alopecia, skin and nail hyperpigmentation (melanonychia), nausea and vomiting, and mucosal ulcerations. Because of the toxicity concerns as well as factors intrinsic to long-term preventive therapy, hydroxyurea therapy has had low effectiveness in spite of high efficacy, with underprescribing by health care professionals and poor patient compliance being major obstacles to its widespread adoption.

Therapy of Pulmonary Hypertension

Because evidence-based guidelines for managing pulmonary hypertension in patients with SCD are not available, recommendations are based upon the pulmonary arterial hypertension literature, case reports, small open-label studies, and expert opinion. For patients with mild pulmonary hypertension (tricuspid regurgitant velocity [TRV], 2.5–2.9 m/sec), it is important to identify and treat risk factors associated with pulmonary hypertension such as rest, exercise or nocturnal hypoxemia, sleep apnea, pulmonary thromboembolic disease, restrictive lung disease or fibrosis, left ventricular systolic and diastolic dysfunction, severe anemia, and iron overload. These patients may benefit from aggressive SCD management, including optimization of hydroxyurea dosage and initiation of a chronic transfusion program in those who do not tolerate or respond poorly to hydroxyurea. Consultation with a pulmonologist or cardiologist experienced in pulmonary hypertension is also recommended.

For patients with TRV 3 m/sec or more, we recommend following the guidelines for TRV 2.5 to 2.9 m/sec. In addition, right heart catheterization is necessary to confirm diagnosis and to directly assess left ventricular diastolic and systolic function. We would consider specific therapy with selective pulmonary vasodilator and remodeling drugs if the patient has pulmonary arterial hypertension defined by right heart catheterization and exercise limitation defined by a low 6-minute walk distance.

FDA-approved drugs for primary pulmonary arterial hypertension include the endothelin receptor antagonists (bosentan [Tracleer] and ambrisentan [Letairis]), prostaglandin-based therapy (epoprostenol [Flolan], treprostinil [Remodulin, Tyvaso, Orenitram], and iloprost [Ventavis]), the phosphodiesterase-5 inhibitors (sildenafil [Revatio]), and riociguat [Adempas], the first member of a new class of drugs, the soluble guanylate cyclase (sGC) stimulators. No published randomized studies in the SCD population exist for any of these agents, although a multicenter placebo-controlled trial of sildenafil for pulmonary hypertension of SCD was stopped early because of an unexpected increase in hospitalizations for vaso-occlusive crisis in the treatment group receiving sildenafil.

Anticoagulation is indicated in patients who have evidence of pulmonary thromboembolic complications and is supported by evidence of benefit in other populations with pulmonary hypertension.

Hematopoietic Stem Cell Transplantation

Despite improvement of supportive care in SCD, life expectancy remains lower than for those not affected. In addition, quality of life for patients with SCD is usually significantly impaired. Although hydroxyurea can decrease acute complications of SCD such as vaso-occlusive episodes and acute chest syndrome, no satisfactory measures exist to prevent the development of irreversible organ damage in adults. Further, therapy with hydroxyurea is lifelong, and only 20% to 30% of eligible patients are prescribed or actually take the drug.

Currently, allogeneic hematopoietic stem cell transplantation (HCT) remains the only curative treatment. Indications for HCT have been empirically determined from prognostic factors derived from studies of the natural history of SCD. The most common indications for which patients with SCD have undergone HCT are a history of stroke, recurrent acute chest syndrome, or frequent vaso-occlusive episodes.

Allogeneic HCT after myeloablative therapy has been performed in hundreds of pediatric and numerous adult patients with SCD. The backbone of the preparative regimens have consisted of busulfan (Busulfex)¹ 14 to 16 mg/kg and cyclophosphamide (Cytosan)¹ 200 mg/kg. Additional immunosuppressive agents used have included antithymocyte globulin (Atgam),¹ rabbit antithymocyte globulin (Thymoglobulin),¹ antilymphocyte globulin, or total lymphoid irradiation ([Figure 4](#)). Cyclosporine A (Neoral),¹ alone or with mercaptopurine (Purinethol)¹ or methotrexate,¹ has been used for post-transplant graft-versus-host disease prophylaxis.

The outcome of HCT for patients with SCD from matched siblings is excellent. Of 1000 recipients of HLA-identical sibling transplants performed between 1986 and 2013 and reported to the European Blood and Marrow Transplant, Eurocord and the Center for International Blood and Marrow Transplant Research, the 5-year event-free and overall survival was 91.4% (95% CI 89.6%–93.3%) and 92.9% (95% CI 91.1%–94.6%), respectively. Event-free survival was lower with increasing age at transplantation (hazard ratio [HR] 1.09; $p < 0.001$) and higher for transplantations performed after 2006 (HR 0.95, $p = 0.013$). Twenty-three patients experienced graft failure; 70 patients (7%) died, the most common cause of death being infection. Stabilization or reversal of organ damage from SCD has been documented after HCT. In patients who have stable donor engraftment, complications related to SCD resolve, and there are no further episodes of pain, stroke, or acute chest syndrome. Patients who successfully receive

¹Not FDA approved for this indication.

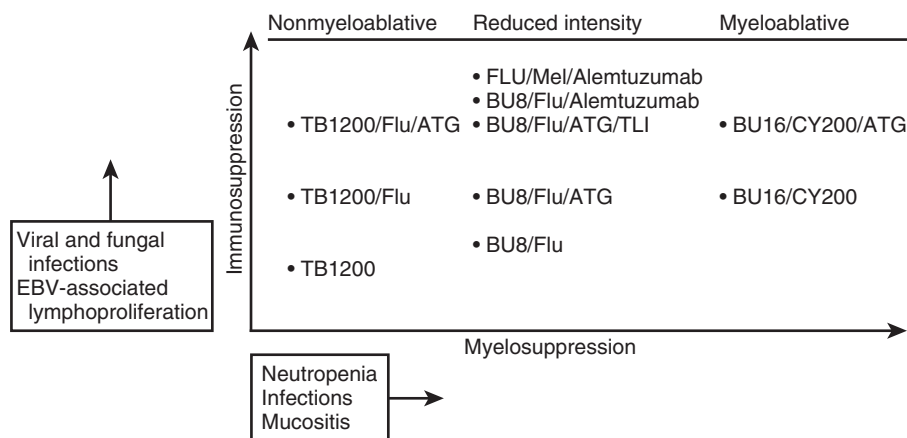

Figure 4 Spectrum of immunosuppression and myelosuppression in preparative regimens in hematopoietic stem cell transplantation (HCT) in sickle cell disease (SCD). Most preparative regimens for HCT in SCD have employed a backbone of busulfan (BU) (Busulfex)¹ and cyclophosphamide (CY) (Cytoxan).¹ Additional immunosuppressive agents include equine antithymocyte globulin (Atgam)¹ or leporine antithymocyte globulin (Thymoglobulin)¹ (ATG), antilymphocyte globulin, total lymphoid or total body irradiation (TLI or TBI), fludarabine (Flu)¹ (Fludara), and alemtuzumab (Campath).¹ Attempts to reduce the intensity of preparative regimens for patients with SCD have been based on one of two approaches. The first is the use of reduced-intensity conditioning regimens to produce less myeloablation. These require donor marrow infusion for hematopoietic recovery. The second is the use of nonmyeloablative regimens, which do not eradicate host hematopoiesis and allow hematopoietic recovery even without donor stem cell infusion. (Adapted with permission from Krishnamurti L: Hematopoietic cell transplantation: A curative option for sickle cell disease. *Pediatr Hematol Oncol* 24:569–575, 2007.)

allografts do not experience sickle-related central nervous system complications and have evidence of stabilization of central nervous system disease by cerebral MRI. However, the impact of successful HCT on reversal of cerebral vasculopathy has been variable. Current research is focused on improving the applicability of HCT to a greater proportion of patients with SCD by the development of novel conditioning regimens minimizing myeloablation (see Figure 4), the use of novel sources of hematopoietic stem cells such as umbilical cord blood, extending HCT to adult recipients and alternate donors such as matched unrelated donors and haploidentical donors. The aim of these studies is to develop safe and effective alternatives for patients without matched sibling donors, thus increasing the applicability of curative therapy for SCD.

New and Experimental Therapies

The recent decade has witnessed a flourishing of new therapeutic approaches for sickle cell disease. In 2018, pharmacologic *L*-glutamine (Endari) has received FDA approval as the second disease-modifying drug in SCD. A randomized, phase III multicenter trial showed that patients in the *L*-glutamine group had significantly fewer pain crises and hospitalizations than those in the placebo group. Of note, two-thirds of the patients in both arms received concomitant hydroxyurea. Reassuringly, the drug had relatively mild side effects including nausea and fatigue. *L*-glutamine presumably acts by reducing oxidant stress in the sickle red blood cells, although its effects on major disease parameters such as hemolysis are unclear.

Other therapeutic approaches are outlined in the following paragraphs.

Modulation of Cellular Adhesion

Adhesive interactions between red blood cells, white blood cells and platelets and between cells and endothelium are implicated in the pathogenesis of vaso-occlusive episodes. Recently, several compounds have been developed to target specific adhesion molecules such as E-selectin and P-selectin. This is a particularly promising area of research that has yielded two compounds in advanced phases of development. The P-selectin inhibitor crizanlizumab⁵ has shown significant reduction of the rate of crises per year and longer median time to the first crisis and second crisis when given as intravenous prophylaxis in a double-blind, randomized, phase II clinical

trial. As in the case of *L*-glutamine, crizanlizumab was used with and without concurrent hydroxyurea therapy. The pan-selectin inhibitor rivipansel⁵ has shown similar promising results and is currently undergoing phase III testing.

Modulation of Hemoglobin Oxygen Affinity

Deoxygenation of HbS leads to polymerization, sickling, and hemolysis. Thus, strategies aimed at increasing the oxygen affinity of HbS may be beneficial. Initial results of a phase IIa study of once daily oral GBT440-007 (now voxelotor) showed improvement in hemoglobin and reduction in daily pain in adolescents and adults with SCD by increasing hemoglobin oxygen affinity and decreasing HbS polymerization and sickling, and a phase III study is currently under way.

Modulation of Nitric Oxide

Nitric oxide (NO) is an active biogas and a free radical species that mediates arterial relaxation, cellular adhesion to endothelium, hemostasis, and blood viscosity. In SCD, NO bioactivity is reduced as a result of decreased production due to endothelial perturbation and NO scavenging by cell-free hemoglobin generated during intravascular hemolysis. Dietary supplementation with *L*-arginine,⁷ a precursor of NO, and delivery of exogenous NO or NO bioactivity to the microvasculature in SCD, should promote dilatation of the terminal arterioles where obstruction to flow and tissue damage occurs, improvement of lung ventilation and perfusion is matching, decrease in pulmonary artery pressures, and inhibition of platelet aggregation and cellular adhesion. Although two recent clinical trials on *L*-arginine supplementation and inhaled NO (DeNOVO trial) for vaso-occlusive episodes failed to show a clinical benefit, optimization of timing and dosing, and novel strategies to target the NO pathway might lead to valuable NO therapeutics in the future.

Gene Therapy

The ultimate cure for sickle cell disease, gene therapy, is finally on the horizon. A French group has reported that a patient has been successfully treated with lentiviral-mediated insertion of an anti-sickling beta globin gene into autologous stem cells. The transduced cells were then transplanted into the patient who is free from the hallmarks of sickle cell disease 15 months post-transplant.

⁵Investigational drug in the United States.

⁵Investigational drug in the United States.

⁷Available as dietary supplement.

Surgical Issues

Preoperative patient optimization includes prophylactic transfusion, close monitoring of pulse oximetry, adequate analgesia based on the patient's opiate tolerance, and monitoring for sickle cell-related complications.

Avascular necrosis (AVN) of the femoral heads, and more rarely of the humeral heads, is the most common orthopedic problem in SCD. Surgery is usually deferred until the pain and disability from AVN become intolerable and usually involves total hip or shoulder arthroplasty. This is usually a more involved procedure than in the general population on account of the altered bone anatomy in SCD. Patients with bone marrow expansion may experience thinning of the cortical bone and prosthetic instability, whereas some may suffer from the opposite problem of obliteration of the medullary shaft by sclerotic bone in response to multiple necrotic events.

Patients with SCD tend to develop pigmented gallstones and cholelithiasis. Cholecystectomy is performed in patients with SCD with cholelithiasis, right upper quadrant pain, and a positive hepatobiliary iminodiacetic acid (HIDA) scan. In SCD, the rate of intraoperative complications is higher and so is the rate of reversal from laparoscopic to open cholecystectomy.

Splenectomy has been reserved for patients with massive splenic infarction (>50% of the spleen volume); intractable, recurrent splenic pain; and splenic abscess in the setting of splenic infarction. It is important to limit splenectomy to these few specific circumstances, because overwhelming sepsis and acute pulmonary hypertension have been reported in the postsplenectomy period in SCD.

Kidney transplantation has been successfully performed in patients with SCD on chronic renal replacement therapy, although survival at 7 years is lower than in African Americans without SCD (67% vs. 83%). This difference is mostly due to vaso-occlusive complications in the transplanted kidney, possibly exacerbated by the higher hematocrit in the postoperative period from resumption of endogenous erythropoietin production and increased blood viscosity. It is therefore critical to closely monitor ESA therapy in the post-transplantation period to prevent overdosing and relative erythrocytosis. A chronic transfusion program to prevent intrarenal sickling and maximization of hydroxyurea therapy should also be entertained, although its benefits need to be balanced against the risk of HLA alloimmunization and rejection. Combined solid organ and HCT protocols are being developed to overcome these complications. Recently, lung transplantation has been successfully performed in a SCD patient with severe pulmonary arterial hypertension and pulmonary veno-occlusive disease.

THALASSEMIA

Method of

Sarah A. Holstein, MD, PhD; and Raymond J. Hohl, MD, PhD

CURRENT DIAGNOSIS

- Complete blood count: anemia (very severe in β -thalassemia major, mild in β -thalassemia minor and α -thalassemia trait), low mean corpuscular volume, variable leukocytosis, thrombocytopenia (secondary to splenomegaly) or thrombocythemia (after splenectomy)
- Peripheral blood smear: hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells, Heinz bodies, nucleated red blood cells

Surgical Issues

Preoperative patient optimization includes prophylactic transfusion, close monitoring of pulse oximetry, adequate analgesia based on the patient's opiate tolerance, and monitoring for sickle cell-related complications.

Avascular necrosis (AVN) of the femoral heads, and more rarely of the humeral heads, is the most common orthopedic problem in SCD. Surgery is usually deferred until the pain and disability from AVN become intolerable and usually involves total hip or shoulder arthroplasty. This is usually a more involved procedure than in the general population on account of the altered bone anatomy in SCD. Patients with bone marrow expansion may experience thinning of the cortical bone and prosthetic instability, whereas some may suffer from the opposite problem of obliteration of the medullary shaft by sclerotic bone in response to multiple necrotic events.

Patients with SCD tend to develop pigmented gallstones and cholelithiasis. Cholecystectomy is performed in patients with SCD with cholelithiasis, right upper quadrant pain, and a positive hepatobiliary iminodiacetic acid (HIDA) scan. In SCD, the rate of intraoperative complications is higher and so is the rate of reversal from laparoscopic to open cholecystectomy.

Splenectomy has been reserved for patients with massive splenic infarction (>50% of the spleen volume); intractable, recurrent splenic pain; and splenic abscess in the setting of splenic infarction. It is important to limit splenectomy to these few specific circumstances, because overwhelming sepsis and acute pulmonary hypertension have been reported in the postsplenectomy period in SCD.

Kidney transplantation has been successfully performed in patients with SCD on chronic renal replacement therapy, although survival at 7 years is lower than in African Americans without SCD (67% vs. 83%). This difference is mostly due to vaso-occlusive complications in the transplanted kidney, possibly exacerbated by the higher hematocrit in the postoperative period from resumption of endogenous erythropoietin production and increased blood viscosity. It is therefore critical to closely monitor ESA therapy in the post-transplantation period to prevent overdosing and relative erythrocytosis. A chronic transfusion program to prevent intrarenal sickling and maximization of hydroxyurea therapy should also be entertained, although its benefits need to be balanced against the risk of HLA alloimmunization and rejection. Combined solid organ and HCT protocols are being developed to overcome these complications. Recently, lung transplantation has been successfully performed in a SCD patient with severe pulmonary arterial hypertension and pulmonary veno-occlusive disease.

THALASSEMIA

Method of

Sarah A. Holstein, MD, PhD; and Raymond J. Hohl, MD, PhD

CURRENT DIAGNOSIS

- Complete blood count: anemia (very severe in β -thalassemia major, mild in β -thalassemia minor and α -thalassemia trait), low mean corpuscular volume, variable leukocytosis, thrombocytopenia (secondary to splenomegaly) or thrombocythemia (after splenectomy)
- Peripheral blood smear: hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells, Heinz bodies, nucleated red blood cells

- Evidence of hemolytic anemia: indirect hyperbilirubinemia, elevated lactate dehydrogenase, decreased haptoglobin
- Hemoglobin electrophoresis pattern:
 - β -Thalassemia minor: elevated HbA₂ ($\alpha_2\delta_2$)
 - β -Thalassemia intermedia: elevated HbA₂, elevated HbF ($\alpha_2\gamma_2$), and decreased HbA ($\alpha_2\beta_2$)
 - β -Thalassemia major: absence of HbA, markedly elevated HbF, and elevated HbA₂
 - α -Thalassemia trait: normal
 - Hemoglobin H disease: decreased HbA, presence of HbH (β_4) and HbBart (γ_4)
 - Hemoglobin Barts hydrops fetalis: HbBart, absence of HbA, HbA₂, and HbF
- Timing of symptomatic disease:
 - β -Thalassemia minor: asymptomatic
 - β -Thalassemia intermedia: variable
 - β -Thalassemia major: within first year of life
 - α -Thalassemia trait: asymptomatic
 - Hemoglobin H disease: symptomatic at time of birth
 - Hemoglobin Barts hydrops fetalis: death during gestation

CURRENT THERAPY

- Chronic packed red blood cell transfusions for β -thalassemia major (1–3 units of packed leukoreduced erythrocytes every 3–5 weeks) with a target hemoglobin concentration of 9 to 10.5 g/dL; variable transfusion needs for β -thalassemia intermedia and hemoglobin H disease
- Splenectomy with antibiotic prophylaxis and vaccination
- Iron chelation: deferoxamine (Desferal), or deferasirox (Exjade); deferiprone (Ferroprox)
- Osteoporosis management: calcium with vitamin D supplementation; bisphosphonates
- Allogeneic hematopoietic cell transplantation for β -thalassemia major

Globin Gene Arrangements

Thalassemia syndromes encompass a spectrum of hemoglobin disorders that arise from impaired production of globin chains. The genes that encode globins are located in two clusters: the β gene cluster on chromosome 11 and the α gene cluster on chromosome 16 (Figure 1). The β gene cluster includes the adult globin genes (β and δ) as well as the fetal $A\gamma$ and $G\gamma$ genes and the embryonic ϵ gene. The arrangement of the 5' to 3' sequence of these genes parallels the order of their developmental expression. Functional hemoglobin is a tetramer that includes two α and two β globin units. The α gene cluster includes two fetal/adult α genes ($\alpha 1$ and $\alpha 2$) and the embryonic ζ genes. In the embryo, three hemoglobins

Figure 1 Representation of the β and α globin gene clusters. Also shown are the globin tetramers produced during embryonic development.

are found ($\zeta_2\epsilon_2$, $\alpha_2\epsilon_2$, and $\zeta_2\gamma_2$). Fetal hemoglobin (HbF) is composed of two α chains and two γ chains ($\alpha_2\gamma_2$). In adults, the predominant hemoglobin is hemoglobin A (HbA), consisting of two α chains and two β chains ($\alpha_2\beta_2$) (see Figure 1). Hemoglobin A₂, consisting of two α chains and two δ chains ($\alpha_2\delta_2$), is a normal variant in adults and typically represents less than 3% of the total hemoglobin (see Figure 1).

In β -thalassemia, there is diminished production of β globin genes, resulting in an excess of α globin chains. Conversely, in α -thalassemia there is impaired production of α globin genes, resulting in an excess of β globin chains. This imbalance of globin production is variable, and the degree of accumulation of unpaired globin chains is directly related to the severity of the disease phenotype. The genetic basis of thalassemia is heterogeneous, and several hundred mutations have been identified. These mutations may affect any level of globin gene expression, including arrangement of the globin gene complex, gene deletion, splicing, transcription, translation, and protein stability. In general, β -thalassemia occurs as a result of mutations, whereas α -thalassemia occurs as a result of gene deletion.

It has been estimated that there are 270 million carriers of thalassemia in the world, including 80 million β -thalassemia carriers. The frequency of β -thalassemia carriers is highest in the malarial tropical and subtropical regions of Asia, the Mediterranean, and the Middle East. The term thalassemia, derived from Greek, refers to the Mediterranean Sea. This distribution is secondary to the selective advantage of heterozygotes against malaria. β -Thalassemia is subdivided into major, intermedia, and minor types (Table 1). α -Thalassemia is classified into four syndromes: α -thalassemia trait 2 (loss of one α globin gene [$\alpha\alpha/\alpha-$]); α -thalassemia trait 1, also referred to as α -thalassemia minor (loss of two α globin genes [$\alpha\alpha/--$ or $\alpha-/\alpha-$]); hemoglobin H (HbH) disease (loss of three alleles [$\alpha-/-$]); and hemoglobin Barts hydrops fetalis (loss of all four α globin loci [$---/-$]).

Pathophysiology

The clinical manifestations of thalassemia and their severity are a consequence of the relative excess of unpaired globin chains. In particular, excess α globin chains are unstable and insoluble and therefore precipitate inside the red blood cell (RBC). These inclusions (precipitated hemoglobin) may be visualized as Heinz bodies. The accumulation of α globin chains leads to a variety of insults to the erythrocyte, including changes in membrane deformability and increased fragility. Free β chains are more soluble than free α chains and are able to form a homotetramer (HbH). The hallmark of thalassemia is an anemia that is a consequence of both increased destruction (i.e., hemolysis) and decreased production (i.e., ineffective erythropoiesis). The bone marrow typically displays erythroid hyperplasia.

Oxidant injury is closely linked with the pathology of thalassemia. Under normal conditions, a small amount of methemoglobin (Fe^{3+}) is formed via oxidation and can then be reduced back to hemoglobin (Fe^{2+}). However, isolated globin chains can be oxidized to hemichromes, some forms of which are irreversibly oxidized. The hemichromes can then generate reactive oxygen species, which can oxidize membrane components, leading to cell injury. There is an increase in membrane rigidity in β -thalassemia, and this appears to be secondary to the binding of partially oxidized α globin chains to components of the membrane skeleton. Increased membrane rigidity in turn leads to decreased membrane deformability and increased destruction. In α -thalassemia, HbH has a left-shifted oxygen disassociation curve and therefore does not readily transport oxygen. HbH erythrocytes have increased rigidity, which is thought to be secondary to interactions between excess β globin chains and the membrane. Unlike with β -thalassemia, HbH erythrocytes have increased membrane stability. Inclusion bodies have been identified in HbH cells, and there appears to be a correlation between RBC age and solubility of HbH. As cells age, the amount of soluble HbH decreases, and the level of inclusions increases.

TABLE 1 Summary of Hematologic and Clinical Features of the Thalassemias

TYPE	HEMATOLOGIC FINDINGS	HEMOGLOBIN ELECTROPHORESIS PATTERN	CLINICAL FEATURES
β -Thalassemia major	Severe anemia, microcytosis, hypochromia, target cells, nucleated RBCs	Absence of HbA, markedly elevated HbF, elevated HbA2	Splenomegaly, jaundice, skeletal abnormalities, abnormal facies; transfusion dependent
β -Thalassemia intermedia	Mild to moderate anemia, microcytosis, hypochromia	Elevated HbA2, elevated HbF, decreased HbA	Splenomegaly; variable transfusion dependence
β -Thalassemia minor	Mild anemia, microcytosis, target cells	Elevated HbA2	None
Hemoglobin Barts hydrops fetalis	Severe anemia, anisopoikilocytosis, hypochromia, nucleated RBCs	HbBart; absence of HbA, HbA2, and HbF	Death during gestation; fetus with massive hepatosplenomegaly, generalized edema
Hemoglobin H disease	Moderately severe anemia, anisopoikilocytosis, microcytosis, Heinz bodies	Decreased HbA; HbH and HbBart present	Splenomegaly, jaundice; generally transfusion-dependent
α -Thalassemia trait 1	Mild anemia, hypochromia, microcytosis, target cells	Normal	None
α -Thalassemia trait 2	Normal	Normal	None

Abbreviations: Hb = hemoglobin; RBCs = red blood cells.

It has also been recognized that there is increased phagocytosis of thalassemia RBCs compared with in normal controls. The etiology is not completely understood, but it may be a consequence of reduction in surface levels of sialic acid, increase in surface immunoglobulin G binding, and changes in phosphatidylserine localization.

Despite the pronounced hemolysis and marrow erythroid hyperplasia, patients with thalassemia generally do not display the compensatory reticulocytosis that is indicative of the other basis for anemia, ineffective erythropoiesis. Accumulation of α chain aggregates is thought to lead to death of erythrocyte precursors. Furthermore, abnormal assembly of membrane proteins in erythroid precursors has been demonstrated.

Iron overload is one of the primary causes of morbidity. Even without transfusion, the long-standing anemia, however mild, leads to increased iron absorption in the gut and eventual chronic iron overload. Excessive iron deposition causes devastating damage to multiple organs, particularly affecting the heart, liver, and endocrine organs.

β -Thalassemia Major

Symptoms of β -thalassemia major are not present at birth, because HbF ($\alpha_2\gamma_2$) is present. However, as HbF levels decline over the first year, the signs and symptoms of severe hemolytic anemia begin to manifest. Affected individuals display hepatosplenomegaly from expansion of the reticuloendothelial system, as well as extramedullary hematopoiesis, pallor, growth retardation, and abnormal skeletal development. If left untreated, 80% of children with β -thalassemia major will die before the age of 5 years.

Laboratory Features

Thalassemia major is characterized by a severe microcytic anemia. Hemoglobin levels may be as low as 3 to 4 g/dL. The peripheral blood smear is markedly abnormal and is notable for hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells, and tear drop cells. Routine stains show the presence of precipitated α globin chains as Heinz bodies. The reticulocyte count is often low. The white blood cell count is often high but may be artifactually elevated as a consequence of automated inclusion of high numbers of circulating nucleated RBCs. The platelet count is typically normal, but progressive hypersplenism can result in decreased platelet counts. Patients who have undergone splenectomy often have increased white blood cell and platelet counts. Iron studies reveal elevated serum iron, transferrin saturation, and ferritin. Consistent with hemolysis and ineffective erythropoiesis, indirect bilirubin and lactate dehydrogenase levels are increased, and haptoglobin levels are low.

Clinical Features

Unique to β -thalassemia major is the development of extramedullary erythropoiesis. This may be so severe that the masses of bone marrow lead to broken bones and spinal cord compression. Sites of involvement include the sinuses and the thoracic and pelvic cavities. The expansion of the erythroid bone marrow can lead to a number of skeletal changes. In particular, characteristic changes in the facial bones and skull result in frontal bossing, overgrowth of the maxillae, and malocclusion. This has sometimes been referred to as chipmunk facies. Other bones are also affected, and premature fusion of the epiphyses results in shortened limbs. Compression fractures of the spine may occur. Even if the disease is managed appropriately with transfusions and iron chelation, patients will still suffer from osteopenia and osteoporosis. Possible mechanisms include changes secondary to hypogonadism or increased bone resorption secondary to vitamin D deficiency.

Hepatosplenomegaly, secondary to extramedullary erythropoiesis and RBC destruction, are prominent. Injury to Kupffer cells and hepatocytes from chronic overload leads to fibrosis and end-stage liver disease. Hepatic iron overload is probably caused in part by comparatively high levels of transferrin receptors. Iron overload, and perhaps other factors, increase susceptibility to viral hepatitis. Laboratory studies show indirect hyperbilirubinemia, hypergammaglobulinemia, and elevated liver markers. The chronic hemolysis leads to formation of bilirubin gallstones, although cholecystitis or cholangitis is not common. Splenic dysfunction results in immune dysfunction. The shortened erythrocyte survival time leaves patients susceptible to aplastic crisis induced by parvovirus B19 infection. Extramedullary hematopoiesis may also affect the kidneys, and patients often have large kidneys. Rapid cell turnover leads to hyperuricemia, and children may develop gouty nephropathy.

A number of endocrine abnormalities are commonly seen in β -thalassemia major, including hypogonadism, growth failure, diabetes, and hypothyroidism. These abnormalities occur even in chronically transfused patients and may be in part related to iron overload. Endocrine glands, like liver and heart, have high levels of transferrin-receptor and therefore are more susceptible to iron overload. The typical growth pattern for a child with β -thalassemia major is relatively normal until the age of 9 to 10 years. After that time, the growth velocity slows, and the pubertal growth spurt is either absent or reduced. Although secretion of growth hormone does not appear to be altered in thalassemic patients, a reduction in peak amplitude and nocturnal levels of growth hormone has been observed. Amenorrhea is quite common, with 50% of girls presenting with primary amenorrhea. Secondary amenorrhea also develops, particularly in patients who do not receive regular

chelation therapy. In males, impotence and azoospermia is common. Primary hypothyroidism typically appears during the second decade of life. The prevalence of diabetes mellitus and impaired glucose intolerance has been estimated at 4% to 20%. Unlike type 1 diabetes mellitus, diabetes associated with thalassemia is rarely complicated by diabetic ketoacidosis. The risk of diabetic retinopathy is lower, but the risk of diabetic nephropathy is higher. Patients with a high ferritin level (above 1800 µg/L) experience a faster progression to hypothyroidism, hypogonadism, and other endocrinopathies.

Thalassemic patients suffer from extensive cardiac abnormalities. Chronic anemia causes cardiac dilation. Although long-term transfusion can help prevent cardiac dilation, the resulting iron overload leads to cardiac hemosiderosis. Pericarditis, ventricular and supraventricular arrhythmias, and end-stage cardiomyopathy can develop. Ventricular arrhythmia is a common cause of death. Patients may also develop pulmonary hypertension. The degree of iron overload in the heart has traditionally been assessed by cardiac biopsy, but cardiac magnetic resonance imaging (MRI) is increasingly being used.

Vitamin and mineral deficiencies may occur. Folic acid deficiency may develop in patients, presumably as a consequence of increased cell turnover. Although the cause is unknown, patients with β -thalassemia major often have very low serum zinc levels. Serum levels of vitamin E and vitamin C may also be low.

Management of β -Thalassemia Major

Transfusion

The key intervention for the management of β -thalassemia major is chronic transfusion therapy. In particular, during the first decade of life, regular transfusion results in improvements in hepatosplenomegaly, skeletal abnormalities, and cardiac dilation. Patients typically require 1 to 3 units of packed RBCs every 3 to 5 weeks. The optimal target total hemoglobin level has yet to be determined. Alloimmunization does occur, and some blood centers try to leukodeplete their products, match donors by ethnicity, and limit the donor pool for any particular patient. Although the risk of blood-borne infections is now quite small, regular transfusion of blood products still carries a risk for infections such as HIV and hepatitis C.

Splenectomy

The general indication for splenectomy is an increase of more than 50% in the RBC transfusion requirement over the period of 1 year. Splenectomy may initially yield a decrease in the RBC transfusion requirement. It has been noted that thalassemia patients are at higher risk for infection after splenectomy than are those patients splenectomized for other reasons. The bacteria that most frequently cause infections in these patients include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Klebsiella*, *Escherichia coli*, and *Staphylococcus aureus*. The increased susceptibility to infection compared with other splenectomized patients is thought to be a result of greater immune dysfunction secondary to iron overload. In particular, it has been reported that iron-overloaded macrophages lose the ability to kill intracellular pathogens. Antibiotic prophylaxis with penicillin, amoxicillin, or erythromycin is recommended for children up to age 16 years. In addition, patients should receive immunizations, including the pneumococcal, influenza, and *Haemophilus influenzae* vaccines.

Iron Chelation Therapy

Because of increased iron absorption and long-term transfusion therapy, iron overload develops. As noted earlier, iron overload causes damage to multiple organs. Because iron is poorly excreted, removal must be accomplished by phlebotomy (not an option in thalassemic patients) or by chelation therapy. Historically, deferoxamine (Desferal) has been the most widely used chelator. This agent may be administered subcutaneously, intramuscularly, or intravenously. The dosing for chronic iron

overload is 20 to 40 mg/kg/day SQ or 500 to 1000 mg/day IM + 2 g IV per unit transfused blood. The IV-only route is indicated for patients with cardiovascular collapse. Multiple studies have shown that deferoxamine therapy improves long-term survival. In addition, intensive therapy with deferoxamine has been shown to improve cardiac function in patients with severe iron overload. However, compliance with daily injections has been a particular problem, and, unless regular therapy is given, iron will reaccumulate.

Deferiprone (Ferriprox) was the first orally active chelator to be introduced. It is given three times daily (total of 75 mg/kg/day). Studies have indicated that deferiprone may be as effective as deferoxamine in lowering iron levels. A recent Cochrane Review concluded that deferiprone is indicated in the treatment of iron overload in thalassemia major if deferoxamine therapy is contraindicated or inadequate. Agranulocytosis associated with deferiprone has been reported, and, because of this risk, the drug is currently not available in the United States except through the FDA Treatment Use Program. Deferiprone is available in Europe and Asia. There has also been interest in combined therapy with deferiprone and deferoxamine, and one study showed that the combination was more effective in removing cardiac and hepatic iron but did not further improve cardiac function.

Deferasirox (Exjade) is the first orally active agent approved for use in the United States. Its longer half-life in comparison to deferiprone allows this drug to be given once daily (total of 20–40 mg/kg/day). A phase III trial comparing deferasirox to deferoxamine in patients with thalassemia revealed similar decreases in liver iron concentrations. Side effects include gastrointestinal complaints (abdominal pain, nausea, vomiting, diarrhea) and skin rash. There have been postmarketing reports of acute renal failure, hepatic failure, and cytopenias. It is recommended that serum creatinine, ferritin, and alanine aminotransferase be monitored monthly during therapy. A prospective, randomized study comparing deferiprone and deferoxamine vs deferiprone and deferasirox in 96 patients with β -thalassemia major demonstrated that both regimens reduced iron overload. However, the latter regimen was found to be superior with respect to improving cardiac iron, patient compliance, and patient satisfaction.

The gold standard for measurement of liver iron concentration has been liver biopsy with iron measurement by atomic absorption spectrometry. More recently, there has been increasing use of MRI technology to measure liver iron levels. In general, iron content determined by MRI methodology correlates with liver iron concentration determined by biopsy. However, the precision of liver MRI measurement appears to be dependent on iron levels, liver fibrosis, and calibration. Hepatic iron concentration has also been measured using a superconducting quantum interference device (SQUID), although reported consistency has varied and widespread use of this technique has been limited by expense and complexity.

Management of Osteoporosis

Even with calcium and vitamin D supplementation, iron chelation, transfusion therapy, and hormonal therapy, bone loss continues to be a significant problem for thalassemia patients. Recently, there has been interest in the use of bisphosphonates. This class of drugs, which includes clodronate (Bonefos),² alendronate (Fosamax), pamidronate (Aredia), zoledronate (Zometa), and neridronate (Nerixia),² inhibit osteoclastic bone resorption and have found extensive use in the management of Paget's disease, osteoporosis, and skeletal metastases. Small studies performed in thalassemia patients have failed to show benefit with clodronate 100 mg IM every 10 days or 300 mg IV every 3 weeks. A very small study using alendronate (Fosamax)¹ 10 mg PO daily revealed an increase in bone mineral density only at the femoral level. Conversely, in a study involving pamidronate (Aredia)¹ 30 or 60 mg IV every

¹Not FDA approved for this indication.

²Not available in the United States.

month, there was an increase in bone density only at the lumbar level. The most promising results have been achieved with the most potent member of the class, zoledronate. Several trials demonstrated that zoledronate (Zometa)¹ 4 mg IV every 3 or 4 months results in significant improvement in femoral and lumbar bone mineral density and reduces bony pain. The largest randomized trial involved 118 β -thalassemia patients who received calcium plus vitamin D with or without neridronate (given every 90 days). At 6 and 12 months, there was increased bone mineral density as well as decreased back pain and analgesic use in the neridronate arm. Larger, long-term trials are necessary before this agent finds widespread use in the management of thalassemia-induced osteoporosis.

Hematopoietic Cell Transplantation

Hematopoietic cell transplantation is the only curative strategy for patients with hemoglobinopathies. Patients are assigned to a risk class (Pesaro class) based on adherence to regular iron chelation therapy, presence or absence of hepatomegaly, and presence or absence of portal fibrosis. Those children with no or little hepatomegaly, no portal fibrosis, and regular iron chelation therapy (class I) have a better than 90% chance of cure, whereas those with both hepatomegaly and portal fibrosis (class III) have long-term survival rates of about 60% in older studies. More recent reports indicate that class III survival has improved to 90%.

The use of human leukocyte antigen (HLA)-identical sibling donors has been preferred, because the use of HLA-mismatched donors has produced inferior results and is associated with increased graft rejection, graft-versus-host disease, and infection. However, it is estimated that only one-third of patients will have a matched donor. The use of unrelated donors has been explored, and initial studies showed poorer outcomes. However, more recent data suggest that matched unrelated donors might be a viable option if a suitable sibling donor is lacking, thanks to improved donor selection and transplantation techniques. The use of partially HLA-matched unrelated cord blood has been reported, although 4 of 9 children did not engraft.

Another emerging technique is the use of reduced-intensity conditioning regimens, although long-term success has yet to be achieved. However, no randomized controlled studies have been performed evaluating the role of transplant in thalassemia patients.

Gene Therapy

Globin gene therapy, achieved through manipulation of autologous stem cells, is an attractive alternative to allogeneic transplantation. There are three major scientific hurdles that must be overcome: design of vectors that yield therapeutic levels of globin gene expression, ability to isolate and transduce autologous stem cells, and development of transplantation conditions that will permit host repopulation. In addition, the safety of viral and nonviral transfection is an issue. Initial studies involved ex vivo transduction of autologous hematopoietic stem cells with a lentiviral vector carrying the transgene. Most of the treated patients achieved sufficient transgene expression to result in an increase in hemoglobin by 4–6 g/dL within 2–5 months. Another approach that is currently under investigation involves the use of genome editing techniques such as CRISPR.

Pharmacologic Induction of Fetal Hemoglobin

Induction of HbF expression has been proposed as a therapeutic strategy. For β -thalassemia, induced γ globin gene expression would be predicted to decrease globin chain imbalance by complexing with free α chains. Hydroxyurea (Hydrea)¹ is an antimetabolite thought to interfere with DNA synthesis. It is well established in the management of sickle cell disease, where it has been shown to increase levels of HbF. The use of hydroxyurea in β -thalassemia is much less well established. In the United States, hydroxyurea has been approved for use in sickle cell disease but

not for thalassemia. Studies published elsewhere in the world have generally shown improvements in hemoglobin levels in thalassemia intermedia patients, with some patients becoming transfusion independent. A recent meta-analysis on the use of hydroxyurea in patients with transfusion dependent β -thalassemia concluded that this agent might offer some benefit but that double-blinded placebo-controlled studies are lacking.

5-Azacytidine (azacitidine [Vidaza]),¹ an inhibitor of DNA methyltransferase, has been shown to induce HbF. However, concerns regarding long-term use have prevented further evaluation in thalassemia. Decitabine (Dacogen),¹ an analogue of 5-azacytidine, has been shown to increase HbF levels in patients with sickle cell disease refractory to hydroxyurea. A small pilot study of low-dose decitabine in β -thalassemia intermedia patients demonstrated an increase in total hemoglobin and hemoglobin F levels. Butyrate,⁵ an inhibitor of histone deacetylases, is another agent capable of inducing HbF. However, butyrate and its derivatives (arginine butyrate,⁵ sodium isobutyramide,⁵ and sodium phenylbutyrate [Buphenyl]¹) have failed to show significant clinical benefit in thalassemia patients. Therefore, at this time, no agent has been approved for use in thalassemia patients. A number of hypotheses have been proposed to explain the lack of success of inducers of HbF in thalassemia: there is simply too little γ globin production to significantly affect globin chain balance; these agents decrease expression of partially active β -thalassemia genes; these agents increase expression of α -globin genes; chronic transfusions appear to reduce HbF levels; and these agents suppress erythropoiesis.

Novel Agents Targeting Ineffective Erythropoiesis

An alternative strategy that is being investigated involves the targeting of ineffective erythropoiesis. Janus kinase 2 (JAK2) plays a key role in erythropoiesis, and there is interest in the potential use of JAK2 inhibitors in thalassemia. A phase II study with ruxolitinib (Jakafi)¹ showed a trend toward reduction in transfusions as well as a reduction in spleen size. Luspatercept (ACE-536)⁵ and sotatercept (ACE-011)⁵ are activin receptor trap ligands that were developed to treat postmenopausal osteoporosis but were noted to increase Hb levels. Initial phase 2 studies with these agents in thalassemia patients revealed reductions in transfusion burden, increase in Hb, and reduction in liver iron levels. A phase 3 study comparing luspatercept plus best supportive care to placebo plus best supportive care is underway.

Antioxidants

Oxidative damage is believed to be an important cause of tissue damage, and there has been interest in the use of antioxidants in thalassemia patients. A variety of substances have been investigated, including ascorbate,¹ vitamin E,¹ N-acetylcysteine (Mucost),¹ flavonoids, and indicaxanthin.⁵ A variety of antioxidant effects have been observed in vitro with these agents, but none have been shown to improve anemia in patients with thalassemia.

β -Thalassemia Intermedia

Given the underlying genetic heterogeneity, it is not surprising that the clinical manifestations of β -thalassemia intermedia are also quite varied. Some patients with more mild forms of β -thalassemia intermedia do not require long-term transfusion therapy. There is not a clear consensus about when long-term transfusion should be initiated. Factors that are considered for children include growth patterns, spleen size, and bone development. Transfusion may be necessary during infection-induced aplastic crises. In some instances, transfusions are begun in childhood to help with growth and then discontinued after puberty. Some adults gradually become more anemic and eventually require transfusion. Some authors have argued that starting transfusions early in life is advantageous, because the prevalence of alloimmunization appears to increase if transfusion is started after the first few years of life.

¹Not FDA approved for this indication.

¹Not FDA approved for this indication.

⁵Investigational drug in the United States.

Splenomegaly usually develops in all patients, including those who do not require transfusion. With progression of splenomegaly and the accompanying sequestration and hemolysis, there is usually worsening of anemia, to the point at which transfusions may be required. Most patients achieve transfusion independence after splenectomy. Gallstones may develop, and a prophylactic cholecystectomy is sometimes performed at the same time as the splenectomy. As with β -thalassemia major patients, intermedia patients are at increased risk for infection and should be appropriately vaccinated.

For reasons that are not entirely clear, there is an increased risk of thromboembolic complications in intermedia patients compared with thalassemia major patients. An Italian study reported that 10% of thalassemia intermedia and 4% of thalassemia major patients experienced a thromboembolic event. Another study reported that thromboembolism occurred four times more frequently in patients with intermedia versus major disease. This report noted that venous events were more common in the thalassemia intermedia population, whereas arterial events were more common in the thalassemia major population. An even higher rate of venous thrombotic events (29%) was reported in a population of splenectomized patients with thalassemia intermedia. It has been suggested that exposed anionic phospholipids on the surface of damaged RBCs may induce a procoagulant effect. There is no consensus regarding the prophylactic use of antiplatelet agents or anticoagulants in this population.

Patients with thalassemia intermedia may develop iron overload, although it is less severe than in patients with thalassemia major. Even those that are not regularly transfused may develop a degree of iron overload, because there is increased iron absorption. Iron overload may be managed with the iron chelating agents as described earlier. Cardiac toxicity, including congestive heart failure, valvular problems, and pulmonary hypertension (leading to secondary right-sided heart failure), resulting from iron overload is not infrequent in the thalassemia intermedia population.

Bone abnormalities and osteoporosis may develop in thalassemia intermedia patients. In a North American study, the prevalence of fractures in these patients was 12%. Leg ulcers involving the medial malleolus are common and are often difficult to treat. Hypogonadism, hypothyroidism, and diabetes may occur, with frequency related to the severity of anemia and iron overload. Pseudoxanthoma elasticum, a syndrome consisting of skin lesions, angioid streaks in the retina, calcified retinal walls, and aortic valve disease, is more common in thalassemia intermedia than in thalassemia major. Currently, no effective therapy exists, although it has been reported that aluminum hydroxide (Alternagel)¹ reduces skin calcification.

β -Thalassemia Minor

Most patients with β -thalassemia minor are asymptomatic. However, they have an abnormal complete blood count that may sometimes lead to the misdiagnosis of iron deficiency. Although these patients have a microcytic anemia, it is much less severe than in patients with β -thalassemia major. In general, the hematocrit is greater than 30%. The mean corpuscular volume is typically less than 75 fL and the RBC distribution width index is normal, in contrast to iron deficiency, in which the degree of microcytosis is less and the distribution width index is usually increased. The peripheral blood smear shows the presence of target cells. Hemoglobin electrophoresis typically reveals an increase in HbA₂. The normal anemia experienced during pregnancy may sometimes be exacerbated in patients with β -thalassemia minor, necessitating transfusion. Otherwise, no long-term effects of β -thalassemia minor have been described, and no interventions are required.

α -Thalassemia

Laboratory and Clinical Features

Patients with α -thalassemia trait 2 are symptom free and have normal laboratory values, including complete blood count, peripheral smear, and hemoglobin electrophoresis. Individuals with

α -thalassemia trait 1 are symptom free, and the disease resembles β -thalassemia minor. The peripheral smear shows a hypochromic microcytic anemia with the presence of target cells. Hemoglobin electrophoresis is normal.

HbH disease does produce symptoms. Unlike β -thalassemia major, in which HbF production protects the fetus, individuals with HbH disease develop hemolytic anemia during gestation and are symptomatic at birth. This is because α globin production is required for HbF ($\alpha_2\gamma_2$). As with β -thalassemia major, patients with HbH disease suffer from the consequences of chronic hemolytic anemia, although the severity is somewhat less. The transfusion requirements for HbH patients resemble those for patients with β -thalassemia intermedia, with transfusion support initiated in the second and third decades of life. These patients also develop iron overload, necessitating treatment with chelation therapy.

Hydrops fetalis with hemoglobin Barts is usually fatal in utero. The utter lack of α globin chain production results in absence of HbF. Hemoglobin Barts, a homotetramer consisting of four γ globin genes, is unable to deliver oxygen to tissues. Severe tissue hypoxia develops, leading to widespread tissue ischemia. High cardiac output failure leads to massive edema (hydrops). In most cases, death occurs in the third trimester or late second trimester. There have been reports of live births after intrauterine transfusion, but survival beyond the perinatal period is exceedingly rare. Prenatal diagnosis of hemoglobin Barts hydrops fetalis may be achieved through DNA-based testing using amniocytes from amniocentesis or chorionic villi sampling. Noninvasive testing is under development, including methods that isolate circulating fetal DNA in maternal peripheral blood.

Management

Patients with α -thalassemia 2 and 1 traits do not require treatment. The management of HbH disease is similar to that described for β -thalassemia.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Method of

Ravi Sarode, MD

CURRENT DIAGNOSIS

- The diagnosis based on unexplained microangiopathic hemolytic anemia (MAHA) and thrombocytopenia in the absence of oliguric renal failure is sufficient to initiate emergent plasma exchange (PLEX) for suspected diagnosis of autoimmune acquired TTP.

¹Not FDA approved for this indication.

- These laboratory tests are recommended for patient evaluation:
 - Complete blood count (shows anemia and decreased platelet count, usually $<30,000/\mu\text{L}$).
 - Peripheral blood smear (shows “schistocytes/fragmented red blood cells,” a hallmark of thrombotic microangiopathy [TMA]).
 - Reticulocyte count (is elevated).
 - Haptoglobin (is usually undetectable in TTP).
 - “Lactate dehydrogenase” (LDH) (usually more than twice the upper limit of normal in TTP).
 - Blood urea nitrogen, serum creatinine (determines non-oliguric renal insufficiency, serum creatinine $<2.5\text{ mg/dL}$).
 - Liver function tests, including direct and indirect bilirubin.
 - Troponin—some patients have ischemic cardiac injury
 - Plasma “ADAMTS13 activity” ($<10\%$ is diagnostic of TTP) and inhibitor level (usually detected in 90% of cases of TTP).
 - Prothrombin time, partial thromboplastin time, fibrinogen, and d-dimers (to rule out DIC).
 - Direct antiglobulin test (to rule out autoimmune hemolytic anemia).
 - Urinalysis.

CURRENT THERAPY

- Daily plasma exchange (PLEX) using plasma as a replacement fluid (1–1.5 total body plasma volume) until platelet count is normal for 2 days, then taper PLEX to three times a week, then twice a week, and then once a week. Discontinue when platelets remain greater than $150,000/\mu\text{L}$.
- Prednisone 1 mg/kg/day taper *pari passu* with PLEX.
- Rituximab (Rituxan)¹ (either 100 mg fixed dose or 375 mg/m^2 weekly x 4) or upfront in the first week once diagnosis of autoimmune TTP is confirmed (reduces length of stay, exacerbation, and number of PLEX)
- Plasma (10–15 mL/kg) or cryoprecipitate (one dose = 10 units of pooled cryoprecipitate) infusion if PLEX will be delayed >6 hours.
- Exacerbation or relapsing TTP.
 - Rituximab (Rituxan)¹ (375 mg/m^2) weekly for 2–4 weeks.
 - Cyclosporine (Neoral)¹ (2–3 mg/kg/day up to 6 months).
 - Vincristine (Oncovin)¹ (1.4 mg/m^2 once a week for 4 weeks).
 - Bortezomib (Velcade)¹ (1.3 mg/m^2 1–2 cycles or 1 mg fixed dose weekly x 4).
 - Splenectomy as a last resort.

¹Not FDA approved for this indication.

Thrombotic thrombocytopenic purpura (TTP) is a rare (1–2 cases/million) but life-threatening thrombotic microangiopathy (TMA) disorder characterized by the presence of microthrombi in microcirculation of various organs, including the brain, kidneys, heart, and abdominal viscera. Microthrombi consist of platelets and von Willebrand factor (VWF), resulting in microangiopathic hemolytic anemia (MAHA) and thrombocytopenia. MAHA refers to the fragmentation of red blood cells (schistocytes) during their passage through partially occluded arterioles and capillaries by microthrombi. TTP diagnosis requires a high degree of suspicion, because a delay in initiating PLEX, the current standard of care, could result in a poor response or fatal outcome. In the past, diagnosis of TTP was made based on a pentad that included MAHA, thrombocytopenia, neurologic involvement, renal affection, and fever. This pentad was found in patients who had died of TTP indicating advanced disease; therefore, one should not wait for development of a pentad, which could delay TTP diagnosis with a potentially fatal outcome. Currently, unexplained MAHA and thrombocytopenia in the absence of oliguric renal failure are

sufficient to make a working diagnosis of TTP and initiate emergent PLEX. Occasionally, a patient may present with only severe thrombocytopenia and be managed as non-responding immune thrombocytopenia, but after a few days develops MAHA establishing TTP diagnosis. Similarly, rarely a young patient may present with unexplained ischemic stroke without hematologic features and later develop hematologic features.

Pathophysiology

In congenital TTP (Upshaw Shulman syndrome), ultra large (UL) multimers of VWF were detected during remission and were absent during relapse. Later, a VWF-cleaving protease (ADAMTS13, a disintegrin and metalloproteinase with thrombospondin 1 motif, 13th member of the family) was identified that was responsible for cleaving UL multimers secreted from endothelium into normal-sized VWF multimers seen in normal plasma. This cleavage occurs under high shear rate flow conditions in smaller blood vessels where the UL-VWF undergoes unfolding, exposing the cleavage site for ADAMTS13. ADAMTS13 is severely deficient ($<10\%$) in patients with both congenital and acquired TTP. Persistence of UL-VWF multimers in microcirculation results in unfolding of the molecule, enabling it to bind to platelets at GPIb, producing platelet-VWF microthrombi in capillaries and arterioles that causes end organ ischemic damage (Figure 1). Elevated lactate dehydrogenase (LDH) reflects not only MAHA but also tissue damage. Thus the higher the LDH, the more severe the disease.

Classification

TTP can be divided into (1) a congenital form resulting from a genetic defect in the ADAMTS13 gene and (2) an acquired form due to an autoantibody against the ADAMTS13 enzyme (Figure 2). Congenital TTP can present in the neonatal period; early childhood; or later in life, when it is usually associated with an inciting trigger in the form of pregnancy, severe infection, surgery, or other stress. Acquired TTP is usually idiopathic without underlying disorder or secondary when associated with an underlying autoimmune disorder such as SLE, HIV, use of ticlopidine, etc. Other clinical conditions that present with MAHA and thrombocytopenia with non-severe ADAMTS13 deficiency are grouped under a broader term called TMA.

Clinical Presentation

Autoimmune TTP is a disease of young adults (20–50 years, F:M ratio 2:1), with the majority being African Americans. Most patients present in the emergency department with an acute onset of vague, anemia-like symptoms (malaise, fatigue, weakness) and thrombocytopenia (petechiae, gum bleed). Detailed evaluation reveals the onset of these symptoms several days before presentation. Up to 70% to 80% of patients have some neurologic features, including severe headaches, visual disturbances, focal neurologic deficits, transient ischemic attack, memory deficits, unusual behavior, confusion, seizures, paraparesis, stupor, and coma. Mild renal insufficiency is seen in $<50\%$ and fever in $<15\%$. Because of the generalized nature of the disease, any organ system could be affected and ischemic insult to the heart is not uncommon.

Diagnosis

Unexplained MAHA and thrombocytopenia constitute the diagnostic features and are associated with elevated LDH, reticulocytosis, undetectable haptoglobin, elevated bilirubin, and non-oliguric renal insufficiency in some patients. A severe deficiency of ADAMTS13 ($<10\%$ activity with a detectable inhibitor in up to 90% of patients) confirms the diagnosis. Because this test is usually sent to a reference laboratory, this measurement is unavailable in most hospitals at the time of clinical diagnosis. Therefore, based on the initial clinical and laboratory features, PLEX should be initiated emergently because a delay could increase not only morbidity but also mortality. A sample for ADAMTS13 must be drawn before initiating PLEX or plasma/cryoprecipitate infusion to avoid measuring enzyme from transfused products. ADAMTS13 is a

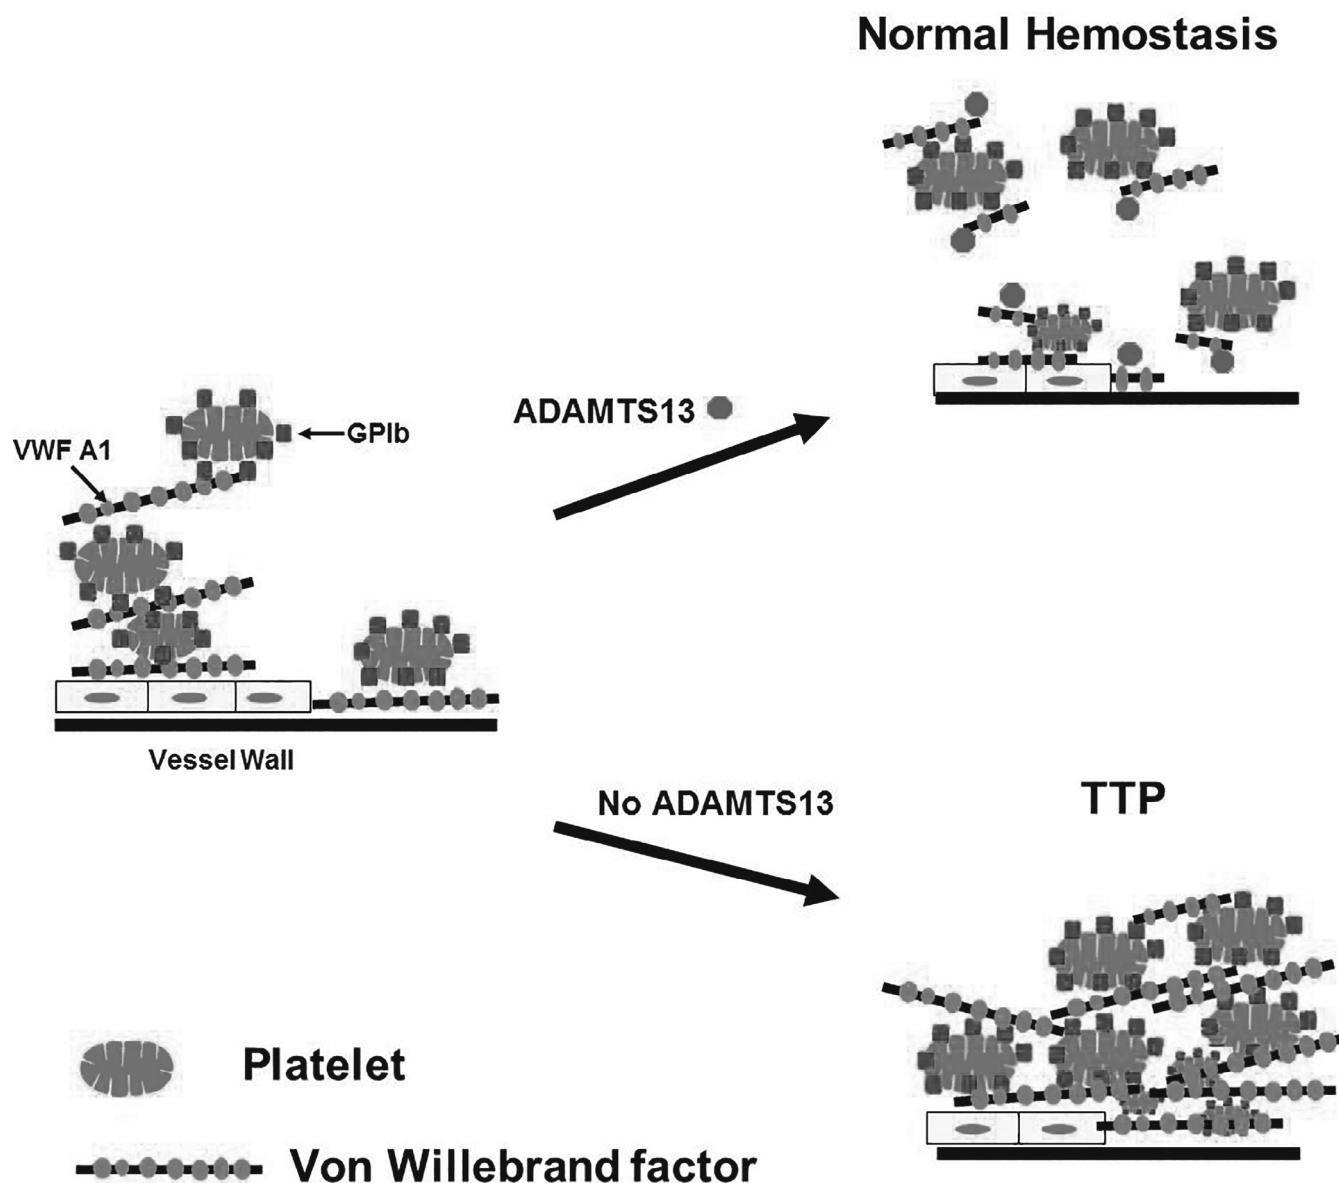

Figure 1 During normal hemostasis, ADAMTS13 enzyme cleaves ultralarge multimers of von Willebrand factor (VWF) in normal sizes and prevents formation of platelet – VWF aggregates under high shear rates. However, in the absence of ADAMTS13 due congenital deficiency or autoantibodies, VWF persist as ultralarge multimers that unfold under high shear rates in small blood vessels and induce VWF-platelet microthrombi in various organs causing ischemic damage.

stable enzyme; if a sample for ADAMTS13 could not be drawn before plasma therapy, a routine coagulation test sample may be used. In congenital TTP, there is persistent severe deficiency of ADAMTS13 (without an inhibitor) associated with ADAMTS13 gene defect. However, this diagnosis is at times made difficult because many patients, especially children and young adults, are often misdiagnosed as immune thrombocytopenia or anemia of unknown origin or Hemolysis Elevated Liver enzymes and Low Platelets (HELLP) syndrome in pregnancy.

Differential Diagnosis

The differential diagnosis of TTP includes clinical conditions that present with MAHA and thrombocytopenia but without severe ADAMTS13 deficiency, that is, TMA. These conditions include hematopoietic stem cell transplantation, drug toxicities (mitomycin, clopidogrel [Plavix], cyclosporine A [Neoral], etc.), malignant hypertension (usually mild to moderate thrombocytopenia), HELLP syndrome with severe preeclampsia, mechanical cardiac devices (for example, left ventricular assist devices, intra aortic balloon pumps, and mechanical heart valves), disseminated

intravascular coagulation (DIC), vasculitis, and both diarrhea-associated and atypical hemolytic uremic syndrome (HUS).

Treatment

PLEX is the standard of care therapy. Its use has reduced mortality from >90% to <20%. Ideally, it should be initiated within 4 to 6 hours of suspected diagnosis. The patient's plasma (which contains autoantibody) is selectively removed during PLEX (1.0–1.5 plasma volume processed) and replaced with donor plasma containing ADAMTS13. Neurologic symptoms usually disappear within 24 to 48 hours. The platelet count is the most useful laboratory parameter to assess response. Complete clinical response, defined as normalization of platelet count for at least 2 days with near normal LDH, generally is achieved with seven to nine daily PLEX in most patients. Thereafter, a gradual taper—that is, PLEX every other day in the first week, twice in the next week, and once in the third week—may be performed. Given the autoimmune nature of the disease, glucocorticoid therapy is often given from the beginning. Approximately 30% to 50% of patients will have exacerbation of the disease (worsening of clinical or laboratory features

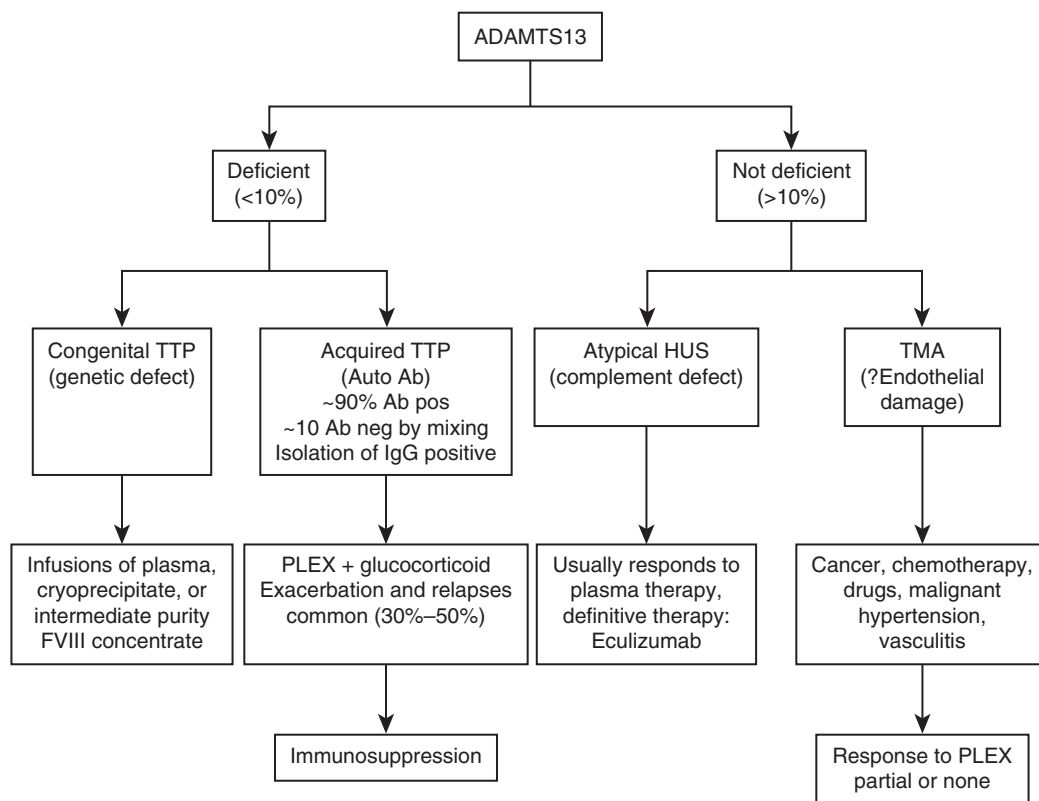

Figure 2 Classification of TTP. *Abbreviations:* MAHA, microangiopathic hemolytic anemia; TTP, thrombotic thrombocytopenic purpura; ADAMTS13, a disintegrin and metalloproteinase with thrombospondin motif 1, 13th member of the family; TMA, thrombotic microangiopathy; HUS, hemolytic uremic syndrome; PLEX, plasma exchange; Ab, antibody.

after initial response) or relapses (recurrence of the disease 30 days after discontinuation of PLEX). Such patients require additional PLEX and other immunomodulatory therapies, e.g., rituximab (Rituxan),¹ cyclosporine (Neoral),¹ vincristine (Oncovin),¹ bortezomib (Velcade),¹ or splenectomy as a last resort. Recently, early rituximab use within the first week has been shown to reduce length of stay, exacerbation/relapse, and number of PLEX. Preliminary data also suggest that a low fixed dose rituximab of 100 mg weekly \times 4 has a similar clinical response to that of 375 mg/m² weekly \times 4, however, has benefits of reduced cost, infusion time, and side effects. A dialysis-type catheter is required for PLEX and can be placed with ultrasound guidance in patients with platelet counts as low as 10,000/ μ L. With the exception of a life-threatening bleed, platelet transfusion is contraindicated in TTP because it is a thrombotic disorder of platelet consumption, and transfused platelets may worsen the condition (appearance of new neurological symptoms, myocardial infarction, etc.). If initiation of PLEX is likely to be delayed, either plasma or cryoprecipitate can be infused temporarily to supplement ADAMTS13. Congenital TTP is treated with plasma infusions (10–15 mL/kg); however, cryoprecipitate and intermediate purity factor FVIII concentrate that contain adequate ADAMTS13 have been used successfully to avoid volume overload in susceptible patients. Recently, a recombinant ADAMTS13 has shown very promising results in a phase 1 clinical trial in congenital TTP. Most fatalities occur during the first few days of diagnosis, probably because of severity of the disease or delay in initiation of PLEX. A recent phase 3 clinical trial of a nanobody, caplacizumab,⁵ that blocks interaction of VWF with platelet GPIb receptor, has promise to reduce this early mortality by disrupting the pathogenic mechanism.

Monitoring

Considering the relatively high frequency of cardiac involvement, cardiac monitoring should be performed initially. Although PLEX is an otherwise safe procedure, complications related to catheter infection and line thrombosis are not uncommon and should be identified as soon as possible to avoid exacerbation of the disease. Exacerbation of TTP is often related to an infection. If the ADAMTS13 is $>10\%$, then TTP diagnosis is generally ruled out and PLEX may be discontinued depending on underlying conditions. There is increasing awareness of delayed long-term psychological and psychosocial effects in up to 50% of patients, and a careful follow-up is recommended to identify and manage these issues.

Prognosis

Although PLEX has reduced TTP mortality in the last 2 decades, most deaths occur within 24 to 48 hours of presentation and are due to delay in administration of PLEX for a variety of reasons, including a delay in diagnosis or line placement or non-availability of PLEX at the institution. After one PLEX, survival rates can increase to $>90\%$. Importantly, no clinical and laboratory parameter exists to predict outcome or relapse. At this stage, ADAMTS13 has a diagnostic but not prognostic value.

DRY EYE SYNDROME

Method of
John N. Dorsch, MD

CURRENT DIAGNOSIS

- Signs and symptoms of dry eye syndrome are nonspecific.
- There are many potential causes of dry eye syndrome. There is no definitive diagnostic test for dry eye syndrome.

CURRENT THERAPY

- Artificial tears may help to palliate symptoms, but preservatives in artificial tears may complicate dry eye syndrome.
- Cyclosporine (Restasis) topical medication should be administered under the care of an ophthalmologist.
- Patients with severe symptoms (especially visual disturbance or eye pain) should be referred to an ophthalmologist.

Introduction

Dry eye syndrome, also known as *dry eye*, *chronic dry eye*, *dry eye disease*, and *keratoconjunctivitis sicca*, is a condition in which reduced tear secretion and/or increased evaporation of tears causes inflammation of the corneal and conjunctival (ocular) surface.

Epidemiology

An estimated 15% to 20% of patients over 65 years of age have dry eye syndrome, with a higher prevalence in females. Dry eye syndrome is common in a mild form in many patients over the age of 40. The prevalence of dry eye syndrome is believed to be rising as patients live longer and a greater proportion of the population is over 65.

Risk factors

Aging is believed to be the most common cause of dry eye syndrome. Decreases in sex hormone concentration, particularly androgens, play a significant role in lacrimal dysfunction. As patients age, they tend to lose function of many of the accessory lacrimal glands and experience relatively less secretion from the major lacrimal glands.¹ In many cases, the cause of tear deficiency is not apparent. [Box 1](#) lists many of the common causes of dry eye syndrome.

Pathophysiology

Desiccation of the ocular surface results in symptoms of discomfort, blurry vision, and instability of tear film. Tears are vital for the protection of the ocular surface, which is constantly challenged by the shearing force of blinking, various microbes, and environmental factors such as dust, smoke, wind, and low humidity. In

order to maintain a healthy film of tears, the patient must have synergistic interaction of lacrimal glands, eyelids, ocular surface, afferent and efferent neural pathways, and meibomian glands. Each component works together with all other components; not in isolation. If there is dysfunction of any of these components or any combination of them, the patient is likely to develop dry eye syndrome.

Healthy tear film consists of an outer oily (lipid) layer, a middle aqueous layer, and an inner mucin layer. The oily layer is secreted by meibomian glands in the posterior portion of the upper and lower eyelids. The aqueous portion of tear film is secreted by the exocrine lacrimal gland located superior and slightly lateral to the eye, as well as smaller accessory lacrimal glands ([Figure 1](#)). The mucinous layer of tears is secreted by goblet cells on the corneal surface, as well as the conjunctivae. The oily outer surface of tear film functions to prevent evaporation of tears. The inner mucin layer of tear film helps to lubricate the ocular surface as it constantly undergoes healing. In dry eye syndrome, tears become hyperosmolar as a result of water evaporation from the exposed ocular surface. Hyperosmolarity stimulates a cascade of inflammatory events in corneal epithelial cells resulting in mast cell release of cytokines, leading to damage. When normal ocular surface defense mechanisms are compromised, the cornea is more susceptible to infections.

Prevention

There is no known prevention for dry eye syndrome.

Clinical Manifestations

Symptoms of dry eye syndrome are listed in [Box 2](#). Excessive tearing is a paradoxical sign of dry eye syndrome. Ocular surface damage or irritation activates the neural reflex that stimulates the lacrimal gland to secrete more aqueous tears. As time goes on, this compensatory ability is often gradually lost. Signs of dry eye from examination are listed in [Box 3](#).

Diagnosis

The presence of symptoms alone is not sufficient to make a diagnosis of dry eye syndrome, because they are often nonspecific and may not be accompanied by ocular changes.

Diagnostic tests for dry eye syndrome include (1) testing for abnormally rapid corneal tear film break-up time (TFBUT), the Schirmer test (can give quite variable results), and fluorescein or rose Bengal staining of the cornea and conjunctiva (usually positive in more advanced cases). There is no single definitive test in the identification of dry eye syndrome or to measure the severity of disease. Several validated patient questionnaires have been developed that may also be useful.

Differential Diagnosis

The differential diagnosis of dry eye includes blepharitis (which may co-exist with dry eye), ocular allergies, viral conjunctivitis (usually a shorter course), and other infections.

Treatment

Treatment of dry eye syndrome is aimed at increasing tear production, decreasing tear evaporation, or reducing tear resorption.

¹Not FDA approved for this indication.

BOX 1 Causes of Dry Eye Syndrome

Aging
 Congenital disorders (e.g., congenital alacrima and familial dysautonomia)
 Evaporative dry eye
 Meibomian gland dysfunction: posterior blepharitis
 Entropion and ectropion
 Low blink rate: Parkinson disease, prolonged computer or microscope use
 Low-humidity environment
 Smoking (direct irritant)
 High estrogen levels
 Lacrimal duct obstruction: trachoma, pemphigoid, erythema multiforme, chemical and thermal burns
 Lacrimal gland denervation
 Lacrimal gland infiltration: sarcoidosis, lymphoma, AIDS, graft-vs-host disease
 Low androgen levels
 Ocular surface disorders: topical anesthetic drops, vitamin A deficiency, preservatives in artificial tears and other ophthalmic medications, contact lens wear, allergic conjunctivitis
 Other autoimmune disorders (rheumatoid arthritis [RA], scleritis, episcleritis)
 Reflex hyposalivation
 Reflex motor block: damage to the VII nerve, systemic drugs (antihistamines, beta-blockers, antispasmodics, diuretics, tricyclic antidepressants, selective serotonin reuptake inhibitors [SSRIs], psychotropic medications, isotretinoin)
 Reflex sensory block: topical anesthetic drops, contact lens wear, laser-assisted in situ keratomileusis (LASIK) surgery, diabetes, keratitis from herpes zoster or ulcerative colitis
 Pregnancy
 Sjogren syndrome

Figure 1 Anatomy of the major lacrimal gland and drainage system.

BOX 2 Symptoms of Dry Eye Syndrome

- Dryness
- Redness
- General irritation of eyes
- Gritty sensation in eyes (especially later in the day)
- Burning sensation in eyes
- Foreign body sensation in eyes
- Excessive tearing
- Light sensitivity
- Blurred vision

BOX 3 Signs from Physical Examination suggesting Dry Eye Syndrome

- Conjunctival injection, usually symmetric
- Excessive tearing
- Blepharitis (erythematous or irritated eyelid edges)
- Malposition of eyelids (entropion/ectropion)
- Reduced blink rate
- Visual impairment
- Scant, white, stringy discharge

Patients usually need to treat dry eye indefinitely. If patients are taking medications (see [Box 1](#)) that cause dry eye, they should stop them if at all possible.

Many forms of artificial tears are available commercially over the counter. Most preparations of artificial tears contain cellulose to increase viscosity, polyethylene glycol or polyvinyl alcohol to help spread the tears across the ocular surface, and a preservative (benzalkonium chloride or cetrimide). Some patients develop sensitivity to preservatives in artificial tears, especially with more frequent or prolonged use. The usual starting dose for artificial tears is one drop in both eyes four times a day. If artificial tears are needed more than four to six times per day, it is best to use preparations without preservatives. Preservative-free artificial tear preparations often range in price from \$16 to \$22 per month, compared to \$4 to \$10 per month for preparations containing preservatives. Examples of preservative-free products include Refresh (Allergan), TheraTears, Soothe (Bausch and Lomb), and Systane (Alcon).

Environmental factors can increase the rate of evaporation of tears. People who do not blink frequently enough (e.g., reading, microscope, and computer use) may need to make a conscious effort to blink more. Patients who work very close to heating and air conditioning ducts need to distance themselves from ducts when possible and should use a humidifier in areas with low humidity. Swim goggles and moisture chambers for glasses may be helpful as well to conserve moisture around the eyes. Lowering computer screens below eye level will decrease exposure of the ocular surface between eyelids. Patients who work at computer terminals should take periodic breaks.

Ophthalmologists may insert silicone plugs to obstruct the puncta and decrease resorption of tears from the surface of the eye. Sodium hyaluronate (over the counter product) is a lipid-like substance that slows the evaporation of tears.

Topical cyclosporine (Restasis) is a second-line agent used in moderate-to-severe disease. It is expensive (about \$400 per month) and should not be used if infection is present since cyclosporine is an immunosuppressive agent. It is probably judicious to leave the decision to use cyclosporine to an ophthalmologist primarily because of cost and possibility of adverse effects. Cyclosporine is usually administered one drop in both eyes twice daily and may take several weeks for symptom reduction. It may cause a temporary burning sensation in the eyes. Lifitegrast (Xiidra) was approved for dry eye by the FDA in 2016. It is from a new class of drugs known as lymphocyte function-associated antigen-1 agents. Like cyclosporine, it is typically prescribed by ophthalmologists.

Topical glucocorticoids may cause symptom reduction in the short term but are not a good option for long-term use because they can cause cataracts and glaucoma.

Dietary supplements containing omega-3 and omega-6 fatty acids are under investigation.⁷

Surgical correction of eyelid abnormalities such as entropion and ectropion may be helpful to prevent or lessen ocular surface damage.

⁷Available as a dietary supplement.

Several new drugs are under investigation for treatment of dry eye syndrome. They are immunomodulators that suppress inflammatory response on the corneal surface.

Complications

Inflammation and damage to the ocular surface can lead to visual disturbance.

Monitoring

Patients using cyclosporine drops should be under the care of an ophthalmologist.

Conclusions

Dry eye syndrome is a multifactorial disease of tears and the ocular surface that can result in discomfort and visual impairment. There is considerable variability in patient-reported symptoms over time.

There is no single definitive diagnostic test for dry eye syndrome. Artificial tears should be used for initial management, but this treatment is only palliative. Environmental strategies should also be considered.

GLAUCOMA

Method of

Albert P. Lin, MD; and Kristin Schmid Biggerstaff, MD

CURRENT DIAGNOSIS

Primary Open Angle Glaucoma

- Primary open angle glaucoma is an irreversible optic neuropathy typically associated with elevated intraocular pressure.
- Primary open angle glaucoma is the most common form of glaucoma and is projected to affect more than 3 million Americans in 2020. It is more common in African-Americans (6%–7%), Asians (2%–3%), and Hispanics (2%) and less common in whites (1%). It is more common in older adults: 1%–2% in 50-year-olds compared with 6%–12% in 80-year-olds.
- Primary open angle glaucoma is diagnosed by a complete ophthalmic examination, including dilated stereoscopic optic nerve examination and formal visual field.
- Untreated primary open angle glaucoma can lead to slow irreversible loss of vision and blindness. Other common causes of slow and progressive vision loss in older adults include cataracts, macular degeneration, and diabetic retinopathy.

Acute Angle Closure Glaucoma

- Pupillary block in susceptible patients leads to block of aqueous drainage and sudden and extreme rise of intraocular pressure. Acute angle closure can damage the optic nerve, resulting in acute angle closure glaucoma.

- About 0.5% to 1.0% of US adults are at risk for acute angle closure. It is more common in Inuits and Asians and rare in African-Americans. The risk of acute angle closure increases with age. It is also more common in hyperopes.
- Patients can present with blurry vision, red eye, pain, headache, nausea, or vomiting. Acute angle closure is sometimes misdiagnosed as migraines or gastrointestinal illnesses. Patients with conjunctivitis, keratitis, uveitis, and corneal abrasion can also present with the same symptoms.
- Peripheral iridotomy prevents acute angle closure in susceptible patients. High intraocular pressure can result in irreversible damage of the optic nerve within hours, making acute angle closure one of the true ophthalmic emergencies.

CURRENT THERAPY

Primary Open Angle Glaucoma

- Topical eye drops, including β -blockers, selective α_2 agonists, carbonic anhydrase inhibitors, and prostaglandin analogues can be used to reduce intraocular pressure.
- Oral carbonic anhydrase inhibitors are typically used in recalcitrant cases until surgery can be performed.
- Laser trabeculoplasty may be used as first-line or adjunct therapy.
- Glaucoma surgery, including trabeculectomy, tube shunt, and cyclodestruction, may be performed if goal intraocular pressure cannot be reached with medical therapy or in nonadherent patients.

Acute Angle Glaucoma

- All glaucoma eye drops are used to reduce intraocular pressure.
- Oral and intravenous medications are added sequentially to reduce intraocular pressure as needed.
- Laser iridotomy can be performed as prophylactic treatment or acutely to break the pupillary block if the patient is unresponsive to medical intervention.
- Emergency glaucoma incisional surgery is performed if the patient is unresponsive to all other treatments.

Glaucoma is an optic neuropathy with characteristic optic nerve head appearance: narrowing of the neuroretinal rim. The optic nerve is a collection of more than 1 million axons from the retinal ganglion cells. The anterior 1-mm portion of the optic nerve within the globe is referred to as the *optic disk* or simply the disk. When the disk is examined with direct or indirect ophthalmoscopy, a cup, or a physiologic empty space, is observed centrally. The remainder of the disk, which has a yellow-orange appearance, contains the axons and is referred to as the *neuroretinal rim*. The area of the cup compared to the entire disk is the cup-to-disk ratio, which is normally less than 0.4 (Figure 1A). When patients develop glaucoma, axons are lost from the neuroretinal rim and the size of the cup increases in relation to the disk. Narrowing of the neuroretinal rim and increased cup-to-disk ratio are the hallmarks of glaucomatous optic neuropathy (Figure 1B).

Glaucoma can result in significant and irreversible loss of vision and is one of the leading causes of blindness in the United States. Early in the disease state, glaucoma is asymptomatic; it is sometimes called “the sneak thief of sight.” As the disease progresses, the patient develops decreased peripheral vision and eventually loss of the central vision.

Glaucoma is typically associated with increased intraocular pressure (IOP), but it is possible to have normal-tension or low-tension glaucoma. Glaucoma treatment is focused on the reduction of IOP to prevent or slow optic nerve damage and preserve visual function.

Glaucoma is classified in many ways, and it is most useful to approach it clinically based on the status of the angle, the area between the cornea and iris where aqueous exits the globe through the trabecular network. We further discuss primary open angle

Several new drugs are under investigation for treatment of dry eye syndrome. They are immunomodulators that suppress inflammatory response on the corneal surface.

Complications

Inflammation and damage to the ocular surface can lead to visual disturbance.

Monitoring

glaucoma, the most common form of glaucoma in the United States, and the management of acute angle closure, one of the true ophthalmic emergencies.

Primary Open Angle Glaucoma

Glaucoma is one of the leading causes of blindness in older adults, especially in patients of African-American descent. Vision loss from glaucoma is irreversible, and the treatment goal is to reduce IOP, slow disease progression, and preserve visual function during the patient's lifetime. Glaucoma is a slowly progressive disease, and progression to blindness often takes more than 10 years, even in untreated patients. Given its slow progression and the fact that central vision loss occurs in late disease, most patients do well with early diagnosis and treatment. Treatment is more difficult in late disease because the rate of disease progression and visual deterioration is accelerated, sometimes despite good control of IOP.

Due to the early asymptomatic nature of the disease, the patient's adherence to and persistence with treatment is often less than optimal. Studies have shown patients who obtain glaucoma information from physicians other than their ophthalmologists have a higher rate of medication adherence. Ophthalmologists have the options to use treatment modalities such as laser and surgery to obtain pressure control and decrease or eliminate the need for medication use.

The American Academy of Ophthalmology recommends asymptomatic patients older than 40 years be referred for ophthalmic evaluation once every several years for early detection of glaucoma and other chronic eye diseases. However, the U.S. Preventive Services Task Force found insufficient evidence to recommend for or against screening for glaucoma in adults. Risks, benefits,

and cost effectiveness of screening are beyond the scope of this chapter, but symptomatic patients or patients at high risk for glaucoma (African American ethnicity and family history) might benefit from ophthalmology consultation. It is possible to diagnose glaucoma by direct ophthalmoscopy, but this is not a substitute for binocular assessment of the disk through dilated pupils and formal visual field testing. If glaucoma is suspected or diagnosed, primary care visits should include inquiries regarding glaucoma medication use, medication side effects, and the time of last eye examination. Primary care physicians can improve glaucoma outcome by promoting adherence to medication and follow-up. Glaucoma patients need to follow up with their ophthalmologists at least annually, and in severe cases every 3 months, for intraocular pressure checks.

Treatment

Topical Glaucoma Medications

Topical glaucoma medications are administered once or twice daily. Patients should look up, pull down their lower eye lid, drop the medication on the inferior conjunctival cul-de-sac, and keep their eyes closed for 5 minutes. Applying gentle pressure next to the bridge of the nose to occlude the puncta can improve absorption of the medication. Medication bottle caps are color-coded by their class, and patients can usually identify their eye drops by color. Glaucoma medications are not subject to first-pass effect through the liver and can sometimes have significant systemic side effects, especially the β -blockers. Topical glaucoma medications are described later and summarized in [Table 1](#).

Prostaglandin Analogues. Latanoprost (Xalatan), travoprost (Travatan), and bimatoprost (Lumigan) are prostaglandin

TABLE 1 Topical Glaucoma Medications: Carbonic Anhydrase Inhibitors

CLASS	β -BLOCKER	SELECTIVE α_2 AGONIST	CARBONIC ANHYDRASE INHIBITOR	PROSTAGLANDIN ANALOGUE	COMBINATION
Medication	Timolol (Timoptic) Betaxolol (Betoptic) Levobunolol (Betagan)	Brimonidine (Alphagan)	Dorzolamide (Trusopt) Brinzolamide (Azopt)	Latanoprost (Xalatan) Travoprost (Travatan) Bimatoprost (Lumigan)	Timolol/Dorzolamide (Cosopt) Timolol/Brimonidine (Combigan) Brimonidine/Brinzolamide (Simbrinza)
Dosing	bid or qd	bid	bid	qhs	bid or tid
Cap color	Yellow	Purple	Orange	Teal	Blue or light green (Simbrinza)
Side effects	Bradycardia, COPD, and asthma exacerbation	Allergic conjunctivitis, dry mouth, fatigue in elderly	Stinging, bitter taste	Hyperemia, lash growth, increased pigmentation	See individual components

Abbreviation: COPD = chronic obstructive pulmonary disease.

analogues and are color-coded by teal caps. They are administered once at bedtime but may be administered once at any time during the day to promote adherence. They decrease IOP by increasing aqueous outflow. Side effects are primarily local and include increased conjunctival hyperemia, increased lash growth, and possible irreversible increase in periocular and iris pigmentation.

β -Blockers. Timolol (Betimol, Istalol, Timoptic), levobunolol (Betagan), and betaxolol (Betoptic) are color-coded by yellow caps. They are administered once or twice daily and decrease IOP by decreasing aqueous production. Side effects include bradycardia, exacerbation of chronic obstructive pulmonary disease (COPD) and asthma, impotence, and decreased serum high-density lipoprotein (HDL) cholesterol. Physicians need to be aware that a topical β -blocker is a potential cause of acute changes in cardiovascular or pulmonary status. There are several reported incidents of death following the use of topical β -blockers mostly due to exacerbation of asthma.

Selective α_2 Agonists. Brimonidine (Alphagan) and apraclonidine (Iopidine) belong to the class of selective α_2 receptor agonists, and brimonidine is more commonly prescribed; it is color-coded by purple caps. It is administered twice daily and decreases IOP by decreasing aqueous production. Allergic conjunctivitis has been reported in up to 25% of patients. Rarely, it causes dry mouth and chronic fatigue and drowsiness in the elderly.

Carbonic Anhydrase Inhibitors. Dorzolamide (Trusopt) and brinzolamide (Azopt) are color-coded by orange caps and are sulfa-based medications. They are administered twice daily and decrease IOP by decreasing aqueous production. This class of medication has minimal systemic side effects. However, some patients complain about transient stinging and a bitter taste in the mouth after administration. These side effects, if tolerable, are not indications for discontinuing therapy.

Combined Topical Medications. Timolol and dorzolamide (Cosopt) and timolol and brimonidine (Combigan) are color-coded by blue caps. Brimonidine and brinzolamide (Simbrinza) is color-coded by a light green cap. Combined medications decrease exposure to preservatives and can decrease irritation and problems with dry eyes. Adherence might also be improved.

Oral Carbonic Anhydrase Inhibitors

Oral carbonic anhydrase inhibitors include acetazolamide (Diamox), 250 mg or 500 mg given twice daily, and methazolamide (Neptazane), 25 mg or 50 mg given twice daily. They are sulfa-based medications and decrease IOP by decreasing aqueous production. Oral carbonic anhydrase inhibitors are not commonly used today because effective topical medications are available. They are typically used on a short-term basis to achieve IOP control in acute or refractory cases. Side effects can include aplastic anemia, kidney stones, bitter taste, indigestion, paresthesia of the extremities, tinnitus, and polyuria. Clinicians need to consider the possibility of hypokalemia when patients take other diuretics to control blood pressure (Table 2). Acetazolamide may also be given intravenously.

Laser Trabeculoplasty

Argon or selective laser trabeculoplasty can be used to increase aqueous outflow. Laser trabeculoplasty is noninvasive and safe,

and it can be performed in the office in less than 10 minutes. Compared to surgery, IOP reduction is limited, up to 25% as primary treatment, but less as an adjunct modality. It is ineffective or less effective in some patients with light trabecular meshwork pigmentation. The effect of laser decreases over time but may be repeated in the case of selective laser trabeculoplasty.

Surgery

The most commonly performed glaucoma surgeries are trabeculectomy, tube shunt, and cyclodestruction. Trabeculectomy and tube shunt are procedures that create an opening in the sclera to increase aqueous outflow. Cyclodestruction destroys the ciliary body and decreases aqueous production. The procedure can be transscleral or endoscopic; the endoscopic method is typically done at the time of cataract surgery. Alternative surgical methods such as deep sclerectomy, Trabectome, canaloplasty, iStent and Cypass are performed at the time of cataract surgery to minimize the invasiveness and potential complications associated with traditional glaucoma surgery however these have lower efficacy.

Visual Impairment and Blindness

Patients who are visually impaired (Snellen vision of less than 20/40) or legally blind (Snellen vision of less than 20/200 or visual field of less than 20 degrees) may have significantly decreased mobility and ability to function. Continued glaucoma treatment is still important in these patients because even maintenance of count-finger vision can allow the patients some degree of independence. Low-vision devices and services, including high-contrast video magnifiers, audiobooks, eccentric viewers, and mobility training, can allow patients maximal use of their residual vision and improve their confidence and quality of life.

Acute Angle Closure Glaucoma

Pupillary block in susceptible patients blocks aqueous drainage and leads to sudden and extreme rise of intraocular pressure. Acute angle closure can damage the optic nerve, resulting in acute angle closure glaucoma.

About 0.5% to 1.0% of US adults is at risk for acute angle closure. It is more common in Inuits and Asians and rare in African Americans. The risk of acute angle closure increases with age. It is also more common in hyperopes (farsightedness).

Mechanism of Acute Angle Closure: Pupillary Block

After aqueous is produced in the ciliary body in the posterior chamber, it travels through the pupil and exits the anterior chamber through the trabecular meshwork located between the iris and the cornea. Pupillary block occurs when the iris comes in contact with the lens and obstructs the flow of aqueous through the pupil. Increased posterior chamber pressure displaces the iris anteriorly against the trabecular meshwork and stops aqueous outflow.

Patients at risk for acute angle closure have narrow occludable angles. These patients have smaller eyes, allowing the lens to contact the iris to initiate pupillary block. The distance between the iris and the lens is the shortest when the pupil is mid-dilated. Therefore patients who present with acute angle closure might have a history of dim light exposure (movies) or use of medications with anticholinergic properties (antihistamines, decongestants,

antispasmodics). High IOP causes iris and corneal endothelial cell dysfunction, resulting in nonreactive pupil and hazy cornea, respectively. High IOP also results in inflammation and red eye, as well as severe pain, nausea, and vomiting (Figure 2). Elevated IOP can damage the optic nerve within hours, and acute angle closure needs to be treated on an emergency basis to prevent permanent loss of vision.

Diagnosis

Patients with acute angle closure can present with blurry vision, red eye, pain, headache, nausea, or vomiting. History can include hyperopia, onset after exposure to a dim environment, or taking anticholinergic medications. Examination findings include decreased vision, conjunctival hyperemia, mid-dilated, nonreactive pupil with or without an afferent papillary defect, and increased IOP (by palpation or tonometry). Acute angle closure is sometimes misdiagnosed as migraines or gastrointestinal illness. Patients with conjunctivitis, keratitis, uveitis, and corneal abrasion can also present with the same symptoms.

Treatment

If acute angle closure is suspected, an emergent referral to ophthalmology is indicated. If an ophthalmologist is not immediately available, the goal will be to medically control the IOP as soon as possible. One drop of topical aqueous suppressant— β -blocker, selective α_2 agonist, or carbonic anhydrase inhibitor—should be administered (timolol, brimonidine, dorzolamide) (see Table 1). The maximum dose of oral or intravenous carbonic anhydrase inhibitor is given: acetazolamide 500 mg or methazolamide 50 mg (see Table 2). The patient is placed in the supine position to allow the lens and iris to fall posteriorly. The patient is reassessed in 30 minutes, and if the condition is not improved, topical drops are repeated. If there is no improvement after another 30 minutes, a hyperosmotic, oral glycerin¹ 1 g/kg or intravenous mannitol (Osmitol) 1 g/kg over 30 minutes, is administered. Hyperosmotics may be contraindicated in patients with congestive heart failure, and glycerin can cause severe hyperglycemia in diabetic patients.

An ophthalmologist can break the pupillary block by medically lowering the IOP or by performing anterior chamber paracentesis, compression gonioscopy, laser peripheral iridotomy, and, in recalcitrant cases, emergent trabeculectomy. Once the pressure is controlled, it is important to perform an iridotomy in both eyes to prevent future episodes. Patients with patent iridotomies may safely take anticholinergic medications.

MÉNIÈRE'S DISEASE

Method of

Terry D. Fife, MD

CURRENT DIAGNOSIS

- Ménière's disease is characterized by recurrent attacks of severe vertigo, nausea, and vomiting typically lasting 1 to 6 hours.
- Ménière's disease causes tinnitus on the side of the affected ear; the tinnitus can change in pitch and loudness during attacks of vertigo.
- Attacks of vertigo are associated with reduced or muffled hearing on the side of the affected ear.
- Fluctuating unilateral hearing loss and low-frequency hearing loss on the side of the affected ear is characteristic.

CURRENT THERAPY

- Initial therapy includes a sodium-restricted diet (preferably <1500 mg of sodium daily) and a diuretic agent (e.g., thiazide diuretics).
- Betahistine,¹ a medication widely used in Europe that may be obtained at compounding pharmacies in the United States, may be helpful in selected patients at a dosage 16 to 24 mg three times daily though some authors have recommended even higher dosages.
- Transtympanic infusion of gentamicin¹ or corticosteroids and endolymphatic sac surgery may be considered as minimally invasive options in patients with serviceable hearing. Gentamicin poses a moderate risk of inducing hearing loss.
- Vestibular nerve sectioning is highly effective in stopping vertigo attacks with a reasonably low risk of causing further hearing loss, but it is a more invasive procedure.
- Labyrinthectomy is highly effective in stopping vertigo attacks but causes complete hearing loss, so it is only an option for patients who have already lost all useful hearing.

Patients who have undergone procedures that cause acute loss of vestibular function often have vertigo for a while after the surgery; the vertigo improves more quickly with vestibular rehabilitative therapy.¹

Patients who have undergone procedures that cause acute loss of vestibular function often have vertigo for a while after the surgery; the vertigo improves more quickly with vestibular rehabilitative therapy.¹

¹Not FDA approved for this indication.

Ménière's disease is a disorder of the inner ear that results in recurrent, spontaneous episodes of vertigo, hearing loss, ear fullness, and

tinnitus affecting the same ear. The hearing loss often fluctuates early in Ménière's disease, but fluctuating hearing is not always present. Eventually permanent hearing loss occurs, affecting the low frequencies initially but ultimately affecting all frequencies.

Epidemiology

The reported prevalence of Ménière's disease varies from about 50 to 200 per 100,000. Females are somewhat more prone to Ménière's disease than males, with a female/male ratio of about 1.9:1.

Risk Factors

Possible risk factors for later development of Ménière's syndrome include autoimmune disorders, migraine, syphilitic otitis and viral infection of the inner ear, head trauma, and a family history of Ménière's disease.

Pathophysiology

The underlying mechanism is generally thought to be due to endolymphatic hydrops, a type of swelling of the endolymphatic compartment that ultimately leads to permanent damage of the inner ear structures. Possible reasons for this periodic swelling of the endolymph compartment include mechanical obstruction of endolymph flow or at least dysregulation of the electrochemical membrane potential between endolymph and perilymph compartments.

Endolymphatic hydrops appears to be the mechanism for a number of conditions that can lead to Ménière's syndrome. When no primary cause is identified, the idiopathic form of the syndrome is called Ménière's disease. When an underlying cause is found, it is referred to as Ménière's syndrome or secondary Ménière's or secondary endolymphatic hydrops. Secondary Ménière's syndrome can result from delayed endolymphatic hydrops in which symptoms come on years after a prior disorder or viral injury of the labyrinth, syphilitic otitis, autoimmune inner ear disease, and trauma.

Prevention

There is no known way of preventing the development of Ménière's disease because it occurs in many people with no risk factors.

Clinical Manifestations

Ménière's disease can manifest with periodic unilateral (or, less commonly, bilateral) hearing loss or isolated attacks of vertigo. Not uncommonly, Ménière's disease has both elements present at its onset, but the vertigo is usually the symptom that gets the

most attention. Vertigo usually lasts 1 to 6 hours but can last as little as 30 minutes or as long as all day. Patients prone to motion sickness often report that their dizziness lasts longer because the aftereffect of vertigo lingers longer in those who are motion sensitive. Vertigo attacks in Ménière's disease are often quite severe and generally render patients unable to move around owing to the vertigo, nausea, and recurrent vomiting.

The hearing loss is usually unilateral, and patients might notice fluctuation in hearing accompanied by ear fullness and a low-pitched roaring tinnitus either before or coincident with the vertigo. If audiometry can be performed during this time, low-frequency (250–1000 Hz) hearing loss may be documented and might improve after the attack ceases. This signature fluctuating low-frequency sensorineural hearing loss is very helpful (Figure 1) when found, but getting patients with vertigo attacks in for testing while they are in the acute stage of vertigo is usually not feasible.

Occasionally, patients with Ménière's have sudden random drop attacks in which they abruptly fall without loss of consciousness. These spells, referred to as otolithic crises of Tumarkin, can lead to serious injury and should prompt aggressive treatment. The mechanism is presumed to be related to sudden mechanical deformation or sudden neural discharges related to the otolith structures of the inner ear. Because there is no specific treatment for Tumarkin crises, treatment entails the standard treatments for Ménière's disease in general.

As Ménière's disease progresses, usually over months to years, permanent low-frequency hearing loss develops that gives way to hearing loss at all frequencies. Eventually, the patient can lose all or most hearing on the affected side. Meanwhile, with each vertigo attack, some vestibular function is lost, and so as vertigo attacks continue, vestibular loss ensues, often paralleling the hearing loss. Ménière's occasionally burns out, meaning that enough vestibular function has been lost that acute hydrops no longer produces vertigo. Patients might report less severe dizziness or just a vague feeling of unsteadiness. This usually indicates advanced Ménière's, and unilateral hearing and vestibular loss should be expected.

Bilateral Ménière's disease is present at the time of initial diagnosis in about 10% of cases and by 10 years of symptoms, about 35% have bilateral involvement. Bilateral Ménière's disease has treatment implications because treating one side alone will be unlikely to stop the vertigo attacks, which could be emanating from the untreated side. Surgical treatment of both sides is also problematic because it could leave the patient with bilateral hearing loss, vestibular loss, or both.

Figure 1 Audiogram showing typical low-frequency hearing trough of Ménière's disease affecting the right ear.

BOX 1 Diagnostic Criteria for Ménière's Disease**Definite Ménière's Disease**

- Two or more spontaneous (non-positional) episodes of vertigo, each lasting 20 minutes to 12 hours
- Audiometrically documented low- to medium-frequency sensorineural hearing loss in the affected ear on at least one occasion before, during, or after one of the episodes of vertigo.
- Fluctuating hearing, tinnitus or ear fullness in the affected ear.
- Not better accounted for by another vestibular diagnosis.

Probable Ménière's Disease

- Two or more episodes of vertigo or dizziness, each lasting 20 minutes to 24 hours
- Fluctuating hearing, tinnitus or ear fullness in the affected ear.
- Not better accounted for by another vestibular diagnosis.

(From Lopez-Escamez JA, et al. Diagnostic criteria for Ménière's disease. *J Vestib Res.* 2015;25(1):1–7.)

Diagnosis

The diagnosis of Ménière's disease is made clinically based on unilateral hearing loss, tinnitus, ear fullness, and episodic vertigo typically lasting 1 to 6 hours. The criteria for definite, probable, and possible Ménière's disease are listed in Box 1. Several recent studies using three-dimensional fluid-attenuated inversion recovery (3D-FLAIR) 24 hours after administration of bilateral intratympanic gadolinium (Gd) injection and similar techniques have demonstrated abnormalities consistent with endolymphatic hydrops. MRI at this point, however, is not yet established as useful in affirming the diagnosis of Ménière's disease.

Differential Diagnosis

Vestibular neuritis causes a single attack of vertigo, sometimes with acute hearing loss (labyrinthitis), but it can usually be distinguished from Ménière's disease because vestibular neuritis has a lifetime recurrence rate of only 2%, whereas Ménière's vertigo attacks recur multiple times and cause fluctuating and gradual decline in hearing.

When a patient reports episodic vertigo attacks in the absence of unilateral tinnitus, ear fullness, and hearing loss, one must be cautious in diagnosing Ménière's disease because vestibular migraine (basilar-type migraine) can produce a similar pattern. Diagnostic criteria have been published for vestibular migraine (Lempert, 2013).

Benign paroxysmal positional vertigo causes brief recurrent spells of spinning without hearing loss, so it is rarely confused with Ménière's disease.

Vertebrobasilar insufficiency can cause isolated vertigo, but the duration is usually only several minutes and without hearing loss, whereas Ménière's attacks last hours and are associated with unilateral auditory symptoms.

Acoustic neuroma (vestibular schwannoma) typically leads to slowly progressive unilateral sensorineural hearing loss, but vertigo is infrequently a prominent feature because patients compensate gradually as their vestibular function wanes due to compressive effects of the tumor.

Fluctuating unilateral hearing loss, ear fullness, and tinnitus can occur without vertigo and is referred to as cochlear hydrops. Such symptoms can precede the development of vertigo but may be treated as Ménière's nonetheless. Lermoyez's syndrome refers to transiently improved hearing and tinnitus during attacks of vertigo. More commonly, however, hearing declines around and during vertigo spells.

Treatment**Medical Management**

Treatment of Ménière's disease is mainly aimed at preventing the vertigo attacks, but no treatments are known that reliably restore or arrest hearing loss or tinnitus. It is presumed that if attacks of vertigo, ear fullness, fluctuating hearing, and tinnitus are all stopped, hearing should stabilize, but this is still a supposition.

The management of Ménière's is hierarchical, starting with a low-sodium diet and a diuretic and proceeding to more-invasive or destructive surgical procedures only when initial medical treatment fails. When a patient has very frequent vertigo attacks and is disabled, more-aggressive treatment may be considered sooner.

Dietary sodium should be restricted to 1000 to 1500 mg daily. The average person consumes about 4000 mg daily, and the maximum recommended daily intake of sodium is 2300 mg. Because more than 70% of the daily sodium comes from processed foods, this dietary restriction generally requires more than simply stopping the use of table salt, which generally accounts for only about 10% of daily sodium intake for most people.

A diuretic is usually added to the sodium restriction. The most commonly prescribed diuretic is hydrochlorothiazide 25 mg combined with triamterene 37.5 mg (Dyazide)¹ because this combination usually obviates the need for potassium supplementation. Acetazolamide (Diamox)¹ 125 to 250 mg bid or furosemide (Lasix)¹ 10 to 20 mg daily are also options. Patients with severe sulfa allergy can use low-dose ethacrynic acid (Edecrin)¹ 12.5 to 25 mg daily.

An acute attack of vertigo from Ménière's disease can be managed with vestibular suppressants such as dimenhydrinate (Dramamine)¹ 50 mg, meclizine (Antivert) 25 to 50 mg, diazepam (Valium)¹ 2 to 5 mg, or promethazine (Phenergen)¹ 12.5 to 50 mg. Scopolamine in patch form (Transderm-Scop)¹ is too slow to be useful because it takes hours to be absorbed transdermally. Scopace (oral scopolamine) has been discontinued and is no longer being manufactured in the United States. Scopolamine tablets¹ may be available in certain compounding pharmacies. Nausea can additionally be managed with prochlorperazine (Compazine) 10 mg orally or 25 mg by suppository, with oral or sublingual ondansetron (Zofran)¹ 4 to 8 mg, or with other antiemetics. Generally, the vertigo attacks subside in several hours even without treatment.

Betahistine (Serc)² may also be helpful in Ménière's, although it is not commonly used in the United States. The role of betahistine is not firmly established, although it is widely prescribed for vertigo throughout the world. Betahistine may be helpful when successful medical management with diet and diuretics has helped but is inadequate to stop attacks. Betahistine is a vasodilator, a modest H₁ histamine agonist, and a powerful H₃ histamine receptor antagonist. Its method of action in Ménière's is unknown, though it increases blood flow and might also influence endolymphatic fluid regulation and receptors in the endolymphatic sac. Doses of betahistine may start at 8 mg PO three times daily and may be increased to 32 mg three times daily. It is available outside the United States in the form of Serc[®] (Trade-mark of Abbott Products). Betahistine may be made within the United States at compounding pharmacies with a physician prescription¹ and may also be imported from outside the United States for individual use. Side effects are few, though occasionally patients report some headache. Betahistine is not histamine, and we have not found it to cause or aggravate urticaria.

Oral corticosteroids are often used but rarely seem effective except in cases of bilateral Ménière's resulting from autoimmune inner ear disease (AIED). Oral corticosteroids rarely seem to be effective in typical Ménière's disease.

Ménière's attacks have been said to be triggered by caffeine, chocolate, stress, visual stimuli, and dropping barometric pressure. Such triggers should be avoided when possible, but strong associations with these triggers can also occur in migrainous vertigo. Vestibular rehabilitative therapy is not generally helpful in Ménière's because most vertigo attacks remit and the patients have few vestibular symptoms between attacks. However, when vestibular loss has occurred and the patient appears to have not compensated well for it, vestibular rehabilitation can be helpful.

Bilateral Ménière's Disease

The estimated incidence of bilateral Ménière's disease varies in the literature but is estimated to occur in about 15% of cases and

¹Not FDA approved for this indication.

²Not available in the United States.

bilateral involvement increases over time. The possibility of bilateral involvement weighs on the decision making for any procedures that sacrifice hearing or vestibular function because it leaves the patient with only one functioning labyrinth.

Serviceability of Hearing

Serviceable hearing is residual hearing that can be useful to the patient by wearing hearing aids. In general, because hearing loss is permanent, one should avoid sacrificing any serviceable hearing.

Injections and Surgical Treatments

Patients who continue to have disabling vertigo despite a low-salt diet, diuretics, and possibly betahistine are considered to have failed conservative medical therapy. The next step in treatment depends on the age, health status, and residual hearing and vestibular function of the patient and also on the surgeon's opinion and experience with the various options. If spells are infrequent, symptomatic management of vertigo attacks may be the best option. Table 1 outlines some of the additional interventional options.

Intratympanic Gentamicin

Transtympanic gentamicin (Garamycin)¹ administration has become increasingly used as an effective treatment of Ménère's disease. This is partly due to the ease of administration of gentamicin and its relative safety. Gentamicin is a commonly used aminoglycoside antimicrobial agent with activity against gram-negative bacteria that also happens to be ototoxic. It damages hair cells of the labyrinth and preferentially affects hair cells of the vestibular neuroepithelium over that of the cochlea. Even so, transtympanic administration still has some risk of causing hearing loss. Gentamicin is administered by injecting a small amount (usually about 0.5 mL) of gentamicin sulfate (80 mg/2 mL) solution through the tympanic membrane into the middle ear space. To avoid rapid drainage through the eustachian tube, the injection is done with the patient supine and kept in that position for an hour or so to allow the gentamicin to absorb through the round window into the inner ear. There are many protocols, but commonly an injection is given once, and additional injections can be considered every 3 to 4 weeks until improvement in vertigo attacks is realized. Studies suggest that intratympanic gentamicin is an effective treatment for vertigo complaints in Ménère's disease but there is some risk of hearing loss.

¹Not FDA approved for this indication.

Endolymphatic Sac Surgery

Another option for patients with residual functional hearing is endolymphatic sac shunt or decompression. This procedure eliminates vertigo in 50% to 75% of those treated. Nevertheless, its effectiveness compared with placebo has remained a point of contention based on a number of studies. It has been suggested that the procedure's effectiveness depends on the operative technique and experience of the surgeon.

Intratympanic Steroids

Sometimes, a trial of intratympanic corticosteroids may be tried, although its effectiveness in controlled trials is still not compelling. Even so, a trial of corticosteroids administered in this manner poses little risk.

Vestibular Neurectomy

The most definitive procedure for stopping vertigo attacks in Ménère's when the goal is to preserve hearing is vestibular neurectomy. This procedure involves craniotomy and severing the vestibular nerve while preserving the cochlear nerve. This procedure requires overnight hospitalization and general anesthesia, and it does pose some risk to facial nerve function and hearing on the affected side.

Labyrinthectomy

For patients who have unilateral Ménère's disease and no serviceable hearing, labyrinthectomy is a commonly used procedure. This procedure entails the removal of the membranous labyrinth and is highly effective in stopping recurrent vertigo attacks from that ear. In elderly patients or those who are poor surgical candidates, a more limited transtympanic cochleosacculotomy may be performed.

Meniett Treatment

The Meniett device is a portable, low-frequency, pressure-wave delivery system that administers a wave of pressure of about 12 cm H₂O to the middle ear via a tympanostomy tube for about 0.6 seconds pulsed at 6 Hz for 5 minutes about three to five times daily. Quality randomized trials demonstrating the effectiveness of this treatment are few, and in at least one recent trial it was not better than patients treated medically. This method has few risks and only requires myringotomy and a pressure equalization tube. A practical limitation is the cost of the device, which is not often paid for by many health insurance companies.

TABLE 1 Procedures Used in the Management of Ménère's Disease

METHOD	TECHNIQUE	ADVANTAGES	DISADVANTAGES
Procedures Intended to Spare Serviceable Hearing			
Meniett device	Applies repetitive low-pressure pulses of air with the aim of enhancing endolymph drainage	Minimally invasive; no significant side effects and no risk of hearing loss	Requires tympanostomy tube placement; usually not covered by insurance; rate of effectiveness still unclear
Intratympanic corticosteroids	Injection of steroid through the tympanic membrane to the middle ear to be absorbed in the inner ear	Minimally invasive, few side effects	Effectiveness unclear when compared to placebo
Intratympanic gentamicin (Garamycin) ¹	Injection of gentamicin through the tympanic membrane to the middle ear to be absorbed in the inner ear	Simple office-based procedure, low risk profile	Number of injections is unpredictable; some risk of hearing loss
Endolymphatic mastoid shunt	Placing a shunt from the endolymphatic sac to the mastoid air cells	Effective in 50%–75% of cases; low risk of hearing loss; day procedure	Vertigo can recur; effectiveness depends on surgical experience and technique
Vestibular neurectomy	Surgical sectioning of the vestibular part of cranial nerve VIII, sparing the auditory part of the nerve	Highly effective in eliminating vertigo attacks	Requires general anesthesia; risk of facial weakness, hearing loss
Procedures Expected to Eliminate Residual Hearing			
Labyrinthectomy or cochleosacculotomy	Several methods of removing all or part of the labyrinth	Highly effective in stopping vertigo attacks	Inevitable complete hearing loss

¹Not FDA approved for this indication.

Monitoring

Following patients with Ménière's disease should include monitoring of the frequency and severity of vertigo spells and the fluctuation in hearing, ear fullness, and tinnitus. Periodic audiometry is probably the most sensitive measure of stabilization of the condition. Vestibular testing may be considered when changes might alter the treatment strategy. Brain imaging is only helpful in excluding other disorders, but does not yet have a role in the management of Ménière's disease.

Complications

Known complications include the progression of unilateral and occasionally bilateral hearing and vestibular function. There may also be complications associated with some of the treatments as described earlier. Owing to the unpredictability of the vertigo attacks, many patients avoid certain activities and might even develop agoraphobic features because the attacks are so severe and disruptive. In most cases, these avoidance behaviors improve if Ménière's disease can be controlled.

Conclusion

The management of Ménière's disease is still part art and part science. Treatment options are many, but patients should be reassured that, in most cases, something can be offered to help improve their vertigo and quality of life.

incidence of about 10%. It affects both adults and children and is commonly known as "swimmer's ear."

Risk Factors

Increased moisture in the ear canal, often caused by swimming, hearing aids, or a humid environment, increases the risk of developing otitis externa. Trauma to the external canal (such as self-inflicted injury with a cotton swab) is also a risk factor. Genetic factors may play a role, and people with narrow external canals or absence of ear wax are at increased risk. Ear wax, which is acidic, is protective except when it causes total occlusion and a moist environment behind the occlusion.

Pathophysiology

Otitis externa is usually (98%) caused by bacteria: the most common culture results are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or polymicrobial. Fungi are an occasional cause. In most cases the infection is superficial, but infection can cause edema of the auditory canal and spread locally, causing cellulitis and even osteomyelitis.

Prevention

Topical acetic acid (VoSol),¹ topical corticosteroids, water exclusion (wearing ear plugs while swimming), and aural toilet have not been evaluated in clinical trials. However, people who have recurrent otitis externa should be advised that water in the ear canal increases risk of developing otitis externa. If they swim, ear plugs may be helpful in preventing water from entering the ear canal. After swimming, the canal can be dried with a hair dryer on the lowest setting. Also, acetic acid 2% (VoSol)¹ 2 to 5 drops could be applied after swimming to reacidify the ear canal.

Clinical Manifestations

The main symptom of acute otitis externa is pain. Mild cases can present with only itching or ear fullness. Often there is otorrhea and debris in the external canal, which can obscure the tympanic membrane and cause hearing loss. There can be preauricular lymphadenopathy. Fever, if present, may indicate local cellulitis.

Diagnosis

Acute otitis externa is diagnosed clinically. It presents with pain, itching or fullness in the ear, appearing within a period of 48 hours, with duration of less than 3 weeks. Tenderness of the tragus or movement of the pinna is a key symptom. Otorrhea and canal erythema and edema may be present but are not necessary for diagnosis (Figure 1). If possible, debris should be cleared from the canal to allow visualization of the tympanic membrane to assess if it is intact.

Granulation tissue at the bone-cartilage junction of the external canal (Figure 2), fever >39°C, and severe pain are signs of malignant otitis externa.

Differential Diagnosis

Though the diagnosis of otitis externa is usually clear-cut, a differential diagnosis should be considered when symptoms do not resolve with usual treatment or the symptoms are particularly severe (Table 1).

Treatment

Topical antibiotics (Table 2) with or without steroid are effective in treating otitis externa. Fluoroquinolones have not been shown to be clearly superior to other antibiotics. Topical 2% acetic acid (VoSol) is also effective, though significantly less effective when compared with antibiotic/steroid drops in terms of cure rate at 2 and 3 weeks (OR 0.29). Oral antibiotics are not helpful unless there are signs of local cellulitis, in which case an antibiotic effective against *Pseudomonas* and *Staphylococcus* should be chosen.

To improve the penetrance of antibiotic drops, cotton ear wicks are often used when there is significant canal edema, but there have been no randomized controlled trials comparing this with

¹Not FDA approved for this indication.

OTITIS EXTERNA

Method of

David Larrabee, MD, MPH

CURRENT DIAGNOSIS

- Ear pain or itching
- External ear tenderness
- Clear or purulent discharge (otorrhea) and debris in ear canal
- Possible ear canal edema

CURRENT THERAPY

- Topical antibiotic therapy, with or without topical corticosteroid
- Topical acetic acid (VoSol) less effective than topical antibiotics
- Oral antibiotics usually unnecessary
- Analgesic therapy

Epidemiology

Otitis externa is inflammation of the external auditory canal, usually caused by bacterial infection. It is a common problem in primary care, with an annual incidence of about 1% and lifetime

Monitoring

Following patients with Ménière's disease should include monitoring of the frequency and severity of vertigo spells and the fluctuation in hearing, ear fullness, and tinnitus. Periodic audiometry is probably the most sensitive measure of stabilization of the condition. Vestibular testing may be considered when changes might alter the treatment strategy. Figure 2 Necrotizing otitis with granulation tissue at junction.

antibiotic drops without ear wicks. Aural toilet by suctioning is recommended by specialists, but this option is often not available in primary care, and there have been no randomized controlled trials showing efficacy. If debris needs to be removed and suction is unavailable, gentle use of cotton-tipped swabs, ear cerumen curette or ear cerumen spoon is safer than irrigation, which is dangerous if the tympanic membrane is ruptured. If the tympanic membrane is perforated or cannot be visualized, topical ofloxacin (Floxin Otic) and ciprofloxacin/dexamethasone (Ciprodex, but not Cipro HC) are nonototoxic and FDA approved for treatment.

Ciprofloxacin (Ciloxan), tobramycin (Tobrex) or gentamicin (Garamycin) ophthalmic drops are sometimes used off-label to treat otitis externa.

TABLE 1 Differential Diagnosis of Otitis Externa

Otitis media with perforated tympanic membrane

Ramsey-Hunt syndrome (otic herpes zoster)
Cellulitis

TABLE 2 Topical Antibiotics

MEDICATION	DOSING AND FREQUENCY	NOTES
Ofloxacin 0.3% solution (Floxin Otic)	10 drops in ear 1 × /day × 7 days	Approved for cases of perforated tympanic membrane
Ciprofloxacin/dexamethasone (Ciprodex)	4 drops bid × 7 days	Ciprodex approved for cases of perforated tympanic membrane
Ciprofloxacin/hydrocortisone (Cipro HC)		
Neomycin/polymyxin B/hydrocortisone (Cortisporin Otic)	4 drops tid/qid × 7 days	Neomycin can cause hypersensitivity reaction
Acetic acid 2% (Vosol Otic)	5 drops tid/qid × 7–14 days	Less effective; can cause stinging when applied
Clotrimazole 1% otic ⁶	4 drops qid × 7 days	When a fungal cause is suspected

⁶May be compounded by pharmacists.

Pain can usually be controlled with nonsteroidal anti-inflammatory drugs or acetaminophen. Opioids can be considered when pain is severe.

Monitoring

Symptoms should improve significantly within the first 24 hours of treatment. The average time to complete resolution of symptoms is 6 days. If a patient is not improving by 48 to 72 hours, he or she should be reassessed and possibly referred to an otolaryngology specialist. Patients at high risk for complications include those with diabetes, immunocompromised patients (such as in HIV), and the elderly.

Complications

Hypersensitivity reactions to otic antibiotics are possible, with neomycin being the most common agent. There will be pruritus and erythema, which can spread from the canal to the external ear. The causative antibiotic should be stopped and a preparation with another topic antibiotic and topical steroid should be used.

The most serious complication is malignant otitis externa, which is an extension of bacterial infection into local tissues and the mastoid or temporal bones, and can be life-threatening. It should be considered if there is fever (>39°C), disproportionate pain, and facial or other cranial nerve palsies. The causative organisms are similar to acute otitis externa (*P. aeruginosa* and *S. aureus* are most common). It occurs mostly in immunocompromised individuals,

such as those with diabetes or HIV, or who are undergoing chemotherapy. Patients should be given parenteral antibiotics and managed in a hospital with ENT consultation. Culture with sensitivity and CT scanning are usually necessary for accurate diagnosis and management.

OTITIS MEDIA

Method of

Gretchen M. Irwin, MD, MBA

CURRENT DIAGNOSIS

- History of acute onset of symptoms
- Middle ear effusion
 - Bulging tympanic membrane
 - Limited mobility of tympanic membrane or air fluid level visible behind tympanic membrane
- Middle ear inflammation
 - Erythema of tympanic membrane or distinct otalgia

CURRENT THERAPY

- Watchful Waiting—appropriate for children:
 - i. Greater than 2 years of age with nonsevere illness
 - ii. Greater than 6 months of age with uncertain diagnosis and nonsevere illness
 - iii. Greater than 2 years of age with severe illness, but uncertain diagnosis
- Need close follow-up in 48 hours
- Consider delayed prescription
- Antibiotics
 - First line should be amoxicillin (Amoxil) 80 to 90 mg/kg/day³
 - Treat 10 days if child less than 6 years of age, 5 to 7 days if greater than 6 years of age
 - Follow-up if not improving in 48 hours
- Analgesia
 - Acetaminophen (Tylenol), ibuprofen (Motrin, Advil)
 - Benzocaine in combination with antipyrine (Allergen, Auroguard), benzocaine with antipyrine and acetic acid (Auralgan)
- Antihistamines and decongestants are of no benefit
- Surgery—consider tympanostomy tubes when:
 - i. First AOM episode at less than 6 months of age and child with 2 or more episodes in 6 months or 3 in 24 months
 - ii. First AOM episode at more than 12 months of age and child with 3 episodes in 6 months, 5 episodes in 12 months or 7 episodes in 24 months

³Exceeds dosage recommended by the manufacturer.

Epidemiology

Acute otitis media (AOM) is a common condition of childhood, with one in four children having at least one episode of AOM by age 10. In fact, 86% of children will have at least one episode of AOM within the first year of life. Younger children are more likely to be affected, with peak incidence noted between ages 6 and

20 months likely because of the relative immaturity of the immune system and eustachian tube function. On average, 5 billion dollars are spent per year on office visits, lost productivity, and diminished parental quality of life due to AOM infections. As a result, research has focused on effective strategies both to prevent episodes of AOM and also to efficiently treat episodes that do occur.

Risk Factors

Identifying children at risk for AOM has been an important strategy to attempt to limit instances of AOM. Unfortunately, many of the risk factors associated with AOM are not modifiable, including male sex, Native American ethnicity, presence of siblings within the home, and a family history of recurrent AOM. Additional risk factors include low socioeconomic status, premature birth, attendance at out-of-home daycare, lack of breastfeeding, and history of poor maternal health during pregnancy. Limited studies have suggested that interventions such as avoiding supine feeding or bottle propping, reducing pacifier use after the first 6 months of life, and eliminating passive tobacco exposure can help to reduce incidence; however, the evidence in which these interventions demonstrate clear impact is limited. Public health programs that encourage breastfeeding and optimal maternal health during pregnancy, as well as those focused on reducing tobacco use, have perhaps the best opportunity to impact AOM incidence rates.

Not only are these identified risk factors for any episode of AOM, but children with these characteristics are also more likely to have recurrent AOM. Although many children will be affected in their lifetimes, those with recurrent disease are most at risk of complications leading to morbidity or mortality. Other risk factors specifically for recurrent AOM include an early onset of first episode and low parental education.

Pathophysiology

AOM has classically been associated with three bacteria; namely, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*. Using data derived from middle-ear fluid analysis, *M catarrhalis* is responsible for only 3% to 20% of AOM, whereas *pneumoniae* and *H influenzae* are more common contributors at 25% to 50% and 15% to 30%, respectively.

The bacteria responsible for AOM become pathogenic in the setting of eustachian tube dysfunction. A relative obstruction of the eustachian tube develops most commonly secondary to secretions from an antecedent viral upper respiratory infection or allergies, but may result from neuromuscular conditions or abnormal anatomy. Such relative obstruction creates a negative pressure within the middle ear leading to serous effusion and secondary infection of this collection of interstitial fluid. Thus prevention of AOM is aimed at both reducing the presence of pathogenic bacteria and preventing upper respiratory infections that may create eustachian tube dysfunction.

Prevention

The successes of immunization programs in virtually eliminating childhood illnesses such as measles, polio, and varicella have led to great interest in the development of vaccines capable of eradicating the causative agents of AOM. Immunizations targeting the specific bacteria most commonly associated with AOM have had mixed success, however.

For example, although the serotypes contained in the 7-valent pneumococcal conjugate vaccine (PCV, Prevnar) are responsible for approximately 66% of pneumococcal-related AOM, only moderate effectiveness has been noted in reducing AOM incidence among vaccinated children. After the introduction of the 7-valent PCV into practice in February of 2000, AOM incidence decreased only 6% to 7% among vaccinated children. The 9-valent and 11-valent PCVs² have been shown to result in a risk reduction of *S pneumoniae* isolates in children with AOM of 17% and 34%, respectively. An increase in serotype 19A has been noted that is

²Not available in the United States.

such as those with diabetes or HIV, or who are undergoing chemotherapy. Patients should be given parenteral antibiotics and managed in a hospital with ENT consultation. Culture with sensitivity and CT scanning are usually necessary for accurate diagnosis and management.

20 months likely because of the relative immaturity of the immune system and eustachian tube function. On average, 5 billion dollars are spent per year on office visits, lost productivity, and diminished parental quality of life due to AOM infections. As a result, research has focused on effective strategies both to prevent episodes of AOM and also to efficiently treat episodes that do occur.

Risk Factors

Identifying children at risk for AOM has been an important strategy to attempt to limit instances of AOM. Unfortunately, many of the risk factors associated with AOM are not modifiable, including male sex, Native American ethnicity, presence of siblings within the home, and a family history of recurrent AOM. Additional risk factors include low socioeconomic status, premature birth, attendance at out-of-home daycare, lack of breastfeeding, and history of poor maternal health during pregnancy. Limited studies have suggested that interventions such as avoiding supine feeding or bottle propping, reducing pacifier use after the first 6 months of life, and eliminating passive tobacco exposure can help to reduce incidence; however, the evidence in which these interventions demonstrate clear impact is limited. Public health programs that encourage breastfeeding and optimal maternal health during pregnancy, as well as those focused on reducing tobacco use, have perhaps the best opportunity to impact AOM incidence rates.

Not only are these identified risk factors for any episode of AOM, but children with these characteristics are also more likely to have recurrent AOM. Although many children will be affected in their lifetimes, those with recurrent disease are most at risk of complications leading to morbidity or mortality. Other risk factors specifically for recurrent AOM include an early onset of first episode and low parental education.

Pathophysiology

AOM has classically been associated with three bacteria; namely, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*. Using data derived from middle-ear fluid analysis, *M catarrhalis* is responsible for only 3% to 20% of AOM, whereas *pneumoniae* and *H influenzae* are more common contributors at 25% to 50% and 15% to 30%, respectively.

The bacteria responsible for AOM become pathogenic in the setting of eustachian tube dysfunction. A relative obstruction of the eustachian tube develops most commonly secondary to secretions from an antecedent viral upper respiratory infection or allergies, but may result from neuromuscular conditions or abnormal anatomy. Such relative obstruction creates a negative pressure within the middle ear leading to serous effusion and secondary infection of this collection of interstitial fluid. Thus prevention of AOM is aimed at both reducing the presence of pathogenic bacteria and preventing upper respiratory infections that may create eustachian tube dysfunction.

Prevention

The successes of immunization programs in virtually eliminating childhood illnesses such as measles, polio, and varicella have led to great interest in the development of vaccines capable of eradicating the causative agents of AOM. Immunizations targeting the specific bacteria most commonly associated with AOM have had mixed success, however.

For example, although the serotypes contained in the 7-valent pneumococcal conjugate vaccine (PCV, Prevnar) are responsible for approximately 66% of pneumococcal-related AOM, only moderate effectiveness has been noted in reducing AOM incidence among vaccinated children. After the introduction of the 7-valent PCV into practice in February of 2000, AOM incidence decreased only 6% to 7% among vaccinated children. The 9-valent and 11-valent PCVs² have been shown to result in a risk reduction of *S pneumoniae* isolates in children with AOM of 17% and 34%, respectively. An increase in serotype 19A has been noted that is

²Not available in the United States.

not covered in the 7-, 9-, or 11-valent PCVs² but is included in the new 13-valent PCV (Prenar 13). The 13-valent PCV was incorporated into the recommended childhood immunization schedule in February 2010. The effect of this change on AOM rates will be interesting to observe.

Although the ability of the vaccine to prevent AOM episodes may be relatively small, recurrent disease has decreased 23% whereas the need for tympanostomy tubes has decreased nearly 25% in vaccinated children. Hence, the power of the vaccine may be in preventing recurrent disease requiring surgical intervention rather than in prevention of any AOM episodes.

Similar vaccines are in development for *H influenzae* and *M catarrhalis* as causative agents of AOM. The current *H influenzae* b vaccine, or Hib, has had little impact on AOM, because less than 5% of episodes are caused by the type b strain of *Haemophilus*. Instead non-typeable *H influenzae* is a much more common cause of AOM.

Although the vaccines targeting specific bacteria that have been shown to cause AOM have been successful, so too has the influenza vaccine been shown to impact the course of AOM. In several studies, children who received seasonal influenza vaccine (Fluzone) were found to have fewer episodes of AOM than unvaccinated children. Furthermore, those who did have an AOM episode were found to use fewer antibiotics and have shorter duration of middle-ear effusion compared with unvaccinated counterparts.

With evidence that reducing incidence of viral influenza may reduce the occurrence of secondary AOM, several other interventions aimed at reducing viral upper respiratory infection incidence have been studied for their impact on AOM rates. The use of zinc⁷ and propolis⁷ as agents to prevent viral upper respiratory infections, for instance, has been shown to have mixed benefit in reducing AOM in children. In multiple studies, zinc has been well tolerated with no contraindications to use identified. Zinc as a single agent has been shown to prevent AOM only when used in children under age 5 who are also malnourished. However, when combined with propolis, zinc was shown to be effective at reducing AOM episodes for children with a history of recurrent AOM. Of note, in several trials zinc did not reduce upper respiratory infection rates; rather, rates of secondary AOM alone were decreased. Although not necessarily effective as a preventive measure for all children, zinc and propolis may be an option for children with recurrent infection.

Similarly, probiotics⁷ added to infant formula have been shown to be beneficial for some children. Although breastfeeding as compared to formula supplementation has been shown to be most beneficial in preventing AOM, infant formulas supplemented with *Lactobacillus rhamnosus* GG and *Bifidobacterium lactis* Bb-12 (Enfamil Premium, Nestle Good Start) were shown to reduce incidence of AOM over the first 7 months and the first 1 year. Children who received placebo formula had an incidence of AOM of 50% in the first 7 months, whereas children who received the probiotic-supplemented formula had an incidence of only 22%.

Dietary supplementation to limit AOM is not limited to infant formulas, however. Xylitol⁷, a polyol sugar alcohol found in birch plants, plums, strawberries, and raspberries, has been demonstrated in several studies to be effective at preventing both dental caries and AOM, although its dosage forms make administration difficult. Xylitol is available as a chewing gum, which raises concern as a choking hazard in young children. Similarly, in its oral syrup form, xylitol must be administered five times daily to be effective. Studies of thrice-daily dosing have not been able to demonstrate the same preventive effect as dosing five times daily despite a consistent total daily dose of 10 grams per day. Furthermore, emerging evidence suggests that xylitol must be given daily to remain effective at reducing AOM episodes, because prophylaxis only during winter months or use only during upper respiratory tract infections is ineffective. Of note, children who have already received tympanostomy tubes receive no prevention benefit from xylitol administration. Research is ongoing to increase physician awareness of xylitol as a possible

prophylactic measure because current studies suggest less than one half of US physicians are aware of xylitol and less than one fourth discuss or recommend its use to patients.

Echinacea⁷ and osteopathic manipulation have also been cited as potential prophylactic treatments, particularly for children at high risk of recurrence. However, little evidence exists that either are effective. In fact, one large study demonstrated an increased risk of AOM with Echinacea use during an upper respiratory tract infection episode and no benefit to manipulation treatment. Ongoing studies are examining the use of these modalities.

Clinical Manifestations

AOM presents with a rapid onset of symptoms that may include fever, chills, ear pain, or ear pulling. In fact, ear pulling and ear rubbing have been demonstrated to be quite sensitive for the diagnosis of AOM in the setting of a history consistent with AOM and middle ear effusion. Often, symptoms may be preceded by upper respiratory symptoms such as rhinorrhea, cough, or congestion. Children who have had tympanostomy tubes placed will likely have a far different presentation, with fever and pain being quite unlikely; rather, a thin, yellow or milky discharge may be the only sign that AOM is present.

Diagnosis

The 2013 update of the guidelines of the American Academy of Pediatrics for the diagnosis and treatment of AOM acknowledged that no gold standard exists for the clinical diagnosis of AOM. History and physical examination should be consistent with rapid onset of inflammation in the middle ear. Both pneumatic otoscopy and tympanometry may be useful in the diagnosis of AOM. Tympanic membranes should be evaluated for position, mobility, color, and degree of translucency using pneumatic otoscopy to assess for presence of middle ear effusion or inflammation. Moderate to severe bulging of the tympanic membrane, new onset of otorrhea without other cause, or mild bulging of the tympanic membrane with intense erythema or ear pain should prompt diagnosis of AOM. Furthermore, tympanometry may be useful in determining whether an effusion is present if the diagnosis is otherwise unclear.

One concern of physicians has been accurately diagnosing middle ear inflammation after a child has been vigorously crying. A study of 125 healthy children, age less than 30 months, assessed the impact of crying on tympanic membrane color by performing otoscopy both before and after administering at least two immunizations. While crying can cause a pinkening of the tympanic membrane, it should disappear when the child quiets and should be less intense than what is observed with inflammation. True middle ear inflammation results in an angry, red eardrum, not the milder, pink flush seen with vigorous crying. The presence of effusion should also help to support a diagnosis of inflammation.

Differential Diagnosis

Otitis media with effusion is often misdiagnosed as an episode of AOM. Like AOM, OME is common, with 2.2 million episodes annually representing an estimated cost of 4 billion dollars. OME can also occur with a viral upper respiratory infection and may follow or precede an episode of AOM. OME differs from AOM, however, because fluid may be present in the middle ear with OME, but there are no signs of acute infection.

Although OME is not associated with acute infection, it is nonetheless critical to diagnose, because research has demonstrated that chronic OME is associated with hearing loss and subsequent developmental delay. In fact, OME in infancy has been shown to be associated with, on average, a 7-point reduction in IQ at age 7.

The cornerstone of treatment for OME is observation for 2 to 3 months to allow the effusion to clear. Avoidance of allergens and tobacco exposure that may worsen eustachian tube dysfunction is also important. Decongestants and antihistamines are not effective. If an effusion does not clear within 2 months, a single course of amoxicillin (Amoxil) or penicillin may be given.

²Not available in the United States.

⁷Available as a dietary supplement.

⁷Available as a dietary supplement.

Audiometry should be performed in all children with OME for longer than 3 months or, in the setting of language delay, learning problems or suspected hearing loss in a child with OME. If the effusion persists, or if a child has multiple episodes of OME or has hearing or learning difficulties as a result of OME, surgical intervention should be considered.

Initial surgical intervention for children with persistent OME should be myringotomy with placement of tympanostomy tubes. Tonsillectomy and myringotomy alone are not indicated for treatment of OME. However, adenoidectomy may have a role, particularly in children ages 4 to 8 years. Current recommendations include adenoidectomy only if repeat surgery for OME is needed. However, emerging evidence suggests adenoidectomy may decrease the need for surgical retreatment, reduce ongoing hearing loss, and be of benefit during initial surgery for older children.

Treatment

The treatment of AOM has been controversial in recent years. Because it is the most common childhood bacterial infection for which antibiotics are prescribed worldwide, debate continues about both the most effective regimen and appropriate time to treat AOM. On average, 2.8 billion dollars are spent per year on antibiotics for episodes of AOM, yet emerging evidence suggests that watchful waiting is appropriate for some children. Judicious use of antibiotic therapy remains key in the prevention of morbidity and mortality associated with otitis media but is not an appropriate therapy for every child. All children require analgesia of some type, as well as close, scheduled follow-up, but use of observation or antibiotic varies with severity of illness and age of the child. Treatment options are summarized in Table 1.

Treatment Options: Observation

For some children with AOM, observation has been shown to be an appropriate therapy that avoids the possible side effects of antibiotics, with low risk of complications developing from an untreated otitis media. Evidence suggests that 78% of AOM episodes will spontaneously resolve within the first few days of infection. In fact, for every 100 otherwise healthy at-risk children with AOM, 80 will improve within 3 days without antibiotic therapy. If the same 100 children were all treated with amoxicillin or ampicillin, 92 would improve, although 3 to 10 would develop a rash and 5 to 10 would develop diarrhea. Thus, in a typical family medicine practice, 16 children with AOM would need to be treated with antibiotics to prevent 1 child from experiencing ongoing otalgia, whereas 1 of every 24 children treated will experience harm related to therapy. Hence, the use of antibiotics is not without risk. Multiple studies have demonstrated that even in children as young as 2 months of age, many will improve without antibiotic therapy, and delaying antibiotics may prevent undesirable side effects without exposing the child to undue risk. No studies have demonstrated a resurgence of either mastoiditis or meningitis with implementation of watchful waiting for AOM.

If observation is chosen as a management strategy for AOM, it is important to re-evaluate the child in 48 to 72 hours to ensure that they are improving and that a rescue antibiotic is prescribed if symptoms are not resolving. Delayed prescriptions are one strategy that has been effective at reducing antibiotic use, maintaining parental satisfaction, and improving healthcare efficiency.

Physicians are often concerned that parental satisfaction will decrease if watchful waiting for an episode of AOM is recommended. Interestingly, satisfaction has been tied to the receipt of an antibiotic prescription, though not necessarily the administration of antibiotics to the child. Declines in satisfaction are noted when parents are advised to return to care in 2 to 3 days if the child is not improving while undergoing watchful waiting. By offering a delayed prescription, the parent can avoid the difficulties associated with needing to be re-seen if the child fails to improve, and parental satisfaction is maintained even if the child never receives any medication. Parents should be educated that up to one third of children who initially are treated with observation will eventually need antibiotic therapy. Although this suggests up to two thirds of children can avoid unnecessary antibiotics, parents should be aware that many children will go on to need antibiotic therapy. Clearly, however, not every child is a candidate for observation therapy.

Treatment Options: Antibiotic Therapy

Antibiotic therapy may be associated with less duration of pain, less analgesic use, and less absence for both children and parents from school and work, respectively. The American Academy of Pediatrics and the American Academy of Family Physicians in a joint position statement have recommended that, when a decision is made to use antibiotics, amoxicillin (Amoxil) be given as a first-line agent at a dose of 80 to 90 mg/kg/day.³ For penicillin-allergic children, cefdinir (Omnicef), cefpodoxime (Vantin), or cefuroxime (Ceftin) may be used. Although the cross-reactivity of cephalosporins and penicillins is likely lower than previously believed, if concern exists about treating a child with a cephalosporin, clindamycin (30–40mg/kg/day) may be used. Macrolide antibiotics may have limited efficacy. Ceftriaxone (Rocephin) may be used as a single dose for a child unable to tolerate oral medications.

Although amoxicillin continues to be the preferred first-line agent, 30% to 70% of *S pneumoniae* strains have become penicillin and macrolide resistant whereas 20% to 40% of *H influenzae* has beta-lactamase-producing capabilities. Given the various resistance patterns of organisms, a child who fails to improve on amoxicillin should receive amoxicillin with clavulanate (Augmentin) or ceftriaxone as second-line therapy. Clindamycin (Cleocin) or tympanocentesis to identify a causative organism may also be considered.

Current evidence continues to suggest that a 10-day course is optimal for children younger than age 2 years. Less benefit to longer-duration therapy is noted in older children, and therefore a shorter 5- to 7-day course is recommended for those older than 2 years.

If a child has a perforation of the tympanic membrane, treatment considerations may be slightly different. Oral antibiotics continue to be recommended if perforation is a result of the AOM episode; however, if a child has an episode of AOM with tympanostomy tubes in place, topical 0.3% ciprofloxacin/0.1% dexamethasone (Ciprodex Otic) should be added to oral amoxicillin. See Table 2 for antibiotic dosing recommendations.

³Exceeds dosage recommended by the manufacturer.

TABLE 1 Treatment Options for Acute Otitis Media

AGE OF CHILD	AOM WITH OTORRHEA		AOM WITHOUT OTORRHEA		AOM WITH SEVERE SYMPTOMS*	
	UNILATERAL	BILATERAL	UNILATERAL	BILATERAL	UNILATERAL	BILATERAL
6 months to 2 years	Antibiotics	Antibiotics	Antibiotics or observation	Antibiotics	Antibiotics	Antibiotics
>2 years	Antibiotics	Antibiotics	Antibiotics or observation	Antibiotics or observation	Antibiotics	Antibiotics

*Severe symptoms include toxic-appearing child, persistent otalgia for >48 hours, temperature >39°C in past 48 hours, or uncertain access to follow-up.

TABLE 2 Antibiotic Selection for Specific Patient Populations

	ANTIBIOTIC OF CHOICE	DOSE (mg/kg/day)	ROUTE	DURATION OF THERAPY
AOM in child older than 2 years	Amoxicillin (Amoxil)	80–90 ³	PO	5–7 days
AOM in child younger than 2 years	Amoxicillin	80–90 ³	PO	10 days
AOM in child with allergy to penicillin	Cefdinir (Omnicef)	14	PO	10 days
	Cefpodoxime (Vantin)	10	PO	5 days
	Cefuroxime (Ceftin)	30	PO	10 days
AOM with inability to tolerate oral medications	Ceftriaxone (Rocephin)	50	IV/IM	1 day
AOM with amoxicillin failure	Amoxicillin with clavulanate (Augmentin)	90 of amoxicillin and 6.4 of clavulanate ³	PO	10 days
	Ceftriaxone (Rocephin)	50	IV/IM	3 days ³
AOM with amoxicillin/clavulanate failure	Ceftriaxone (Rocephin)	50	IV/IM	3 days ³
AOM with ceftriaxone failure and tympanocentesis not available	Clindamycin (Cleocin) ¹	30–40 ³	PO	10 days
Perforated tympanic membrane	Amoxicillin	80–90 ³	PO	10 days
Tympanostomy tube in place	Amoxicillin and topical 0.3% ciprofloxacin/ 0.1% dexamethasone (Ciprodex Otic)	80–90	PO	10 days
		8 drops	Topical bid	7 days

¹Not FDA approved for this indication.³Exceeds dosage recommended by the manufacturer.

Abbreviation: AOM = acute otitis media.

Regardless of the decision to implement watchful waiting or antibiotic therapy, any child with AOM should be expected to improve within 48 to 72 hours. If improvement is not occurring, the child should be re-evaluated.

Treatment Options: Surgery

For some children, AOM will not be an isolated event. Instead, they will have recurrent infections and require multiple antibiotic courses throughout a year, prompting consideration of tympanostomy tube placement. Currently, referral for evaluation for tympanostomy tubes is recommended when a child has had three or more episodes of AOM within a 6-month period or more than four episodes within a 12-month period. Some have argued, however, that this recommendation should be considered within the context of the child's age at first presentation. A child who has the first episode of AOM before 6 months of age is likely to go on to have many more episodes. Ultimately, they will likely meet the criteria for myringotomy and thus may warrant a more aggressive approach from the outset. Conversely, a child who presents with a first episode of AOM as an older child is less likely to have recurrent episodes and can therefore be treated in a more conservative manner.

Using an age-stratified approach, children who experience a first episode of AOM prior to 6 months of age should receive tympanostomy tubes if they have two episodes in a 6- or 12-month time period or three episodes in 24 months. Similarly, children who have a first episode of AOM after 1 year of age should receive tympanostomy tubes only if they have three episodes within 6 months, five within 12 months, or seven within 24 months.

Referral may also occur if a child has a history of AOM associated with meningitis, facial nerve paralysis, coalescent mastoiditis, or brain abscess. Tympanostomy tubes are also often placed due to prolonged OME resulting in hearing loss and language delay. Myringotomy without tube placement may be considered for either diagnosis of an infection that has not responded to numerous antibiotics or for relief of severe otalgia.

AOM episodes will continue to occur despite tympanostomy tube placement. However, episodes will likely be less severe, of shorter duration, and less frequent. In addition to ongoing AOM

episodes, tympanostomy tubes can be problematic if they become clogged. New studies in animal models suggest that applying colchicine¹ in the external ear may prevent this complication.

Treatment Options: Analgesia

Regardless of a decision to pursue watchful waiting or antibiotics, analgesics are an important component in the treatment of AOM. Multiple homeopathic interventions and home remedies including application of heat, ice, or mineral oil (Min-O-Ear)¹ have been used for pain control, although no studies exist to verify their effectiveness. Acetaminophen (Tylenol), ibuprofen (Motrin), narcotics, and tympanostomy have all been demonstrated to be effective at reducing pain. However, the side effects of altered mental status, gastrointestinal upset, and respiratory depression with narcotics, as well as the skill needed to perform tympanostomy, limit the usefulness of these interventions in primary care practice. Topical medications may help avoid the systemic effects of oral medication. Antipyrine and benzocaine are the only topical analgesics available in the United States. Topical benzocaine has been demonstrated to have minimal side effects and in patients older than 5 years of age may offer more relief than acetaminophen alone. Benzocaine is available in combination with antipyrine (Allergen Ear Drops, Auroguard Otic). Benzocaine is also available with antipyrine and acetic acid (Auralgan) but may be expensive. In other countries, antipyrine, also known as phenazone, is available in combination with procaine and is effective.

Antihistamines have often been prescribed, as have decongestants, in an attempt to reduce the fluid volume in the middle ear and hence provide relief. Unfortunately, use of antihistamines and decongestants has been shown to result in a fivefold to eightfold increase in the risk of side effects with no benefits, including no decreased time to cure, no prevention of surgery or complications, and no increased symptom resolution. Therefore antihistamines and decongestants have not been routinely recommended.

¹Not FDA approved for this indication.

Conclusion

AOM continues to be one of the most costly and common childhood illnesses in developed nations throughout the world. Successful management of this condition requires much more than choosing amoxicillin at an appropriate dose and duration or appropriately timing a surgical referral. Vigilant attention to modifying risk factors when possible, promoting immunization, and limiting the spread of viral illnesses has been shown to prevent AOM instances. Furthermore, adherence to diagnostic criteria to attempt to accurately distinguish between AOM and OME, as well as implementing observation when appropriate, can significantly reduce antibiotic usage, thereby minimizing side effects for patients and opportunity to develop resistance in pathogens.

RED EYE

Method of

John N. Dorsch, MD

CURRENT DIAGNOSIS

- Patients with traumatic injury to the eye, loss of vision, extreme pain not explained by pathology, keratitis, suspected uveitis or glaucoma, chemical injury, or nonhealing corneal abrasion should be referred to an ophthalmologist.
- Bacterial, viral, and allergic conjunctivitis can often be distinguished by the type of ocular discharge present.
- Subconjunctival hemorrhage can occur from trauma, from increased intrathoracic pressure, from anticoagulants, or idiopathically.

CURRENT THERAPY

- Do not use eye patches in patients with corneal abrasions.
- Do not use topical anesthetics for the eye outside a clinic or hospital setting, because corneal toxicity can occur.
- Patients with corneal abrasions should be reexamined the following day.
- Patients with corneal abrasions from extended-wear contact lenses often become colonized with *Pseudomonas aeruginosa* and should be treated with appropriate antibiotics (quinolones).

In the primary care office, the most common causes of red eye are conjunctivitis, subconjunctival hemorrhage, and foreign body causing corneal abrasions. Other common causes of red eye include blepharitis and hordeolum. Less common but serious causes of red eye include viral keratitis, uveitis, scleritis, and angle-closure glaucoma. Other usually less serious causes of red eye include episcleritis, pingueculum, and pterygium. All primary care physicians should have expertise in recognizing and treating the common causes of red eye and should recognize and refer patients with higher-stakes diagnoses (Boxes 1 and 2).

Physical Examination

Always check visual acuity in any patient with an eye complaint. Fluorescein strips (Flu-Glo, Fluorets), topical anesthetic drops, and cobalt blue light are used to examine the cornea for abrasions, keratitis, and ulceration. Cotton-tipped applicators are used to evert the upper eyelid and look for a foreign body.

Pupillary reaction is often affected by angle closure glaucoma and uveitis, but it is rarely affected by conjunctivitis, blepharitis, and corneal disorders. The pupil may be irregular in the patient with uveitis.

BOX 1

Approach to the Patient with Red Eye

The following questions are often helpful in making the diagnosis in patients with red eyes.

- *Is one eye or are both eyes involved?* Infections, allergy, and systemic illness are more likely to cause bilateral eye involvement.
- *Does the patient have intense eye pain?* If yes, likely diagnoses include acute angle closure glaucoma, uveitis, scleritis, keratitis, foreign body, or corneal abrasion.
- *Does the patient have a foreign body sensation?* If so, consider corneal abrasion, trauma, dry eye, keratitis, and other corneal disorders.
- *Is there a discharge?* If it is very copious and purulent, consider gonococcal conjunctivitis. If it is discolored and purulent, consider bacterial conjunctivitis. Copious watery discharge is typical of viral conjunctivitis. Stringy, mucoid discharge is typical of allergic or chlamydial conjunctivitis.
- *Do the eyes itch?* If so, consider blepharitis or allergy in the differential.
- *Are the eyelids swollen?* Consider allergy or infection.
- *Do the eyelids have lumps?* Hordeolum and chalazion should be considered.
- *Do the eyes burn?* Consider blepharitis or dry eye.
- *Is the eye redness recurrent?* Consider herpes keratitis, uveitis, and allergic conjunctivitis.
- *Does the patient have photophobia?* Corneal problems (abrasions, keratitis) and uveitis should be considered.
- *Is there loss of vision?* Consider corneal ulcer, uveitis, and angle closure glaucoma.
- *Is the patient using ocular medications?* Prolonged use of neomycin and sulfa ophthalmic medications can cause sensitization and redness of the eyes.

BOX 2

Red Eye

Common Causes

- Conjunctivitis: bacterial, viral, allergic
- Subconjunctival hemorrhage
- Corneal abrasion
- Blepharitis

Less Common Causes

- Episcleritis

- Pingueculum
- Pterygium

More Serious

- Viral keratitis
- Uveitis
- Scleritis
- Angle closure glaucoma

Patients with uveitis often have pain in the closed affected eye when a bright light is shined in the normal eye or with convergence of the eyes. This is due to consensual reflex of the pupils to light and accommodation.

The diagnosis of conjunctivitis is made by pulling the lower eyelid down with the examiner's finger. If the bulbar or palpebral conjunctivae are inflamed (i.e., hyperemic, edematous, discharge), conjunctivitis is present. Palpable preauricular nodes may be present with viral conjunctivitis and chlamydial conjunctivitis.

Conjunctivitis

Conjunctivitis is the most common cause of red eye encountered by primary care providers. Among the etiologies of conjunctivitis, viral conjunctivitis is the most common. Although patients with conjunctivitis might have some minor irritation of the eyes, they usually do not complain of pain in the eye or loss of vision. Ocular discharge is generally considered to be an important diagnostic feature of conjunctivitis (Table 1). Although much has been written

Conclusion

Patients with uveitis often have pain in the closed affected eye when a bright light is shined in the normal eye or with convergence of the eyes. This is due to consensual reflex of the pupils to light and accommodation.

The diagnosis of conjunctivitis is made by pulling the lower eyelid down with the examiner's finger. If the bulbar or palpebral conjunctivae are inflamed (i.e., hyperemic, edematous, discharge), conjunctivitis is present. Palpable preauricular nodes may be present with viral conjunctivitis and chlamydial conjunctivitis.

Conjunctivitis

Conjunctivitis is the most common cause of red eye encountered by primary care providers. Among the etiologies of conjunctivitis, viral conjunctivitis is the most common. Although patients with conjunctivitis might have some minor irritation of the eyes, they usually do not complain of pain in the eye or loss of vision. Ocular discharge is generally considered to be an important diagnostic feature of conjunctivitis (Table 1). Although much has been written

TABLE 1 Conjunctivitis

TYPE	COURSE	CHARACTERISTICS	DISCHARGE
Bacterial	Starts in one eye, often spreads to other eye		Purulent
Allergic	Accompanies allergic rhinitis	Itchy eyes	Mucus
Viral	Usually bilateral	Very red eyes	Watery

**Figure 1** Viral conjunctivitis. (Reproduced with permission from the University of Michigan Kellogg Eye Center, <http://www.kellogg.umich.edu>.)

about characterizing conjunctivitis by the nature of the discharge, one meta-analysis failed to find evidence of the diagnostic usefulness of clinical signs or symptoms in distinguishing bacterial conjunctivitis from viral conjunctivitis.

Viral Conjunctivitis

Viral conjunctivitis is often seen in epidemics and is most commonly caused by members of the Adenovirus family. Typically, viral conjunctivitis starts in one eye and spreads to the other eye a few days later. The conjunctivae appear red and swollen, with copious watery discharge (Figure 1). The natural course of viral conjunctivitis is self-limiting, lasting 10 to 14 days. Tender preauricular lymph nodes, when present, indicate the presence of viral or chlamydial conjunctivitis. Management should be directed at scrupulous hygiene. Patients must be informed that their infection is highly contagious. They should avoid close contact with other persons (e.g., towels, direct contact, swimming pools) for 2 weeks and wash hands frequently to prevent the spread of their infection. Topical antibiotics have been prescribed to try to prevent bacterial superinfection, but there is no good evidence that they have any significant impact. Symptomatic treatment with cold compresses and topical vasoconstrictors may be helpful. Conjunctivitis has very recently (end of 2015) been reported in patients with Zika virus.

Bacterial Conjunctivitis

Bacterial conjunctivitis typically starts abruptly in one eye and spreads to the other eye in 1 to 2 days. Usually a purulent discharge is present that persists throughout the day. A variety of gram-positive and gram-negative organisms cause bacterial conjunctivitis, but the most common causes are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus pneumoniae*. Treatment of bacterial conjunctivitis is usually empiric, but conjunctival scraping for smears and cultures should be done in infants, immunocompromised patients, and patients with hyperacute conjunctivitis in which *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection is suspected. Treatment of bacterial conjunctivitis (excluding gonococcal or chlamydial conjunctivitis) usually consists of a topical antibiotic used four times a day (Table 2). Topical antibiotics are usually prescribed for 5 to 7 days, and resolution of conjunctivitis is expected within that time.

Hyperacute bacterial conjunctivitis has an abrupt onset, copious purulent discharge, and rapid progression, and it is usually associated with gonococcal infection in a sexually active patient. Chemosis (edema of the conjunctivae) may be present.

TABLE 2 Topical Antibiotics Used to Treat Bacterial Conjunctivitis

DRUG	DOSAGE
Bacitracin (Ak-Tracin, Bacticin) ointment	Apply 0.5 inch in eye q3–4h
Ciprofloxacin (Ciloxan) 0.3% ophthalmic solution	1–2 gtt in eye q15min × 6h, then q30min × 18h, then q1h × 1 d, then q4h × 12 d ³
Gatifloxacin (Zymaxid) 0.5% ophthalmic solution	1 gtt in eye q2h up to 8 ×/day on Day1, then 1 gtt 2–4 ×/day on Day 2–7
Gentamicin (Gentak, Gentsol) 0.3% ophthalmic solution or ointment	Ointment: 0.5 inch applied to eye 2–3 times per day Solution: 1–2 gtt in eye q4h
Levofloxacin (Quixin) 0.5% ophthalmic solution	1–2 gtt in eye q2h × 2 d while awake, then q4h while awake × 5 d
Moxifloxacin (Vigamox) 0.5% ophthalmic solution	1 gt in eye tid × 7 d
Neomycin/polymyxin B/gramicidin (Neosporin) ophthalmic solution	1–2 gtt in eye q4h × 7–10 d
Ofloxacin (Ocuflox) 0.3% ophthalmic solution	1–2 gtt in eye q2–4h × 2 d, then 1–2 gtt in eye qid × 5 d
Polymyxin B and trimethoprim (Polytrim) ophthalmic solution	1 gt in eye q3h × 7–10 d
Sulfacetamide (Isopto Cetamide, Ocusulf-10, Sodium Sulamyd, Sulf-10, AK-Sulf) 10% ophthalmic solution, ointment	Ointment: 0.5-inch ribbon in eye q3–4h and qhs × 7 d Solution: 1–2 gtt in eye q2–3h × 7–10 d
Tobramycin (AK-Tob, Tobrex) 0.3% ophthalmic solution	1–2 gtt in eye q4h

³Exceeds dosage recommended by the manufacturer.

Chlamydial conjunctivitis is acquired through exposure to infected secretions from the genital tract, either direct or indirect. The infection is usually unilateral (at least initially), and often there is involvement of the preauricular node on the ipsilateral side. Gonococcal and chlamydial infections are treated systemically (Box 3).

Conjunctivitis of the Newborn

Chlamydial conjunctivitis is the most common cause of infectious conjunctivitis of the newborn in the United States. Onset of conjunctivitis is 3 to 10 days after birth, but it has been reported as late as 2 months after birth. *Chlamydia trachomatis* infection can also cause pneumonia, otitis media, proctitis, and vulvovaginitis in infants. Treatment consists of erythromycin (EryPed Drops) orally 50 mg/kg/day in four divided doses for 14 days. Erythromycin ointment (Ilotycin 0.5%) or tetracycline ointment² given shortly after delivery is effective in preventing chlamydial conjunctivitis but not systemic chlamydial infections.

²Not available in the United States.

BOX 3 Treatment of Chlamydial and Gonococcal Conjunctivitis

Chlamydial Conjunctivitis

- Erythromycin (Ery-Tab)¹ 250 mg PO qid × 14 d
- or
- Doxycycline (Vibramycin) 100 mg PO bid × 14 d
- Treat partners

Gonococcal Conjunctivitis

- Ceftriaxone (Rocephin 1 g IM)

¹Not FDA approved for this indication.

Gonococcal conjunctivitis of the newborn is a hyperacute infection that occurs 2 to 4 days after birth. It can cause corneal ulceration and loss of vision. Gonococcal conjunctivitis can be prevented with silver nitrate drops² or erythromycin (Ilotycin) or tetracycline ointment² administered shortly after delivery. Silver nitrate commonly causes a self-limited chemical conjunctivitis, which can delay visual bonding of the infant to the parents in the first few hours of life. Therapy of gonococcal conjunctivitis of the newborn consists of IV penicillin G¹ given four times a day for 7 days or ceftriaxone (Rocephin) IV or IM once a day for 7 days or gentamicin (Garamycin)¹ IM given twice a day for 7 days.

Conjunctivitis–Otitis Media Syndrome

Conjunctivitis–otitis media syndrome is a common condition in which children with otitis media also have purulent bilateral ocular discharge. It responds to treatment of otitis media; no topical treatment of conjunctivitis is required.

Methicillin-Resistant *Staphylococcus Aureus* Conjunctivitis

Increasing numbers of cases of bacterial conjunctivitis are caused by methicillin-resistant *S. aureus* (MRSA). MRSA conjunctivitis manifests as bacterial conjunctivitis resistant to conventional

¹Not FDA approved for this indication.

²Not available in the United States.

therapy and is treated with the same drugs used to treat MRSA in other parts of the body (Doxycycline [Vibramycin],¹ vancomycin [Vancocin], sulfamethoxazole-trimethoprim [Bactrim]¹). Cultures should be obtained when MRSA is suspected.

Allergic Conjunctivitis

Allergic conjunctivitis is an immunoglobulin E (IgE)-mediated condition characterized by bilateral eye involvement, itchy eyes, and mucoid discharge. *Seasonal* conjunctivitis is caused by exposure to common allergens (e.g., pollens, dander) and usually accompanies allergic rhinitis. *Perennial* allergic conjunctivitis is similar to seasonal allergic conjunctivitis, but the symptoms are usually less severe. Patients are usually treated with a systemic antihistamine. Ophthalmic (topical) medications include antihistamine or decongestants, mast cell inhibitors, nonsteroidal antiinflammatory drugs (NSAIDs), H₁-antagonists, and various combinations of these (Table 3). Milder cases can be treated with a decongestant-antihistamine combination for about 2 weeks. Moderate to more severe cases can require longer use of these medications or the addition of systemic antihistamines or mast cell inhibitors. Some patients require topical corticosteroids or cyclosporine (Restasis)¹ for severe allergic conjunctivitis, but these should be evaluated by an ophthalmologist because of potential complications of therapy.

Subconjunctival Hemorrhage

In subconjunctival hemorrhage, the redness of the eye is localized and sharply circumscribed, and the underlying sclera is not visible (Figure 2). Conjunctivitis is not present, and there is no discharge. There is typically no pain or visual change. Subconjunctival hemorrhage may be spontaneous, but it can also result from trauma, hypertension, bleeding disorders, or increased intrathoracic pressure (e.g., straining, coughing, retching). No treatment is necessary, but investigation may be warranted if the etiology is in question or the hemorrhage is recurrent. Referral to an ophthalmologist should be considered if the subconjunctival hemorrhage is from trauma or has not resolved within 2 to 3 weeks.

Corneal Abrasion

Corneal abrasions typically result from scratching of the corneal epithelium due to trauma, but they can also occur from

¹Not FDA approved for this indication.

TABLE 3 Topical Medications for Allergic Conjunctivitis

GENERIC NAME	BRAND NAME(S)	DOSING	MODE OF ACTION
Azelastine 0.05% solution	Optivar	1 gt in eye(s) bid	H ₁ -antagonist, mast cell inhibitor
Cromolyn 4% solution	Crolom, generic	1–2 gtt in eye(s) 4–6 times per day	Mast cell inhibitor
Emedastine 0.05% solution	Emadine	1 gt in eye(s) qid	H ₁ -antagonist
Epinastine 0.05% solution	Elestat	1 gt in eye(s) bid	H ₁ - and H ₂ -antagonist, mast cell inhibitor
Ketorolac 0.5% solution	Acular	1 gt in eye(s) qid up to 1 wk	NSAID
Diclofenac 0.1% solution ¹	Voltaren ophthalmic	1 gt in eye(s) qid × 2 wk	NSAID
Lodoxamide 0.1% solution	Alomide	1–2 gtt in eye(s) qid up to 3 mo	Mast cell inhibitor
Loteprednol 0.2% susp.	Alrex	1 gt in eye(s) qd	Corticosteroid
Naphazoline/pheniramine (solution)	Naphcon-A (OTC) Opcon-A (OTC) Visine-A (OTC)	1–2 gtt in eye(s) qd-qid prn	Antihistamine, decongestant
Nedrocomil 2% solution	Alocril	1–2 gtt in eye(s) bid	H ₁ -antagonist, mast cell inhibitor
Olopatadine 0.1% solution	Patanol	1 gt in eye(s) bid	H ₁ -antagonist, mast cell inhibitor
Olopatadine 0.2% solution	Pataday	1 gt in eye(s) qd	Mast cell inhibitor

¹Not FDA approved for this indication.

Abbreviation: NSAID = nonsteroidal antiinflammatory drug.

Figure 3 Corneal abrasion with fluorescein stain with cobalt blue light. (Reprinted with permission from American Academy of Ophthalmology: Managing the Red Eye. Eye Care Skills for the Primary Care Physician Series. San Francisco: American Academy of Ophthalmology, 2001.)

extended-wear contact lenses. Patients with corneal abrasions present with pain, excessive tearing from the involved eye, photophobia, a foreign-body sensation (like having sand in the eye), and blurry vision.

Corneal abrasions are identified by staining the cornea with fluorescein and examining under cobalt blue light (Figure 3). The eye should also be examined carefully to check for foreign bodies. Topical anesthetic is administered to make the patient comfortable during the examination, but continued use can cause corneal damage.

Management of corneal abrasions consists of pain relief and prevention of infection. Pain can be relieved with topical NSAIDs such as ketorolac (Acular)¹ and Diclofenac (Voltaren),¹ oral over-the-counter analgesics, and occasionally oral narcotics. Topical antibiotics are usually prescribed to prevent infection. Antibiotic ointments are lubricating and soothing to the eye, making them a good option for traumatic corneal abrasions. Topical ophthalmic antibiotic ointments commonly used are bacitracin (Bacticin), erythromycin (Ilotycin), and gentamicin (Gentak).

In patients who have corneal abrasions from contact lens overwear, eyes are commonly colonized with *Pseudomonas aeruginosa*.

¹Not FDA approved for this indication.

These patients should be treated with topical antibiotics such as ciprofloxacin (Ciloxan) or ofloxacin (Ocuflox) solutions.

Patching of the eye, though a common practice of the past, has not shown evidence of benefit in recent studies. It was found that eye patching can actually cause harm, so this practice is no longer recommended.

Infrequently, patients have traumatic uveitis accompanying corneal abrasion. Traumatic uveitis usually causes significantly more pain than a corneal abrasion, and, if uveitis is suspected, the patient should be evaluated by an ophthalmologist.

Patients with corneal abrasions should be reexamined in 24 hours. Corneal abrasions typically should be healed or greatly improved in 24 hours. If the abrasion is not completely healed after 24 hours, the patient should be examined again in 2 or 3 days. Referral should be considered if any worsening occurs or if the abrasion does not heal within 5 days. Corneal abrasions can be prevented by using protective eyewear.

Other Causes of Red Eye

Other causes of red eye are somewhat less common.

Blepharitis

Blepharitis are inflammatory conditions of the eyelid caused by infection or obstruction of eyelid glands (Table 4). Blepharitis may be accompanied by conjunctivitis. Staphylococcal blepharitis arises from the accessory glands to the eyelashes and causes discharge from the eyelid, often associated with erythema, induration, loss of eyelashes, and crusting of the eyelid (Figure 4). This is treated with hot, moist packs to the eyes, baby shampoo scrubs (3 oz. water and 3 drops baby shampoo used on a washcloth bid), and erythromycin ointment (Ilotycin) at bedtime. Seborrheic blepharitis, a more chronic form of blepharitis, arises from the meibomian glands and causes scaling of the eyelids (Figure 5). Seborrheic blepharitis is often associated with skin disorders such as rosacea, eczema, and seborrheic dermatitis. This is treated with hot, moist packs and baby shampoo scrubs. Resistant cases are treated with oral tetracycline (Sumycin) (or one of its derivatives).

Hordeolum (Stye)

A hordeolum is an acute, painful mass of the eyelid that is caused by inflammation of the glands (Figure 6). It does not usually cause the eye to become red as well. Warm compresses to the eyelid four times a day for 3 to 5 minutes typically causes resolution within 1 week. Because they arise from the same glands, hordeola and blepharitis commonly occur together.

Episcleritis

Episcleritis is a self-limited inflammation of the episcleral vessels and is believed to be autoimmune. It has a rapid onset and usually minimal discomfort. Redness is most often confined to a sector of the eye. Episcleritis usually resolves in 7 to 10 days. Recurrence is not uncommon. Oral NSAID drugs may be prescribed, but treatment is usually not necessary.

Scleritis

Scleritis is, fortunately, much less common than episcleritis. Patients with scleritis experience intense inflammation and deep eye pain. Scleritis is commonly associated with rheumatoid

TABLE 4 Blepharitis

TYPE	SITE OF ORIGIN	CLINICAL CHARACTERISTICS	TREATMENT
Staphylococcal	Accessory glands of eyelids	Erythema and induration of eyelid; crusting; discharge; loss of eyelashes	Warm compresses Baby shampoo scrubs Erythromycin ointment (Ilotycin)
Seborrheic	Meibomian glands	More chronic, scaling	Warm compresses Baby shampoo scrubs Oral tetracycline for resistant cases

Figure 5 Seborrheic blepharitis. (Reprinted with permission from American Academy of Ophthalmology: *Managing the Red Eye*. Eye Care Skills for the Primary Care Physician Series. San Francisco: American Academy of Ophthalmology, 2001.)

Figure 6 Hordeolum. (Reprinted with permission from American Academy of Ophthalmology: *Managing the Red Eye*. Eye Care Skills for the Primary Care Physician Series. San Francisco: American Academy of Ophthalmology, 2001.)

arthritis and inflammatory bowel disease. The patient should be promptly referred to an ophthalmologist if scleritis is suspected.

Acute Angle Closure Glaucoma

Acute angle closure glaucoma is characterized by acute ocular pain and is often accompanied by vomiting, blurred vision, acute photophobia, pupils unreactive to light, and circumcorneal redness (ciliary flush). Treatment of glaucoma with pilocarpine (Isopto Carpine), topical timolol (Timoptic), and acetazolamide (Diamox) should be started, and the patient should be given an urgent referral to an ophthalmologist.

Anterior Uveitis

Uveitis is the inflammation of the iris and ciliary muscle, often associated with autoimmune disease. Trauma can also cause uveitis. Signs of uveitis include ocular pain, ciliary flush, and occasionally irregularity of the pupil. Prompt referral should be arranged for a patient in whom uveitis is suspected.

In general, referral to an ophthalmologist should strongly be considered for:

- Traumatic injury to the eye
- Loss of vision
- Extreme eye pain not explained by pathology
- Keratitis
- Suspected uveitis or glaucoma
- Chemical injury (especially alkali)
- Corneal abrasion not healing

RHINOSINUSITIS

Method of

Ann M. Aring, MD

CURRENT DIAGNOSIS

- Because inflammation of the sinuses rarely occurs without concurrent inflammation of the nasal mucosa, rhinosinusitis is a more accurate term for what is commonly called sinusitis.
- Most cases of sinusitis are caused by viral infections associated with the common cold. Viral rhinosinusitis improves in 7 to 10 days.
- Four signs and symptoms with a high likelihood ratio for acute bacterial sinusitis are double sickening, purulent rhinorrhea, erythrocyte sedimentation rate (ESR) >10 mm, and purulent secretion in the nasal cavity. A combination of at least three of these four symptoms and signs has a specificity of 0.81 and sensitivity of 0.66 for acute bacterial rhinosinusitis.

Figure 4 Staphylococcal blepharitis. (Reprinted with permission from American Academy of Ophthalmology: *Managing the Red Eye*. Eye Care Skills for the Primary Care Physician Series. San Francisco: American Academy of Ophthalmology, 2001.)

Figure 5 Seborrheic blepharitis. (Reprinted with permission from American Academy of Ophthalmology: *Managing the Red Eye*. Eye Care Skills for the Primary Care Physician Series. San Francisco: American Academy of Ophthalmology, 2001.)

RHINOSINUSITIS

Method of

Ann M. Aring, MD

CURRENT DIAGNOSIS

- Because inflammation of the sinuses rarely occurs without concurrent inflammation of the nasal mucosa, rhinosinusitis is a more accurate term for what is commonly called sinusitis.
- Most cases of sinusitis are caused by viral infections associated with the common cold. Viral rhinosinusitis improves in 7 to 10 days.
- Four signs and symptoms with a high likelihood ratio for acute bacterial sinusitis are double sickening, purulent rhinorrhea, erythrocyte sedimentation rate (ESR) >10 mm, and purulent secretion in the nasal cavity. A combination of at least three of these four symptoms and signs has a specificity of 0.81 and sensitivity of 0.66 for acute bacterial rhinosinusitis.

- Acute rhinosinusitis lasts up to 4 weeks, subacute rhinosinusitis lasts from 4 to 12 weeks, and chronic rhinosinusitis lasts 12 weeks or longer. Recurrent acute rhinosinusitis is defined as four or more episodes per year with complete resolution between episodes.
- Radiographic imaging in a patient with acute rhinosinusitis is not recommended unless a complication or an alternative diagnosis is suspected. Computed tomography of the sinuses without contrast media is the imaging method of choice.

CURRENT THERAPY

- Mild rhinosinusitis symptoms of less than 7 days' duration can be managed with supportive care including analgesics, saline nasal irrigation, and intranasal corticosteroids.
- Antibiotic therapy is recommended for patients with sinusitis symptoms that do not improve within 7 to 10 days or that worsen at any time.
- First-line antibiotics include amoxicillin with or without clavulanate.
- Macrolides and trimethoprim sulfamethoxazole (Bactrim) are not recommended for empiric therapy owing to high rates of resistance among *Streptococcus pneumoniae* and *Haemophilus influenzae*.
- For adults allergic to penicillin, doxycycline may be used as an alternative regimen for initial empiric therapy for bacterial rhinosinusitis. According to a recent US Food and Drug Administration (FDA) safety alert, fluoroquinolones such as levofloxacin (Levaquin) and moxifloxacin (Avelox) should be reserved for patients who do not have other treatment options.
- In adults with confirmed acute rhinosinusitis, more than 70% will clinically improve after 2 weeks with or without antibiotic therapy.
- Antibiotic use increases the absolute cure rate by 5% compared with placebo at 7 to 15 days.

Epidemiology of Acute Rhinosinusitis and Predisposing Factors

Each year in the United States, rhinosinusitis affects one in seven adults and is diagnosed in 31 million patients. Rhinosinusitis is the fifth most common diagnosis for which antibiotics are prescribed. Rhinosinusitis has a higher frequency in the winter months and lower frequency in the summer and autumn months.

Predisposing Factors

Predisposing factors for acute rhinosinusitis include viral upper respiratory infections and allergic rhinitis. Anatomic malformations including polyps, deviated nasal septum, foreign bodies, and tumors can also predispose to acute rhinosinusitis.

Pathogenesis and Etiology of Rhinosinusitis

Most cases of acute rhinosinusitis are caused by viral infections associated with the common cold. The most common viruses in acute viral rhinosinusitis are rhinovirus, adenovirus, influenza virus, and parainfluenza virus. Mucosal edema occurs with the viral infection with subsequent obstruction of the sinus ostia. In addition, viral and bacterial infections impair the cilia, which help transport the mucus. The ostia obstruction and slowed mucus transport cause stagnation of secretions and lowered oxygen tension within the sinuses. This environment is an excellent culture medium for both viruses and bacteria and the infectious particles grow rapidly. The body responds with an inflammatory reaction. Polymorphonuclear leukocytes are mobilized, which results in pus formation. The most common bacteria found in acute community-acquired bacterial rhinosinusitis are *S pneumoniae*, *H influenzae*, *Staphylococcus aureus*, and *Moraxella catarrhalis*. Acute adult rhinosinusitis most commonly involves the maxillary and ethmoid sinuses. More than one of the paranasal sinuses can be affected.

Diagnosis of Acute Rhinosinusitis

Diagnosis of acute bacterial rhinosinusitis requires that symptoms persist for longer than 10 days or worsen after 5 to 7 days. Four signs and symptoms with a high likelihood ratio for acute bacterial sinusitis are double sickening, purulent rhinorrhea, ESR >10 mm, and purulent secretion in the nasal cavity. A combination of at least three of these four symptoms and signs has a specificity of 0.81 and sensitivity of 0.66 for acute bacterial rhinosinusitis. Table 1 lists the sensitivity, specificity, likelihood ratio, and odds ratio of criteria used to diagnose acute rhinosinusitis. If resistant pathogens are suspected or if the patient's immune system is compromised, bacterial culture of the secretions may be used for diagnosis and to direct therapy.

Imaging

For uncomplicated acute rhinosinusitis, radiographic imaging is not recommended. Plain sinus radiography shows air-fluid levels in patients with both viral and bacterial rhinosinusitis. Sinus computed tomography should not be used for routine evaluation of acute bacterial rhinosinusitis. However, sinus computed tomography without contrast media can be used to identify suspected complications and define anatomic abnormalities.

Differential Diagnosis

The signs and symptoms of acute bacterial rhinosinusitis and prolonged viral upper respiratory infection are similar, which can lead to overdiagnosis of acute bacterial rhinosinusitis. Other conditions that mimic bacterial rhinosinusitis are migraine headache, tension headache, trigeminal neuralgia, and temporomandibular joint disorders.

Treatment of Acute Rhinosinusitis

Symptomatic Treatment

Mild rhinosinusitis symptoms less than 7 days in duration can be managed with supportive care including analgesics, saline nasal irrigation, and intranasal corticosteroids. There are no randomized controlled trials that evaluate the effectiveness of decongestants in patients with sinusitis. Nasal saline is used to soften viscous secretions and improve mucociliary clearance. The mechanical cleansing of the nasal cavity with saline has been shown to benefit

TABLE 1 Signs and Symptoms of Acute Bacterial Rhinosinusitis

SIGN/ SYMPTOM	SENSITIVITY (%)	SPECIFICITY (%)	LR +	ODDS RATIO
Symptoms after upper respiratory tract infection	99	8	1.1	2.1
Facial pain on bending forward	90	22	1.2	0.9
Nasal congestion	90	14	1.0	1.1
Purulent rhinorrhea	89	42	1.5	1.6
Bilateral facial pain, pressure, or fullness	78	32	1.2	1.4
Double sickening	72	65	2.1	*
Previous sinusitis	57	38	0.9	0.4
Upper teeth pain	50	50	1.0	1.2
Unilateral facial pain, pressure, or fullness	46	73	1.7	1.9

Abbreviation: LR = Likelihood ratio.

*No data given in reference.

TABLE 2 Indications for Subspecialist Referral for Acute Bacterial Rhinosinusitis

Anatomic defects causing obstruction
Complications such as orbital involvement, altered mental status, meningitis, cavernous sinus thrombosis, intracranial abscess, Pott's puffy tumor (osteomyelitis of front bone)
Evaluation of immunotherapy for allergic rhinitis
Frequent recurrences (3–4 episodes per year)
Fungal sinusitis, granulomatous disease, or possible neoplasm
Immunocompromised host
Nosocomial infection
Severe infection with persistent fever >102°F or 39°C
Treatment failure after extended antibiotic courses
Unusual or resistant bacteria

From Aring AM, Chan MM. Current concepts in adult acute rhinosinusitis. *Am Fam Physician* 2016;94[2]:97–105.

patients with rhinosinusitis. Most studies of intranasal corticosteroids are industry sponsored. A 2013 Cochrane review found that patients receiving intranasal corticosteroids were more likely to experience symptom improvement after 15 to 21 days compared with those receiving placebo (73% vs. 66.4%; $p < .05$; number needed to treat [NNT]=15). Antihistamines should not be used for symptomatic relief of acute rhinosinusitis, except in patients with a history of allergic rhinitis.

Antibiotic Treatment

Antibiotic therapy is recommended for patients with sinusitis symptoms that do not improve within 7 to 10 days or that worsen at any time. Amoxicillin with or without clavulanate is recommended as the first-line antibiotic in adults with acute bacterial rhinosinusitis. “High-dose” amoxicillin-clavulanate (Augmentin XR) is recommended for patients with high risk of *S pneumoniae* resistance, recent antibiotic use, or treatment failure. Macrolides and trimethoprim sulfamethoxazole are not recommended for empiric therapy owing to high rates of resistance among *S pneumoniae* and *H influenzae*. Fluoroquinolones are not recommended as first-line antibiotics because they do not demonstrate benefit over beta-lactam antibiotics and are associated with a variety of adverse effects. According to a recent FDA safety alert, fluoroquinolones should be reserved for patients who do not have other treatment options.

Complications and Referral

Complications of acute bacterial rhinosinusitis are estimated to occur in 1 in 1000 cases. Patients with acute bacterial rhinosinusitis who present with visual symptoms (diplopia, decreased visual acuity, disconjugate gaze, difficulty opening the eye), severe headache, somnolence, or high fever should be evaluated with emergency computed tomography with contrast. Sinonasal cancers are uncommon in the United States, with an annual incidence of less than 1 in 100,000 patients. However, cancer should be included in the differential diagnosis. Referral to an otolaryngologist is needed if symptoms persist or progress after maximal medical therapy when computed tomography shows evidence of sinus disease. [Table 2](#) summarizes indications for subspecialist referral in a patient with acute bacterial rhinosinusitis.

TEMPOROMANDIBULAR DISORDERS

Method of

Jeffrey P. Okeson, DMD

Temporomandibular disorder (TMD) is a collective term that includes a number of clinical complaints involving the muscles of mastication, the temporomandibular joints (TMJs) and associated orofacial structures. Other commonly used terms are Costen's syndrome, TMJ dysfunction, and craniomandibular disorders. TMDs are a major cause of nondental pain in the orofacial region and are considered a subclassification of musculoskeletal disorders. In many TMD patients the most common complaint is not with the TMJs but rather the muscles of mastication. Therefore the terms *TMJ dysfunction* or *TMJ disorder* are actually inappropriate for many of these complaints. It is for this reason that the American Dental Association adopted the term *temporomandibular disorder*.

Signs and symptoms associated with TMDs are a common source of pain complaints in the head and orofacial structures. These complaints can be associated with general joint problems and somatization. Approximately 50% of patients suffering with TMDs do not first consult with a dentist but seek advice for the problem from a physician. The family physician should be able to appropriately diagnose many TMDs. In many instances the physician can provide valuable information and simple therapies that will reduce the patient's TMD symptoms. In other instances, it is appropriate to refer the patient to a dentist for additional evaluation and treatment.

Epidemiology

Cross-sectional population-based studies reveal that 40% to 75% of adult populations have at least one sign of TMJ dysfunction (e.g., jaw movement abnormalities, joint noise, tenderness on palpation), and approximately 33% have at least one symptom (e.g., face pain, joint pain). Many of these signs and symptoms are not troublesome for the patient, and only 3% to 7% of the population seeks any advice or care. Although in the general population women seem to have only a slightly greater incidence of TMD symptoms, women seek care for TMD more often than men at a ratio ranging from 3:1 to 9:1. For many patients TMDs are self-limiting or are associated with symptoms that fluctuate over time without evidence of progression. Even though many of these disorders are self-limiting, the health care provider can provide conservative therapies that will minimize the patient's painful experience.

Signs and Symptoms

The primary signs and symptoms associated with TMD originate from the masticatory structures and are associated with jaw function ([Box 1](#)). Pain during opening of the mouth or during chewing is common. Some persons even report difficulty speaking or

TEMPOROMANDIBULAR DISORDERS

Method of

Jeffrey P. Okeson, DMD

Temporomandibular disorder (TMD) is a collective term that includes a number of clinical complaints involving the muscles of mastication, the temporomandibular joints (TMJs) and associated orofacial structures. Other commonly used terms are Costen's syndrome, TMJ dysfunction, and craniomandibular disorders. TMDs are a major cause of nondental pain in the orofacial region and are considered a subclassification of musculoskeletal disorders. In many TMD patients the most common complaint is not with the TMJs but rather the muscles of mastication. Therefore the terms *TMJ dysfunction* or *TMJ disorder* are actually inappropriate for many of these complaints. It is for this reason that the American Dental Association adopted the term *temporomandibular disorder*.

Signs and symptoms associated with TMDs are a common source of pain complaints in the head and orofacial structures. These complaints can be associated with general joint problems and somatization. Approximately 50% of patients suffering with TMDs do not first consult with a dentist but seek advice for the problem from a physician. The family physician should be able to appropriately diagnose many TMDs. In many instances the physician can provide valuable information and simple therapies that will reduce the patient's TMD symptoms. In other instances, it is appropriate to refer the patient to a dentist for additional evaluation and treatment.

Epidemiology

Cross-sectional population-based studies reveal that 40% to 75% of adult populations have at least one sign of TMJ dysfunction (e.g., jaw movement abnormalities, joint noise, tenderness on palpation), and approximately 33% have at least one symptom (e.g., face pain, joint pain). Many of these signs and symptoms are not troublesome for the patient, and only 3% to 7% of the population seeks any advice or care. Although in the general population women seem to have only a slightly greater incidence of TMD symptoms, women seek care for TMD more often than men at a ratio ranging from 3:1 to 9:1. For many patients TMDs are self-limiting or are associated with symptoms that fluctuate over time without evidence of progression. Even though many of these disorders are self-limiting, the health care provider can provide conservative therapies that will minimize the patient's painful experience.

Signs and Symptoms

The primary signs and symptoms associated with TMD originate from the masticatory structures and are associated with jaw function ([Box 1](#)). Pain during opening of the mouth or during chewing is common. Some persons even report difficulty speaking or

Primary Symptoms

Facial muscle pain
Preauricular (TMJ) pain
TMJ sounds: jaw clicking, popping, catching, locking
Limited mouth opening
Increased pain associated with chewing

Secondary Symptoms

Earache
Headache
Neckache

Abbreviation: TMJ = temporomandibular joint.

singing. Patients often report pain in the preauricular areas, face, or temples. TMJ sounds are often described as clicking, popping, grating, or crepitus and can produce locking of the jaw during opening or closing. Patients commonly report painful jaw muscles, and, on occasion, they even report a sudden change in their bite coincident with the onset of the painful condition.

It is important to appreciate that pain associated with most TMDs is increased with jaw function. Because this is a condition of the musculoskeletal structures, function of these structures generally increases the pain. When a patient's pain complaint is not influenced by jaw function, other sources of orofacial pain should be suspected.

The spectrum of TMD often includes commonly associated complaints such as headache, neckache, or earache. These associated complaints are often referred pains and must be differentiated from primary pains. As a general rule, referred pains associated with TMDs are increased with any activity that provokes the TMD pain. Therefore, if the patient reports that the headache is aggravated by jaw function, it could very well represent a secondary pain related to the TMD. Likewise, if the secondary symptom is unaffected by jaw use, one should question its relationship to the TMD and suspect two separate pain conditions. Pain or dysfunction due to non-musculoskeletal causes such as otolaryngologic, neurologic, vascular, neoplastic, or infectious disease in the orofacial region is not considered a primary TMD even though musculoskeletal pain may be present. However, TMDs often coexist with other craniofacial and orofacial pain disorders.

Anatomy and Pathophysiology

The TMJ is formed by the mandibular condyle fitting into the mandibular fossa of the temporal bone. The movement of this joint is quite complex as it allows hinging movement in one plane and at the same time allows gliding movements in another plane.

Separating these two bones from direct articulation is the articular disk. The articular disk is composed of dense fibrous connective tissue devoid of any blood vessels or nerve fibers. The articular disk is attached posteriorly to a region of loose connective tissue that is highly vascularized and well innervated, known as the retrodiscal tissue. The anterior region of the disk is attached to the superior lateral pterygoid muscle.

The movement of the mandible is accomplished by four pairs of muscles called the muscles of mastication: the masseter, temporalis, medial pterygoid, and lateral pterygoid. Although not considered to be muscles of mastication, the digastric muscles also play an important role in mandibular function. The masseter, temporalis, and medial pterygoid muscles elevate the mandible and therefore provide the major forces used for chewing and other jaw functions. The inferior lateral pterygoid muscles provide protrusive movement of the mandible, and the digastric muscles serve to depress the mandible (open the mouth).

When discussing the pathophysiology of TMD, one needs to consider two main categories: joint pathophysiology and muscle pathophysiology. Because etiologic considerations and treatment

strategies are different for these conditions, they are presented separately.

Pathophysiology of Intracapsular TMJ Pain Disorders

Several common arthritic conditions such as rheumatoid arthritis, traumatic arthritis, hyperuricemia, and psoriatic arthritis can affect the TMJ. These conditions, however, are not nearly as common as local osteoarthritis. As with most other joints, osteoarthritis results from overloading the articular surface of the joint, thus breaking down the dense fibrocartilage articular surface and ultimately affecting the subarticular bone. In the TMJ, this overloading commonly occurs as a result of an alteration in the morphology and position of the articular disc. In the healthy TMJ, the disc maintains its position on the condyle during movement because of its morphology (i.e., the thicker anterior and posterior borders) and interarticular pressure maintained by the elevator muscles. If, however, the morphology of the disc is altered and the discal ligaments become elongated, the disk can be displaced from its normal position between the condyle and fossa. If the disc is displaced, normal opening and closing of the mouth can result in an unusual translatory movement between the condyle and the disc, which is felt as a click or pop. Disc displacements that result in joint sounds might or might not be painful. When pain is present it is believed to be related to either loading forces applied to the highly vascularized retrodiscal tissues or a general inflammatory response of the surrounding soft tissues (capsulitis or synovitis).

Pathophysiology of Masticatory Muscle Pain Disorders

The muscles of mastication are a very common source of TMD pain. Understanding the pathophysiology of muscle pain, however, is very complex and still not well understood. The simple explanation of muscle spasm does not account for most TMD muscle pain complaints. It appears that a better explanation would include a central nervous system effect on the muscle that results in an increase in peripheral nociceptive activity originating from the muscle tissue itself. This explanation more accurately accounts for the high levels of emotional stress that are commonly associated with TMD muscle pain complaints. In other words, an increase in emotional stress activates the autonomic nervous system, which in turn seems to be associated with changes in muscle nociception.

These masticatory muscle pain conditions are further complicated when one considers the unique masticatory muscle activity known as bruxism. Bruxism is the subconscious, often rhythmic, grinding or gnashing of the teeth. This type of muscle activity is considered to be parafunctional and can also occur as a simple static loading of the teeth known as clenching. This activity commonly occurs while sleeping but can also be present during the day. These parafunctional activities alone can represent a significant source of masticatory muscle pain, and certainly bruxism in the presence of central nervous system-induced muscle pain can further accentuate the patient's muscle pain complaints.

Etiology

Because TMD represents a group of disorders, any of several etiologies may be associated. Problems arising from intracapsular conditions (clicking, popping, catching, locking) may be associated with various types of trauma. Gross trauma, such as a blow to the chin, can immediately alter ligamentous structures of the joint, leading to joint sounds. Trauma can also be associated with a subtler injury such as stretching, twisting or compressing forces during eating, yawning, yelling, or prolonged mouth opening.

When the patient's chief complaint is muscle pain, etiologic factors other than trauma should be considered. Masticatory muscle pain disorders have etiologic considerations similar to other muscle pain disorders of the neck and back. Emotional stress seems to play a significant role for many patients. This can explain why patients often report that their painful symptoms fluctuate greatly over time.

Although most TMD patients do not have a major psychiatric disorder, psychological factors can certainly enhance the pain condition. The clinician needs to consider such factors as anxiety, depression, secondary gain, somatization, and hypochondriasis.

Psychosocial factors can predispose certain people to TMD and can also perpetuate TMD once symptoms have become established. A careful consideration of psychosocial factors is therefore important in the evaluation and treatment of every TMD patient.

TMDs have a few unique etiologic factors that differentiate them from other musculoskeletal disorders. One such factor is the occlusal relationship of the teeth. Traditionally it was thought that malocclusion was the primary etiologic factor responsible for TMD. Recent investigations, however, do not support this concept. Still, in certain instances occlusal instability of the teeth can contribute to a TMD. This may be true in patients with or without teeth. Poorly fitting dental prostheses can also contribute to occlusal instability. The occlusal condition should especially be suspected if the pain problem began with a change in the patient's occlusion (e.g., following a dental appointment).

History and Examination

All patients reporting pain in the orofacial structures should be screened for TMD. This can be accomplished with a brief history and physical examination. The screening questions and examination are performed to rule in or out the possibility of a TMD. If a positive response is found, a more extensive history and examination is indicated. [Box 2](#) lists questions that should be asked during a screening assessment for TMD. Any positive response should be followed by additional clarifying questions.

Patients experiencing orofacial pain should also be briefly examined for any clinical signs associated with TMD. The clinician can easily palpate a few sites to assess tenderness or pain, as well as assess for jaw mobility. The masseter muscles can be palpated bilaterally while asking the patient to report any pain or tenderness. The same assessment should be made for the temporal regions, as well as the preauricular (TMJ) areas. While the examiner's hands are over the preauricular areas, the patient should repeatedly open and close the mouth. The presence of joint sounds should be noted along with whether these sounds are associated with joint pain.

A simple measurement of mouth opening should be made. This can be accomplished by placing a millimeter ruler on the lower anterior teeth and asking the patient to open as wide as possible. The distance should be measured between the maxillary and mandibular anterior teeth. It is generally accepted that less than 40 mm is a restricted mouth opening.

BOX 2 Recommended Screening Questionnaire for Temporomandibular Disorder

All patients reporting pain in the orofacial region should be screened for TMD with a questionnaire that includes these questions. The decision to complete a comprehensive history and clinical examination depends on the number of positive responses and the apparent seriousness of the problem for the patient. A positive response to any question may be sufficient to warrant a comprehensive examination if it is of concern to the patient or viewed as clinically significant by the physician.

1. Do you have difficulty, pain, or both when opening your mouth, for instance when yawning?
2. Does your jaw get stuck or locked or go out?
3. Do you have difficulty, pain, or both when chewing, talking, or using your jaws?
4. Are you aware of noises in the jaw joints?
5. Do your jaws regularly feel stiff, tight, or tired?
6. Do you have pain in or about the ears, temples, or cheeks?
7. Do you have frequent headaches, neckaches, or toothaches?
8. Have you had a recent injury to your head, neck, or jaw?
9. Have you been aware of any recent changes in your bite?
10. Have you been previously treated for unexplained facial pain or a jaw joint problem?

Abbreviation: TMD = temporomandibular disorder.

BOX 3 Recommended Screening Examination Procedures for Temporomandibular Disorder

All patients with face pain should be briefly screened for TMD using this or a similar cursory clinical examination. The need for a comprehensive history and clinical examination depends on the number of positive findings and the clinical significance of each finding.

1. Palpate for pain or tenderness in the masseter and temporalis muscles.
2. Palpate for pain or tenderness in the preauricular (TMJ) areas.
3. Measure the range of mouth opening. Note any incoordination in the movements.
4. Auscultate and palpate for TMJ sounds (i.e., clicking or crepitus).
5. Note excessive occlusal wear, excessive tooth mobility, buccal mucosal ridging, or lateral tongue scalloping.
6. Inspect symmetry and alignment of the face, jaws, and dental arches.

Abbreviation: TMJ = temporomandibular joint.

It is also helpful to inspect the teeth for significant wear, mobility, or decay that may be related to the pain condition. The clinician should examine the buccal mucosa for ridging and the lateral aspect of the tongue for scalloping. These are often signs of clenching and bruxism. A general inspection for symmetry and alignment of the face, jaws, and dental arches may also be helpful. A summary of this screening examination is shown in [Box 3](#).

Treatment

Most recent studies suggest that TMDs are generally self-limiting, and symptoms often fluctuate over time. Understanding this natural course does not mean these conditions should be ignored. TMD can be a very painful condition leading to a significant decrease in the patient's quality of life. Understanding the natural course of TMD does suggest, however, that therapy might not need to be very aggressive. In general, initial therapy should begin very conservatively and only escalate when therapy fails to relieve the symptoms.

When the physician identifies a patient with a TMD, he or she has two options. The physician can elect to treat the patient or refer the patient to a dentist who specializes in TMD for further evaluation and treatment. The decision to refer the patient should be based on whether the patient needs any unique care provided only in a dental office. The following are some indications for referral to a dentist:

- History of trauma to the face related to the onset of the pain condition
- The presence of significant TMJ sounds during function
- A feeling of jaw catching or locking during mouth opening
- The report of a sudden change in the occlusal contacts of the teeth
- The presence of significant occlusal instability
- Significant findings related to the teeth (e.g., tooth mobility, tooth sensitivity, tooth decay, tooth wear)
- Significant pain in the jaws or masticatory muscles upon awakening
- The presence of an orofacial pain condition that is aggravated by jaw function and has been present for more than several months

The specific therapy for a TMD varies according to the precise type of disorder identified. In other words, masticatory muscle pain is managed somewhat differently than intracapsular pain. Generally, however, the initial therapy for any type of TMD should be directed toward the relief of pain and the improvement of function. This initial conservative therapy can be divided into three general types: patient education, pharmacologic therapy, and physical therapy.

Patient Education

It is very important that patients have an appreciation for the factors that may be associated with their disorder, as well as the natural course of the disorder. Patients should be reassured and if necessary, convinced by appropriate tests, that they are not suffering from a malignancy. Properly educated patients can contribute greatly to their own treatment. For example, knowing that emotional stress is an influencing factor in many TMDs can help the patient understand the reason for daily fluctuations of pain intensity. Attention should be directed toward changing the patient's response to stress or, when possible, reducing exposure to stressful conditions. Patients with pain during chewing should be told to begin a softer diet, chew slower, and eat smaller bites. As a general rule the patient should be told "if it hurts, don't do it." Continued pain can contribute to the cycling of pain and should always be avoided. The patient should be instructed to let the jaw muscles relax, maintaining the teeth apart. This will discourage clenching activities and minimize loading of the teeth and joints.

When pain is associated with a clicking TM joint, the patient should be informed of the biomechanics of the joint. This information often allows the patient to select functional activities that are less traumatic to the joint structures. For example, some patients may report that the pain and clicking are less when they chew on a particular side of the mouth. When this occurs, they should be encouraged to continue this type of chewing.

Pharmacologic Therapy

Pharmacologic therapy can be an effective adjunct in managing symptoms associated with TMDs. Patients should be aware that medication alone will not likely solve or cure the problem. Medication, however, in conjunction with appropriate physical therapy and definitive treatment, does offer the most complete approach to many TMD problems. Mild analgesics are often helpful for many TMDs. Control of pain is not only appreciated by the patient but also reduces the likelihood of other complicating pain disorders such as muscle co-contraction, referred pain, and central sensitization.

Nonsteroidal antiinflammatory drugs (NSAIDs) are very helpful with many TMDs. Included in this category are aspirin, acetaminophen (Tylenol), and ibuprofen. Ibuprofen (Motrin, Advil, Nuprin) is often very effective in reducing musculoskeletal pains. A dosage of 600 to 800 mg three times a day for 3 to 5 days commonly reduces pain and stops the cyclic effects of the deep pain input. For patients with gastrointestinal issues, short-term use of a cyclooxygenase-2 (COX-2) inhibitor such as celecoxib (Celebrex) can also be useful.

Physical Therapy

In many patients with TMD, symptoms are relieved with very simple physical therapy methods. Simple instructions for the use of moist heat or cold can be very helpful. Surface heat can be applied by laying a hot, moist towel over the symptomatic area. A hot water bottle wrapped inside the towel will help maintain the heat. This combination should remain in place for 10 to 15 minutes, not to exceed 30 minutes. An electric heating pad may be used, but care should be taken not to leave it on the face too long. Patients should be discouraged from using the heating pad while sleeping because prolonged use is likely.

Like thermotherapy, coolant therapy can provide a simple and often effective method of reducing pain. Ice should be applied directly to the symptomatic joint or muscles and moved in a circular motion without pressure to the tissues. The patient will initially experience an uncomfortable feeling that will quickly turn into a burning sensation. Continued icing will result in a mild aching and then numbness. When numbness begins the ice should be removed. The ice should not be left on the tissues for longer than 5 minutes. After a period of warming a second cold application may be desirable.

The physician should be aware that many TMDs respond to the use of orthopedic appliances such as occlusal appliances, bite

guards, and splints. These appliances are made by the dentist and are custom fabricated for each patient. Several types of appliances are available. Each is specific for the type of TMD present. The dentist should be consulted for this type of therapy.

Other Therapeutic Considerations

Sometimes TMDs become chronic and, as with other chronic pain conditions, might then be best managed by a multidisciplinary approach. If the patient reports a long history of TMD complaints, the physician should consider referring the patient to a dentist associated with a team of therapists, such as a psychologist, a physical therapist, and even a chronic pain physician. Generally, patients with chronic TMD are not managed well by the simple initial therapies discussed in this chapter. Often other factors, such as mechanical conditions within the TMJs or psychological factors, need to be addressed. The physician who attempts to manage these conditions in the private practice setting can become very frustrated with the results. It is therefore recommended that if the patient's history suggests chronicity or if initial therapy fails to reduce the patient's symptoms, referral is indicated.

UVEITIS

Method of

Petros E. Carvounis, MD

CURRENT DIAGNOSIS

- The most common form of uveitis is anterior uveitis.
- Anterior uveitis is commonly idiopathic.
- Posterior uveitis is most likely infectious.
- In any form of uveitis, syphilis, tuberculosis, and Lyme disease need to be ruled out.
- In immunosuppressed individuals, the uveitis is most likely infectious: the patient's HIV status needs to be determined, because a positive status completely changes the diagnostic approach.
- The key to correct diagnosis is a good history, including a thorough review of systems and a careful ophthalmologic examination as well as dilated funduscopy; laboratory and radiographic investigations, sometimes including aqueous or vitreous polymerase chain reaction or cytologic studies, are frequently necessary.
- Involvement of an ophthalmologist with expertise in the diagnosis and treatment of uveitis is mandatory.

CURRENT THERAPY

- Uveitis resulting from a systemic infection (e.g., syphilis, Lyme disease, tuberculosis) needs to be treated as a central nervous system infection.
- Idiopathic anterior uveitis or anterior uveitis related to an autoimmune disease responds to topical corticosteroids (e.g., prednisolone acetate [Pred Forte] 1% 1 drop every 2 hours while awake³) and cycloplegia (e.g., homatropine [Isopto Homatropine]¹ 2% 1 drop three times daily).

Patient Education

It is very important that patients have an appreciation for the factors that may be associated with their disorder, as well as the natural course of the disorder. Patients should be reassured and if necessary, convinced by appropriate tests, that they are not suffering from a malignancy. Properly educated patients can contribute greatly to their own treatment. For example, knowing that emotional stress is an influencing factor in many TMDs can help the patient understand the reason for daily fluctuations of pain intensity. Attention should be directed toward changing the patient's response to stress or, when possible, reducing exposure to stressful conditions. Patients with pain during chewing should be told to begin a softer diet, chew slower, and eat smaller bites. As a general rule the patient should be told "if it hurts, don't do it." Continued pain can contribute to the cycling of pain and should always be avoided. The patient should be instructed to let the jaw muscles relax, maintaining the teeth apart. This will discourage clenching activities and minimize loading of the teeth and joints.

When pain is associated with a clicking TM joint, the patient should be informed of the biomechanics of the joint. This information often allows the patient to select functional activities that are less traumatic to the joint structures. For example, some patients may report that the pain and clicking are less when they chew on a particular side of the mouth. When this occurs, they should be encouraged to continue this type of chewing.

Pharmacologic Therapy

Pharmacologic therapy can be an effective adjunct in managing symptoms associated with TMDs. Patients should be aware that medication alone will not likely solve or cure the problem. Medication, however, in conjunction with appropriate physical therapy and definitive treatment, does offer the most complete approach to many TMD problems. Mild analgesics are often helpful for many TMDs. Control of pain is not only appreciated by the patient but also reduces the likelihood of other complicating pain disorders such as muscle co-contraction, referred pain, and central sensitization.

Nonsteroidal antiinflammatory drugs (NSAIDs) are very helpful with many TMDs. Included in this category are aspirin, acetaminophen (Tylenol), and ibuprofen.
